The falls are approximately 10% to 20% of the preceding peak and, apart from the last which was only a century in length, may last up to three, four, or five centuries. The peak/trough cycle is very irregular, varying between 8 and 12 centuries, so an extrapolation, even based on a multicentury trend, would give no pointer as to the future world population. Calculated on the 4th and 3rd centuries BCE, it would have given over 20 billion inhabitants in 2000, but projected from the 3rd and 4th centuries CE would have given a 35 million decrease!

Variations of this magnitude seem to have occurred in all periods of history and prehistory, but, as was seen, some have been of such extraordinary magnitude as to suggest sudden, sharp, stepwise population growth. These step increases were first natural, through the evolution from one species of humankind into another, from *H. habilis* to *H. erectus* and then *H. sapiens*, but also occurred to an increasingly cultural extent (e.g., the taming of fire), becoming almost entirely cultural, that is, much more rapid and closer together than in all other species. Upper Palaeolithic technologies—clothing, bow and arrows, spear throwers, etc.—are one sharp step-change; the Neolithic era, with farming and sedentarism, another.

We are living through the industrialization step, the hesitant, localized beginnings of which are to be found in the Renaissance (see Chapters 68, 69) and will probably come to an end in the 21st century, as will be seen in Chapter 77.

Figure 66–1 summarizes the long history of humankind's population of the Earth.

CHAPTER

67

Migration as a Primary Force in Human Population Processes

DAVID A. COLEMAN

Department of Social Policy and Social Work, University of Oxford, United Kingdom

INTRODUCTION

This chapter will review selected migration processes in the longer term. It will seek to place modern migration patterns into a wider range of the migration behavior that human populations have experienced in their history and prehistory. It will emphasize that the forms of migration that we see today, and on which we judge the demographic effects of migration, are only a subset of possible migratory behavior. Other forms of migration, some now extinct, have had much more substantial effects upon the numbers, distribution, and characteristics of human populations than do most current forms of migration, even the recent substantial international movements to Western Europe and the United States.

Migration is defined here by a change of dwelling-place by individuals or peoples usually (but not always) at a distance greater than that of day-to-day mobility and for a substantial period of time, usually at least a year. In modern terminology, the chapter will concentrate on international more than on internal migration within countries. However, during much of the period considered, national boundaries for countries did not exist and the concept of regulated migration across them was far in the future. Indeed, during most of human prehistory, human populations had no permanent location but moved continually as hunters and gatherers or as pastoral nomads between sites within a roughly defined larger territory. In the absence of a permanent settlement, everyone may be regarded as a permanent migrant, and the distinction between migration among sites or to new territories, as well as daily mobility around a (temporarily) fixed site, becomes blurred but does not disappear. Such continual movement dominated the demographic environment, and the risk environment, in which the human species has developed. These issues will become apparent in this chapter, in which the term "migration" will have to encompass a wider variety of human behavior than it is usually called upon to do.

I. THE STATUS OF MIGRATION IN DEMOGRAPHY

1. Migration as a "Weak Sister"

Until recently, migration has typically been regarded as the "weak sister" of modern demography. Although its effects have always been preeminent on local populations, at the larger level of aggregation that demographers traditionally study, especially the national level, its statistical effects in peacetime upon size, growth rates, and age-structure have usually been small until recently (Voets *et al*. 1995). In recent historical times, immigrant populations have usually comprised a relatively small component of established populations and have not tended to displace them. Postwar immigration has not much retarded the process of ageing in mature societies (Kuijsten 1995). That which is caused primarily by trends in fertility cannot be put right by trends in migration. This marginal demographic status may be changing, however. In recent years new migratory flows, especially from the Third World, have been making increasingly large demographic contributions to Western European populations and to those of North America and the Antipodes. By the beginning of the 21st century, net immigration had become the major component of remaining population growth in most Western European countries. Where the death rate exceeds the birth rate (e.g., Sweden, Germany, Italy), net immigration has prevented population decline (see Council of Europe 2003). Major ethnic consequences in the host population can follow from immigration if permanent migration chains develop among immigrant populations with extended family and kinship obligations and high fertility. Based on current and projected trends, population projections suggest that between 20% and 30% of the population of a number of Western European countries, and of the United States, are likely to be of first- or second-generation foreign descent by midcentury (Coleman 2004). This pattern is reestablishing migration as a primary demographic factor in demographic processes, after a long period of relative unimportance. This chapter, however, is not concerned in detail with this recent renaissance of international migration, which is reviewed elsewhere, but with its varying significance in past times and long-term influence on human population characteristics.

2. Why Most Demographers Do Not Like Migration

The process of migration itself is fundamentally different from the vital processes with which demographers have traditionally concerned themselves. That is one of several reasons why migration is often thought to be a subject more fit for geographers than for demographers. Births and deaths are well defined as irreversible beginnings and ends, but migration is continually repeatable. International movement varies in its intensity, duration, and frequency from permanent exile to border commuting and, in the latter case, can hardly be considered to be "migration" at all. Migration has no firm statistical definition shared by the different countries that exchange migrants (see United Nations 1998). Even an apparently clear category such as "labor migration" is shown to be ill-defined when scrutinized (Salt *et al*. 2004). Migration generates statistics only insofar as it is controlled. So in the modern world, there are as many migration definitions as there are systems of migration control. These laws define migration for different purposes, durations of stay, and so on (Salt *et al*. 1993). However, labor migration under work permit, asylum seeking, and family re-union migration—some of most significant components of modern migration flows into the industrial countries—are potentially more comparable. Migration can be estimated indirectly by population statistics on birthplace or nationality from censuses or, more usefully, from registration systems. Indeed most of the "migration" statistics presented in the annual SOPEMI report (OECD 2003) are derived indirectly from the latter sources, not the least because emigration data are absent or defective. "Internal" migration may share many of the processes and patterns of international migration, but the relation between the two is little studied. Migration and mobility in historical and prehistoric times gives us further problems of measurement but also presents us with forms of migration that, once dominant, are now extinct or nearly so and that are not included in modern typologies.

3. Migration Paramount

The relative unimportance of migration except at the small scale was a relatively recent phenomenon, which now, as we saw above, is proving to have been a transient episode. The particular range of the forms of migration that we nowadays take for granted as being the norm is also a recent phenomenon. We should abandon any notion of a "principle of uniformity" in the study of migration. By no means can all forms of human migration be observed in contemporary populations. Some aspects of migration are new, and many others that have radically shaped human settlement are now extinct. In the past, migration dominated human populations. It often involved the movement of whole peoples, whose cultural entity was much more permanent than their shifting homeland, which indeed often had recently belonged to someone else. For example, it was not until the late 10th century that the "Kings of the English" began to describe themselves as the "Kings of England" (Wormald 1994). The ancient impermanence of human attachment to a homeland in many populations is too easily forgotten.

In the beginning, and for all but the last 10,000 of the 5 million years or so of human prehistory and history, all human groups have been in a state of continual migration at the local level, moving around their home range to hunt and gather food. That mobility, at a small scale and on a daily basis, determined the mortality and fertility risk regimes to which all human populations had to accommodate in prehistory, and to which a few still adhered until recently (see, e.g., Blurton-Jones 1986). Human species—specific patterns of natural fertility and of age-related senescence evolved under such conditions of mobility. At the other end of the scale is the long-range migration by which the world was initially populated and by which peoples subsequently moved, displaced others, and were displaced in their turn. Such past movements have powerfully influenced human distribution and fertility and mortality patterns and created, as well as moderated, the genetic and linguistic diversity of human populations (Cavalli-Sforza 2000). The impact of current migration patterns, which attract so much interest and concern at present, appear trivial by comparison. However, it is important, before we examine the events of the remote past, not to forget that time becomes compressed at long range. Changes that appear sudden, even brutal, to us are likely in reality to have taken place over a long period of time, so that their unfolding could have been perceived by a contemporary observer to have been very gradual. The development of the structure of the population consequent upon the direct and indirect effects of the current migration toward Western Europe and to North America is of this kind.

II. TYPES OF MIGRATION ANCIENT AND MODERN

It might be helpful to illustrate the complexity of the process by briefly reviewing the diverse array of the forms of human mobility. A simple list is presented below of various forms of migration grouped according to chronology, transience or permanence, and motivation. It includes old and extinct forms of migration as well as persistent and new ones. Most contemporary attention is devoted, not surprisingly, to contemporary migration, which is complex and diverse enough. Much more detailed typologies and analyses of the processes behind contemporary migration will be found in Salt (1989), Massey *et al*. (1993), and elsewhere, but such treatments rarely attempt to incorporate ancient or historical forms of migration into their schemata. Some of these will be considered in more detail in the sections that follow. The more modern forms of migration will not be discussed further; they are dealt with in other chapters of this section.

1. Local Mobility and Short-Range Migration

1. *Local migration and mobility*—The list is long and varied: daily food foraging and hunting by individuals and by small groups in their home range or territory; raiding neighbors; traveling for the exchange of goods, gifts, and trade; commuting for work, local house-moves for work; traveling for education. These are the essential movements of everyday life, prerequisites for survival, subsistence, advancement, and reproduction and their essential concomitants. The earlier forms will be as old as the human species. Some are almost extinct. Few constitute "migration" in the sense discussed here. Their motivation requires no new or special explanation.

2. *Migration associated with particular stages of the life cycle*—This includes marriage migration and retirement migration; the former is probably almost as old as humanity, fundamental to the kinship relationships and intergroup contact and cohesion of traditional societies. The latter, however, dates only from the invention of retirement and in the ancient world was a privilege solely of the elite.

These forms of mobility will not be considered further. Instead, attention will be concentrated on movement at longer range and in the longer term, and with various of its consequences.

2. Movement at Longer Range and in the Longer Term

1. *Initial world colonizing migration*—This probably arose in two stages, the first around 1.5 million years BC, the second around 100,000 years BC. By about 8000 BC, the process was mostly complete, with the exceptions noted below. Both episodes involved movement out of Africa to most parts of the globe; probably not by "purposeful" migration but by the spread of settlement by population growth at the margins, as discussed below under the concept of the "wave of advance."

2. *Regular longer-term movement associated with nomadism, pastoralism, and early forms of "unsettled" agriculture*—These include regular movement of whole groups to different parts of their home range to exploit new resources; nomadic pastoralism; transhumance; and swidden, or slash-and-burn agriculture, rotating around the same very large territory in cycles of 25 years or more (Allan 1967).

3. *Völkerwanderung*—This term is given to the movement of whole peoples, or large parts of them, with (some) means of subsistence and with all their impedimenta, over large geographical areas as a directional, opportunity, or plunder-seeking migration or as a refugee movement after displacement by other stronger peoples. This form of migration had overwhelming consequences for neighboring settled populations if the wandering people proved to be

militarily superior, as they often did, especially if they were mounted pastoral nomads. Such movements are recorded from the earliest times but peaked in Eurasia between the end of the first millennium BC to the beginning of the second millennium, a time often denoted as the *Völkerwanderungszeit* (Diesner 1978).

McNeill has proposed a fourfold classification to include the migratory movements of the ancient world once initial colonization was completed, some of which include elements of this phenomenon (McNeill 1984:4). These are presented in modified form below:

Displacement of one population by another by force (invasion/extermination).

Conquest of one population by an invader, leading to coexistence of two previously separate populations (creation of new ruling class and/or incorporation into a larger empire).

Infiltration by outsiders with some degree of acquiescence from existing populations, without displacing rulers (trade, special skills, mercenaries, missionaries, refugees).

Movement by force of individuals or whole communities from their initial homeland by slave raiders or traders (forced labor migration, especially for domestic and sexual services; North Africa and Arabia) and also for agriculture or manufacture (Rome, West Indies, Southern United States, and South America) or administration and military service (such as the *devshirme* of the Ottoman empire, a tribute of Christian children taken to form the armies of the Janissaries). Also forced movements within empires for labor or security reasons (the *corvée* in China, slave labor in Nazi Germany, Ottoman rearrangements, deportations and the *Gulag* in the Soviet Union)

Further forms of migration are more characteristic of money-based market economies and more advanced forms of division of labor:

4. *Importation by invitation*—Individuals or groups keen to increase permanent population, diversify their economy, or expand their labor force. In earlier centuries these were typically minorities with "private" special skills who might often require state protection and privileges specific to their communities. Examples include the encouragement by Peter the Great and his successors of German settlers in Russia, whose descendants became the *aussiedler* of modern times, as well as the attraction of Flemish weavers to England by Edward III. Mercenaries might become permanent settlers through the same process or even displace their employers as did, according to tradition, Hengist and Horsa in the Kingdom of Kent (449).

5. *Conventional voluntary international labor migration*—With the growth of markets and the convenience of modern transport, the previous category matures into something more general. Modern labor migration occurs between economies of equal rank, as within the first 15 countries of the European Union (EU15) countries, but large-scale movement is typically driven by wage differentials between economies and by economic growth that is rapid by historical standards. At the present time, differentials in living standards, of the order of 10-fold between the modern economies and the Third World, are the widest ever. In monetized and internationalized economies of the 20th and 21st centuries, labor migration has often been promoted by recruitment policies and has been managed and limited by work-permit arrangements. Such relatively formal movements began before the 20th century but reached a new high from the 1960s to the mid 1970s during the postwar "guest worker" migration, mostly from southern Europe and the Third World into Western Europe. That movement was expected to be temporary, and indeed some workers did return, but for the most part that movement has perpetuated itself on a large scale through the chain migration of spouses, dependants, and relatives.

Labor migration is a global phenomenon (Stalker 1994), in Europe (Salt *et al*. 2004), in North America, in the growing economies of the Pacific Rim (e.g., Taiwan, Korea, Malaysia, even Japan) (see Salt 1989), and, often less formally, in the Southern Cone of Latin America and throughout Africa. Over historical time, its formalization was developed following the consolidation of nation-states and the control and counting of movement across their borders. Modern labor migration into rich countries is focused particularly upon the active recruitment of persons with specific modern technological skills, often from specific countries. Much highly skilled movement is managed through "intracompany transfers," though which multinational companies shuffle their own employees between countries.

6. *Migration for settlement* (peaceful variants of displacement, conquest, and movement by force)—There is a substantial division today between the major "countries of immigration" outside Europe (the United States, Australia, Canada, and New Zealand), which welcome population for settlement, and others that wish to recruit temporary labor but not necessarily a permanent population. Although the countries of immigration justify their positive migration policies on economic grounds, only a small proportion of their immigrants—under one-fifth in the United States—enter under workforce preferences; the rest enter under various family preference schemes. These coun-

tries of immigration usually recognize a formal category of "permanent settler migration" unknown elsewhere, although in fact many such "permanent" immigrants return to their origins as do participants in all other migration streams.

7. *Entitlement migration*—These streams are forms of chain migration, in particular as a consequence of postwar labor migration to the developed world, in a moral and legal climate that has recognized, unlike in previous times, entitlements to family unification in the receiving country and an increasing equality of rights of immigrants with those of citizens. After the 1970s, postwar migration involving the developed countries has been dominated by the continuation of migration from poorer countries into the richer ones. These flows consist primarily of the dependents and relatives of those labor migrants and their new spouses and, increasingly, the spouses of their children in the growing populations of immigrant origin. These persons, not workers, comprise the majority of regular immigrants to Europe in recent decades.

8. *New irregular avenues of migration*—A substantial flow of asylum-claiming immigration and of illegal immigration, sometimes from the same poor countries as those that provided early labor migration, has arisen since the early 1980s. Asylum claiming, as a large-scale migration stream, depends specifically on rights to asylum formally specified only in the 1951 Geneva Convention and to other benefits of welfare economies. Information on these entitlements is now globalized, together with familiarity about the welfare and other provisions that accompany them. In the majority of countries that receive asylum seekers, only a minority are accepted as qualifying as "refugees" (although most remain anyway). The process is as much one of settlement as of protection and appears to overlap substantially with a more general "betterment" migration, much of it irregular or clandestine. There have been over 6 million claims of asylum in Europe since 1980.

In the discussion that follows, particular attention is given to the earlier forms of migration that are less familiar today and that stand in the greatest contrast to those with which we are most familiar. The characteristics of contemporary migration streams at the end of the 20th and the beginning of the 21st centuries, labor migration toward Europe and North America, family reunion and formation, asylum claiming, and illegal immigration are considered in other chapters, particularly in Volume II, but also in the chapters of Volume III devoted to the demographic transition (Chapters 68, 69) and to the projection of population (Chapters 76, 77).

III. THE INITIAL COLONIZATIONS OF THE WORLD: OUT OF AFRICA

The further back into prehistory we look, the more different—and the more demographically and evolutionarily salient—are the migration processes of the human species. Much controversy about migration in prehistory exists, both about facts and about processes. But it is clear that something quite new migrated out of Africa about 1.5 million years ago and then again about 100,000 years ago—us or, at least, our ancestors. The colonization of the world by the human species began by migration—probably twice—out of Africa. It seems established that hominids first evolved there. No remains of the earliest kinds of hominid—the genus or group of genera *Australopithecus* dating from about 5 million years to about 2 million years ago—are to be found anywhere outside that continent. What first came out of Africa was something more advanced than were the Australopithecines but not yet like modern man. About 1.5 million years ago, *Homo erectus* (now often called *H. ergaster*) had the unique opportunity of colonizing the 75% of the world's remaining land surface that had absolutely no other human beings on it at all. In the end—through processes still unclear in detail—no part of the world came to be free of the human species. We are thus faced with at least three migration questions: Why did *H. erectus* and, later on, early *H. sapiens* escape from Africa when *Australopithecus* did not; what kind of migration should we consider this to be; and why are human beings now found more or less everywhere?

An enhanced capacity for adapting to new environments might have been a first essential. *H. erectus/H. ergaster* had better tools and weapons than those that were available to his predecessors. But even more important, it is claimed, were fundamental human properties, such as the ability to act socially, to collaborate in groups, and to gossip (Dunbar 1996). The demands on intelligence and memory arising from complex human social life are now thought to be a more potent source of evolutionary pressure for enhanced brain development than are the simpler demands of tool-making, which are by no means confined to the human species. According to Gamble (1995), human migration beyond the local area had to await human social organization and possibly speech. It is also noteworthy that the time of the first migration out of Africa coincided with the rise of a type of human whose sexual dimorphism in stature and estimated weight was much less prominent than it had been in previous hominids (McHenry 1994). That argues for a more complex, co-operative attitude between the sexes, away from the dominance of a substantially polygamous harem social structure, which is inferred to have been characteristic of earlier hominids.

Debate continues between two rival explanations of the peopling of the world. Fossil remains of *H. erectus* are found outside Africa, from Java to Wales, but not in the Americas or Australasia. Somehow *H. erectus* were replaced by populations of anatomically modern man. Did *Homo* evolve from the *erectus* level to the *sapiens* level *in situ* in several places throughout the Old World (the "polygenic" or "multiregional" hypothesis) (Wolpoff 1989)? Or were earlier forms, including the Neandertals, who are believed to be descended from earlier *H. erectus*, replaced by a new migratory stream of anatomically modern man out of Africa in much more recent times, beginning about 100,000 years ago? According to the latter "monogenic," "recent African origin," or "out of Africa" hypothesis, the colonization of Europe by anatomically modern man was only complete in Europe by about 35,000 years ago. Anatomically modern man may have colonized Australia and New Guinea as early as 60,000 years ago (Stringer 1989), although evidence in China is lacking before 30,000 years ago, and the characteristic anatomical features of modern Chinese populations are only clearly evident in specimens dated to about 10,000 years ago (Stringer 2001). In this later migration, the human species reached the Americas (via northeast Asia) and Australasia for the first time. This proposed migration coincides with the significant improvement in tools between about 100,000 and 50,000 years ago. Suggestions that the major colonization was also associated with significant improvements in language remain conjectural. However, it seems certain that migration into the dry cold of northeast Asia, and thence to the Americas, would require clothing and other cultural adaptations to climate that were not available to the earlier migrants. And even though the sea voyages would have been much shorter in the lower sea levels at the end of the ice age, man could not have reached Australia without navigation.

The polygenic or multiregional hypothesis would bestow a much greater antiquity upon the genetic and racial differences observed between modern human populations. Accordingly, it requires some migratory contact between separated groups over long periods of time, otherwise the hypothesis would not be compatible with the relatively modest genetic differentiation observed between contemporary human populations. The monogenic or out of Africa hypothesis implies that contemporary human racial differences all arose within the past 100,000 years, without denying the possibility of gene flow with the previous populations whom they replaced or displaced. The low density of fossil remains and the problems of dating them maintains this controversy. But biochemical evidence favors the latter view, suggesting that modern human divergence is more likely to be the result of a migratory radiation in the past 100,000 to 200,000 years, with (until recent times) only restricted subsequent gene flow (by migration) between the separated human groups and between earlier groups and their successors. For example, a DNA comparison of contemporary European populations with fossil Neanderthal material revealed no significant genetic admixture that could be attributed to the earlier Neanderthal populations (Krings *et al*. 1999).

Estimates of genetic distance based on numerous genetic loci, most of which are not thought to be affected by adaptive processes relating to climate (and therefore to geographical location), usually place African populations at a considerably greater distance from European, Asian, or native American populations than the latter are from each other. An African cluster is almost always identified by statistical processes as being primarily distinct from all the others (Cavalli-Sforza *et al*. 1988). Methods based on the analysis of genetic polymorphisms are superior to measures based on biometrical characteristics (body and skull size, shape, and color). Some of the latter are thought to be adaptive with respect to climate and therefore convergent between tropical populations (e.g., skin color in Africans and Melanesians). The trees of genetic distance created from analysis of these populations cannot of itself produce a migratory path with an origin. But connections between the populations by minimum migratory paths fit the supposed migration from Africa to Europe and separately to Asia, and from Asia separately to the Pacific and the Americas.

More detailed patterns will emerge from the analysis of the DNA of the complete human genome. In the meantime, further information bearing on early migration comes from the complete sequencing of another type of DNA, that found in the mitochondria of the cell cytoplasm (mtDNA). Mitochondria are transmitted entirely through the female line. This mtDNA is much shorter than is the nuclear DNA (about 1/200,000 of the size) and is therefore much easier to sequence, although by no means necessarily representative of the whole genome. Results support the theory of recent African origin, suggesting that about 200,000 years has elapsed since the time of the oldest African mtDNA ancestor whose mitochondrial descendants have survived to the present time. This is based on assumptions about the constancy of mitochondrial mutation rates and the nonselective nature of the variations observed (Stoneking and Cann 1989), which does not prevent the actual fission of populations taking place much later. Unless the assumed mutation rate is wrong by an order of magnitude, this evidence is generally held to rule out a multiregional model of human origins and migration, and to favor a later migration and radiation throughout the world for the immediate ancestors of modern man.

Recent studies of genetic distance based on 100 DNA polymorphisms (but based on a restricted group of populations) have suggested that the genetic distance of European origin populations is anomalous in that it is closer to African origins than expected (Bowcock *et al*. 1991). Another, somewhat contradictory study, based on 186 genetic loci, suggests that European populations are closer to Asian than to African populations (Nei and Livshits 1989). Admixture (arising from migration) between African and Asian populations in west Asia about 30,000 years ago, after the initial dispersal from Africa, may have led the ancestors of European populations to become intermediate between the two before their expansion from their west Asian homeland into Europe. Later reinforcements of genes from west Asia would be expected from the much later movements noted below.

IV. POPULATION GROWTH RATES, COLONIZATION, AND THE "WAVE OF ADVANCE"

After the second of the two expansions described above, two new continents were colonized for the first time. Only modern man has been able to migrate to and through the dry cold areas of northeast Asia and thence across the Baring Strait to colonize the New World, acquiring marked racial features in doing so. The orthodox view is that no human remains from the New World are older than about 30,000 years or possibly 20,000 years. However, the colonization of Australasia—by very different kinds of people—occurred somewhat earlier, possibly helped by changes in sea level. In both areas, however, the precise dating of the first human settlement is continually being revised by new archaeological discoveries.

What kind of migratory process produced this global distribution? Textbooks commonly depict these migrations with arrows, as if they were military advances, purposeful and rapid. But there is no need to assume that the migrations were directed, conscious or fast. The slowly moving diffuse fronts of the weatherman might be a better model. Simple population growth, rather than migratory waves, would be enough to push a human frontier of first settlement at a respectable pace across previously untenanted areas. This is the "wave of advance" model. Thus, if annual population growth rates of up to 1% can be allowed at the margins of an area of human colonization, then the initial peopling of the Americas and of Australasia could have been accomplished by that process alone (maintaining population density by settling into marginal new land) within between 1000 and 3000 years (Carneiro and Hilse 1966). That is nothing in the light of the long time-span involved. In the Palaeolithic, in the very long term, average rates of population growth must have been very slow indeed. Only an order of magnitude can be specified, inferred from the obviously small increase of population over a very long period of time. A long-term rate of about 0.001% per year is much more likely than a rate of about 0.01% per year. However, in the short run in individual populations, vital rates would probably have been quite erratic, both for stochastic reasons and in response to changing local encouragements to population growth or decline. At the rate of 0.001% per year, it would take 2 centuries, on average, to add an average of one imperceptible extra person to a band of 500 people.

During parts of the Neolithic, however, when human carrying capacity was raised by an order of magnitude by the development of agriculture, average growth rates may have risen to 0.1% per year (Birdsell 1957; Hassan 1973; Martin 1973) and locally and occasionally to 1% or more. In the short run, population and vital rates are likely to have fluctuated considerably. Population losses from high death rates arising from epidemics, adverse weather, and raids would have to be repaired by a robust capacity for growth, at least in the short term, otherwise populations would simply have become extinct. Some no doubt did become extinct. Such episodes are recorded in the early ethnographic literature and even in historical time, and such was the fate of many early European colonies in the New World. Some populations are too small to be viable, depending on the type of economy being practiced and the standards of living deemed acceptable (Sutter 1951). In recent years some small settlements in inhospitable environments have been abandoned as unsustainable. For example the entire population (diminished to 35) of the remote Scottish island of St. Kilda was evacuated to the mainland in 1930, at the islanders' request.

Among animal species, temporary migration is a key response to adverse conditions of every sort and is also a crucial way in which local population loss or extinction can be repaired from neighboring populations. No doubt the same was true of early man. Most models of early human population envisage local population exchange with neighboring groups, particularly through marriage (Wobst 1974, 1976). That would have had a homeostatic effect upon local populations by increasing effective size.

By about 8000 years ago, this colonizing phase of migration was complete in respect of the larger landmasses of the globe, although lesser colonization of unpeopled land has continued to the present day. The latter includes agriculturally marginal land colonized only during periods of population pressure, for example, uplands and hill slopes in mediaeval Europe. The expansion of the human settled area by agriculturalists continues in parts of the Third World today, for example, on the slopes of the Himalayas and on the thin soils of tropical rain forests. In some of those cases, the agriculturalists displace pastoralists or the few remaining hunters. Other examples are oceanic islands and zones of extreme climate that require modern survival equipment for year-round residence, as in the Antarctic. Many of the Pacific islands near Indonesia and the Philippines were first colonized by about 1500 BC; others, such as Hawaii, New Zealand, and Easter Island, were not colonized until historical times (in the case of New Zealand, 800 to 1100 AD) (Bellwood 1989). This second expansion required developments in navigation, especially the outrigger canoe. Later expansion, mostly European, brought humans to the most remote islands for the first time: Pitcairn was not occupied until 1790, and in the south Atlantic, the Falkland Islands had no recorded landing before 1690 and no permanent population before 1833. Really hostile environments such as the seabed, space, and the other planets in our system still lack permanent residents, although they are likely to gain them in the coming century. But for most practical purposes, the process of new colonizing migration is long over. Migratory newcomers everywhere now have to deal with established residents.

In the Palaeolithic, human populations once established in a new area were invariably locally nomadic; with rare exceptions nomadism was an essential prerequisite for a hunting and gathering existence. Even after the development of agriculture, populations shifted their fields or gardens on a regular basis to maintain soil fertility as swidden agriculturalists. What was once universal in the human species is still practiced by a few remaining hunters and gatherers, swidden agriculturalists in arid areas, and a larger number of pastoral nomads and transhumants. On a local level, even daily life was continuously or episodically migratory. But such populations also began to interact with their neighbors and others further afield through various media: the routine connections of trade and exchange and marriage (which are familiar in modern guise today) and, more radically, those of directed migration, conquest, and replacement.

V. PREHISTORIC MIGRATION OF PEOPLE OR MIGRATION OF CULTURES?

Constant small-scale local migratory exchanges between neighboring human groups can be taken for granted. What is so surprising about early migratory behavior on the larger scale, insofar as we can reconstruct it, is that it tends to develop in particular directions. Judging from artifacts, living floors and settlements, remains of cultivated plants, and so on, successive "waves" of migrants appear to manifest themselves repeatedly, displacing previous peoples and cultures over large areas and long periods of time. Generally, the movements in Eurasia west of the Urals have proceeded from east to west, movements within the Americas and in south and east Asia and in Africa, from north to south. Such a succession of waves of migrants, so easily caricatured and apparently implausible, seems to be the incontrovertible conclusion from abundant archaeological and linguistic evidence, although a different story may be told by the genes. These processes were very different from the migratory processes with which we are familiar today, although they continued in sub-Saharan Africa up to the 19th century.

Peoples are named primarily from the artifacts found at type sites, which are much more distinctive and numerous than are the small number of poorly preserved human remains, which may not be so readily distinguished from each other. However, we do not make such inferences about the migration of peoples from the presence of Japanese televisions in Paris, for example. It may be that cultures, as identified by artifacts, cereal grains, and other evidence of the cultural traditions of the past, may also have traveled quite independently of their original begetters, and their spread could have proceeded without population replacement. That is so for individual objects of value, such as jewels and coins used as grave goods in cultures that clearly did not produce them, with no other evidence of general cultural change. Thus the spread of agriculture, dated at successively more recent places from the Fertile Crescent to its eventual arrival in the British Isles and Scandinavia, has been interpreted by some as evidence of the spread of techniques and artifacts rather than of people. However, others (e.g., Ammerman and Cavalli-Sforza 1985) claim that evidence from gene frequencies in European populations point to a process of demographic diffusion and (partial) replacement of population through a demographic wave of advance, proceeding at about 1 km/year on average. According to this view, barley and wheat traveled across Eurasia in 5000 years primarily because the people who grew them spread from east to west in that time.

Other, more recent work (e.g., Sykes *et al*. 1999), however, suggests that genetic contributions of Middle Eastern origin (and therefore net demographic contributions) to modern European populations comprise between 10% and 15% of the total, and that overall, most current European ancestry derives from earlier populations. Further analysis of mtDNA from European and Middle Eastern samples, which attempts to take reverse migration into account, has suggested that less than 10% of mtDNA lineages in contemporary European populations date from the first colonization by anatomically modern humans; about 20% is derived from Neolithic colonizers, and the rest is from several waves of migrants in the Upper Palaeolithic (Richards *et al*. 2000). The populations known to archaeologists from the Cro-Magnon period, from about 35,000 years ago, were initially hunters and gatherers, and in this view, their descendants learned agricultural techniques and were not mostly displaced during the Neolithic. If that is so, then the wave of advance was more cultural than demographic. The much later spread of the use of the stirrup, however, appears by contrast to have been more or less instantaneous by the standards of prehistory. This debate remains lively and unsettled, although more recent investigations that use detailed biochemical analysis of human remains suggest that considerable population replacement did take place at least in some areas, for example, in England between the sixth and the eight centuries (Weale *et al*. 2002), reinforcing older views based on language change.

The biochemical genetics of modern human populations permits some reconstruction of human migratory patterns and even some dating of the divisions between major human groups. Much prehistoric "diffusion" of techniques and/or of peoples would have taken place before the organization of states and involved small populations combined, if at all, only relatively loosely. The problems of defining migratory populations on a cultural basis with imperfect knowledge of their human biology is exemplified by the difficulties involved in defining the Celts. Everyone knows what is meant by the word "Celts," who as Gauls gave the name to Gaul, to Gallipoli in Turkey, to Galicia in Poland, and to Galicia in Spain. Native speakers of Celtic languages, however, are nowadays only found in the western fringes of Europe. But everyone appears to know a different Celt, at once described as tall and blond, short and dark, and every other combination; even the Celtic artifacts have little coherence of style over their whole range (Chapman 1992).

When most of the habitable world was already occupied, early movements of whole known populations often seem to have been set in motion by pressure from others. According to this Dark Age domino theory, such pressure inevitably created a cascade of repercussions as the migrants then collided with other migrant and settled peoples. Thus, the arrival of the Sarmatians is "explained" by pressure from the Scythians, that of Goths and of Alans by Huns, and so on. These movements dominate the history of Eurasia for several centuries, and their origins require a special explanation, one that is so far lacking.

VI. THE EFFECT OF MIGRATION ON DEMOGRAPHIC REGIMES

In the past the process of migration has dominated the magnitude of human population levels and the patterns of fertility and mortality, which have to adapt to the conditions of mobile and migratory regimes over the greater part of human existence. Nomads may need long birth intervals, especially those among whom the women, as well as the men, travel frequently on foot both to gather food and to change campsites. !Kung Bushman women would have to carry impossible loads for much of their lives if they could not space their children such that two would never need to be carried at once (Lee 1972). A subtle environment/nutrition interaction with characteristic "shallow and frequent" breast feeding patterns may be the possible mechanism whereby their unusual birth intervals are achieved (Howell 1986). Whatever the process, birth intervals in the Bushmen are known to have been very long, and completed family size are correspondingly modest (Blurton-Jones 1986). Perhaps surprisingly, abortion and infanticide are believed to be rare (about 5%) in that population. But they are strikingly prevalent among many other nomadic and shifting populations—aboriginal Australian hunters and gatherers, the Yanomamö Indians of Brazil (Chagnon 1974; Chagnon and Irons 1979), the garden cultivators of Papua New Guinea (Schiefenhovel 1984), and others—to the extent that up to 30% of births, especially female births, are thereby eliminated (Hausfater and Blaffer Hrdy 1984; Harris and Ross 1987). Other studies, however, do not show a clear relationship between economic type and demographic regime (Campbell and Wood 1988).

The influence of migration or its absence on mortality has been even more potent. When human populations migrated for the first time out of Africa and more generally out of the tropics, they probably gained in survival terms because they may have left behind many of the dangerous parasitic organisms, especially those with insect vectors, that depend on a tropical African habitat. Furthermore, nomadic human populations, necessarily relatively small scale, cannot harbor some major causes of death that can become prominent in settled populations; for examples, nomads are typically free of diseases of contaminated water supplies as typhoid and cholera, of the parasites of contaminated soil such as hookworm, or of nest-pests such as fleas. They do not usually stay in one place long enough to complete the life cycle of parasites carried in local populations of insect vectors of human diseases such as malaria. They are unlikely to be able to harbor tuberculosis; without domestic animals, ancient populations would develop neither tuberculosis nor influenza. Small population size would protect them from smallpox and measles. Such diseases could not evolve in humans until populations had settled and grown in size (Fiennes 1978; McKeown 1988); many require a large minimum population size (about 500,000 in the case of measles) for their existence. Contact with settled people who had developed such diseases, however, would be all the more disastrous as nomadic populations would typically lack any acquired or genetic immunity to crowd diseases (Cockburn 1963).

On the other hand, the migration of small-scale societies would take them into areas—especially new and hitherto unpopulated areas—where contact with wild animals and their insect parasites would expose them to serious zoonoses such as bubonic plague, scrub typhus, and other rickettsias; leishmaniasis; and other serious acute or chronic diseases (Pavlovsky 1966).

The most dramatic example of the new burden of disease brought by migration is the destruction of population in North America, in especially Central and South America, on numerous Pacific Islands, and elsewhere following the arrival of Europeans. The aboriginal populations of those hitherto isolated areas, never having experienced the extensive armory of Old-World diseases brought to them for the first time by transoceanic migrants, conquistadores, settlers, and traders succumbed to them with extraordinarily high mortality rates. That was perhaps the biggest proportional depopulation ever arising (indirectly) from migratory processes, although there are many other examples arising from the "globalization" of diseases after human migration (McNeill 1977). Exactly how big the decline was is almost impossible to state. Estimates of the precontact population sizes of North and South America are highly contentious and vary by an order of magnitude (Thornton 1980; Henige 1992; Zambardino 1997). Conservative numbers are given in Table 67–2 below.

Early agriculturalists from about 6000 BC started to contract diseases from their domestic animals, which in many cases then evolved into specifically human parasites (Stanley and Joske 1980). The same problem would have affected pastoral nomads, although the nomads rise is thought to have been later than that of agriculturalists (about 3000 BC) and depended on the spread of genetic polymorphisms for lactose tolerance, which enabled adults to digest substantial quantities of milk. Subsequent migratory exchanges between settled populations—for trade, slavery, conquest, exploration, or whatever—would tend to increase the sum total of human disease mortality. Through migration at all levels of magnitude, all settled populations eventually acquired the diseases of all other populations without being able to lose any of their own. The historical timetable whereby populations acquired for the first time new diseases that had evolved in other areas of the world is reasonably well known for the last two millennia (McNeill 1977). The process of circulation of disease has, if anything speeded up and intensified in the age of universal mobility with new diseases such as AIDS, new variants of cholera, or antibiotic-resistant strains of other bacteria.

The transition from more mobile nomadic human populations to less mobile and larger settled populations of swidden farmers and intensive cultivators is believed to have reduced average human life expectation by several years (Cohen and Armelagos 1984) through the heavier burdens of infectious disease noted above. In the recent past at least, hunting and gathering societies in Africa seem to have enjoyed lighter mortality than did simple cultivators. For example, the nomadic !Kung of the Kalahari and the Hadza of Tanzania were estimated to have had life expectations of 32 years and 31 years, respectively (Dyson 1977; Howell 1986), compared with about 24 years for simple cultivators in a village in the Gambia in the 1950s (Billewicz and McGregor 1981). Earlier Palaeolithic populations, however, may have suffered higher mortality, according to some skeletal evidence (Acsádi and Nemeskëri 1970). Some hunting and gathering environments were intrinsically very dangerous.

VII. MIGRATION, WARFARE, AND ORGANIZED STATES

In prehistory patterns of migration must be inferred from the relics of genes, bones, artifacts, and contemporary language and place names. These leave much room for argument. History starts with and comes from organized states with writing. At long range at least, its account is dominated by expansion, trade, control, warfare, and destruction. Much of this is connected with migration. From the beginning of written records, usually first attributed to the Sumerians of Uruk from about 3000 BC, high levels of migration and population displacement are at once apparent and almost invariably associated with warfare and conquest and with the extinction of some political entities and the coalescence of others. Some of these shifts of population occur between organized states, usually centered on defensible cities. Sometimes conquest leads to the destruction of those cities and, it may be assumed, of their populations. Most of the first Sumerian cities of Mesopotamia were eventually burned, as were the cities and palaces of Crete. The warlike cities of Assyria expanded their harsh control over the area of modern Iraq and beyond in to Asia Minor and Lower Egypt until they ceased winning in about 703 BC. Conquered populations paid tribute if they submitted, under centrally appointed officials, and were destroyed or transported if they rebelled, as were the northern Hebrews under Sargon II (reign, 721–705 BC). In an Empire without natural defenses, constant victory is the price of survival. In 612 the capital Nineveh, the population of which may have been the first to exceed 100,000, was itself destroyed by its former subjects in Babylon and their Scythian nomad allies, never again to be inhabited and leaving neither cultural vestiges nor mourners. Babylon in turn was to be captured 75 years later by Cyrus the Achaemenid. A later Achaemenid, Xerxes (reign, 486–465 BC), set new standards for the size of mobile armies, possibly taking half the Empire's total levy of 360,000 men for his successful invasion of Greece.

Quite often, however, in the relations between settled populations, the permanent migration of peoples was not an important component of political change. Conquered populations were not necessarily displaced or destroyed, although this may have been more usual after conquest by nomads. Often political control and the recipients of taxes changed, rather than the people who generated the taxes, as befits the spirit of mercantilism. The Achaemenid Persians, their successors the Parthians and Sassanids, and the later neighboring Roman empires behaved in this way: aggressive and absorptive (especially the Roman) and explicitly multicultural and multifaith. As equipotent neighbors they remained incapable for centuries of making serious permanent inroads into each others' territory until the final reduction of the Sassanids by the emperor Heraclius in 628.

1. Migrant Peoples

The expansion or migration of population of warlike nomads or transhumants into territory occupied by other people is a distinctive ancient historical phenomenon, which is unknown to modern Europe although it still occured in parts of sub-Saharan Africa into the 19th century. Nomads moved into lands occupied by other nomads, but the nomads more significantly (and more often recorded) moved from marginal areas into more central areas occupied by denser, settled agricultural populations who could write. As a result of expanding their area or in moving *en masse*, they frequently caused the previous resident population to disappear as a recognizable culture, although the genetic inheritance might continue. On other occasions, as with the Mongol and Manchu invasions of China, the nomads replaced only the ruling class, albeit destroying much of the population in the process. These movements constitute one of the most potent forces affecting the population density and the vital rates of neighboring populations in the past, nomadic and settled, helping to damp world population growth for a millennium. The picture that we can present of them undoubtedly foreshortens events and combines diverse peoples into rather oversimplified groupings, but some major events do seem to be established beyond much controversy.

One of the world's first empires, that of Sargon of Akkad (Mesopotamia), was put to an end by invasion of Indo-European tribes ("Guti") from the Zagros Mountains in modern Iran around 2200 BC. Another example are the Indo-European Hittites, who expanded southward out of Anatolia around the same time (late third millennium BC). They appear to have arrived at the edge of Mesopotamia by moving around the north of the Black Sea and through the Balkans. In the second millennium BC (and later), one of the chief foci of the emigration of mostly pastoral people was the area east of the Black and Caspian seas. Indo-European speaking pastoral nomads, popularly "Aryans" or "Iranians" generated a number of population movements. Aryans moved east into modern Pakistan and then India, permanently destroying *en route* the early isolated centers of literacy at Harappa and Mohenjo-daro around 1600 BC. Others, in the form of the Mitanni, moved into northern Mesopotamia; yet others moved into central Asia. The Dorian Greeks and Phrygians moving south out of the Balkans around 1200 BC overthrew the Achaean Greek and Hittite kingdoms of Southern Greece, Crete, and Asia Minor. Other marginal areas also provided notable examples of expansion and conquest. For example, the Semitic Amorites moved north from Arabia and, with others, overthrew the Sumerian empire of Ur at the end of the 21st century BC. Semitic Hyksos "shepherd kings" (possible also Amorites) moving from the east across Palestine established by force their own dynasty in Egypt in the early second millennium BC (around 1700 BC), possibly at the time of Joseph. A continual series of such incursions is recorded in early history (see, e.g., McEvedy 1967), as well as more "conventional" rivalries and warfare between settled states (often themselves the descendants of previous invaders or ruled by their dynasties.)

A formidable impression is given of an alarming transience of political systems, life, and property in these areas, arising partly out of migratory processes, although the effect is exaggerated by the foreshortening effect of the remoteness of time. Naturally some areas on migratory crossroads were more prone to invasion than were others. Recovery when it occurred could be very fast. For short periods, human populations might have grown at up to 1% per year in recovering from previous even sharper declines, rather than at the tiny average growth rates typical of longer periods. Mesopotamia, Central Asia, and to a lesser extent the borders of India are littered with the mounds of abandoned cities (some destroyed and rendered uninhabitable by local climatic change or by deforestation, overgrazing, soil exhaustion, or salination after intensive cultivation). Part of the key to the success of the later nomads is their use of the horse, first to draw chariots and then, later and more important, for riding, which appears to have been first developed by the Scythians around the seventh century BC (Ferrill 1985).

2. Völkerwanderung—The Coming of the Barbarians

The most dramatic manifestation of these migratory pressures are those in the so-called "migration period," or "*völkerwanderungszeit*," which occurred from perhaps the 2nd century BC to the 16th and which had its European peak in the 4th to the 11th century. This was a period in which migratory activity, despite all the uncertainties and distortions of history, was clearly of a different kind to anything experienced since. Over that long period, the history of the Later Roman and Byzantine Empires, China, and India, as well as other areas of settled population in between, are to a depressing extent the stories of their attempts to defend themselves against such incursions. Accounts of this "great migration of peoples" read as something not short of fantasy or of a caricature of history memorably satirized by Sellar and Yeatman (1931). We are invited to believe that successive "waves" of people emerged from a few focal points in marginal areas—the Baltic shores, the steppes of Central Asia, the Arabian peninsula, Mongolia, and Manchuria—and were able to extend their control over huge areas of western Eurasia, central and western Asia, China, and India. In the course of this migration, much of the settled populations and settlements in their path were allegedly destroyed, the rest overruled or enslaved, and previous migrant settlers or conquerors replaced. But, however implausible, much of it appears to be true.

The migrations appears to have involved demographic processes of a kind whose free operation and consequences are today unknown. Unfortunately, their origins are to be found in remote continental areas, which are devoid of historians and offer few archaeological relics and from which no data will ever come. Writings and linguistic evidence are likewise sparse. All we usually know are the consequences and records of their outward expansion, when they touch on the civilized world. At serious risk of oversimplification; two basic groups of migratory invaders can be recognized. The first are groups of cultivators primarily from Scandinavia, Germany, and other parts of Europe west of the steppes (Teutons, Vikings, and others), whose migratory routes were varied—sometimes taking them with wagons or boats further east to the Black Sea before colliding with the western and eastern parts of the Roman Empire. For example, Scythians and Sarmatians, associated with an Eastern origin, nonetheless appear to have spoken Indo-European languages. Further east, pastoral steppe nomads from central Asia and further east of very different languages and culture (Huns, Mongols, Turks, Manchus) pressed more on north China and the northern fringes of India, although extended their power west to Eastern Europe, the plains of Hungary, and the Middle East. Only the Arabs had a southern origin. It is widely supposed that population pressure is more likely to be episodically generated from the most remote and marginal areas of simple cultivation or pastoral nomad subsistence: the unproductive agriculture of northern Europe; the Arabian deserts and its fringes to the south, the steppes to the north of the Caspian, and further eastward to the East. From such places, all roads led to more prosperous areas and eventually to settled areas of cultivators, as one set of migrants or nomads displaced another. The Asian populations mostly spoke a variety of Ural-Altaic languages: Altaic includes Mongol (a language family including Kirghiz, Tatar, and Turkish); Ural includes Magyar, Finnish, Estonian, and Lapp. In many cases (Huns, Avars, Hsiung-nu) we do not know what languages were spoken. In this area many assertions rest on thin foundations: central Eurasia has been described as the "last of the happy hunting-groups of the dilettante historians," where the "first quality needed by the historian is distrust" (Sinor 1977:113–114).

These nurseries of nomads were the areas least equipped to sustain any population growth, and from which any outward migration would by definition encounter more attractive and easier southern and western environments. By the fourth century, the growing weakness of the Roman Empire, especially its western part, was sufficiently well known to be a further attraction. Precarious and marginal lands can most readily be exploited by mounted nomads, who may require the habit of raiding as a necessary insurance against risk and disaster to herds, as well as a potent contributor to them. Neighboring agricultural populations (e.g., the Persian and Tadjik neighbors of the Turkomans and Kirghiz) typically suffer continuous slave raiding and servitude. Outward expansion from these centeres would exert pressure of neighboring peoples, who would themselves migrate. Thus, pressure from the Huns mobilized Iranians, Goths, and many others; the Avars appear to have been driven into Europe by pressure from the Turks, and the Turks in turn were driven out from 1225 by the Mongols to Armenia and Asia Minor, as were the Cumans to Hungary. Some of these movements were promoted by coalitions with a proper leadership structure, such as the early Turkish Khanate. The Mongols of the 13th century, unified politically in 1206 AD, had become a mobile organized state, with a well-developed and highly successful exploitative military strategy (Sinor 1977:XVI).

Satisfactory explanations are lacking to show why large sections of the usually fissiparous peoples from these areas should be able from time to time to unite themselves in large numbers and depart bent on conquest (or at least more than usually extended and systematic plunder) as well as raiding. Some population was usually left behind in the steppes, unless the whole tribe was being driven out by others. It also remains to be explained why nomads in harsher environments, characterized by unpredictable extremes of heat and cold, were able to generate natural increase. It may be that intrinsic mortality rates in such environments were lower than were rates among densely settled populations, for reasons outlined earlier. On some occasions unusual climatic change, or reverses by settled populations at the other edge of their range, may have mobilized them. It may be recalled that pastoral nomads have three elements of potential instability in their ecology—that of people, herds, and the plants that they eat—not just the two (people, plants) that characterize agricultural populations. Herds may become too numerous to be sustained, plant productivity may fall, or human numbers increase; all requiring new grazing grounds (J. Landers, personal communication).

The consequences on settled populations at the end of this chain of dominos was severe. For a long time, the nomads gained considerable advantage from their mastery of the horse (most others fought on foot), mobility (all they needed was readily portable), and their hardiness from familiarity with severe conditions and long migrations (the Kirghiz annual transhumance was about 1000 miles), to which might be added the unique long-distance strategy, strict military timetabling, and fierce discipline of the Mongols. Relatively small numbers of migrants appeared able to overcome more numerous settled people or to live on tribute from them over long periods. For example, the population of Han China, about 54 million, was for long periods of time unable to defend itself effectively from the Hsiung-nu, who numbered perhaps 1 million at most. It was difficult for settled populations to acquire the lifelong skills of lightly armed nomad horse archers or to concentrate or maneuver fast, as mobile people could. On the other hand, the nomad mode of fighting was an "ethnic technology" limited geographically by its need for substantial supplies of grazing and remounts. That helped to explain why the Hunnish center remained on the Hungarian plain. Their possible relatives, the Hsiung-nu, appear to have exploited their mobility with great subtlety in order to maintain a long-term policy of economic extortion and predation upon the settled Chinese. Deep mobile strikes would retreat before Chinese retaliation could be arranged. This violent raiding had the twin aims of loot and terrorism, the latter to persuade Chinese rulers to accept temporary, more favorable peace treaties through which more tribute could be exacted by what was in essence a huge protection racket. The Hsiung-nu usually declined to occupy Chinese territory even after victories, relying upon the Chinese to build them up again so that they could be looted once more in due course. The Mongol empire, too, appears to have depended primarily on tribute rather than on natural resources (Barfield 1989:49–50).

Sometimes, however, even without gunpowder, the empires could strike back. For example, the Chinese responded to the northern nomads (known to them as the "five barbarian tribes": Hsiung Nu, Chieh, Hsien Pei, Ti, and Chiang) not only with extraordinary defensive measures such as the Great Wall begun by Ch'in Shi Huang (reign, 221–206 BC) but also with active campaigns, such as the unusually successful ones undertaken by the Early Han emperor Wu Ti (reign, 140–87 BC) to knock out the western Hsiung-nu in 44 and 36 BC. Later Chinese resistance is believed to have diverted some Hunnish interest further West, to the discomfiture of Europe. It was not really until the age of gunpowder that settled populations could become more secure from the depredations of nomads on the fringe of settlement (Landers 2003) and could start to push them back to their heartlands.

One of the most consequential of the ripples of pressure arose from the destruction by the Huns of the Ostrogothic empire on the Dniester in 375. After this disaster the Goths obtained the permission of the Roman Emperor to settle within the Roman Empire in Thrace—a kind of mass asylum claim from which a certain element of threat was not absent. Through developments too complex to relate here (see Heather 1991), the Goths eventually inflicted one of the most decisive victories ever over Roman arms at Adrianople (Edirne) in 378. That victory established them permanently within the empire. That migration was eventually to contribute to the end of the western Roman Empire in 475 and the establishment of the Goths in many parts of the Western Europe (Ferrill 1983)—the Ostrogoths primarily in Italy and the Visigoths in France and Spain—albeit in part through negotiations with their nominal Roman overlords, which established them and other invaders as "allies" *(foederati)*.

The Huns, who originally set in motion this sequence of migration, themselves invaded Western Europe later on. By the fifth century, they were no longer mere pastoral nomads. United under Attila from his "palace" in the Hungarian plain (more a shanty town of wooden buildings, tents, and wagons), where Latin and German were allegedly spoken more than was Hunnish, they ruled large numbers of both Slavic and Germanic peoples and bordered both halves of the Roman Empire. As with all the barbarian tribes, relations with the Romans were complex and included periodical alliances, including the use of Hunnish mercenaries by Rome and ruinous tribute extracted from the eastern Empire. Unlike many of the other barbarians who entered Europe (e.g., Magyars, Bulgars, Burgundians, Lombards), the Huns under Attila did not become a settled people, to be attacked in turn by new invaders. They remained on horseback; their subsistence was derived almost entirely from Roman tribute as the subsistence of others derived substantially from plunder. Active conflict with Rome began on the pretext of the Roman acceptance of what we would now term asylum-seekers, who would undoubtedly, under those circumstances, have entertained a well-founded fear of persecution. Checked by almost the last gasp of western Roman arms in alliance with Burgundian and other (barbarian) allies at Châlons-sur-Marne (451), the Hunnish Empire fell apart on the death of Attila (453, following his stag-night binge) and, unlike most of the other invaders, featured no further in Western European history.

Perhaps the most remarkable of these mass migrations of whole peoples is that of the Vandals. They, along with many other Teutonic tribes, breached the Roman defenses on the Rhine (406) and established themselves in France and Spain, partly through force and partly through Roman appeasement, treaty, and partition of the land with local landowners. When established in Spain under their king Gaisarix, the Vandals looked, as the Goths under Alaric had also done, to the richest province of the Roman Empire in North Africa, the key to the food supply for Italy. In 429 they crossed to North Africa. Initially established as *foederati* after early military successes, they soon (442) became *de jure* as well as de facto rulers of the western part of North Africa, around Carthage, and no longer regarded themselves as part of the Roman Empire. Previous inhabitants, although dispossessed and regarded as a subject people, do not appear to have been generally slaughtered. In 455 the Vandals invaded Italy and sacked Rome, removing most the objects left behind by the Visigoths in 410 but did not settle. By 476 the empire of Gaisarix (died, 477) included all the Roman province of Africa, Corsica, Sardinia, and Sicily and was raiding the coasts of Greece. But even this established state could not defend itself against the reprisals of the eastern Empire, and its culture was eventually swept away entirely by the Arab Muslim invasions of the seventh century. The Arab invastions eliminated a "European" cultural and political presence in former Roman North Africa and, shortly after, took over most of the Vandal's former territory in Spain itself, for the next six centuries.

The litany of such migrant peoples is perhaps usefully, if inevitably very partially, recalled in a table (Table 67–1). Their (very approximate) dates are those when they first come to the notice of people with writing. The numbers claimed are sometimes surprisingly high. Contingents of 30,000 are regularly mentioned. Confederations of barbarians could raise armies estimated by contemporary sources to be up to 300,000 men (e.g., a union of Ostrogoths and Visigoths defeated by the Emperor Claudius II on the Danube in 269 AD). Even if this represents all the men of military age, it still seems to be a very large figure, about the maximum size of the Roman army at its height, and not then surpassed until mass armies were raised for the first time in modern Europe from the time of Louis XIV (Landers 2003; Tables 13–1, 13–2). How such a large force could have been sustained at that time,

TABLE 67–1 Some Migrant Peoples of Eurasia, 400 BCE–1600 CE

Peoples	Time	Origin	Settlement
Teutons			
(Suevi, Marcomanni, Cimbri, Ambrones etc.)	4th BC	West Baltic	Germany, France
Other members of Teutonic confederacy			
Alemans	3rd AD	Elbe	France
Franks	3rd AD	Weser-Rhine	France
Vandals	3rd AD	Jutland, Norway	France, Spain, north Africa, Italy
Ostrogoths (East Goths, east of Dniester)	3rd AD	Scandinavia/Black Sea, Italy	Germany
Visigoths (West Goths, west of Dniester)	3rd AD	Scandinavia/Black Sea, Italy	France, Spain
Angles	3rd AD	Schleswig-Holstein	England, lowland Scotland
Saxons	3rd AD	lower Elbe region	England, lowland Scotland
Jutes	3rd AD	north of Rhine	England, lowland Scotland
Burgundians	3rd AD	Oder/Vistula	France
Lombards	6th AD	south Scandinavia	Italy
Huns	4th AD	Steppes	central/east Europe, north India
(Hsiung-nu / Xiongnu)	3rd BC	Steppes	North China
Bulgarians	7th AD	Steppes	Balkans, Italy
Magyars (Hungarians)	8th AD	Steppes	Hungary
Mongols (Tatars)	12th AD	Manchuria	Middle East, Russia 13th–16th century, Yüan dynasty (China) 1276–1368
Moguls	16th AD	central Asia	Indian dynasty 1527–1857
Manchus (Ch'ing)	17th AD	Manchuria	Ch'ing dynasty 1644–1908
Scythians	7rd BC	central Asia	Balkans, Caucasus, northwest India
Sarmatians	3rd BC	central Asia	Transcaucasia, south Russia
Alans	1st AD	central Asia	Caucasus
Turks			
Seljuk	11th AD	central Asia	north India
Western	6th AD	Mongolia	central Asia
Eastern (Uighurs)			central Asia
Ottoman	13th AD	central Asia	Balkans, north Africa, Arabia,
Asia			Asia Minor, Egypt
Arabs	7th AD	south Arabia	Spain, north Africa, Persia, central Asia
Vikings	8th AD	Scandinavia	Normandy, east England, Iceland

This list is far from complete; no list can hope to do justice to a complex process covering two continents and a millennium. Migration histories were usually much more complex than given here; for example, the Germanic Goths began, or were first recognized, in the area of the Vistula and moved south to the area of the Dniestr before moving west.

Some supposedly related peoples are grouped by indentation, but many relationships or origins are unknown or vague at best. The dates and locations can only be approximate.

even by plundering all the countryside through which it moved, is not clear; such estimates are unlikely to have been based on any kind of actual counting. The contemporary (professional) Roman army on all fronts of the empire about that time is known to have been about 250,000 strong (Ferrill 1994). A more modern estimate of the numbers of all the warriors in all the Gothic hosts in the late 4th century (which were never unified) suggests about 60,000 men and therefore a total population of perhaps 300,000 in all the Gothic groups together. Estimates of the Thracian Ostrogoths alone in the late 5th century suggest a population total of between 30,000 and 50,000 (Burns 1978, Heather 1991).

VIII. THE DEMOGRAPHIC CONSEQUENCES OF THE "MIGRATION PERIOD"

The consequences of this form of migration on most of the peoples visited by it appears to have been almost entirely negative in demographic terms and probably in almost all other terms as well. The visiting peoples added little in terms of population and typically nothing in terms of cultural and technical advance (except possibly in warfare). Through destruction of people, habitations, and the infrastructure of cultivation (especially in the dry East), they caused a perceptible and often long-term diminution of human numbers. Estimates of the numbers of the migrants are obviously difficult and are likely to have been exaggerated by contemporaries. On the other hand, from the first century AD onward, we do at least have somewhat firmer bases for estimating regional populations, from remnants of Han and Augustan censuses and a much more intensive archaeological knowledge of the number and extent of settlements.

According to the estimates of Jean-Noël Biraben, discussed in the previous chapter (Table 67–2), the world population is thought to have diminished from about 250 million in 1 AD to 205 million by 500 AD, not recovering to its previous level until about 1000 AD. (It can only be repeated that all such estimates are tentative and uncertain; figures for 1 AD vary from 169 to 297 million) (Caldwell and Schindlmayr 2002: Table 4). Much of such loss can be attributed to the disruption of settled populations. The recovery to 1000 AD did not include Europe, whose population fell from 35 million in 1 AD to about 30 million in 500 AD and in 1000 AD, nor did the recovery include the population of North Africa, which fell from 14 million to 9 million over the same millennium. European population by 1500 was little larger than it had been in 1250. China and south Asia suffered worse from the invasions of Huns and their relatives and from Aryans and Muslims from the north and west. China's population fell from 70 million in 1 AD to 32 million in 500 AD, recovering to only 56 million by the end of that millennium. The period between the capture of the Tsin dynasty capital (then at Loyang on the Yellow River) in 316 AD by the Hsiung-nu until the reestablishment of complete Chinese control over the North by the Sui dynasty in 589 AD is regarded as China's Dark Age. The capital had to be removed to Nanking on the Yangtse over 300 miles further south, with the consequent migration of many of the survivors from the Yellow River valley, which was effectively abandoned, to that of the Yang-tse. Exact numbers are unknown, but the losses and migrations together must have involved millions of people. India's population is estimated to have fallen from 46 million to 33 million to 500 AD, then only recovering to 40 millon by 1000 AD (Biraben 1979). A basically similar picture is given by other estimates (e.g., those summarized by Durand 1974; McEvedy and Jones 1978), all of which must be regarded as being rather precarious.

Most parts of Eurasia also had to endure the impact of the bubonic plagues, which reached Europe in 1347 from the Crimea and had afflicted China earlier. China in particular, however, from the mid 13th century, also suffered from immense destruction inflicted by the Mongols, who also enslaved Kiev (1210), much of Russia, and parts of eastern Europe but who failed to reach Western Europe. The expeditions and depopulations through slavery instituted by Tamurlane (1336–1405) are claimed to have caused the deaths of up to 17 million people; an opinion impossible to verify, of course. The Mongols may have reduced the population of China by up to 35 million people during their protracted conquest in the 13th century, in an invasion reminiscent of that of the Hsiung-nu (sometimes identified, on thin evidence, with the Huns) in the 4th century. However the Hsiung-nu remained essentially raiders, whereas the Mongols, having eventually abandoned their preference for depopulating China in favor of exploiting its riches, founded a new (Yüan) dynasty in 1271. North China (then the most populous part) is thought to have lost about three-quarters of its population (McEvedy and Jones 1978): the Chin census of 1195 enumerated 50 million in North China; that of the Mongols in 1235–6, admittedly in a time of turmoil, counted just 8.5 million. As a result of massacre and forced migration, the demographic center of gravity in China seems to have shifted to the south, as maps based on contemporary censuses appear to show (Population Census Office 1987:70–71). By 1500 the population of China was still

TABLE 67–2 Some Estimates of Regional Population 1 BC–1500 AD (millions)

Population	1 BC	500 AD	1000 AD	1250 AD	1500 AD
China	70	32	56	112	84
South Asia	46	33	40	83	95
Russia	12	11	13	14	17
Europe	35	29	30	57	67
North Africa	14	11	9	8	8
North America	2	2	2	3	3
Central/South America	8	11	14	23	34
World	250	205	257	413	458

Note: South Asia comprises India, Pakistan, and Bangladesh. (From Biraben 1979) less than it had been in 1250: 84 million compared with 112 million. These figures cannot be exact, but similarly large estimates of population loss appear in all estimates that have been made. They are at least based on some of the few (albeit discontinuous) registration systems of the time, and the losses are in accord with the contemporary reports of the ferocious genocide practiced by the Mongols in the process of their conquest of north China.

As an earlier commentator noted

> This is the role of nomadism in the history of the world: countries too distant from its base it could only ravage transitorily, with robbery, murder, fire and slavery. But the stamp it left upon the peoples which it directly dominated or adjoined remains uneffacable. The Orient, the cradle and chief nursery of civilization, it delivered over to barbarism; it completely paralyzed the greater part of Europe . . . had Germany or France possessed steppes like Hungary, where the nomads could also have maintained themselves and thence completed their work of destruction, in all probability the light of West European civilization would long ago have been extinguished, the entire Old World would have been barbarized and at the head of civilization today would be China (Peisker 1911:359).

As a slight counterpoint, it should be noted, following earlier allusions, that settled and migratory peoples also engaged in trade and military alliances with each other. Thus Pope Innocent IV opened correspondence with the Mongols (some of whom later became Christian for a while) in 1245 in the hope of deflecting their attacks on Europe, securing their aid to restore the Holy Land, and converting them to Christianity. Although ultimately fruitless, this enterprise continued when, for example, Philip the Fair, King of France, corresponded with his ally the Mongol Ilkhan Arghun in 1289 on a joint project to capture Damascus from the Moslem Mamelukes, and Prince Edward of England (later Edward I, 1274–1307) successfully sought an alliance with the Ilkhan Abaga when on crusade at Acre in 1271 (Sinor 1977: IX) although it eventually came to nothing.

It is these processes, the weakness and instability of settled populations in the face of new populations of migrants, that perhaps marks the greatest contrast between the world of the prehistoric and remote historic past and the present day. In the past, settled populations or their elites often could not withstand the migrants. As time as gone on, the settle populations have been more successful, and it is the less settled populations who have been marginalized. In the course of that process, migratory forces, at least of that kind, have ceased to exercise their once dominant role on human population. Instead, variation in vital rates arising from other more endogenous causes, notably the onset of the "demographic transition," has exercised the predominant effect on human population trends. That in turn has affected migration rates.

IX. EUROPEAN EXPANSION AND ITS CONSEQUENCES

The more recent European expansion is much better documented and needs little further description here. Much of it has been summarized in Cohen's magisterial encyclopedia (Cohen 1995) as well as in earlier works (e.g., Segal 1993; Chaliand et al. 1994). Although essentially another once-off process that has run its course, in small ways it grades into the present day. In some areas it is now reversed, with the return to Europe of settler populations ousted, often by violence or its threat, from Angola and Mozambique (Portuguese), North Africa (French, Italians, and Spanish), Central Asia, and the Baltic (Russians); a question mark hangs over the white populations of southern Africa. Other changes in population distribution and density arising from the European expansion are irreversible, notably the 300 million people mostly of European origin now settled in North America, Australia, and New Zealand, as well as many of the ancestors of a further 300 million people in Central and South America. Some of its earliest manifestations of European expansion, of Teutonic Knights into the region of the Baltic and Eastern Europe and of the return of Europeans to the shores of the Middle East and of North Africa in the 12th, 15th, and 19th centuries—with success that endured for a similar length of time—were the familiar form of armed invasion of relatively populous but (in the latter case) less-developed regions. This expansion coincided with, and was in some respects a component of, the rolling back of the nomadic conquests of previous centuries. In Spain it culminated in the final reduction of Granada, the last Moorish stronghold in Spain, in 1491. At the other end of Europe, in Russia, the removal of Tatar (Mongol) rule was confirmed by the capture of Kazan and Astrakhan from the Mongol Khans by Ivan the Terrible in 1552 and 1556. That was just the beginning of an arduous process of conquest and colonization that reached the shores of the North Pacific by the end of the 17th century but that did not finally occupy the central Asian homelands of the (former) nomads until 1873 (Linedy 1994).

Other aspects of European expansion, however, were of a quite different kind with little previous parallel (Scammell 1989; Pohl 1990), such as the transport over hitherto impossible sea distances, thanks to advances in navigation, of small but technically proficient populations, at times explorers, soldiers, adventurers, pirates, traders, settlers, refugees, and missionaries (Crosby 1986). The only partial comparison was with the Vikings of the 7th to 11th centuries and some earlier Mediterranean seafarers. But the latter, mainly interested in plunder and trade, respectively, did not enjoy overwhelming technical superiority against the peoples they encountered. Neither could they depend on reliable navigation. Their transatlantic adventure to Greenland and to "Vinland" failed. In Greenland, a long-term deterioration of climate during the Middle Ages may have been partially responsible for their eventual extinction. However, their transatlantic and global successors were able to overcome and displace simple societies living at a low population density and others of a more advanced and densely populated culture. In the earlier ventures to the New World from the 15th century, culture shock and above all the impact of the new diseases that came with the immigrants enabled them to displace aboriginal populations in part or whole, as well as to establish new populations of their own. In some cases (e.g., Tasmania, Argentina) a deliberate policy of extermination was initiated.

Once colonial or independent states were established in the Americas and the Antipodes, peaceful and regular migration out of Europe to these colonial New Worlds became the most salient global migration stream from the late 18th to the early 20th centuries. About 54 million people are believed to have migrated from Europe to the Americas from 1815–1930 alone (Baines 1991), although it must also be recalled that about one-third probably returned to Europe. This strand of migration continues, although at a much reduced level, and is overshadowed by the migration of populations from the Third World into North America and Western Europe. Meanwhile, in the "Wild East," substantial European population movements continued in an opposite direction. Migration to the "empty lands" of Siberia had only been encouraged from 1889, and freedom of "internal colonization" was granted only in 1906. Between 1906 and 1915, about 3.5 million Russians emigrated to Siberia. Elsewhere, the processes of voluntary and of forced migration within the Tsarist and then the Soviet Empires had created, by 1989, a position whereby 25 million people of Russian "nationality" lived in those parts of the former Soviet Union outside the Russian Federation; that is, not counting the migrants to Siberia, which is within that Federation. The return of some of these migrants or their descendants, some of it forced, had turned Russia in Europe's biggest net receiver of migrants by 1994.

In India, China, and other parts of the Orient, settled populations were already dense, and the main motive of initial European contact was trade (Emmer and Mörner 1992). By the 18th century, military superiority in weapons, discipline, and tactics enabled small European forces to overcome oriental dynasties that could field huge but ineffectual feudal armies. But despite conquest, no settlement was usually attempted in Asia or Africa except in Indonesia, central Asia and Siberia, southern Africa, and a few other places where climatic or demographic circumstances seemed propitious. In the tropical Old World, disease organisms generally favored the native, not the invading, populations (Curtin 1989, 1990). New navigation combined the ancient habit of forced labor migration through slavery brought a new component of population in the New World and an additional element of population destruction for Africa, in addition to the slave trade already organized for centuries to other parts of Africa and the Middle East.

Estimates of the number of slaves transported across the Atlantic vary from 3.5 to 25 million. A careful analysis suggests that 9.6 million were landed in the Americas between 1451 and 1870 (Curtin 1969), although the population loss to Africa must be inflated by the mortality at sea (variously estimated at 13% to 33%) and the direct and indirect mortality involved in the slave-taking process itself. This is only part of the damage to Africa as a whole, although the magnitude of the effects of slavery on African economy and society, previously taken for granted as highly damaging, has been questioned (Eltis 1991).

Slavery to other parts of Africa and the Middle East had continued from the earliest times and was formally suppressed progressively up the early 20th century. In the late 20th century, slavery was reported to be reviving in the Sudan and elsewhere. In the case of the transatlantic trade, for the first time since Roman times, slavery was primarily devoted to agriculture and manufacture. For the first time, it formed the basis of major intercontinental flows of money and goods (Lovejoy 1986; Solow 1991).

X. THE RISE OF "MODERN" FORMS OF MIGRATION

In the beginning, there was no labor migration. The nonmarket subsistence agriculture of traditional peasant economies did not need it. Specialist skills would later increasingly be concentrated in villages and towns, which implies migration. And once agrarian economies developed sufficiently to produce a division of labor greater than that between priests, rulers, warriors, and peasants, groups of people with special but often alien skills, in metalwork, textiles, and later finance were encouraged to enter the domain, often giving an ethnic component to the division of labor. In early economies, merchants too often had to be migrants, at least in the short term, but over long distances. Mercenaries, often migrants, are a special case, sometimes accepted into the society (as in the later western Roman Empire) in order to avoid having to fight them and at the risk of their overthrowing the regime they were paid to support (as in fifth century Rome and in seventh century Britain). Slaves might occasionally do the same, for example, the Mamelukes in Egypt (1250–1517) and the blacks in Haiti (1790–1804).

Most states in the past, and some to the present day, have been pronatalist and mercantilist in their approach to population. Explicit responses to that included encouragement of the birth rate, the inhibition of emigration, and the selective encouragement of immigration, including permanent immigration for settlement. This was above all the response of many of the European settlements in sparsely populated areas of the world overseas in the latter part of the second millennium, especially by countries in South America, North America, and Australasia. Only the latter three, and Israel for special reasons, continue such a policy today, although France has in the past had a more favorable attitude to the demographic consequences of immigration than has its European neighbors.

Agricultural labor migration remains undeveloped in an early subsistence economy, with its locally produced and sustained labor force, especially if the economy is not yet monetized. Voluntary labor migration becomes common as markets in labor develop on a seasonal and longer term basis within market-based agricultural economies (Coleman 1984). Mobility became the norm in the early modern period in Europe through such pervasive Western European practices as husbandry service (local not international) (Kussmaul 1981), through the hiring of adult labor among an increasingly landless population (Moch 1992), and as "internal" rural-urban migration (Wrigley 1967; Clark 1979) promoted by a more specialized and differentiated society. Elsewhere, especially where forms of serfdom were practiced that tied peasants to the land, the mobility revolution (Zelinsky 1971) comes much later. Labor movement does not become generally international until a much later date, particularly during the Industrial Revolution, although large populations left Europe in increasing numbers from the 18th century in pursuit of more general aspirations for a better life in a less rigid world—about 54 million crossed the Atlantic between 1830 and 1914. The growth and survival of cities, especially the larger cities and those in more recent periods, depended on constant positive in-migration streams to make good the natural loss of population arising from the usual excess of urban deaths over births (Landers 1987).

CONCLUSIONS

Human (international) migration has generally been conceptualized in modern demographic studies as being of relatively small numbers of people moving for reasons of labor and personal improvement of prospects, family connection, or asylum-seeking between or, at least into, established states. It has generally been considered to be a minor force in demographic change compared with vital processes. Although generally true at the present time, except for its increasing scale, that picture gives a partial and restricted view of the full range of human migratory possibilities. A much wider variety of forms of migration has existed over time, some of which are now extinct. A few were once-off and unrepeatable events. Although at the present time migration is usually regarded in the demography of large-scale populations as being a second-order and separate process compared with the prime demographic engines of fertility and mortality, this has not always been so. And it may not be so in the future in view of the potential transformation of low-fertility developed populations by immigration from third-world countries.

At various times in the past, particularly in the remote past and during the "migration period," migration has been primary in determining human population size and composition over large areas of the world's surface. The demands and conditions of a migratory life determined the disease and risk environment of human populations—for all of prehistory, of all human populations—and therefore the level and pattern of mortality and fertility of populations over than immense period of time. This is the risk environment to which the human species has adapted in the course of its evolution. The effects of the interaction between settled and nomadic populations for the past 4000 years has had substantial and usually with negative effects on the populations of the latter, particularly at the beginning of the period of urban settlement and later between the 3rd and the 14th centuries. Frequently during that time, the depredations of mobile populations on settled peoples put human population growth substantially into reverse over large areas of the world's surface. And although expansion of European populations out of the Old World eventually led to much larger populations in the areas in which they settled, the effects of the transported new diseases on the aboriginal populations were initially disastrous and the political, cultural, and social consequences endure to the present. Although migration again engages the attention of the industrial world's political systems, and for good reason, modern concerns are of a different, and in many respects of a lesser kind, than are those of the past.

Europe's Demographic Transition, 1740–1940

JACQUES VALLIN

Institut national d'études démographiques (INED), Paris, France

INTRODUCTION

The Industrial Revolution had many antecedents, whose analysis lies outside the scope of this chapter: they include cultural emancipation and scientific revival in the Renaissance, the formation of powerful centralized states, the saga of great discoveries (the compass, printing, gunpowder, America, etc.), the accumulation of merchant wealth, and 18th century progress in agriculture. These economic and social changes in Western Europe also triggered another revolution: the *demographic transition*.[1]

For several hundred thousand years—as Jean-Noël Biraben shows in Chapter 66—mortality and fertility had been governed largely by natural factors. In the late 18th century, they came within the sphere of human control. Medical progress, as well as changes in attitudes and behaviors, radically transformed the old demographic regime. These new factors made it possible to combat disease and death efficiently and to control fertility. At the same time, they stimulated a massive demographic expansion. But, as they first occurred in Europe,[2] the Industrial Revolution and the demographic transition also caused a radical shift in the planet's geopolitical balance. They gave the European continent both the technological means and the demographic impetus that would enable it to dominate the world (Vallin 1986).

One of the last witnesses to the old demographic regime, as well as one of the first inventors of a general theory of population, was Thomas Malthus. Struck by the harshness of natural constraints on mankind, he believed that humans, as all living beings, tended to increase the population of their species beyond the level sustainable by the quantity of food that they were able to procure or produce (Malthus 1798). Thomas Malthus believed that economic development stimulated fertility, leading to excess population growth and inevitably a food crisis, hence excess mortality. To prevent such drastic adjustments, he proposed controlling the number of births by means of continence. To say the least, his suggestion has been overtaken by events, although the neo-Malthusian school admittedly gave new luster to his arguments later on. In the 2 centuries from 1750–1950, the population of Europe (with first the Russian Empire and then the Soviet Union included) rose from 146 million to 573 million; moreover, it contributed massively to demographic

[1] The first author to have described the process in depth named it the "demographic revolution" (Landry, 1934). However, it is now universally referred to as the "demographic transition," a term borrowed from postwar U.S. authors (Davis 1945; Notestein 1945).

[2] Albeit not throughout the continent or in a consistent pattern in all European countries. As discussed below, this major historical process actually began in northwest Europe (England, France, Scandinavian countries, Netherlands) before spreading to central Europe (Germany, Austria, Northern Italy) and then finally to Mediterranean Europe (Spain, Portugal, Italy, Greece) and eastern Europe (Poland, Romania, Russia, etc.).

TABLE 68–1 Growth of World Population by Major Region, 1500–1950

Region	1500	1600	1700	1750	1800	1850	1900	1950
Population size (million)								
Europe and ex-USSR	84	111	125	146	195	288	422	573
North America	3	3	2	3	5	25	90	172
Latin America	39	10	10	15	19	34	75	167
Oceania	3	3	3	3	2	2	6	13
Africa	86	114	106	104	101	103	118	221
Asia (not including Soviet Union)	243	339	436	504	646	791	902	1377
Total	458	580	682	775	968	1243	1613	2522
Proportional distribution (%)								
Europe and ex-USSR	18.3	19.1	18.3	18.8	20.1	23.2	26.2	22.7
North America	0.7	0.5	0.3	0.4	0.5	2.0	5.6	6.8
Latin America	8.5	1.7	1.5	1.9	2.0	2.7	4.6	6.6
Oceania	0.7	0.5	0.4	0.4	0.2	0.2	0.4	0.5

Sources: Biraben [see Chapter 66]; United Nations 2001.

growth in North America and Australia–New Zealand, whose combined population went from 6 million to 185 million in the same interval (Table 68–1). Nor should we forget Europe's more modest but not negligible contribution to the settlement of many other regions of the world, most notably Latin America.

True, the first shock that followed the conquest of America was, if anything, negative. Latin America, in particular, had suffered devastating population losses owing not only to the massacres but also to the microbial shock[3] and the collapse of pre-Columbian civilizations. Authors differ,[4] but, according to the estimate given by Jean-Noël Biraben in Chapter 66 and reproduced here, the population of Latin America was divided by 4 between 1500 and 1600, decreasing by almost 40 million to 10 million. Although far more sparsely inhabited, North America underwent a roughly similar fate in the 17th century. America did not regain its 15th century population size until the second half of the 19th century. Yet, thanks to European emigration (see Chapter 58, Volume II), it has since registered an extraordinary boom.

In Africa, population decline owing to the European shock and, in particular, to the slave trade persisted until the 19th century. From 1600–1800, the population fell an estimated 10%, from 113 million to 102 million. The numbers started rising again slowly until the mid-20th century.

In contrast, Asia (in fact, mostly China) experienced robust population growth between the 16th and 18th centuries. Its share of world population expanded from 53% to 64%. Since then—with European domination a later and more incomplete phenomenon than in Africa and America—the Asian population has grown steadily but at a slower pace. From 1750–1950, it rose from 500 million to 1.377 billion.

In the same period, the demographic equilibrium between continents shifted unquestionably to the benefit of Europe. In 1750, Asia held two-thirds of the world population (65%) and Europe less than one-fifth (19%). Africa had most of the rest (13%), because America and Oceania were very sparsely inhabited at the time, with less than 3% of the total.

By 1900, a century and half later, Asia's share had dropped to 55% and Europe's share had climbed to 26%. North America, a true outgrowth of Europe, now represented 5.6%, and Latin America, also heavily dependent on European emigration, accounted for 4.6%. In contrast, Africa's share had fallen to 7.3%.

What had happened? First, Europe had experienced an unprecedented long-term mortality decline, which paved the way for steady, accelerating population growth. True, the mortality downturn had been followed by a restriction of fertility that eventually

[3] The importation of new germs by the Spanish conquistadors devastated the American Indian population, cut off from the rest of the world for millennia.

[4] Colin McEvedy and Richard Jones (1978), for example, estimated that the American Indian population fell by only 25% and not by almost 75%, the figure chosen by Jean-Noël Biraben.

slowed population growth and led to the emergence of a new demographic regime with low mortality and low fertility. In most cases, however, the timing difference between the mortality and fertility downswings has generated unprecedented excesses of population over a variable but usually rather long period. This large-scale historical trend radically altered Europe's position vis-à-vis the rest of the world. Initially named the "demographic revolution" by Adolphe Landry (1934), it spawned an abundant literature that ultimately gave birth, after World War II, to the theory of "demographic transition"—a major explanatory framework for the macro-demographic phenomena of the second half of the 20th century.[5]

Although this momentous historical trend clearly originated in Europe in the mid-18th century, its point of arrival is harder to identify (assuming it even exists, as we shall see in the chapters that follow). However, the present chapter discusses only the European transition. Its spread to the rest of the world is examined in the next chapter, and, for clarity's sake, I prefer to give precedence to the historical division and conclude this chapter where the following one begins, using World War II as the cutoff point. Indeed, it was largely after World War II that the transition phenomenon spread to the rest of the world; it is also fairly clear that the postwar baby boom marked a turning-point in the process in Europe. Consequently, although all the changes described were far from complete by 1940, all the charts illustrating the phenomenon here will stop (provisionally) in that year.

I. AN UNPRECEDENTED MORTALITY DECLINE

Humans have always sought to avoid disease and death, but for millennia, their struggle for survival was relatively inefficient and their life expectancy at birth very short. As far back as evidence exists for their behavior, humans seem to have consistently made a rather conscious effort to vanquish disease and delay death. Initially, of course, they did so by trying to make arrangements with the gods or the forces of evil; with the accumulation of knowledge, however, they gradually turned to seeking medications that would improve the efficiency of prayers and spells—and eventually replace them. Did this millennial quest have any effect on the mortality level before the 18th century? Presumably not, as Jean-Noël Biraben notes in Chapter 66. In contrast, the second half of the 18th century saw the start of an unprecedented rise in life expectancy in northwest Europe.

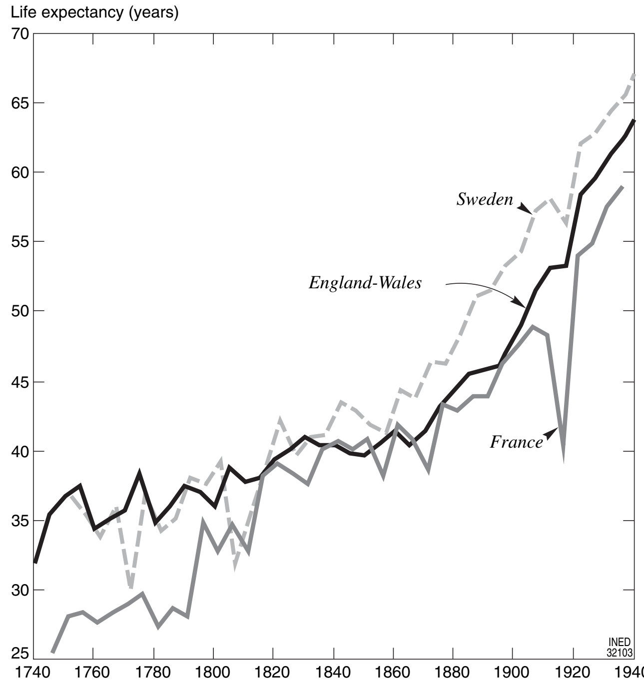

FIGURE 68–1 Change in life expectancy at birth in Sweden, England-Wales, and France from the mid-18th century to the eve of World War II (by 5-year period). (From: England-Wales, Wrigley and Schofield 1981; Sweden, Holmberg 1970; France, Vallin and Meslé 2001.)

1. Two Centuries of Spectacular Progress

Figure 68–1 plots life expectancy at birth over 2 centuries, from 1740–1940, in Sweden, England-Wales, and France, countries for which we have the longest complete statistical series on the subject.[6] Life expectancy at birth nearly doubled from 25 to 35 years in 1740 to 55 to 65 years in 1940.

The starting point of this momentous change is partly in dispute. It is much lower for France than for the two other countries in Fig. 68–1. In fact, the Swedish data are based solely on recorded deaths: however high the quality of the Swedish registers even at the start of the period, we can assume that a percentage of deaths—particularly of infants—went unrecorded. For England-Wales and France, on the contrary, we have time-series reconstructions by historical demographers. The English estimates also incorporate a backward projection from later data by Edward Wrigley and Roger Schofield (1981), whereas

[5] It cannot, however, claim to explain everything. In particular, the baby boom of the 1940s to 1960s was no doubt largely driven by other factors.

[6] Thanks to early recording of current statistics in Sweden and historical reconstructions in France (Henry and Blayo 1967; Blayo 1975) and England (Wrigley and Schofield 1981).

the French estimates are based on the late-1950s study by Louis Henry of a national sample of parish registers (Blayo 1975). It is surprising to find so wide a divergence in the results of these studies for two countries that shared so many common economic, social, and political features at the time. The studies suggest a life expectancy of only 24.8 years in France in 1740–1749, versus 35.3 years in England-Wales in 1746—a gap of more than 10 years. France did experience several years of food shortages in the 1740s.[7] Indeed, in the far more clement 1750s, French life expectancy rose to 27.9 years, but this figure remained well below that of England-Wales, which also increased to 37.3 years in 1756, preserving a differential of nearly 10 years. There are two conflicting explanations of this (Vallin 1989c, 1992). Some authors—most notably those of the English reconstruction—argue that health conditions genuinely differed between the two countries. True, the climate may have played a role. England's prevailing oceanic climate may have given it an advantage not extended to France, whose climate is more continental and Mediterranean. Jean-Noël Biraben and Louis Henry (1957) have shown, for example, that infant mortality was higher in the Mediterranean countries than in the Scandinavian countries because of the risk of infection owing to the hotter summers, which promoted the development of germs in children's food. One can also argue that France was more densely inhabited than was England-Wales in the 18th century and thus closer to the maximum population compatible with its carrying capacity. Although this situation may have prompted couples to limit their births, it initially, no doubt, contributed to worsening the population's health conditions.[8] But some of the difference is also likely owing to conflicting estimation biases. The English estimate probably underestimates mortality.[9] Louis Henry adjusted France infant and child mortality heavily to allow for underrecording of infant deaths, whereas British authors seem to have paid less attention to this issue (Henry and Blanchet 1983); they may also have overlooked the size of the migration-induced bias in the backward projection.[10] Conversely, the adjustment of French data for underrecording of infant deaths may have been exaggerated. It is thus highly probable that life expectancy has been underestimated in France and overestimated in England-Wales. This does not in itself, of course, invalidate the thesis of a real gap. Other examples of pretransition differences have been observed between European countries and, most importantly, between regions. In the early 19th century, even before the start of the large-scale mortality decline, life expectancy in Italy (Breschi and Livi Bacci 1986; Breschi et al. 1994; Del Pant 1998) and Spain (Dopico and Reher 1998) exhibited sizable regional differences of about 10 years. It is usually argued that the lesser demographic pressure in some regions enabled them to enjoy higher life expectancy. One of the likely effects of this lesser pressure was that mortality crises were less frequent and less severe there, as shown by the comparison between France and England in Fig. 68–2. Yet life expectancy at birth was no doubt of about 30 years in the 1740s, probably somewhat less in France and somewhat more in England-Wales.

A few decades later, the three countries (Sweden, England-Wales, and France) actually had far closer life expectancy values of 41.7, 39.5 and 40.7 years, respectively. Sweden and England-Wales subsequently outpaced France. By 1935–1939, French life expectancy, at 58.9 years, lagged almost 8 years behind Sweden's 65.6 years, with England-Wales in an intermediate position at 62.3 years. However, as we shall see, the explanation lies in the countries' different histories.[11] Yet, despite these notable distinctions, the three countries—and probably also a few others whose past is less precisely documented, such as Denmark, Norway, and the Netherlands—spearheaded the major advances in health conditions that began in the mid-18th century and gradually spread to all of Europe.

2. Attenuation of Fluctuations

This historical progress involved several phenomena. At the outset, the most salient was certainly the attenuation of wide fluctuations. We lack sufficiently precise data to track earlier annual variations in mortality through the life-expectancy indicator. However, the crude death rate makes a perfectly adequate proxy, given the minimal change in the age distribution from year to year (see Chapters 3, 15 of Volume I). Figure 68–2 shows just how abrupt those swings still were. In France mid-18th century, for example, the annual

[7] In this context, a life expectancy of 25 years is hardly implausible. Compare this with the average 20 years estimated by Kingsley Davis (1951) for 19th century India.

[8] "France was as full as an egg and its inhabitants poorly nourished" (Chesnais, Chapter 119 of Volume IV).

[9] See, in particular, Ronald Lee's critical analysis (1993) of the backward extrapolation method used for England.

[10] "From the early 16th to late 18th centuries, English trans-Atlantic emigration totaled about 7000 a year, out of an average population of 4 million" (Livi Bacci 1997)—an outflow that, over the long run, can have sizable effects on population and mortality estimates.

[11] Special emphasis should be placed here on the rise of alcoholism in France and the spread of tuberculosis.

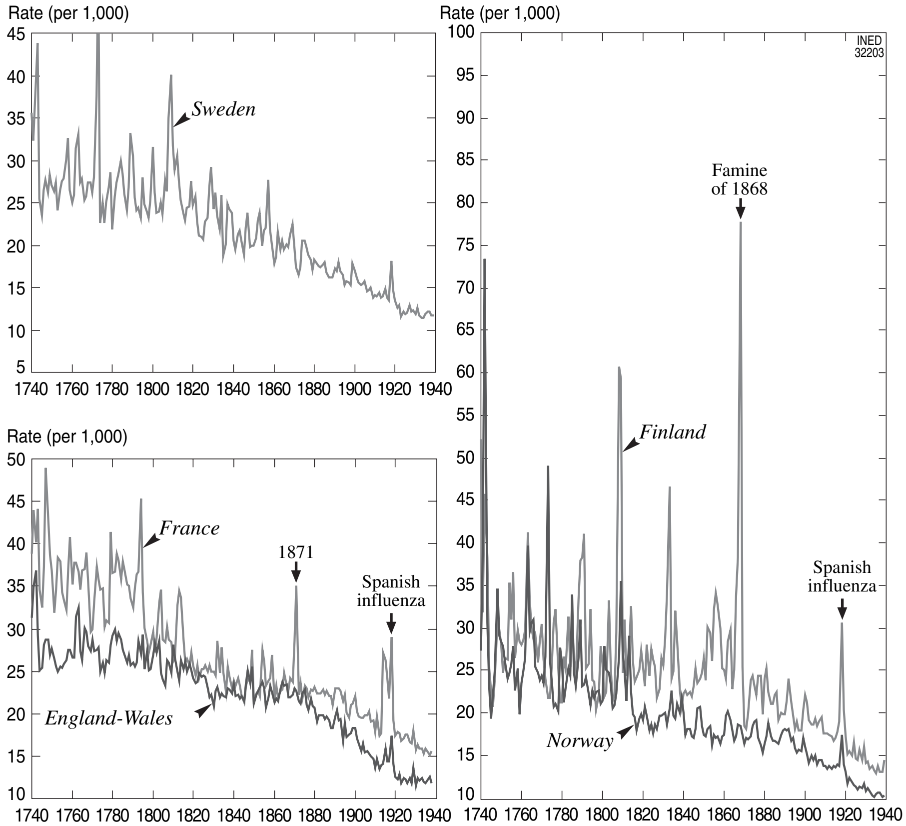

FIGURE 68–2 Annual change in crude death rate in Sweden, England-Wales, France, Norway, and Finland, 1740–1939. (From Mitchell 1975; Wrigley and Schofield 1981.)

death rate varied between 30 and 50 per 1000. The fluctuations were smaller in England-Wales. Should this be seen as a corroboration of the effects of a milder and more regular climate or as the sign that England-Wales managed to control its major crises even earlier than did France? Or—a third alternative—is the difference an artificial consequence of the reconstruction method? The issue cannot be settled conclusively. In contrast, it is clear that, whatever the initial size of the fluctuations, they had been substantially dampened in less than a century. By the mid-19th century, they were very modest in both countries; had France not experienced the Franco-Prussian War of 1870 (aggravated by the Paris Commune and the siege of the capital), World War I, and the 1918 Spanish flu to revive their memory, the fluctuations would have almost entirely disappeared after the mid-19th century. In less populous Sweden and Norway, the fluctuations were even sharper in the 18th century. In the worst years, the crude death rate could rise to 60 to 70 per 1000. In both countries, the easing of the crises in the 19th century was all the more spectacular as a result. The attenuation was all the more pronounced as neither country took part in the Franco-Prussian War of 1870 or World War I, and both were far less severely hit by the Spanish flu than was France.

The case of Finland is slightly different, offering partial evidence of the size of the timing lags between European countries in their march toward better health. Finland long remained a poor agrarian country, supplying labor to the Swedish economy. Its mortality was very high until the end of the 19th century. As late as 1868, it suffered a major famine (Pitkänen 1993) that drove up the crude death rate to 80 per 1000—a fairly late reminder of the severity of earlier large-scale crises. The four other countries experienced food shortages rather than famines in the 18th century and after: the severe famines of the past were not repeated, but it has never been possible to measure the exact impact on mortality. At a time when its national death register was already almost comprehensive, Finland shows us the potential consequences of such crises: the loss of nearly one-tenth of the population in a year! However, in Finland as elsewhere, albeit with a lag of at least half a century, the fluctuations ceased after this last major crisis; by comparison, the 1918 influenza 50 years later seemed just a pale replica (although Finland was harder hit than were Sweden and Norway).

Thus, between the mid-18th and mid-19th centuries, northwest Europe rid itself almost entirely of two leading causes of short-term mortality crises: epidemics and famine. As we saw, full-scale famine had nearly vanished (Finland, on this criterion, clearly fit the eastern European pattern) and the most recent food shortages were less damaging. These had been conclusively eliminated thanks to progress in agriculture, better transportation and communication, and the abolition of internal borders (most notably, a freer circulation of grain). As regards epidemics, although the plague had been almost totally contained by the early 18th century, it was soon replaced by cholera, particularly in the 19th century, which in turn was superseded by influenza in the 20th. But, whatever their infectious agents, the severity of health crises steadily diminished. Step by step, before even identifying the true causes and action mechanisms of the crises, the health authorities learned to take increasingly effective protection measures (such as quarantine) and to stop epidemics ever more swiftly. Influenza, the last great epidemic disease (before AIDS), never killed as many people—even in 1918—as did the plague and cholera in earlier times.

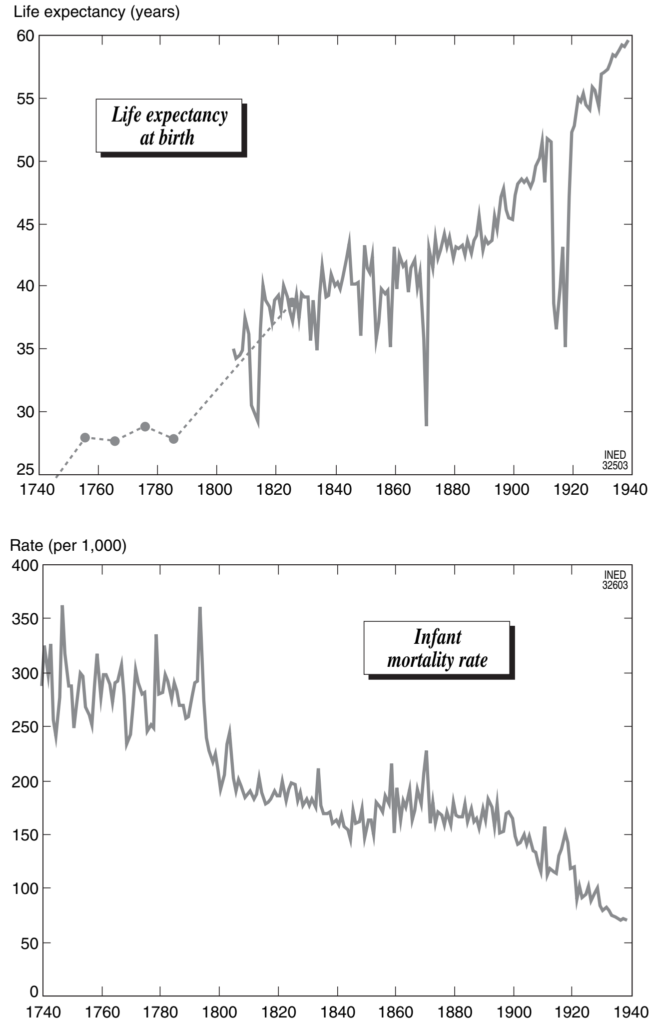

FIGURE 68–3 Annual changes in life expectancy at birth and infant mortality in France, 1740–1939. (From: 18th century, survey by Louis Henry [Blayo 1975]; 19th-20th centuries, Vallin and Meslé 2001.)

3. Progress Phases and Stagnation Phases

Despite its sizable contribution to reducing the average death rate, the smoothing of fluctuations would not have sufficed to generate the spectacular uptrend in life expectancy discussed at the start of this section. There were virtually no further occurrences of excess-mortality peaks in crisis periods. But mortality in prosperous years declined substantially as well. In France, for example, in the best years of the 18th century, the crude rate exceeded 30 per 1000. In 1769, the best year of the Ancien Régime, it was 29.5 per 1000; it did not dip slightly under 28 per 1000 until 1798. By the 1930s, it had fallen to 15 to 16 per 1000. But it should be recalled that the French population had aged sharply in the meantime, and this powerfully inhibited the fall in the crude rate (see Chapter 4 of Volume I). Annual estimates of life expectancy for France are available only from 1806 on (Vallin and Meslé 2001). Nevertheless, whereas life expectancy (for both sexes) was still only 37.4 years in 1810—the best of the earliest documented years of the 19th century—it had reached 59.5 years by 1939. This represents a gain of over 22 years in 130 years, not including the already considerable progress achieved before 1810 (Fig. 68–3). The magnitude of the gains in non-crisis periods is even more visible if we look at infant mortality rates, available on an annual basis since the mid-18th century. Although these rates reflect only one aspect of total mortality, they are independent of age distribution. In 1769, the best year of the Ancien Régime, infant mortality was still at 232 per 1000 (Fig. 68–3). By the late 1930s, it had fallen more than threefold to under 70 per 1000. Because of population aging, the crude death rate had been only halved.[12]

However, the drop in mortality was not achieved in a single step. In France, over the 2 centuries that have seen demographic transition in the classic sense, two stages of major progress were separated by a phase of stagnation, if not regression (Fig. 68–3). This phenomenon, already perceptible in the curve of the crude death rate, is very clear from the data on life

[12] However, aging does not explain the entire difference, which is also owing to the change in the age distribution of mortality itself.

expectancy at birth and infant mortality (Fig. 68–3). The first phase of decisive progress runs from the 1780s to the 1840s: life expectancy rose from under 29 years to more than 40 (disregarding the gain recorded between the 1740s and 1750s, attributable mainly to the fact that the first decade saw more food shortages than did the second, rather than to a genuine mortality decline outside of crisis periods).

Taking a closer look, we see that this gain, in turn, was achieved in two stages. First, excluding the darkest years of the Napoleonic wars (1812, 1813, and 1814), the French Revolution and the First Empire brought dramatic life-expectancy gains.[13] By 1816, life expectancy stood at almost 40 years. History textbooks generally emphasize the heroic or deadly aspects of the period. They are less likely to discuss the huge economic, social, and cultural progress accomplished in the same years, which largely contributed to the improvement in health conditions for the French. This was followed by a brief interlude of stagnation, or even mild decline, during the Restoration, before life-expectancy gains resumed under the July Monarchy. By 1845, the mean length of life peaked at over 43 years.

More than 40 years would then be needed before the start of a second major phase of progress in the late 1880s. Meanwhile, life expectancy had lastingly stalled or even declined, in particular during the Second Empire. France underwent a series of changes that anchored the country to the industrial era but had a broadly negative impact on health conditions. The 1850s, 1860s, and 1870s saw new crises, particularly outbreaks of cholera and, of course, the Franco-Prussian War of 1870 (above all, the siege of Paris and the repression that followed the Commune). But, even in the good years, life expectancy declined slightly. In 1867, for example, a rather positive year for the decade, life expectancy was under 42 years, almost a year and a half less than in 1845. Despite a mild increase at the fall of the Second Empire, life expectancy in 1887, at 43.5 years, had just barely caught up with its 1845 level.

[13] One of the major drivers of this improvement came, in fact, from England: "vaccination," i.e., immunization against smallpox through the inoculation of exudate of vaccine (a cow disease similar to smallpox), invented by Edward Jenner in 1796. Inoculation—borrowed from the Chinese—was a slightly older method but rather dangerous as administered with smallpox itself. Vaccination spread fairly quickly in France and explains some of the rise in life expectancy in the early 19th century, but the method was not extended to other diseases until the late 19th century, after the work of Louis Pasteur. This role of medicine in the initial fall in mortality has been vigorously challenged by Thomas McKeown (1976). But McKeown's arguments have, in turn, sparked extensive controversy (Vallin 1989c; see Chapter 57).

As discussed earlier, the fall in infant mortality played a major role in improving life expectancy in these various stages (see Chapter 57, Volume II). The second chart in Fig. 68–3 effectively shows the close fit between the successive periods of rising life expectancy at birth and the declines in infant mortality. However, some variations in infant mortality were more pronounced than were those in life expectancy. In particular, the long break in life-expectancy gains in the period around the Second Empire was clearly a regression as regards child survival. Setting aside the terrible year 1871, the infant mortality rate climbed steadily between the 1840s and 1870s—from 144 per 1000 in 1845 to 190 per 1000 in 1867 and almost 180 per 1000 in 1880. Despite undeniable economic progress, child-raising conditions worsened for many French families in the second half of the 19th century (Rollet 1990, 1997). With industrialization, a growing share of the population left the countryside to swell the ranks of the urban proletariat, whose working, housing, and living conditions undermined their life expectancy. This period saw urban mortality overtake rural mortality more than ever before. In addition, lack of time to raise their own children forced many working-class mothers to place them with nurses, which correspondingly diminished their chances of survival. This phenomenon is the main cause of the resurgence of infant mortality during the Second Empire.

Decisive progress did not resume until Pasteur's discoveries on the microbial origin of infectious diseases and the mechanisms for inhibiting their effects. From the late 1880s to the eve of World War II, life expectancy rose from 43 years to almost 60. These brisk gains were halted only by World War I, whose impact was heavily compounded by the Spanish flu in 1918. But Pasteur's discoveries alone would not have sufficed; they occurred in an economic and social context that promoted their dissemination and application. During the Third Republic, the social struggles against the perverse effects of industrialization began to bear fruit. Work laws were introduced, and the Villermé Report (1840) fostered greater concern for public health. In particular, this was the period in which large-scale sanitation infrastructure projects were realized in the major cities—from the improvement of sewer systems to the construction of drinking-water distribution networks. The late 19th century also saw the introduction of compulsory, secular, and free public schooling with the Jules Ferry education laws. Schoolteachers—the "hussars of the Republic," in the phrase of writer Charles Péguy (1913)—played a key role in furthering not only formal instruction and human and civic training but also hygiene and health education. This widespread diffusion of basic knowledge (from medical congresses to compulsory schooling and information conveyed in the media) was one of the main reasons why the Pasteurian revolution was so easily incorporated into personal habits and stimulated the life-expectancy gains observed between the 1890s and the eve of World War II.

The rise in life expectancy did not cease in 1940. On the contrary, it resumed vigorously just after World War II. After the first vaccines and the sulfonamide vogue of the 1930s, France was able to take Pasteur's ideas to their logical conclusion thanks to the discovery of antibiotics and the establishment of general social-insurance systems. Indeed, on the mortality side, there was no intrinsic change in the drivers of life-expectancy gains until the late 1960s (see Chapter 57 of Volume II). It is the developments on the fertility side that offer a more decisive explanation of why the profile of European demographic transition given here stops in 1940. Suffice it to say that in France, as in the other Western countries, life expectancy is still a long way from peaking (see Chapters 48, 57 of Volume II), although its recent trends are now shaped by factors that lie outside the scope of the most classic model of demographic transition, to which the present chapter is deliberately restricted.

4. Timing Differences

The above reminder of the main stages in the improvement of French public health is just one of several examples. Each country has had its own history, with accelerations and slowdowns linked to economic and social developments. But even more striking than the distinctive features of each national profile is the steady spread of this health revolution throughout Europe, which resulted in major timing differences between countries.

As noted earlier, the three pioneering countries—Sweden, England, and France—did not make gains at the same pace. France began by closing what was its partly genuine gap with the first two countries. It was then overtaken again, most vigorously by Sweden but also by England-Wales. More generally, it took at least a century for the progress initially achieved in northwest Europe to spread to the central, southern, and eastern parts of the continent. Figure 68–4 charts life expectancy at birth and infant mortality in selected countries. Owing to the lack of data, not all the curves go back to the 18th century—far from it—but the leads and lags are obvious.

In four of the countries shown—Netherlands, Italy, Spain, and Russia—the known life-expectancy path

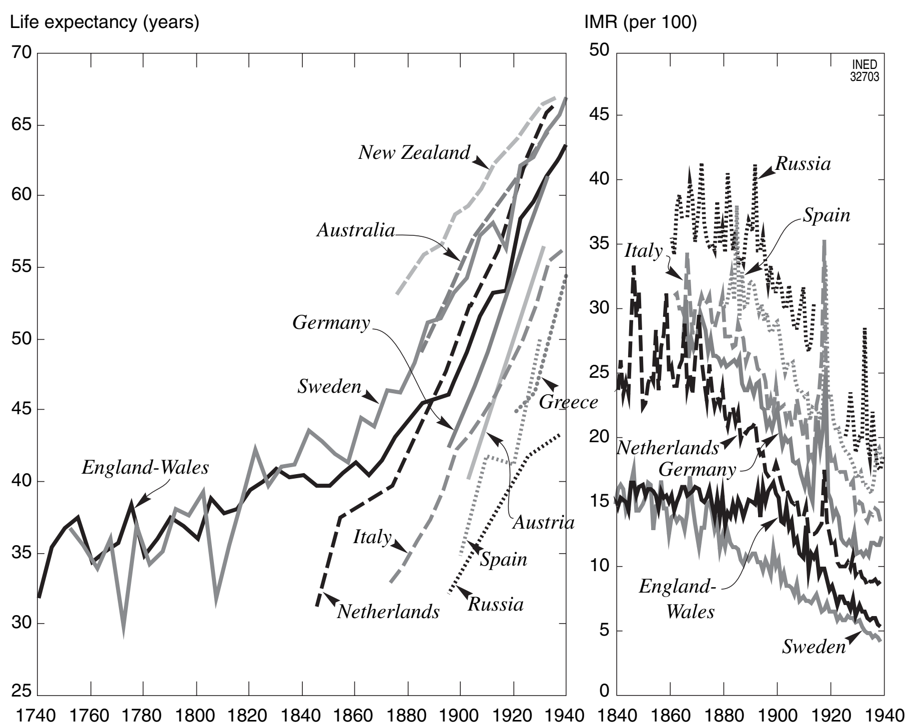

FIGURE 68–4 Changes in life expectancy at birth, 1740–1939, and in infant mortality rate, 1840–1939, in selected European countries. (From Vallin 1989b, 1991; Mitchell 1975.)

starts at about 30 years, which is comparable to the level prevailing in the three pioneering countries in the mid-18th century. If we consider the beginning of these paths as the starting points of the health revolution, the latter appears to have begun at about 1840 in the Netherlands, about 1880 in Italy, and about 1900 in Spain and Russia. From the more partial curves for Germany, Austria, and Greece, we can easily surmise that their starting points must have been interspersed with those of the previous four. This is confirmed, incidentally, by the section of Fig. 68–4 on infant mortality, for which we have a greater number of complete series since the mid-19th century.

We also note that, in many cases, gains were achieved faster in the countries where they began later. The most obvious case is the Netherlands, whose life expectancy exceeded Sweden's on the eve of World War II. Likewise, Germany caught up with England. More modestly, Italy, for example, closed the life-expectancy gap with Sweden from 15 years in about 1880 to 11 years in the late 1930s. Russia did not fit this pattern in the period charted in Fig. 68–4, but it did so after World War II. In fact, as described in Chapter 55 of Volume II, all European countries converged to very similar levels by the mid-1960.

5. Conjunction of Positive Factors

This convergence of European countries toward new health conditions characterized by a massive decline in infant mortality and infectious mortality (see Chapter 57 of Volume II) results from a conjunction of several positive factors. As we have seen in the case of France, these were linked to the dramatic changes brought by the Industrial Revolution in European countries. Although medical advances were critical, they were far from being the only driver. Despite the controversies over the issue, medical progress before Pasteur's discoveries, although significant, does not appear to given much momentum to the improvement of survival rates. Initially, it was by improving their political and administrative organizations that European countries were able to contain major epidemics and—if not to cure the victims—at least to protect the uncontaminated and prevent the spread of diseases. Famine and food shortages were eliminated thanks to progress in agriculture and to more efficient commercial distribution of foodstuffs through better transportation and storage and the abolition of obstacles to free circulation. Lastly, the initial decline in ordinary infectious mortality, i.e., in noncrisis years—was mainly owing to the construction of urban sanitation infrastructure (sewers and drinking-water networks).

That is no reason to deny the decisive role of the Pasteurian revolution, which, in turn, enabled many earlier medical advances to achieve their full effects. For example, surgery, which had taken huge technical strides forward since the age of Ambroise Paré (about 1509–90), often remained powerless for lack of resources to prevent postoperative infection. The discovery of the principles of asepsis dramatically broadened surgery's scope of action and its chances of success. More generally, vaccines, sulfonamides, and antibiotics paved the way for a near-eradication of infectious mortality. But here again, as we saw with France, medicine alone would probably have had scant impact if social change had not provided the momentum needed to disseminate its benefits: the growth of education systems, the implementation of social-insurance systems, better living standards and housing conditions, environmental control, and so on.

II. A STEEP FALL IN FERTILITY

The modernization of European societies not only revolutionized health conditions and caused a massive drop in mortality but also led to a near-total control of fertility. The decrease in mortality, most notably infant mortality, allowed more children to survive until the reproductive ages and eliminated the need to maintain high fertility for generational replacement. This created an opportunity for a parallel decline in fertility wholly consistent with macrodemographic logic. However, the decision to have children is not directly determined by official authorities. It is taken by individual couples, who act in accordance with their outlook and views about the family and procreation, even if these are inspired by collective norms and are informed by environmental constraints. It is therefore equally possible to imagine situations in which couples continue to have as many children despite lower mortality or, on the contrary, restrict their fertility for reasons other than the mortality decline. These behavioral differences have momentous consequences on populations, as we shall see later. Let us simply note here, at the outset, that most European countries experienced a fertility decline after a mortality decline.

1. Decline in Total Fertility Rate and Completed Fertility

Figure 68–5 plots the total fertility rate (TFR)[14] observed since the mid-18th century in the three coun-

[14] The TFR, the sum of the age-specific fertility rates, is an indicator of the period level of fertility (see Chapter 14 of Volume I).

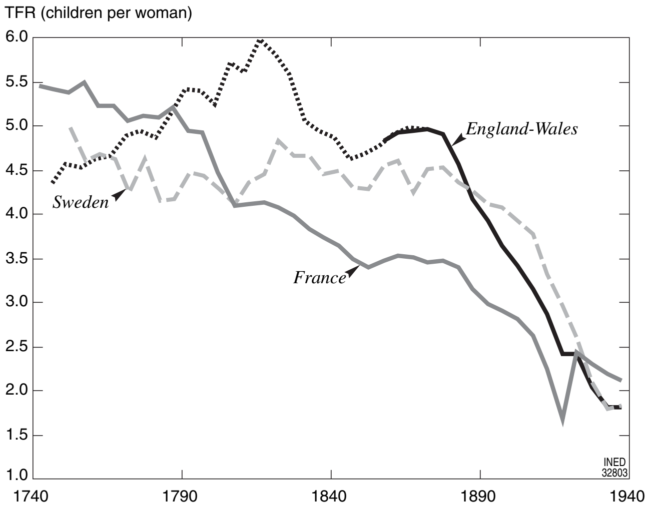

FIGURE 68–5 Changes in total fertility rates in England-Wales, France, and Sweden, 1740–1940.

tries mentioned earlier that first registered a mortality decline: England-Wales, France, and Sweden.

In France, Louis Henry's survey results suggest a fertility of about 5.5 children per woman in the first half of the 18th century.[15] The rate seems to have been significantly lower in Sweden (about 5 in 1750–55) and England-Wales (4.3 in about 1746). Again, one can debate whether these measures are fully comparable, but England does appear to have registered a genuine increase in fertility in the second half of the 18th century, as agricultural progress and the new jobs created by the early Industrial Revolution enabled young people to marry sooner and thus to have more children (see Chapter 119 in Volume IV) (Deane and Cole 1964; Kindleberger 1964). In any event, from this relatively high level, France also experienced the earliest and most sustained fertility decline. Its TFR had dropped to 4 children per woman in the early 19th century (3.96 in 1805–10) and had fallen below 2.5 on the eve of World War I (2.23 in 1910–15). In Sweden as well, fertility apparently started to fall by the second half of the 18th century, incidentally matching French fertility in the early 19th century; however, it then rebounded almost to its initial level in 1820–25 (4.82 children per woman) and stayed fairly high until the late 19th century (4.51 in 1875–80). By then, the gap with France stood at more than one child per woman. In fact, it was only in the late 19th century and even more so in the early 20th century that Swedish fertility dropped sharply; by the eve of World War II, it had fallen below that of France, at 1.79 versus 2.09 for the period 1935–40.

Almost the same pattern was repeated in England-Wales, where, as in Sweden, fertility fell much later but also much faster than in France. In the 1870s, it was still nearly 5 children per woman (4.88 in 1875–80), but then it plunged to exactly the same level as Sweden's on the eve of World War II (1.79 in 1935–40).

In fact, France is a fairly exceptional case. It is the only major country where the long-term fertility decline began in the 18th century and persisted without a break. Everywhere else, this trend never truly started until after 1870, as in Sweden and England, or, even more often, in the early 20th century (Fig. 68–6a). The probable starting points are the 1890s in Denmark, the 1900s in Norway and the Netherlands, and the 1910s in Finland.

However, it is hard to give a full picture of these trends, as the distribution of births by mother's age—an element needed to compute TFRs—has not been available for a sufficiently long period. In the 1870s, births by mother's age were compiled only in Scandinavian countries (for France and England, they have been reconstructed); in many European countries, they did not begin until the 1920s or 1930s (Festy 1979). We have fuller information on completed fertility, thanks to census questions on women's past fertility. By using the data developed by Patrick Festy (1979), we obtain Fig. 68–6b for completed fertility, which is fuller than is Fig. 68–6a.

Belgium and Switzerland rank between Sweden and England-Wales, but in almost all the other countries the fertility downtrend began later. This is especially true of the two Mediterranean countries represented: Italy and Spain. The decline was delayed even further in the central/east European countries (data not shown). In these agrarian countries on the Mediterranean and eastern rim of the Industrial Revolution heartland, fertility did not start to decrease until later.

In sum, although the fertility decline (as the mortality decline) was common to all European countries, it did not occur everywhere simultaneously. Even if we overlook France's exceptionally early start, the downtrend began at dates ranging from the 1870s to the 1920s. On this criterion as well, the demographic transition was slow in spreading to all European countries.

2. Immediate Determinants of the Fertility Decline

Demographers conventionally distinguish between two fertility regimes: *natural fertility* and *controlled fertility*, the latter being defined by the use of methods

[15] No reconstruction for all of France has yet been published, but Henri Leridon (personal communication) estimates the TFR at 5.56 in 1700–1740. An indirect estimate by Patrick Festy from birth rates gives 5.43 for 1740–1744.

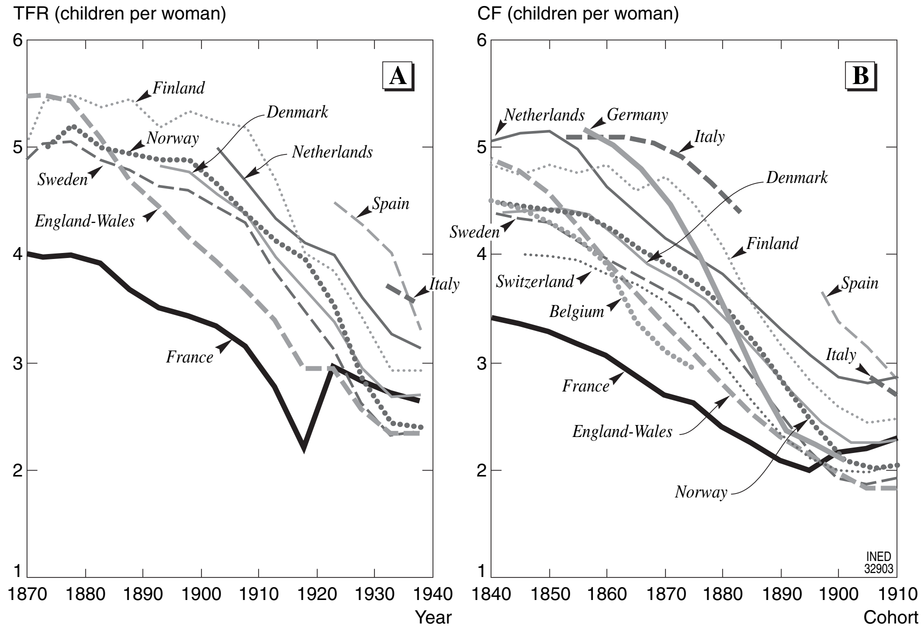

FIGURE 68–6 Changes in total fertility rate (TFR), 1870–1940 (A), and completed fertility (CF), 1840–1910 (B), in selected European countries. (From Festy 1979.)

explicitly aimed at restricting births. It is the shift from the first to the second that is largely responsible for the long-term decline in European fertility. However, the determinants of natural fertility, which are not exclusively biological, are themselves susceptible to change and contribute to the trend shifts. The extraordinary paradox of the fertility decline is precisely its occurrence at a time when the evolution of these natural-regime determinants should have triggered a steep rise.[16]

a. Increase in Reproductive Capacity

But that should not come as a surprise. A fundamental determinant of the fertility downtrend—albeit not the only one—was the decline in infant and youth mortality. This was achieved thanks to the improvement in children's living and survival conditions, i.e., progress in nutrition and health. Unsurprisingly, these same advances had a positive impact on the decline in causes of sterility and in fetal mortality. But beyond these effects of medical progress itself, other factors—including behavioral patterns—are also responsible for the rise in reproductive capacity.

Assuming a woman were to live in a union from puberty to menopause and refrain from all contraception, five biological factors would determine the number of her children: the duration of the *childbearing period* between puberty and menopause, the couple's *fecundity* (reproductive capacity), *fecundability* (probability for a woman living in a union of conceiving during each menstrual cycle), *intrauterine mortality* (miscarriages and stillbirths), and *nonsusceptible periods* (pregnancy and time before resumption of ovulation) (see Chapters 30, 31 of Volume I). At least four of these factors have moved in a direction that promotes an increase in reproductive capacity.

First, apparently because of gains in nutrition, the mean age at puberty has fallen from about 16 years in around 1750 to approximately 13 years today in Western societies (Chapters 30, 31 of Volume I). In the same interval, the mean age at menopause has risen significantly, from about 40 to 47 to 48 years. The theoretic childbearing period has thus presumably lengthened from 25 to 35 years, a 40% increase! At the same time, thanks to better healthcare and hygiene, as well as a reduction in the frequency and seriousness of spousal diseases, both sterility (primary or acquired) and intrauterine mortality have fallen. Lastly, and perhaps most important, although the length of pregnancy has not changed, the mean period of postpartum temporary infertility has dropped sharply. The two basic reasons for this are very different but are both related to changing behavior. The growing use of bottle-feeding has reduced the influence of temporary sterility owing to breast-feeding, whereas the weakening of sexual taboos has allowed an ever-earlier resumption of sexual intercourse after a birth. The

[16] As we shall see in Chapter 69, some developing countries have registered such uptrends at the start of their fertility transitions.

duration of the postpregnancy nonsusceptible period has shorted considerably—from 1 to 2 years in premodern Europe to 1 or 2 months in the industrialized countries. We know less about the fifth factor, fecundability, which depends on the frequency of sexual intercourse, its closeness to ovulation, and the quality of the ovum–sperm encounter. It may have changed hardly at all from its earlier value of about one chance in four in each cycle.

On balance, the theoretical reproductive capacity has increased significantly. Putting together the available estimates for the five parameters, the imaginary woman living in a union from puberty to menopause would have had roughly 10 children in around 1750. Today, she would have had 15—but, in Europe, the gain was nearly achieved by the eve of World War II. However, there is more to the story.

b. Lengthening of Childbearing Period

In premodern Europe, *fertility outside marriage*[17] was statistically negligible owing to social conventions and strict social control of female sexuality. As a result, this theoretical reproductive capacity effectively depended on the actual duration of marriage. Its complete realization required very early marriage (before puberty) and its nontermination by divorce or widowhood before menopause. The fulfillment of either condition was exceptionally uncommon.

In mid-18th century France, for example, age at first marriage for women was relatively late, at about 26 years, and a significant proportion of women—about 10%—never married. Although divorce was forbidden, de facto separation was not; most important, widowhood was very frequent, and remarriage was neither the rule nor very rapid. As John Hajnal has shown (1965, 1982), this model of late marriage with a high proportion of never-marrieds was typical of premodern Western Europe. In some population groups, the rate of exclusion from sexuality was as high as 50% of women of reproductive age. The period in which fertility could express itself was, on balance, rather short. However "natural" it may have been—in the sense of being uninhibited by effective contraception—fertility was rather limited. A woman surviving to at least age 50 had only 5.5 children on average, compared with the 9.8 she would have had if married from ages 15 to 50. In other words, the mere fact that women in that period spent a significant part of their reproductive years outside marriage nearly halved the number of children they could bear. This vividly illustrates the extent to which marriage and widowhood, combined with strict control of female sexuality, could regulate the number of births in a natural-fertility regime.

By way of comparison, in otherwise fairly similar conditions (no contraception, no fertility outside marriage), the fertility of marriages in Algeria in about 1970 (9.5 children per married woman between ages 15 and 50) was more or less the same as in France in 1750, but overall fertility was sharply higher at 7.5 versus 5.5 children per woman. The reason is that women in Algeria first married at a much younger age (18 years, on average) and the proportion of never-marrieds was far lower (1%); at the same time, despite many terminations through repudiation, the time lost outside marriage was much shorter thanks to the lesser frequency of widowhood (lower mortality) and the speed of remarriages. In consequence, the natural potential was reduced by only one-quarter rather than one-half.

On the eve of World War II, if they had not voluntarily limited their births, French women would have had an even higher overall fertility. Although not as precocious as their Algerian counterparts of the 1970s, they did marry much sooner[18] than their 18th century ancestors, and their risk of widowhood before age 50 was almost negligible. Although fertility outside marriage was still socially condemned and uncommon, the average number of children would have been close to 9—almost as much as an 18th century woman could have expected had she lived in an uninterrupted marriage between the ages of 15 and 50.

c. The Start of Transition: Control through Marriage

In reality, the restrictive marriage regime prevailing in 18th century France—characterized by a late mean age at marriage and a high proportion of never-marrieds—was a recent innovation. At the start of transition, it replaced the previous traditional pattern of early and near-universal marriage in France sooner than elsewhere, but it eventually spread throughout Europe. As a result, fertility control was initially achieved through marriage control. One could call this the Malthusian phase of transition, for although Thomas Malthus (1798) had forcefully advocated birth control, he never recommended contraception.

This first stage of the fertility regime, intuited by Adolphe Landry (1934) in the interwar period, was confirmed by the large-scale study by the Office of Population Research at Princeton, under the leader-

[17] We use this term in the manual in preference to the classic term illegitimate fertility (see Chapter 29 of Volume I).

[18] For example, the French female cohort born in 1931 married at an average age of 23.1 years (see Chapter 25 of Volume I), compared with 26 for women born in the mid-18th century.

ship of Ansley Coale (Coale and Watkins 1986). To analyze the change in fertility in 700 European regions and provinces, the authors developed three now famous indicators: *If*, *Ig*, and *Im*.

The method is benchmarked to the fertility of the Hutterites, a Central European Protestant sect that had taken refuge in North Dakota and still refrained from contraception in the 1950s. The following indicators were developed:

If—Index of overall fertility, the ratio of total observed births N to the number that would be observed by applying to women F_x of age x the age-specific rates of Hutterite marital fertility[19] f_x:

$$If = \frac{N}{\sum f_x F_x}$$

Ig—Index of marital fertility, the ratio of observed births in marriage Nl to the number that would be observed by applying to women M_x of age x the age-specific rates of Hutterite marital fertility f_x:

$$Ig = \frac{Nl}{\sum f_x M_x}$$

Im—Index of proportion married, the ratio of (1) births that would be observed by applying Hutterite marital fertility to married women only to (2) births that would be observed by applying Hutterite marital fertility to all women:

$$\mathrm{Im} = \frac{\sum f_x M_x}{\sum f_x F_x}$$

If there are no births outside marriage, $N = Nl$ and so, by definition, $If = Ig \cdot Im$. If fertility outside marriage was not negligible, one could introduce an adjustment to allow for the variable.

The values of the three indices obtained for Russia, France, and Ireland in the early 20th century are summarized in Table 68–2.

At the time, Russia was still in a typical pretransition stage in which high marital fertility and high nuptiality combined to produce an even higher overall fertility. In France, in contrast, the age at marriage had fallen substantially—albeit not to Russian levels—and

TABLE 68–2 Indices of Overall Fertility, Marital Fertility, and Nuptiality in Russia, France, and Ireland in the Early 20th Century

Country	*If*	*Ig*	*Im*
Russia, 1897	0.546	0.773	0.687
France, 1901	0.238	0.383	0.543
Ireland, 1901	0.235	0.706	0.325

Source: Coale and Watkins 1986.

therefore had a less restraining effect on overall fertility. However, the latter was twice as low as in Russia, for contraception was already widespread, sharply reducing marital fertility. In Ireland, instead, overall fertility nearly matched France's by then, whereas the very low nuptiality rate kept marital fertility almost as high as Russia's. Ireland found itself in very special circumstances, because it had shifted to a new fertility regime after the Great Famine of 1845–48; in the early 20th century, it adopted an extreme version of the principle of fertility control through marriage that had prevailed throughout most of Europe at the start of the fertility transition but had later been abandoned rather quickly. France, in contrast, had by then fully converted to the controlled fertility regime—even in marriage—thanks to contraception.

d. Controlled Fertility: Abortion and Contraception

By the second half of the 18th century in France, later in the Scandinavian and Anglo-Saxon countries, toward the end of the 19th century in the other European countries, and even more recently in the central/east European countries and especially in Russia, fertility control through marriage gave way to control through contraception and abortion: *Malthusianism*[20] was followed by *neo-Malthusianism*. This new school of thought, founded by Francis Place, drove the 19th century rehabilitation of practices hitherto reserved for prostitutes, as well as the development and dissemination of new methods such as the condom and the diaphragm—most notably in the Scandinavian and Anglo-Saxon countries. In France, however, where these developments occurred far earlier, the spread of contraception relied exclusively on the method least dependent on technological progress: coitus interruptus (withdrawal). This remained the only method effectively in use until the advent of the pill and the loop in the 1960s.

[19] Although the authors use the terms legitimate fertility or legitimate births—in keeping with the universal practice of the time—to denote fertility and births in marriage, we prefer in this manual to speak of fertility and births in marriage (as indicated in footnote 17, and as in Chapter 29 of Volume I). Although arguably less concise, the term is more respectful of the rights now granted to unwed mothers and their children.

[20] Apart from late marriage, the only birth-control method contemplated by Thomas Malthus (a Protestant minister) was sexual continence, also accepted by the Catholic Church. But it was never actually practiced.

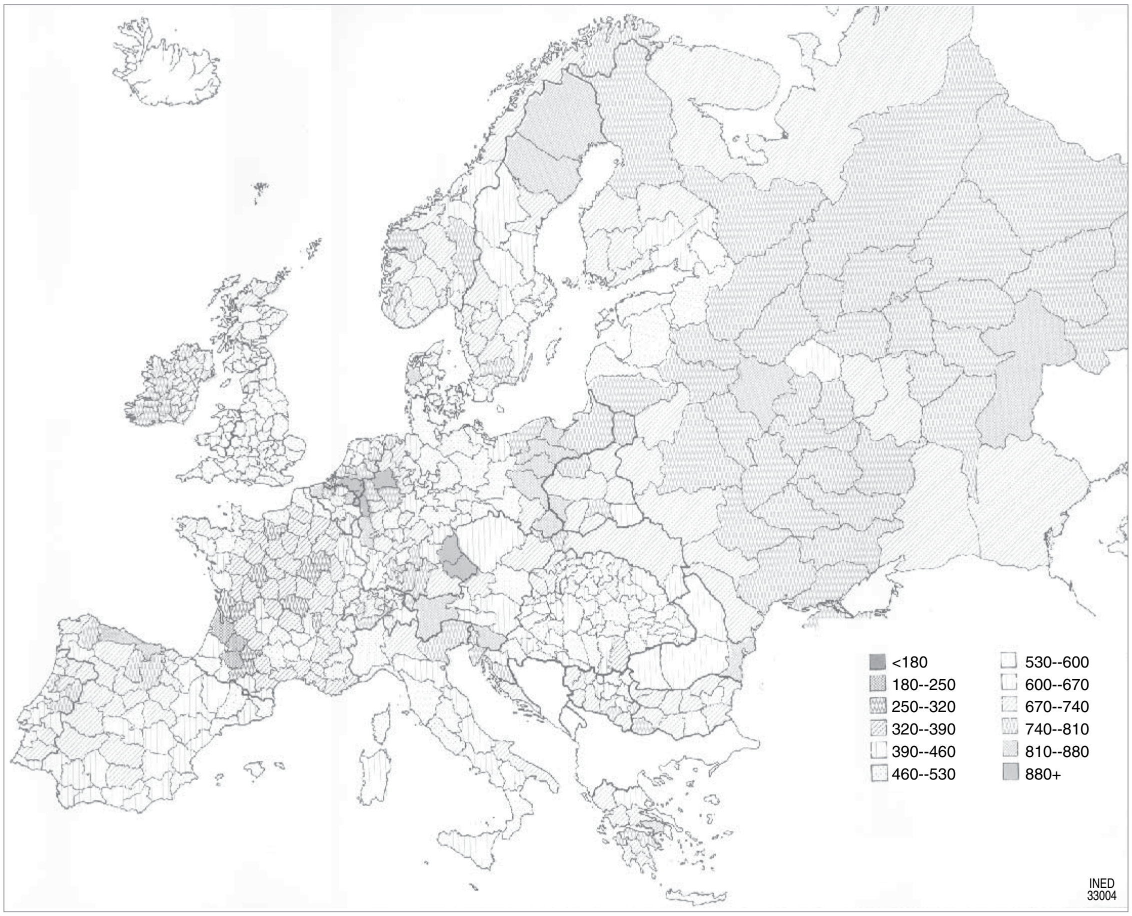

FIGURE 68–7 Values of *Ig* index (marital fertility) by European provinces,around 1900. (Source: Coale and Watkins 1986.) (Figure 68–7 also reproduced in color plate section.)

Abortion, an age-old technique, was the focus of moral reprobation and religious prohibition for even longer than was contraceptives. Indeed, until very recently, it was a penal offense in almost all countries. Although this never prevented clandestine abortions, they were severely restricted by the difficulties and risks involved, not only in the legal sphere but also in medical terms: illegality sometimes encouraged quack doctors and often meant appalling medical conditions. The first country to legalize abortion was the Soviet Union in 1920.[21] It was followed after World War II by the now Communist countries of central/eastern Europe and, in 1948, by Japan, which was struggling with the economic problems created by its defeat. Hardly surprisingly, these are the countries in which abortion—even today—is the most common birth-control method. Elsewhere, even after legalization, abortion is only a last resort to remedy the failures of other, increasingly effective contraception techniques.

[21] At least until 1936, when Stalin abruptly back-tracked on this liberalization.

Each country thus shifted to the new controlled-fertility regimes at its own pace and following a distinctive path (Fig. 68–7 illustrates this diversity by showing the values of the *Ig* index in the early 20th century in Europe's different regions). The new regimes drastically reduced the number of children per woman. Control via marriage had enabled French women to cut their biological potential from about 10 to 5.5. In the 20th century, birth control allowed them to reduce a realistic potential of about 9 to 2, based in turn on a biological potential of nearly 15.

3. Key Factors in the Fertility Decline

Although birth control has followed different courses according to time and place, its dissemination has never been primarily determined by the development of reasonably efficient techniques. The best proof of this, no doubt, is provided by French couples. They were the first to embark on this adventure, with coitus interruptus as their only resource. The key factor is couples' intentions, as effectively demonstrated by the pioneering Indianapolis survey[22] (Kiser and Whelpton 1953). Identifying how these intentions were expressed does not suffice to understand why they have changed.

The basic idea in the transition theory formulated by Adolphe Landry (on which more is below) is that the decision to limit the number of births is a response to the decrease in infant mortality, which enables a growing proportion of newborns to survive and thus to form the family. This reaction is lagged for two reasons. First, the individual awareness of the lasting decline of a phenomenon as random as infant mortality is not immediate. Second, and more important, the adoption of the new reproductive behavior runs counter to an age-old prejudice in favor of high fertility—a prejudice so strongly anchored in people's minds as to be the object of a cult in nearly all traditional societies. Taking this postulate as the starting point, the transition process can apparently move ahead unimpeded.

As always, reality is more complex. To begin with, the precedence of the decline in infant mortality is not an absolute rule. In France, in particular, the fertility decline was more or less concomitant[23] with the mortality decline. But the Princeton study cited earlier (Coale and Watkins 1986) also showed that a more detailed breakdown by region identifies cases in which fertility fell before mortality. In contrast, the economist Sydney Coontz (1957) suggests an additional cause for the lag. He argues that industrialization, by triggering greater labor demand, kept fertility high in areas where the drop in infant mortality should have made fertility decline sooner.

But, more generally, the downtrends in mortality and fertility take hold amid a modernization of society with many elements that are liable to influence both trends. The economic factors were emphasized in particular by Ansley Coale and Edgar Hoover (1958), who took up the arguments of Frank Notestein and other authors: the change in production structures leads to (1) the decline of the family as unit of production, (2) the emergence of impersonal systems of job allocation, and (3) the participation of women in economic activity outside the home. These phenomena tend to reduce the economic advantages of large families and to increase the need for mobility, which is easier to satisfy with a small family. The child, ever less capable of being incorporated into a productive family activity, becomes an ever greater burden.

At the frontier between the economic and social spheres, John Caldwell (1982), after other authors (see, in particular, Bertillon 1911), would generalize the latter notion by identifying the changes in parent–children transfers as a key factor in the fertility decline in Third World countries.

But cultural transformations, largely induced by economic change, probably had a more decisive effect. The diffusionist model (see Chapter 39 of Volume I) was described by Dudley Kirk (1946, 1996), who illustrated his theory with detailed maps of Europe and explained its mechanisms; it has since been the topic of many research studies. There is an abundant literature on the influence of education and women's emancipation—whether to explain the differences currently observed in the developing countries or the trend in European fertility in the 19th and in early 20th centuries. For ultimately this is a sector in which the diffusion of ideas played a central role. And it is certainly no coincidence that the new reproductive behaviors appeared in France in the century of the Enlightenment, the *philosophes*, and the Revolution. Some researchers have, in fact, attempted to measure the extent to which the diffusion of contraception was informed by the *secularization* of society, in other words, the emancipation of individuals from religious authorities and the moral imperatives imposed by the latter. In France, for example, the most Catholic regions continued for decades to practice the old regime of late marriage combined with near-natural fertility (as did Ireland), whereas birth control and earlier marriage were quickly adopted by the de-Christianized regions (Bardet 1988). Elsewhere in Western Europe, other authors have sought to relate the fertility decline in the late 19th century to a second wave of secularization, in which the social programs of new political groups faced a late offensive from traditional religion (Lesthaeghe and Wilson 1986). On this point, the reader will find it useful to refer to Chapter 38 of Volume I.

Not only is the fertility decline shaped by multiple factors but, as Étienne van de Walle writes (1998):

> The analysis of the Princeton project monographs enables us . . . to glimpse, in each country's "provinces," one or more specific factors apparently linked to the emergence of birth

[22] Survey conducted in Indianapolis in 1941 on the psychological and social determinants of fertility. Analyzed in 33 reports, of which the final one, published in *Population Studies* in 1953, summarizes the findings of the entire series.

[23] The concomitance was not absolute, because mortality gains had been achieved by the early 18th century. Jean-Claude Chesnais (1986), for example, dates the start of the mortality decline to 1715 and that of the fertility decline to 1780. In France, however, the gap between mortality and fertility rates has never been very significant.

control: the pattern of employment and female economic activity (Germany, Switzerland, Belgium), urban residence (Italy), education (England), real-estate ownership (France), etc. There is no unique combination of characteristics for modernization, but sets of factors that are different and sometimes contradictory from country to country, reflecting their particular circumstances. However, while socio-economic factors and fertility do not always interact in the same way, the fertility decline is a general phenomenon.

I would add that one always finds couples' intentions, not technology, at the center of the process—an observation that was not negated in the posttransition era with the advent of modern contraceptives.

4. A Phase of Exceptional Growth

As mortality and fertility declined between the 18th and 20th centuries, European populations shifted to a new demographic regime. The old combination of high mortality (life expectancy of about 30 years) and high fertility (TFR of about five children per woman) gave way to a new regime with low mortality (life expectancy of over 60 years) and low fertility (TFR of about two children per woman). This large-scale historical movement was first called *demographic revolution* by Adolphe Landry, then *demographic transition* after World War II. Its first consequence, as noted in the "Introduction," was a massive increase in the European population owing to the time lag between the mortality and fertility declines. This lag and its effect have been modeled, and the resulting diagram serves as the initial basis for the expression "demographic transition." The theory that bears the same name seeks to rationalize the terms of the model. But, before the theory is even applied, the model itself comprises variants. Not only does the timing differ from one population to another, but so do the scale of the gap (between the declines in mortality and fertility) and the length of the transition. This naturally entails different consequences on population dynamics.

5. Birth Rate, Death Rate, and Rate of Population Increase

To grasp this, we need to move away from specific measures of mortality and fertility such as life expectancy and the TFR. We must return to the effective incidence of these phenomena on population growth via the crude death and birth rates. Although it represents in many ways a borderline case in Europe, we can take the example of England, where the changes in these parameters between 1760 and 1940[24] illustrate the demographic-transition diagram perfectly (Fig. 68–8).

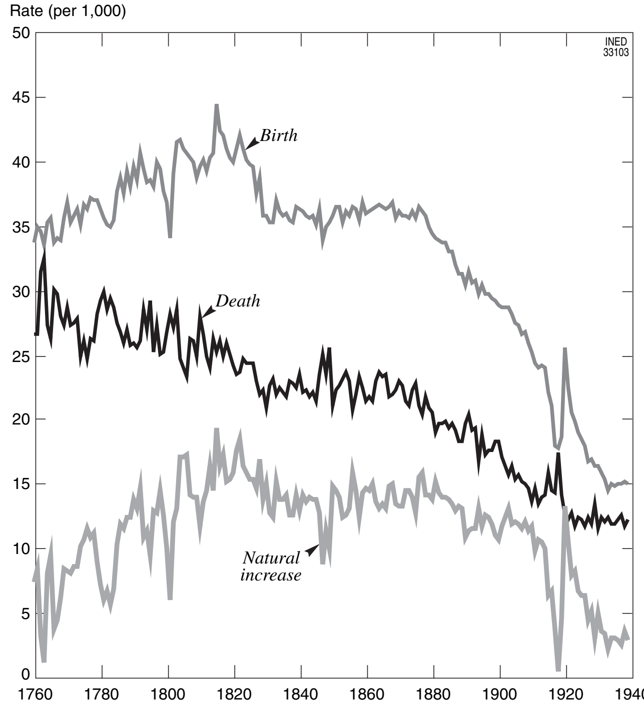

FIGURE 68–8 A typical example of demographic transition: crude birth rate, death rate, and natural increase in England-Wales, 1760–1940. (From: to 1860, Wrigley and Schofield 1981; since 1860, Mitchell 1975.)

Toward 1760, ignoring small fluctuations, the birth rates and death rates converged closely at a high level of about 30–35 per 1000. This resulted in a weak annual natural increase of around 5 per 1000. Throughout the 1760–1940 period, the death rate fell almost continuously (disregarding short-term fluctuations). In contrast, the birth rate rose from 1760 to 1820 for various reasons—most notably the decline in the age at marriage[25]—after which it plunged to its 1760 level; however, it stayed there for half a century (1830–80) before the start of its lasting decrease, driven by the historic decline in fertility. By 1934, the birth rate had sunk below 15 per 1000, a level at which—in those days—it seemed bound to remain.[26] The figure was barely higher than the level reached contempora-

[24] However, in England-Wales before 1760, the changes in birth and death rates were anything but monotonous.

[25] Anthony Wrigley and Roger Schofield (1981) estimate the mean age at first marriage for women at 26.5 years in 1650–99, 26.2 years in 1700–49, 24.9 years in 1750–99, and 23.4 years in 1800–40. The turning point of the 1800s was therefore still characterized by a long-term downtrend in the age at marriage.

[26] We know today that events turned out quite differently, but this is, of course, what an observer in the early 1940s would have projected.

neously by the crude death rate (slightly above 12 per 1000). Consequently, by the late 1930s, the natural increase had slipped again to a mere 3 per 1000 or so.

Meanwhile, however, England-Wales had enjoyed nearly a century and a half of outstanding demographic growth. The rate of natural increase accelerated swiftly in the late 18th century, first from 5 to 10 per 1000 in the 1780s, then to 15 in the 1800s, and even approaching 20 per 1000 in the early 1820s. More generally, it remained almost consistently above 10 per 1000 from 1775–1914 (barring a few exceptional years) before retreating rapidly in the interwar years. For over a century (1790–1900), it even exceeded 13 per 1000 almost without a break—no doubt for the first time in history. It is this long period of vibrant growth that enabled the population of England-Wales not only to rise from 6.1 million in around 1750 (Wrigley and Schofield 1981) to almost 42 million on the eve of World War II[27] but also to export large contingents of emigrants overseas, particularly to North America. Indeed, if we applied the annual natural increases for the total 1760–1939 period to an initial population of 6.1 million, we would obtain 45.8 million for 1940 rather than 41.5 million. Admittedly, this is just a rough approximation, given the complex effects of migrations on long-term demographic trends. First, a large majority of emigrants are often working-age males. This can cause a reduction in female nuptiality, which—in 19th century England—significantly inhibited fertility. Second, emigration is selective and may have comprised the healthier and more fertile individuals. This would influence not only fertility but also mortality. In other words, emigration is very likely to reduce the birth rate and raise the death rate of the population remaining in the home country. Nevertheless, this approximation indicates that in less than 2 centuries, without migrations, the population of England-Wales would have grown by a factor of at least 7.5 as a result of the demographic transition. Historians agree that England's extraordinary demographic dynamism stems from the speed of its industrial takeoff, characterized by a plentiful supply of jobs and a massive influx of young people into payroll employment, which facilitated family formation.

6. Length of Transition and Growth Intensity: the Transition Multiplier

In sum, the effect of transition on demographic growth depends on two factors: (1) the size of gap between the crude birth rate and the crude death rate, which yields an exceptional rate of natural increase; and (2) the length of the period in which this exceptional gap prevails. Jean-Claude Chesnais (1986) suggests a description of the phenomenon by means of what he calls the *transition multiplier*. In theory, the indicator is obtained as above for England-Wales, but Chesnais simplifies the computation by taking only the average annual natural increases over fairly long periods and combining the potential increases for each period. He performs the calculation for only five European countries: Sweden, Germany, Italy, the Soviet Union, and France (Table 68–3).

Chesnais' proposed simplification of the computation is entirely acceptable. For Sweden, for example, the complete annual computation on the lines of the one performed earlier for England-Wales would yield almost exactly the same result (3.84). In contrast, the dating of the transition period is a far more debatable choice and weighs heavily on the result. In particular, it is rather questionable to set the end of the transition at 1960 for Sweden, 1965 for Germany, and even 1970 for France. We know that fertility after World War II registered a broad uptrend followed by a downtrend: this pattern is almost entirely unrelated to the large-scale historical movement that gave birth to transition theory. For those three countries, I prefer—as in this chapter—to regard the transition as ending on the eve of World War II. Italy and the Soviet Union are different. It seems to me that the transition should be seen as complete when the TFR approaches two children per woman after a roughly constant decline over a long period. Sweden, Germany, and France had met this condition by the eve of World War II; Italy and the Soviet Union had not. The Soviet Union is such a patchwork in demographic terms that its profile is not very meaningful in itself: the central Asian republics experienced a transition far closer in time to that of the developing countries discussed in the next chapter than to the transition in European countries. Italy is a more interesting case. Admittedly, the fertility decline—as defined here—did not end before the 1970s since Italy's TFR did not reach 2.1 for the first time in history until 1976.

One can also debate the validity of Chesnais' choice of transition start dates. The transition obviously began with the start of the long-term downtrend in mortality, but how do we identify that starting point? As we saw in the opening pages of this chapter, our information on the subject is often fragmentary or imprecise. To go back to the example of Sweden, I believe the transition began some time between 1760 and 1800, but that 1810 is certainly too late (Fig. 68–1). Table 68–4 gives the values obtained for the transition multiplier by choice of transition start and end dates. The multiplier varies from 3.4 to 4.4 depending on whether we use Jean-Claude Chesnais' hypotheses or

[27] That is, 41.5 in 1939 (CSO 1952).

TABLE 68–3 Measure of Transition Multiplier for Five European Countries after Method of Jean-Claude Chesnais (1986)

Country	Demographic transition period	Main phases	Average annual natural increase	Index (start of phase = 100)	Transition multiplier*
Sweden	1810–1960	1810–1910	1.05	284.2	3.83
		1911–40	0.61	119.9	
		1941–65	0.59	112.5	
Germany†	1876–1965	1876–1910	1.32	157.2	2.11
		1911–40	0.60	119.8	
		1941–65	0.45	111.9	
Italy	1876–1965	1876–1910	1.03	143.1	2.26
		1911–40	0.88	130.0	
		1941–65	0.78	121.6

†West Germany only after 1946.

TABLE 68–4 Sensitivity of Transition Multiplier at Selected Transition Start and End Dates: The Case of Sweden

End of demographic transition	Start of demographic transition			
	1780	1790	1800	1810*
1940	3.90	3.75	3.46	3.37
1960*	4.44	4.27	3.94	3.84

*Jean-Claude Chesnais's assumption.

other plausible ones. In particular, if we take 1940 rather than 1960 as the end date, the multiplier is reduced from 3.8 to 3.4, but if we also take 1780 instead of 1810 as the start date, the multiplier rises back to 3.9. Admittedly, this value is not all that different from Chesnais' choice, but it is, no doubt, obtained with assumptions more consistent with the conventional transition model. In contrast, if we took the entire 1780–1960 period into account, we would obtain a much bigger multiplier (4.4); again, however, I do not find it very relevant to include the fertility increase of the 1940s and 1950s in the transition period.

For Germany, Jean-Claude Chesnais' choice of start date is certainly too late. By 1876, the crude death rate had already fallen to 26.4 per 1000 for a crude birth rate of 40.9 per 1000. The peak mortality of 31 per 1000 observed in 1866 is probably not the best starting point. However, the earlier data—all of which indicate lower values—are very likely biased by an underrecording of deaths that increases as one moves back in time. In 1817, the first year available, the crude death rate was only 26.7 for a birth rate of 39.5 per 1000. In these conditions, it is very difficult to estimate the transition multiplier. If we took 1866 as the start date and 1940 as the end date, we would, however, already obtain a multiplier of 4.4—well above the 2.1 chosen by Jean-Claude Chesnais, but almost certainly below the real value. If, instead, we took 1817 as the start date, we would obtain 15.8, a result certainly highly exaggerated by the underrecording of deaths.

For Italy, the estimate is even more difficult as the earliest data available are from 1862. They do indicate, however, that 1876 is surely too late, because the crude death rate (29 per 1000) was already more than 10 points below the birth rate (40) and, most important, it was already declining in 1862–1876. Assuming an effective transition start date of around 1845 and an average annual natural increase of 9 per 1000 between 1845 and 1862, we obtain a transition multiplier of 2.9 (instead of Chesnais' 2.3) or even 3.2 if we take 1976 (not 1965) as the transition end date, as suggested earlier.

For France, Chesnais finds a multiplier of only 1.6: this value is overstated as it includes the postwar fertility upswing, which was particularly robust in France. Taking 1940 as the end date, we obtain less than 1.4. Admittedly, if we assume the transition began in 1750 (rather than 1785, Chesnais' choice), the value rises to 1.5.

Despite these uncertainties, we can clearly see the wide differences between European countries with regard to the outstanding growth they were able to achieve thanks to the demographic transition. Had there been no migrations, the French population would have enjoyed extra growth of about 40%, the Italian population could have increased more than threefold, the population of Sweden could have multiplied by 3.8, that of Germany, no doubt, by nearly 5 or even more, and that of England-Wales by 7.5! Actually, England-Wales and France seem to have been fairly exceptional borderline cases. Although it is hard to estimate all the transition multipliers with precision, we can reasonably assume a value of about four in most of Europe. Indeed, that is very roughly the order of magnitude suggested by the comparison between the population estimates given for Europe and its North American extension around 1750 (150 million) and on the eve of World War II (720 million).[28]

III. STRUCTURAL CONSEQUENCES: POPULATION AGING AND MIGRATIONS

This phase of exceptional growth is one of the most striking effects of the demographic transition, but it is not the only one. Naturally we cannot discuss all the direct and indirect consequences here, but we must at least mention two crucial corollaries: population aging and the build-up of exceptional migration flows.

1. Population Aging

One of the main effects of the demographic transition is a radical change in the age distribution. We already saw in Chapter 4 of Volume I how the dynamics of a population are driven by the interaction between movement factors (fertility, mortality, and migration) and age distribution. A variation in any single factor entails a change in the age distribution; reciprocally, any change in the age distribution influences the rate of population growth, because—assuming stable fertility, mortality, and migration—it modifies the crude birth, death, and migration rates. Let us concentrate in this section on the first aspect of this interaction—the impact of the transition on age distribution—by taking up the comparison between France and England begun in Chapter 4. The two countries were not picked at random. France had a transitional multiplier of 1.4, and England-Wales had a value of 7.5. By choosing two extremes, we cover the entire field of possible paths for the European demographic transition. In essence, we are comparing a situation of aging and little or no growth with a situation of aging after steep growth (Fig. 68–9).

The age distributions of Fig. 68–9 are plotted as absolute values in order to display both the population growth and the shift in the population pyramid. The French case is actually rather untypical of the demographic transition, because the latter generated only a minimal population growth, little different from what could occur in the boom years of the pretransition regime. The total surface occupied by the age groups in the pyramid barely changed between 1750 and 1936 (the last census before World War II). In contrast, the profile of the French pyramid indicates population aging by the early 19th century. From 1750 to 1800, the decrease in infant and youth mortality, which tends to rejuvenate the distribution from the bottom up, was almost completely offset by the fertility decline already under way. The pyramid was practically unchanged (apart from the impact of the Revolutionary and Napoleonic wars, which impacted on young working males). But the pyramid base was visibly narrowing as early as 1800–51; the phenomenon gained momentum up to the 1936 pyramid, narrower at the base than in the adult age groups. England-Wales registered brisk population growth because fertility declined well after mortality. As a result, the decline in infant and youth mortality displayed its rejuvenating effects very clearly: between 1751 and 1801, and even more so between 1801 and 1851, the pyramid base widened.

Only in the second half of the 19th century did this phenomenon begin to be offset by the fertility decline, but this occurred at a far quicker pace than in France and, from that time on, the English population aged more quickly as well. By 1931 (last census before World War II), the shape of the English pyramid almost matched that of its French counterpart. But there was one difference: the French pyramid displayed a deep "gash" caused by the huge birth deficit in the cohorts depleted by World War I, a phenomenon almost imperceptible in England-Wales.

As a result, in the French transition, the proportion of young people aged under 15 stagnated from 1750–1800 and then diminished steadily from 1800–1950. In England-Wales, it rose sharply from 1750–1820 and later declined, fairly slowly until 1900 then more quickly (Fig. 68–10). Conversely, the proportion of persons aged 60 or older rose continuously during both centuries in France, whereas it declined slightly in England-Wales until 1900 and surged abruptly thereafter.

[28] In 1940, Europe without the Soviet Union had 375 million inhabitants (Livi Bacci and Tapinos 1999); the Soviet Union, 193 million (Blum and Darskij 1999); and the United States and Canada, slightly over 150 million (Biraben 1979). At the time, however, a sizable part of the North American population came from Africa, Asia, and Latin America.

2. A Dual Migration Flow

Migration is certainly not an original feature of the European transition period. Since time immemorial, humans have migrated across territories and frontiers, chiefly in search of better resources for their livelihood and survival (see, in particular, Chapter 67). In Europe, however, external and internal migrations climaxed during the "extended" 19th century that stretched from the second half of the 18th century to the first half of the 20th—a period in which Europe witnessed the steady build-up of industrialization. In addition to seasonal, temporary migrations, often on a large scale (Poussou 1998), two types of flows dominated Europe in that period (Zelinsky 1971): urbanization and emigration to the rest of the world. It is worth recalling the key features of both.

a. Overseas Emigration

Fueled by sharp natural demographic growth, European emigration to other continents took on exceptional proportions. From 1850–1930, "51.7 million departures were recorded . . . in other words, in 80 years, ten times as many as before" (Poussou 1998)—not counting Russian emigration to Asia, within the frontiers of the Empire, then the Soviet Union. Four European countries topped the list of this tremendous massive emigration overseas: Great Britain, with 11.4 million departures (22% of the total), Italy with 9.9 million (19.1%), Germany with 9.8 million (18.9%), and Ireland with 7.3 million (14.1%). Ireland is a very special case, on account of the Great Potato Famine of 1845–48. In contrast, in strictly proportional terms, France was a modest exporter of migrants (2.4 million) because of its weak transition multiplier, and would probably have been far less so without the need to maintain its rank as colonial power. Unlike its neighbors, France was also a net importer of migrants throughout the period. Meanwhile, migrations from Spain and Portugal resumed vigorously. On balance, the flow of emigrants from all over Europe swelled continuously until World War I, particularly in the last decade of 19th century and the first decade of the 20th.

The emigrants' main destination was the Americas, particularly North America. The United States obviously attracted the greatest number, with 28 million European immigrants between 1850 and 1930 (Poussou 1998)—an overwhelming 63%. Argentina came a distant second with 6 million (12.3%). It was followed by Canada with 5.2 million (but the country was often just a stepping-stone to the United States), Brazil (4.6 million), and Australia (3.5 million), with Algeria and South Africa lagging far behind. The rest of the colonial empires ultimately played a very minor role in Europe's global demographic expansion, except as witness to the geographic diversity of the destinations. No barrier truly stood up against this tidal wave. However, the predominantly English-speaking first waves focused on North America, whose vast expanses were weakly populated and already very heavily Anglicized. Apart from the Spanish and Portuguese—historically tied to Latin America—most of the rest of Europe followed the same trail, which sounded so promising. Admittedly, with rare exceptions, the other regions already under European domination were subjected to a colonial system more concerned with exploiting resources (and the local population) than with developing "settlement colonies" there.

As an entire chapter is devoted to the topic in the previous section, there is hardly any need to say more here about European emigration overseas. However, for the sake of completeness, we should add that the phenomenon was not the only migratory outlet for the European countries with the largest transition multipliers. By way of confirming its distinctive historical position, France, too, was a major destination for almost all its neighbors and even beyond: first Belgians, Germans, Swiss, and Austro-Hungarians, then Poles and Russians, Italians, and Spaniards. France experienced labor shortages in several industries by the mid-19th century. Its foreign population surged from 400,000 in 1851 to 3 million in 1931—not counting, of course, all those who had been naturalized in the meantime. In the same period, many Germans went east, gradually Germanizing the eastern fringes of the Empire and beyond, as far as the Volga regions (in so doing, they amplified a flow that began in the Middle Ages—most notably toward Transylvania—and revived in the 18th century, particularly toward Catherine the Great's Russia). Lastly, under the fierce pressure of the famine, many Irish began by trying to seek refuge and sustenance in Britain itself, even as the country was exporting its population surplus.

These population transfers naturally had sizable effects on the demographic trends at the main points of arrival. They affected not only the total population size there, which literally exploded, but also the mortality and fertility patterns, which closely mirrored Europe's transition stages. In terms of mortality, some overseas countries even outperformed their home countries. New Zealand, in particular, quickly achieved a record life expectancy that long remained the world's highest by a wide margin (Oeppen and Vaupel 2002). The European pattern was also copied for fertility. As in the Old World, of course, the timing and intensity varied, but there was ultimately a close convergence, at least in the English-speaking overseas countries.

b. Internal Migrations: Rural-Urban Migration and Urbanization

Interacting with the Industrial Revolution, the demographic transition also spawned a massive transfer of rural dwellers to towns and cities. Changes in farming methods from the 18th century onward, combined with the modernization of production techniques, reduced farm-labor demand. At the same time, the rise of manufacturing and, shortly after, of the service industries created new types of employment. This inevitably spurred urban growth, but the phenomenon was intensified by the fact that the demographic transition created overpopulation in rural areas, where most people initially lived. The only choice was to leave, mainly for cities. To oversimplify, we could say that international emigration actually consisted of the residual flows that cities were incapable of absorbing. At all events, in quantitative terms, it was dwarfed by the masses displaced from the countryside to the towns.

Of Europe's 146 million inhabitants[29] in 1750, only 23 million were urban dwellers and 132 million lived in rural areas (Bairoch 1998).[30] By 1950, of a total 573 million, 300 million were urban dwellers versus 272 million rural dwellers. If the rural population had grown at the same pace as the total population (a 370% increase between 1750 and 1950), it should have reached 486 million in 1950 instead of 272 million. In other words, the rural-urban migration can be estimated very roughly at over 200 million (486 − 272 = 214).

True, cities were not born with the Industrial Revolution. They date from the Neolithic and the discovery of agriculture, which promoted the growing settlement of the human population. This also generated surpluses that allowed economic specialization and the emergence of urban centers, which gave rise to the great civilizations of Antiquity. But the Industrial Revolution and the demographic transition radically altered the nature of cities and completely reversed the demographic equilibrium between urban centers and rural areas.

Table 68–5 draws on Paul Bairoch's estimates (1998) to plot urbanization rates in the main European countries from 1750–1913. The last column, for 1950, is based on United Nations estimates (2001).

Once again, we can only underscore the diversity of timing and paces of change. Although there is no doubt as to the overall trend, each country participated in it consistently with its specific history, sometimes with huge lags but also with distinctive variations. For example, let us take Spain, Italy, and, generally speaking, the Mediterranean countries, which have had a strong urban tradition since Antiquity. Their demographic transition came later; urbanization rates were already rather high in 1700 but rose rather slowly thereafter in comparison with the United Kingdom or Germany. In Italy, for instance, the urbanization rate rose from 23% in 1700 to 54% in 1950, whereas in the United Kingdom it grew from 12% to 84%. Once again, England's singularity deserved to be emphasized: the establishment of enclosures—which ended free access to commons—triggered a massive rural-urban migration, and the proliferation of manufactures offered attractive wages in town. Both developments quickened the pace of urbanization.

In almost all countries, the urbanization trend accelerated sharply at a time when transition was triggering a demographic boom, that is, at fairly different dates but seldom before 1850, with the sole exception of the United Kingdom (Fig. 68–11). Interestingly, the same happened in France: although the demographic transition generated only very modest overpopulation, the change in the urbanization rate diverged very little from the average. This was largely thanks to immigration, even though its first destination was not

[29] Including the Asian part of Russia.

[30] Urban environment is not easy to define (see Chapter 61 of Volume II). Paul Bairoch (1998) has estimated the probable real level of urbanization in 18th century Europe.

TABLE 68–5 Urbanization Rate (%)*in Europe, 1700–1950

Country	1700	1750	1800	1830	1850	1870	1890	1900	1913	1950
Austria-Hungary	4.8	7.1	7.8	8.0	9.7	12.1	19.7	25.6	29.4	36.5

always the city. But another reason was the preservation of a rather archaic form of subsistence farming and heavy pressure on land. This stimulated rural-urban migration such as the Breton emigration to Paris.

An interesting indicator of the diversity of urbanization timing can be obtained by identifying the date at which the urban population exceeded 50% of the total population. The switchover occurred by the mid-1860s in the United Kingdom but in the early 1890s in Belgium. It should be noted that Belgium (particularly Wallonia) was the first country to industrialize after England. The Netherlands had long been heavily urbanized, but the rate leveled off to nearly 40% between 1700 and 1850. It crossed the 50% threshold, as did Germany, shortly before World War I. France and Italy did so in the mid-1930s; Switzerland and Spain, on the eve of World War I. Russia and Austria-Hungary did not catch up until the late 1940s; Portugal and the Balkan countries, much later still. In fact, the process was far from over by 1950: at that date, the urbanization rates varied from less than 20% in Portugal to over 90% in Belgium.

IV. BIRTH OF A THEORY

Adolphe Landry (1934) gave the name *demographic revolution* to the shift observed in Europe from an old demographic regime with high mortality and fertility to a new regime in which healthcare resources and new behaviors drove both variables to very low long-term levels. Although Landry confined the term to the description of observed facts, he nevertheless sought to provide a general explanation for it in the shape of a *contemporary theory*. This would replace the two population theories that, according to Landry, had contended for the explanation of past demographic regimes: Joseph Townsend's theory and Richard Cantillon's theory[31] (Landry 1909, 1934). As did all their contemporary peers, Townsend and Cantillon agreed that the population is determined by food resources and that a given quantity of food corresponds to a sustainable maximum population. However, Townsend (1786) noted, people "*multiply like mice in a barn*" whenever their means of subsistence enable them to do so; as a result, that maximum depends directly on the quantity of food, and all populations would aim for the maximum. Richard Cantillon (1755), instead, argued that the maximum only partly depended on the quantity of food; it was determined by people's way of life—which varied considerably from one place and period to another—and in particular by whether they were willing to live in poverty or sought to improve their living conditions. If a group wants to eat meat, it cannot afford to be as large as if it is content with grain. The two theories differ not only over the role of the population/food ratio but also over the way in which the ratio is established. In Townsend's theory, the adjustment is performed only through mortality; in Cantillon's theory, fertility also plays a part, most notably through control of sexual activity via marriage.

For Adolphe Landry, Townsend's theory "*applies only to the most backward societies*," whereas Cantillon's was valid for "*most of the societies that history tells us about*" and even still at the beginning of the transition to the new regime. Yet, Landry continued, Cantillon's theory ceases to apply to the contemporary demographic regime. That is why he offered to replace it with a *contemporary theory* that diverged from the previous two over one key aspect: the available quantity of food ceased to have any effect whatsoever on the population size. Owing to economic, social, and medical progress, mortality has fallen more sharply than ever, but population sizes have not necessarily grown as a result (even less so in France than elsewhere). This is because fertility has diminished well beyond the level that would have been dictated by the subsistence law—even in Cantillon's theory. Landry believed that the spectacular increase in life expectancy would soon encounter the insurmountable biological barrier.[32] Interestingly, however, he set no minimum level for fertility, merely arguing that it would be very unlikely to drop to zero. Landry's theory therefore does not incorporate the notion that modern populations would converge toward the stationary state. On the contrary, he argued, the near-equilibrium observed between fertility and mortality in the 1930s could well be short-lived, and he feared *depopulation*. The earlier theories viewed *populationist* models as fallacious. Landry, instead, stressed that the new demographic regime paved a wide path for

[31] It is worth noting that Adolphe Landry accused Thomas Malthus of sowing confusion between the two theories: "We may legitimately regret . . . that these theories have been confused as often as they have. The author who displays this confusion most vividly is at the same time the one who has focused his attention most powerfully on the issue of population and who owes his reputation to the book he wrote on the subject: I am referring to Malthus." (Landry 1934:176).

[32] "Will one want to set at an average of 85 years the end-point at which human life, in the best conditions, should cease? The actual mean length of life will never reach that point." It is rather striking to note that this endpoint of 85 is identical to the one recently put forward by the believers in a biological limit to human longevity, such as James Fries and Jay Olshanski (see Chapter 48 of Volume II).

population policies capable of stabilizing population size at an *optimum* level by promoting behavior that could at least maintain fertility at the generational-replacement level. In fact, all the ingredients of the transition theory that came on the scene after World War II—most notably in the work of Kingsley Davis (1945) and Frank Notestein (1945)—were already in place. This is all the more remarkable as the main focus of Adolphe Landry's research was France, a country that never experienced strong population growth in the transition period. In other words, the French situation was the opposite of the one that prevailed after World War II in the Third World, whose demographic explosion would become the key issue in transition theory.

CHAPTER

69

From the Globalization of the Transition to the Return of Uncertainty (1940–2000)

JACQUES VALLIN

Institut national d'études démographiques (INED), Paris, France

INTRODUCTION

Industrialization, expansion, European imperialism, and colonization: for 2 centuries Europe led the way. But in so doing, it also started a process leading once more to unprecedented growth rates in the rest of the world. After the devastating era of colonization, the effects of which were particularly severe for pre-Columbian America but also were of sad memory for Africa bled by the slave trade, European domination was accompanied by medical progress that was extremely rapid because techniques that were already tried and tested could be exported. Between the two world wars, some countries in Latin America and Asia had already experienced a significant decline in mortality. But particularly after World War II, this progress was accelerated with the development of simple methods to combat infectious and parasitic diseases and the development of concerted programs notably through the World Health Organization (WHO). For example, Sri Lanka and Mexico gained as many years of life expectancy in a decade or two as Sweden did in a century. As in Europe, however, the response to medical progress was slower for fertility, the gap between birth rates and fertility rates increased rapidly, and demographic growth accelerated up to rates significantly higher than those seen in Europe during the 14th century. This was the population explosion of the Third World (Sauvy, 1952; Balandier, 1956).[1]

Very rapidly after World War II, the international political community was concerned by the question of how far this growth would go, as well as what economic, social, political, and ecological consequences it would have. Was it necessary to develop global policies capable of controlling it? Obviously this question also mobilized the scientific community and notably encouraged the development of data collection and demographic research at all levels. From the end of the 1940s, the need to understand the acceleration in growth occurring in all the countries of the south incited a certain number of researchers to base their studies on Adolphe Landry's work (1934) on *demographic revolution* (*Révolution démographique*; see Chapter 68) and to propose a new theory, that of the "demographic transition" (Davis, 1945; Notestein,

[1] The expression Third World (Tiers-Monde) was created by Alfred Sauvy to signify the emergence of a third world between the West and the East. He used this term for the first time in an article that appeared in the French weekly *L'Observateur*, on August 14, 1952, which he concluded, "as finally, this Third World which is ignored, exploited, and despised like the Third State also wants to be something." He thus transposed Sieyès' famous phrase about the Third State during the French Revolution. He sometimes jokingly added that the capitalist world could be assimilated with the Nobility and the communist world with the Clergy.

1945; Chesnais, 1986). Under demographic transition, with the help of economic and social development, all societies and notably those of the Third World would eventually go from a primitive demographic system to a new system, already established in Europe, in which fertility and mortality would become more or less balanced but at very low levels.

Simply stating such a theory was obviously not sufficient to end the debate between the neo-Malthusians, according to whom only a strong birth-control program could re-establish the balance, and Third-World activists, for whom the best contraceptive was development. In their initial world population projections, United Nations experts avoided exploring the future beyond the year 2000, for fear of not being able to correctly translate the theory into a concrete forecast (see Chapter 77). The main uncertainty concerned the schedule that future fertility trends might follow: when and at what rate fertility would begin to decline. However, at the end of the 1970s the facts were there. The second phase of the transition (fertility decline) had started in nearly all the southern countries, and the growth rate of the world population was already calming down. It was therefore possible to envisage and then ascertain the generalization of the demographic transition.

Could the forecast of a general stabilization of the world population be trusted nevertheless (Poursin, 1989)? Although growth rates have certainly been decreasing continually for 30 years, the general stabilization (still present even today in the United Nations' forecasts) in the strictest sense suggests growth rates are moving toward a convergence towards zero, combining a peak in life expectancy imposed by biology with the stabilization of fertility at 2.1 children per woman. This would result in the convergence of collective policies and individual decisions based on the simple idea of only ensuring the replacement of generations. The world population would then become permanently *stationary*, in the strict sense of the word (see Chapter 20 of Volume I). It is indeed probable that all populations will approach this balance. But will they remain there? Already Europe has largely committed itself to trends that infallibly lead to negative growth, toward population decline. What reasons could be proposey to certify that this is only an accident and that the rest of the planet will not follow the same example? The transition theory gives no clues on this point. Better still, the paradigm disappears at the same time as it occurs, for it does not tell us anything about what comes next.

Consequently, announcing a general stabilization of the world population as a result of reaching a point of permanent balance is not to trust in the outcome of a theory but in an act of faith that is no doubt imprudent. Without a new theory capable of completely understanding the new trends, we are indeed in the long-term future faced with an uncertainty that at least equals the one that prevailed after the World War II (see Chapter 78). In other words, although the fear of the Third World explosion is dissolving in the generalization of the demographic transition, the very realization of the latter ruins the theory and increases uncertainties.

I. THE THIRD WORLD POPULATION EXPLOSION AND THE GENERALIZATION OF THE DEMOGRAPHIC TRANSITION

I have already mentioned the first negative consequences of colonization for the populations of Africa and America (see Chapter 68). In its final phase, colonization produced the opposite effect. With the 20th century, the population of Africa again experienced positive growth, comparable to that of the Asian population, which had not experienced a decline, whereas the populations of the two Americas and Oceania increased more than ever with the mass immigration of prolific Europeans (see Chapter 58 of Volume II). In 1900, 37% of the world population was either in Europe[2] (26.2%), North America (5.6%), Latin America (4.6%), or Oceania (0.4%). In 1950, this proportion remained largely unchanged, but Europe's proportion[3] had diminished by 3 points, falling to 22.7%, whereas America's increased from 10.2% to 13.4%. Furthermore, since the beginning of the 20th century, the American expansion has been occurring differently in the north and south. The United States and Canada, totally committed to the industrial revolution of which they would soon take the leadership, also advanced in their demographic transition and followed quite closely the European model of a natural growth of 1% to 1.5% per year, although doubled by very high immigration. Latin America, on the contrary, only took one shaky step toward industrialization and only started a mortality decline, with fertility remaining high and even increasing in some countries. Natural increase rapidly rose more than in North America and was reinforced by a significant migratory contribution. From 1900–1950 North America's proportion of the world population increased from 5.5% to 6.6%, whereas that of Latin America increased from 4.6% to 6.6%. The first closely followed Europe, with the second falling into

[2] Including Russia.

[3] Including the Soviet Union.

what will henceforth be known as the Third World. In the opposite direction during the same period, Japan caught up with the Western countries, the industrial model of which it copied brilliantly, on the path to demographic transition. The first half of the 20th century thus marked the division between the developed countries and the developing countries, which was to dominate the second half of the century.

Thus on the eve of the World War II, the premise of the population explosion in the Third World that would rock the demographic-political balance of the planet was already set: a decline in mortality without an immediate response in fertility. The same scenario that characterized the European expansion during the preceding century was to be reproduced in the rest of the world with increased rapidity, opening the way to unprecedented growth rates.

1. Mortality Decline in the Southern Countries

In the wake of World War II, the decline in mortality, which had already started in several southern countries in the 1920s and 1930s, experienced significant acceleration. In the course of a few decades, the mass use of cheap but efficient methods developed in the industrial countries to fight infectious and parasitic diseases quickly increased the chance of survival in most Third World countries. At the beginning of the 1960s, the United Nations (1962) published an eloquent graph comparing the rapid increases in several Third World countries during the 1940s and 1950s compared with the secular evolution of Swedish life expectancy (Fig. 69–1). One of the most striking examples was that of Ceylon (since renamed Sri Lanka). In 8 years, from 1945–1947 to 1954, owing to a campaign to eradicate malaria through mass spraying of dichloro-diphenyl-trichloroethane (DDT) organized under the auspices of WHO, life expectancy at birth increased from 46 to 60 years![4] In Sweden, 60 years of progress in health had been necessary from 1865–1925 to obtain the same increase of 14 years of the expectation of life. The case of Sri Lanka is not an isolated one, or the most spectacular; according to the above-mentioned graph, Mauritius during the same period gained 18 years of life expectancy in 8 years. Trinidad and Tobago gained nearly 25 years of life expectancy

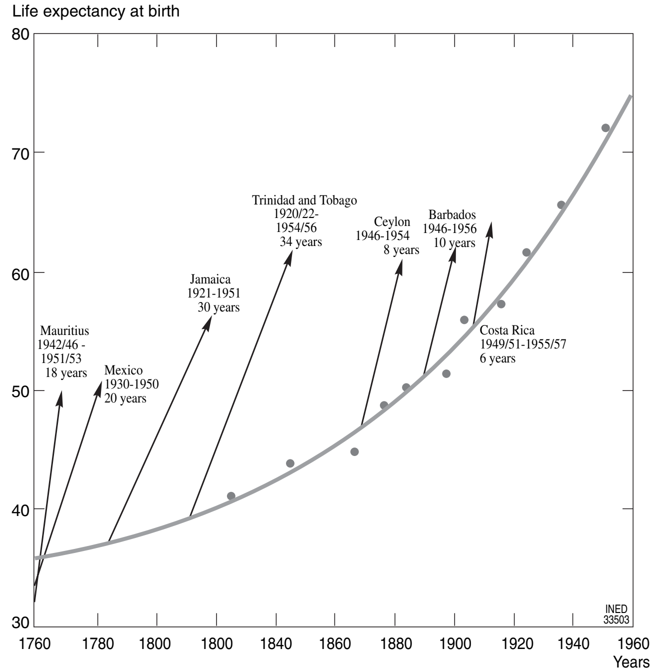

FIGURE 69–1 Increases in life expectancy in some Third World countries after World War II compared with that of the Swedish secular evolution. The curve is a freehand adjustment of the cloud of points representing Swedish life expectancies at birth during different periods. Each arrow represents the trajectory of a Third World country between the two indicated dates, and its starting point is placed on the Swedish curve at the point where it reaches the starting level for Sweden. (Data from United Nations, 1962.)

in 34 years (between the 1920s and the 1950s). But these increases are not limited to small insular countries. In 20 years (1930–1950), Mexico gained 17 years in life expectancy, as much as Sweden did in 150 years (between comparable levels).

Generally, especially during the first decades after World War II, a significant convergence in life expectancies was observed, as large regions of the Third World reduced the gap between them and the developed countries (Fig. 69–2).

From 1950–1955 to 1995–2000, the average life expectancy for the developing countries as a whole increased from 41 to 62.5 years, an increase of nearly 22 years, and at the same time, that of the developed countries increased by less than 9 years, rising from 66.1 to 74.8 years (Table 69–1). Thus, the overall gap between the two, which was 25 years at the beginning of the 1950s, was only 12 years on the eve of the 21st century. If we put aside sub-Saharan Africa, where progress is slower than in other regions of the south and where the AIDS epidemic is a threat, then the convergence is even more remarkable. The average life expectancy of all the developing countries, without including sub-Saharan Africa, reached nearly 65 years

[4] The role of this eradication campaign in the decline of mortality was the subject of great controversy (Molineaux, 1985). In 1961 Harald Frederiksen even went as far as to state that this increase in life expectancy obtained in Sri Lanka could be explained only by the improvement in the standard of living, but this hypothesis was easily contradicted by Paul Newman (1965).

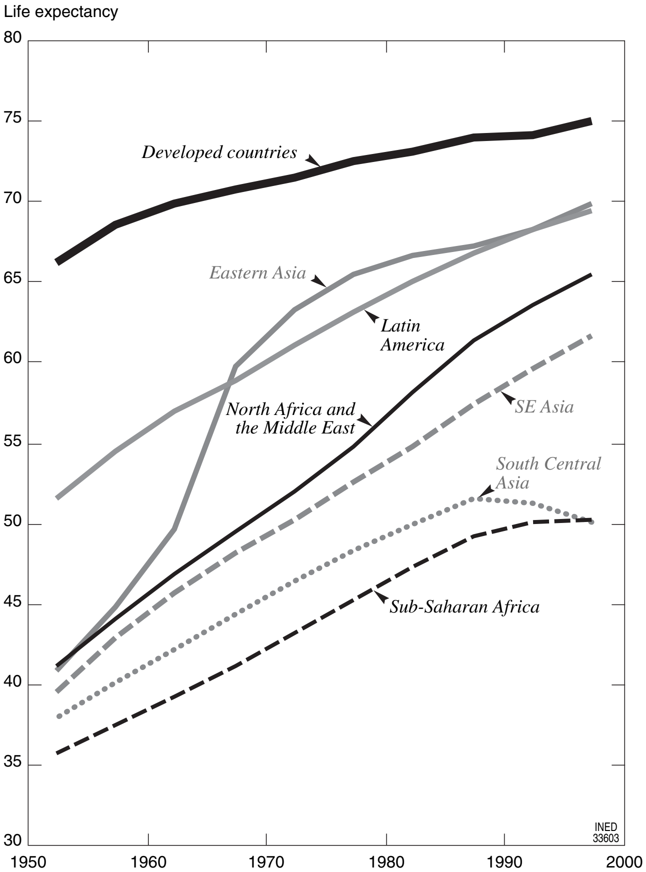

FIGURE 69–2 Evolution since 1950 of life expectancy at birth by large Third World regions compared to developed countries. (Data from United Nations, 2003.)

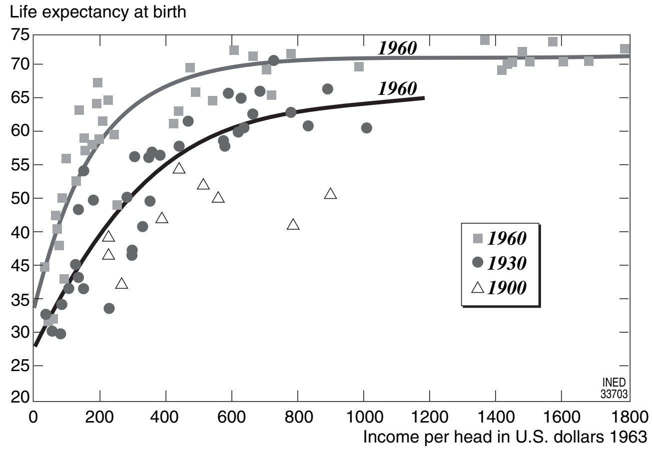

FIGURE 69–3 Life expectancy at birth in relation to income per head in 1900, 1930, and 1960. (Data from Samuel Preston, 1975.)

in 1995–2000, the gap with the developed countries being less than 10 years (Table 69–1).

East Asia's recovery is particularly spectacular[5] and is dominated by China with a current life expectancy of nearly 70 years, equal to that of Latin America and separated by less than 5 years from that of the developed countries (against over 26 years at the beginning of the 1950s). The recovery is also very distinct for southeast Asia and north Africa and the entire Middle East, which have a gap of 8 to 9 years with the developed countries. Considered individually, many countries that previously belonged to the Third World now have life expectancy levels close to those of the developed countries. Even if we put aside the microstates of the Caribbean and the Pacific and only consider countries with more than 1 million inhabitants, 8 developing countries (South Korea, United Arab Emirates, Panama, Jamaica, Puerto Rico, Argentina, Chile, and Uruguay) have a life expectancy of 74 to 76 years, close to the average level in the developed countries; 20 others are between 70 and 74 years (Mauritius, China, Malaysia, Sri Lanka, Azerbaijan, Armenia, Georgia, Syria, Kuwait, Jordan, Lebanon, Palestine, Saudi Arabia, Oman, Libya, Tunisia, Trinidad and Tobago, Mexico, Venezuela, Colombia); and 5 are just over 76 years (Hong Kong, Singapore, Israel, Cuba, Costa Rica).

The determinants of this mortality decline have already been discussed abundantly in Volume II. In Europe's case, medical progress depended generally on economic and social progress, but in the developing countries they are not so closely linked. The progress already made in the developed countries meant the means of fighting most infectious diseases already existed, and health policies created at national and international levels have made the decline in mortality possible in even the poorest countries. Figure 69–3 from Samuel Preston (1975) combines life expectancy at birth and income per head in 10 countries in 1900–1910, 38 countries in 1930–1940, and 57 countries in 1960–1970. These groups of countries were selected according to the quality of data available and are obviously of unequal value. The first, in particular, is not very representative of the world situation, as it only consists of countries that are today considered developed. The significant deformation of the adjustment curve between the 1930s and the 1960s nevertheless clearly illustrates the evolution in the association between mortality and standard of living from the 1930s to the 1960s. By comparing the average global life span that would have resulted in the 1960s if the structure of this association observed in the 1930s had been maintained and, reciprocally, the life expectancy that would have been produced in the 1930s with the application of the structure of the 1960s,

[5] Not including Japan.

TABLE 69–1 Evolution of Life Expectancy at Birth from 1950–1955 to 1995–2000

Regions	Life expectancy (in years)			Increase (in years)		
	1950–1955	1975–1980	1995–2000	1950–1955/ 1975–1980	1975–1980/ 1995–2000	1950–1955/ 1995–2000
Sub-Saharan Africa[a]	36.7	46.8	47.1	10.1	0.3	10.4
North Africa and the Middle East	43.5	57.2	66.3	13.7	9.0	22.8
North Africa	41.8	53.9	64.6	12.0	10.7	22.7

[b] The United Nations western Asia region (including the countries of the Caucasus).
[c] Consisting of three regions in the United Nations' sense: northern Europe, western Europe, and southern Europe.
[d] Including Russian Asia.
Data from estimates adopted by the United Nations for their 2002 population projections (United Nations, 2003).

Samuel Preston (1975) estimated the proportion of the increase in life expectancy that was owing to the increase in income per head and the proportion owing to the modification in the association between mortality and standard of living. He concluded that, "Factors exogenous to a country's current level of income probably account for 75% to 90% of the growth of life expectancy for the world as a whole between the 1930s and the 1960s. Income growth per se accounts for only 10% to 25%." Preston continued by stating that the same type of results appear when income per head is replaced by a population's literacy level or by the average number of calories consumed per person. Although these three factors make a real contribution, they alone do not explain the rapid decline in mortality observed after World War II.

This relative independence of medical progress to economic development results from the fact that after World War II, numerous Third World countries benefited from the technical progress already achieved in the most developed countries. The association nevertheless exists and varies with the level of development of each country. Jean Bourgeois-Pichat (1966) noted during the 1960s that in the most advanced Third World countries where the evolution of mortality was known with enough precision, this evolution occurred in three stages. First of all, there was a slow increase in life expectancy followed by a sudden jump before it finally returned to a slower growth rate. This evolution was very distinct in the case of Mexico, studied by Jean Bourgeois-Pichat, and was also observed in many Third World countries (Vallin, 1968). This hypothesis corresponds to the *health transition* as Abdel Omran (1971) conceived it (see Chapter 57 of Volume II), in which economic and social progress and an intermediate-phase reduction of infectious diseases help populations move from an *age of plague and famine* when progress is very slow to an *age of degenerative and social diseases* when, with a higher level of life expectancy, progress is again very slow. We know that this theory can no longer explain recent development, taking particularly into consideration the progress made since then in the successful treatment of cardiovascular diseases (Olshansky, 1986; Vallin, 1993; Meslé and Vallin, 2003; Vallin and Meslé, 2004), but it corresponds well enough to the phase of medical progress in the eradication of infectious diseases. Figure 69–4 gives an illustration of it by comparing the progress in life

FIGURE 69–4 Increases in life expectancy between 1950–1955 and 1980–1985 according to the level already reached in 1950–1955. (Data from Vallin, 1989.)

expectancy observed from the beginning of the 1950s up to the beginning of the 1980s, with the initial level already reached in 1950–1955. Where the level of life expectancy is low at the beginning, progress has been modest, and it has also been modest in the countries that were initially the most advanced. On the other hand, in the countries that have just started progress, the increase is very rapid. At the lowest levels, the start of medical progress necessitates a relatively expensive global development effort; when it has already begun, the effectiveness of health policies is far greater and far cheaper as the medical tools have already been developed in the advanced countries. Finally, in the more advanced countries, progress is again more difficult as efficient methods of fighting on new fronts must now be invented.

This is how, during this period, a number of developing countries bridged a significant part of the gap with the developed countries (Fig. 69–5a,b). Although at the beginning of the 1950s life expectancies of the Third World were homogenous and low, with a mode of around 40 to 45 years, this changed at the beginning of the 1980s, with two distinct modes appearing, one at 65 to 70 years and near to that of the developed

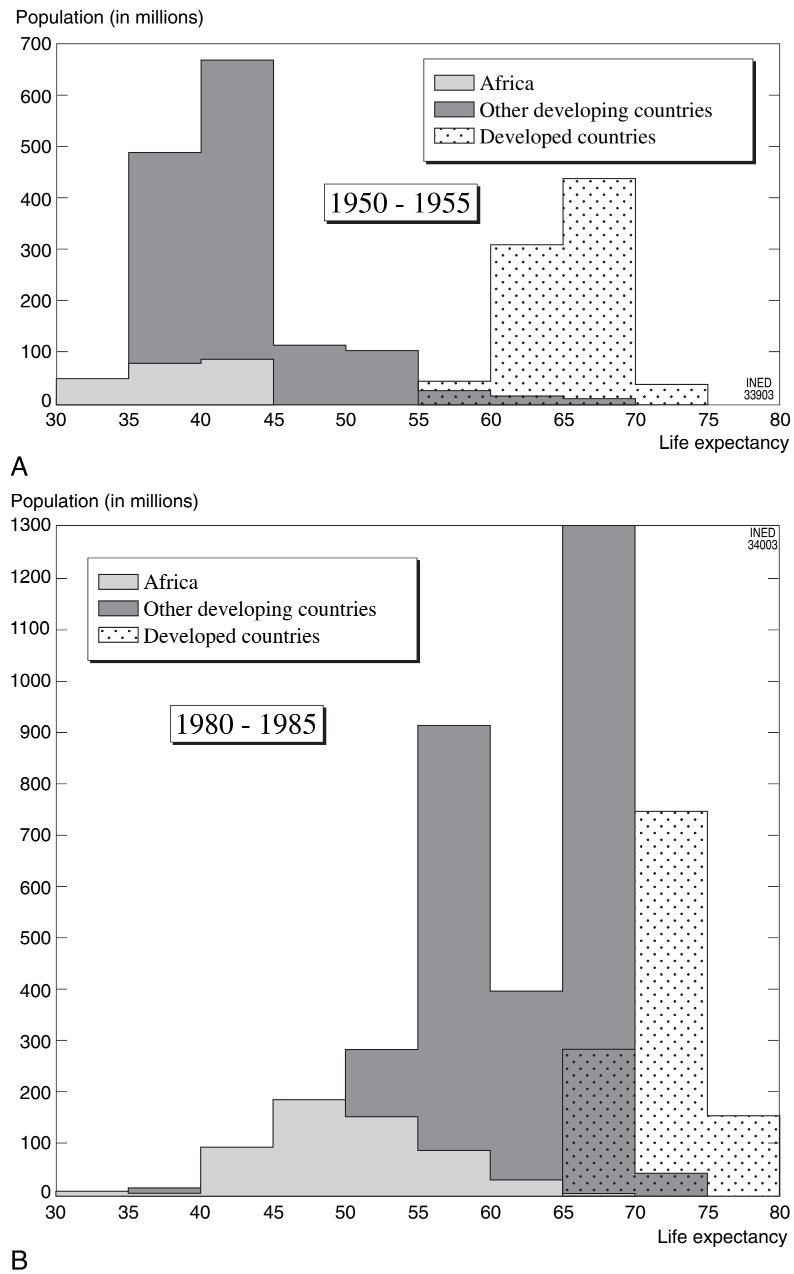

FIGURE 69–5 **(Top)** Distribution of the different countries of the world (weighted by their population), by 5-year sections of life expectancy in 1950–1955. (Data from Vallin, 1989.) **(Bottom)** Distribution of the different countries of the world (weighted by their population), by 5-year sections of life expectancy in 1980–1985. (Data from Vallin, 1989.)

countries and the other 10 years lower, at 55 to 60 years. All the southern countries had made progress, but some much more rapidly than others, leaving sub-Saharan Africa in particular resolutely lagging behind.

2. The Evolution of Fertility

Faced with mortality decline, fertility (as was previously the case in Europe) remained high for a certain period of time. It did not decline before the 1970s in hardly any of the large Third World regions (Fig. 69–6). In some countries it even increased quite significantly as a result of social and cultural changes associated with the modernization of society. In some cases it was as a result of current events. For example, in Tunisia, fertility increased rapidly in 1964 owing to a peak in marriages, which itself was provoked by an increase in the legal age at marriage: the new law having been

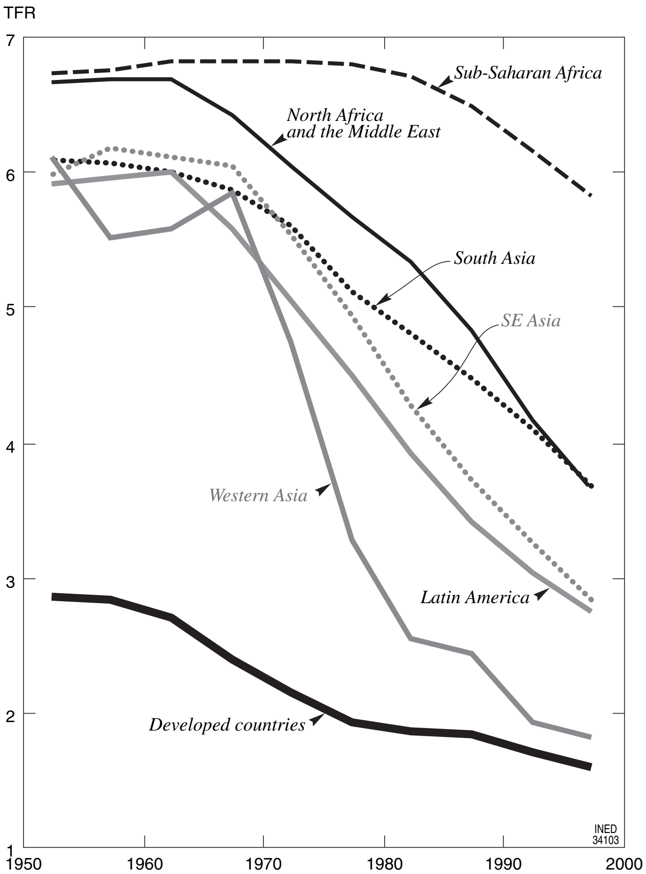

FIGURE 69–6 Evolution since 1950 of the total fertility rate by large Third World regions compared with that of the developed countries. (Data from United Nations, 2003.)

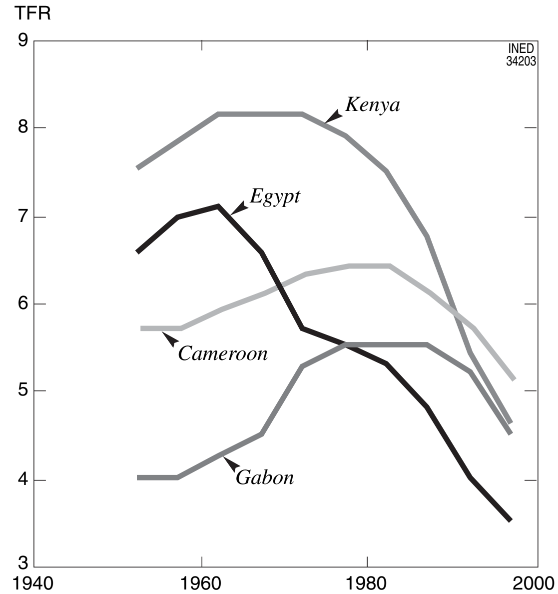

FIGURE 69–7 Evolution since 1950 of the total fertility rate in four countries that had experienced a significant increase in fertility at the beginning of the transition. (Data from United Nations, 2003.)

announced beforehand, families rushed to conclude the marriages of very young girls that would have been prevented by it (Vallin and Lapham, 1969), and the total fertility rate (TFR) increased from 7 in previous years to 7.9 children per woman during that year (Waltisperger *et al*., 2001). In the same way, in Algeria the period after independence provoked a return to traditional values, which resulted notably in a lowering of the age of marriage for girls and consequently in a sharp rise in fertility. Although the TFR had an average of 7.2 between 1960 and 1967, it increased rapidly in 1968–1969 to reach 8.1 in 1970 (Ouadah and Vallin, 2000).

But more fundamentally than these increases associated with very specific events, fertility has often tended to increase in developing countries with the premise of the modernization of society. Several factors worked in this direction, whether it was the progressive abandoning of practices that favored long birth intervals in traditional societies or progress made in the treatment or prevention of sterility and infertility. In numerous traditional societies, and notably in Africa, the duration of breast-feeding could on average be very long, from 18 months to over 2 years, and the fertility reduction resulting from this could be increased by a quite strict observance of *postpartum* abstinence. With the transformation of social relations and notably the evolution in women's education and employment, breast-feeding has tended to decline and sexual taboos to weaken, thus provoking significant increases in fertility in many countries, particularly in urban areas. In addition, medical progress has in general been accompanied by a reduction in infertility, especially in societies in which childlessness means a serious loss of status for a woman. In some countries particularly affected by sterilizing venereal diseases, such as Central Africa, which was for a long time a subfecund region compared with the rest of the continent (Retel-Laurentin, 1974, 1979; Larsen, 1996), this phenomenon was particularly important: fertility experienced significant growth with the arrival of antibiotics, information campaigns, and the prevention of sexually transmitted diseases.

Before the above-mentioned specific events, the countries of the Maghreb experienced a certain increase in fertility until the 1960s (for Algeria, see Breil and Biraben, 1969; Negadi *et al*., 1974). But this phenomenon mainly affected the Middle East and sub-Saharan Africa, as well as some Latin American countries to a lesser extent. Figure 69–7 traces the evolution of the TFR since 1950 in four other countries that were particularly affected by an increase in fertility that preceded the beginning of a decline. In Egypt, as well as in Kenya, this was caused by a reduction in the period of breast-feeding. In Cameroon and Gabon, the main factor was the reduction of infertility that resulted from venereal diseases. In all these cases as in many other Third World countries, fertility decline was preceded by this increase: it could even be said that the decline was announced by the increase, as the increase was itself associated with social and cultural changes that would thereafter result in fertility decline. Thus, at the first phase of the demographic transition of Third World countries, not only did mortality decline significantly more rapidly than was the case in the European countries, but also fertility was generally higher, often with more than seven children per woman, whereas in the old Europe the figure was five to six (see Chapter 68).

But as in Europe previously, once this first phase was over, with the transformation of societies, economic and cultural evolution, urbanization, increase in education, and improvement in women's status, these populations responded to the decline in mortality with increasingly improved fertility control. And just as with mortality, the decline in fertility was and will be far more rapid than it was during the European demographic transition (Fig. 69–6).

From the second half of the 1970s, all of the Third World regions, except for sub-Saharan Africa, experienced significant fertility decline, which accelerated during the last quarter of the 20th century (Table 69–2). Some investigators for a long time believed that sub-Saharan Africa would continue to be an exception (Locoh and Makdessi, 1995), but it finally fell in with the rest of the Third World at the end of the 1980s, as has been clearly confirmed by the results of each new demographic survey (Locoh and Vallin, 1998).

The factors of the fertility decline have already been discussed in Volume I. Let us therefore simply summarize the essentials here. As in the European countries in the past, the recent drop in fertility in the developing countries is affected by two key elements, the increase in age at marriage and the diffusion of contraception, which have diverse effects in different countries and cultures.

a. The Increase in Age at Marriage

The increase in age at marriage has, initially at least, had a decisive role in societies in which marriage was and still largely remains a requisite condition to any

TABLE 69–2 Evolution in Total Fertility Rates from 1950–1955 to 1995–2000

[a] Consisting of four regions in the United Nations' sense: West Africa, Central Africa, East Africa, and Southern Africa.
[b] The United Nations western Asia region (including the countries of the Caucasus).
[c] Consisting of three regions in the United Nations' sense: northern Europe, western Europe, and southern Europe.
[d] Including Russian Asia.
Data from estimates adopted by the United Nations for their 2002 population projections (United Nations, 2003).

sexual relation and to procreation and in which spinsterhood was extremely rare. In Tunisia, for example, despite a very active family planning policy that has been in existence since the mid-1960s, it has been established that the decline in fertility not only was initially largely caused by the increase in women's age at marriage (Vallin and Lapham, 1969; Vallin, 1971; Jemai and Jemai, 1979) but also explained a little over half of the fertility decline observed between 1978 and 1995 (Ayad and Jemai, 2001), with contraception only becoming an essential factor at the end of the 1980s. It must be said that the increase in women's age at marriage was particularly spectacular in this country, increasing from 19.5 years in 1956 to 26.6 in 1994 (Ben Salem and Locoh, 2001). The situation is more or less the same in the majority of the Maghreb and Middle-Eastern countries such as Algeria, where the average age of women at their first marriage increased suddenly from 18.3 years in 1966 to 27.6 in 1998 (Kouaouci, 1992; Ouadah and Vallin, 2000, 2003). In other countries the evolution is less striking, for example, in Iran the average age of women at their first marriage increased from 19.7 years in 1976 to 22.0 in 1996, but this evolution nevertheless constitutes "a factor of the first order for fertility where it is nearly nonexistent outside marriage"[6] (Ladier-Fouladi, 2003). In all these countries, nuptiality has played an important role in the beginning of fertility decline, whereas contraception only complimented it. It was only at a second phase of varying duration that contraception took over.

b. The Spread of Contraception

In other contexts the evolution in age at marriage made a lesser contribution and contraception was from the start the main factor. This is obviously the case of populations in which prenuptial sexual relations and fertility outside marriage have an important place, for example, in the Caribbean and recently in sub-Saharan populations, where fertility has only very recently started to decline. In such a context, fertility decline owes little to the increase in age at marriage. But even in cultures in which marriage is traditionally a preliminary condition for reproduction, fertility decline has not necessarily been owing to the delay in nuptiality. In general, the evolution of nuptiality has only played a minor role in Latin American countries where contraception has from the beginning been in the forefront. As Lorenzo Moreno and Susheela Singh (1996) show, from the 1970s to the 1980s, women's age at first marriage increased little in this region when measured by using Bongaarts' model (1978) (see Chapter 34 of Volume I), its effect on fertility decline appears inferior to that of the development of contraception. The situation is more varied in Asia (Leete and Alam, 1993), where the increase in age at marriage has not been negligible and has at times contributed to the start of fertility decline. Nevertheless, fertility decline has often occurred without a significant increase in age at marriage (Rele and Alam, 1993). In Thailand, for example, from 1960 to 1980 women's age at their first marriage barely increased by a year (from 22.0 to 23.4), whereas fertility declined by nearly half (from 6.4 to 3.5 children per woman). On the contrary, the average age at the first marriage of Pakistani women increased by over 3 years during the same period (from 16.7 to 19.8 years), whereas fertility remained constant at 7 children per woman. It is true that marriages of very young adolescents are not always consummated immediately. The case of China (Attané, 2002; Peng, 2002), is characterized by an extremely severe policy of birth limitation associated from the start with the effects of the evolution in nuptiality (delay in marrying, separation of couples) and fertility control within marriage (contraception, induced abortion).

Whatever the role played by age at marriage in the fertility transition, the latter can only be complete with fertility control within marriage owing to contraception and induced abortion. Here again, as in Europe in the past, the paths taken vary according to country and culture. Henri Leridon and Laurent Toulemon (2003) recently drew a world panorama of the levels of contraception and the methods used. Figure 69–8 summarizes the results.

In terms of the intensity of contraceptive use, the diversity remains large. Although in East Asia and Latin America in 1997 nearly 70% of women in conjugal unions used one form of contraception or another, nearly as much as in Europe and North America, the equivalent in the rest of Asia was only 50% and a mere 20% in Africa. But there is also diversity in the contraceptive methods. Sterilization is much more widespread in Western Asia than in Europe and North America, and it is even more common in Latin America, where nearly 30% of women in conjugal union are sterilized (less than 10% in Europe and North America). This practice is marginal in Africa. The pill is used nearly as much in Latin America as in Europe or North America, and far less in western Asia, where women use the intrauterine device (IUD) much more than elsewhere. Condoms and other methods (including traditional methods) are used far less in the southern countries than in the northern countries.

[6] "Un facteur de premier ordre pour la fécondité lorque celle-ci est quasi inexistante hors marriage."

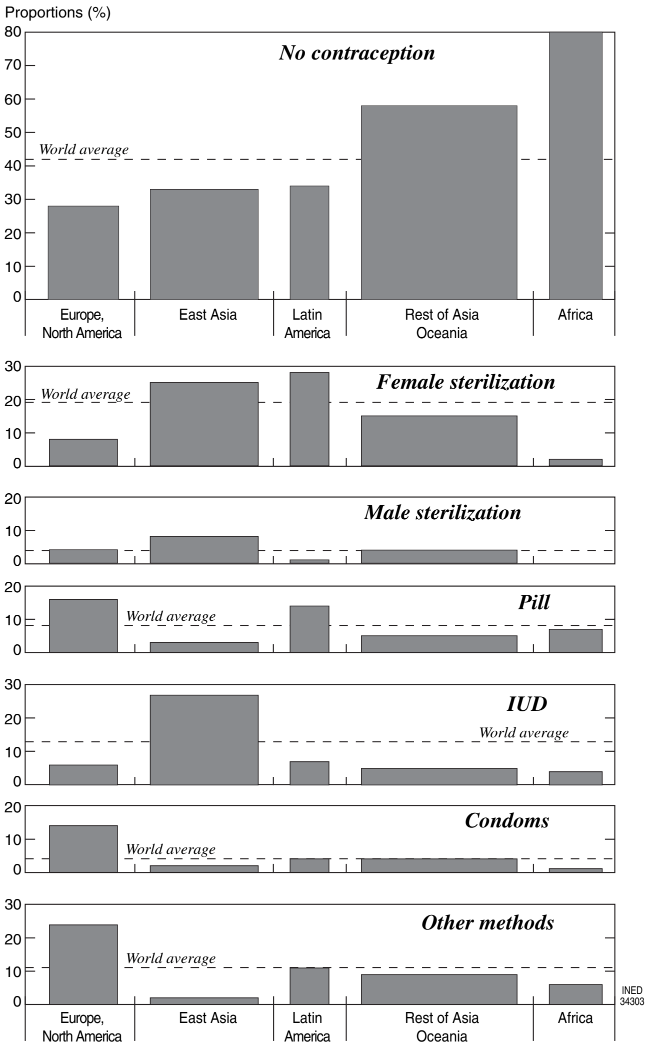

FIGURE 69–8 Distribution of 100 women from each world region in 1997, aged 15–49, married or living in conjugal union, according to contraceptive use. The width of the histograms is proportional to the population of the region. (Data from Henri Leridon and Laurent Toulemon, 2003.)

c. Recourse to Induced Abortion

Recourse to induced abortion also varies significantly from one country to another, and from one region to another. According to Henri Leridon and Laurent Toulemon, the rate of legal induced abortion per 1000 women aged 15 to 49 varied in 1995–2000, from 0 per 1000 in Africa to 79 per 1000 in eastern Europe and the rate of illegal induced abortion from 0 in East Asia to 33 in Latin America. In fact, if both legal and illegal induced abortions are cumulated, then the rate varies little between the large southern regions (36 per 1000 in east Asia, 35 in Latin America, 31 in Africa, and 30 in the rest of Asia), which all find themselves between the two extremes observed in the developed countries (25 per 1000 in Western Europe and North America, 91 in eastern Europe).

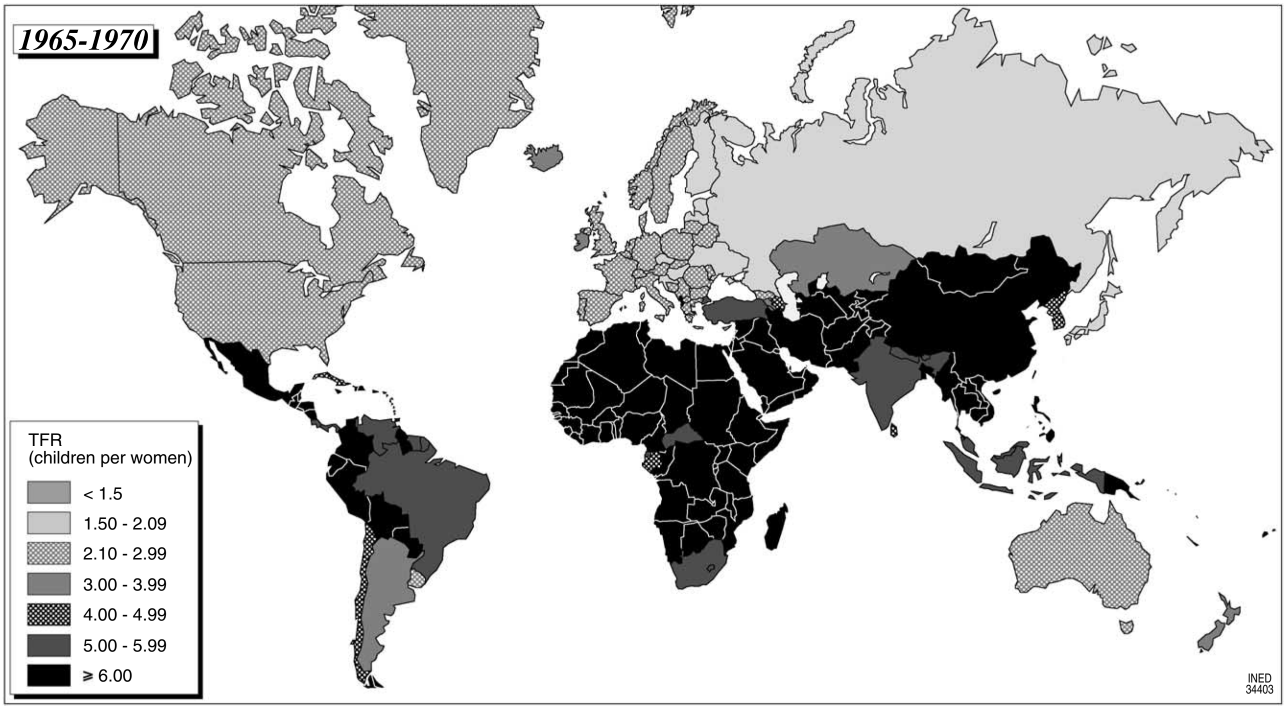
d. The Determinants of Fertility Decline

But whatever the context, age at marriage, contraception, and induced abortion are only intermediate variables. What fundamentally causes fertility decline is the evolution in couples' attitudes regarding procreation. It has certainly been affected by more or less active fertility policies carried out by various governments (see the chapters of Volume IV on this subject). However, these birth control policies, however firm and intelligent they may be, are only one element among others, and their success depends on the evolution of the society as a whole, whether it be the generalization of education, the diversification and the complexification of economic activities, the development of urban life, the evolution in women's status and their place in society and in the economy, or that of gender relationships. These questions have already been addressed in Volume I, and it is not necessary to discuss them in detail here. Let us only say that it is the diversity of experiences in all these areas that has led to the differences in timing and rates observed in the Third World countries, and it is this that explains the diversity of fertility levels observed in the world today. Fertility has declined everywhere, but the diversity of current levels remains large, as is illustrated by the two maps produced by Jean-Claude Chesnais (Fig. 69–9a,b).

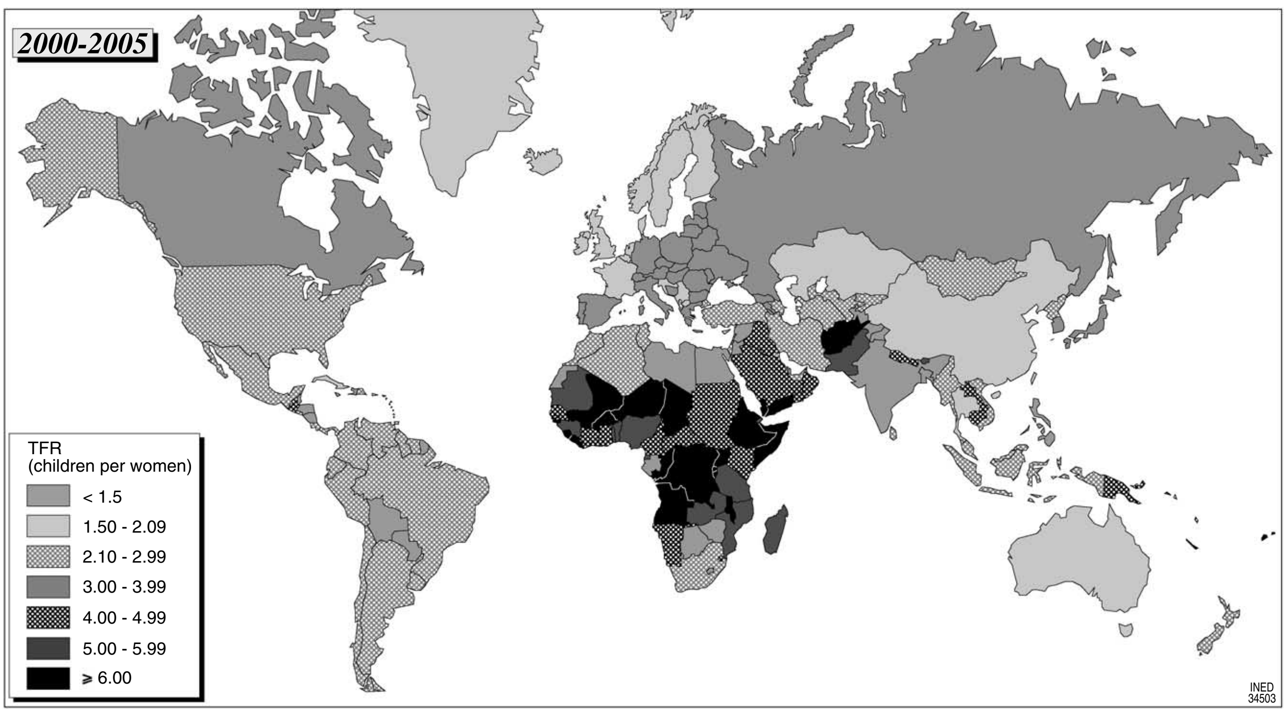
We can nevertheless begin to talk about convergence. The diversity doubtless reached its peak at the end of the 1960s, when the TFR culminated at 8 children per woman in some Third World countries such as Kenya, whereas it was already below 1.5 in some European countries. By today fertility rates of over seven children per woman have become exceptional, and rates of six are already rare.

3. Half a Century of Exceptional Growth: The Third World Explosion

The expression "Third World explosion" is most often used when the speaker is referring to the exceptional phase of world population growth that resulted from its demographic transition. Nevertheless, it could also be used in a completely different sense as we have just seen that the Third World, relatively homogenous in its demographic characteristics, literally exploded over the course of a few decades as much in the context of mortality as in that of fertility. Whereas around 1950 Third World countries were all grouped together with high levels of mortality and fertility that were very far



A



B

FIGURE 69–9 (**A**) Total fertility rate by country in 1965–1970. (**B**) Total fertility rate by country in 1995–2000. (Data from Jean-Claude Chesnais, 2003.)

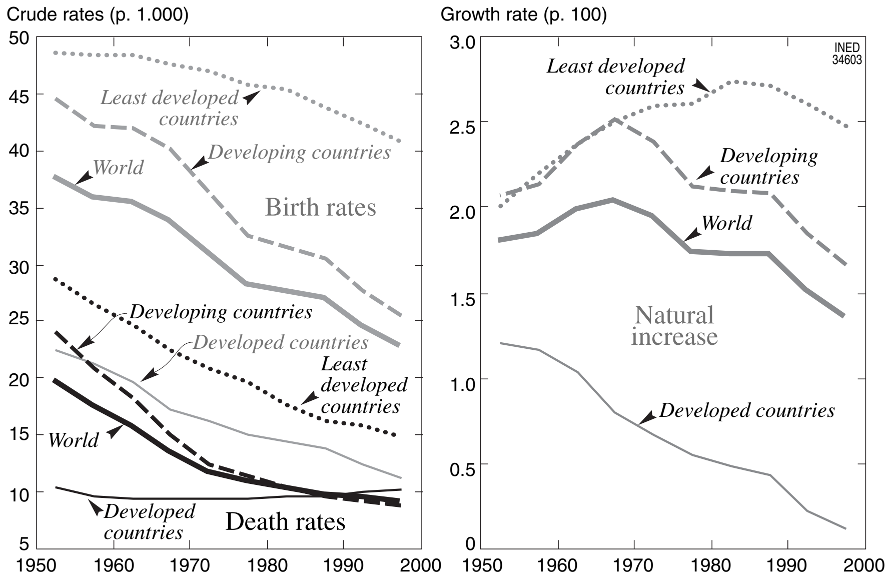


FIGURE 69–10 Evolution since 1950 of crude birth and death rates and the rate of natural increase. (Data from United Nations, 2003.)

from those of the developed countries, they are now dispersed, with some of them reaching or close to reaching European and North American standards, whereas others are still far behind on the transition path.

It is therefore in a dispersed order, with different schedules and rates, that these countries contributed to the exceptional population growth of the second half of the 20th century, generally referred to as the "population explosion."

As in Europe, this phase of exceptional growth results from the time lag between mortality decline and fertility decline. Figure 69–10, which shows the United Nations' most recent data (2003), only partially takes this phenomenon into account as it had begun before 1950 and was obviously not yet completed in 2000. In 1950, the crude death rate of the *developing countries*[7] had already significantly lessened. There is no reliable overall estimate available for this group of countries before World War II, but it is likely that it was more than 30 or even 35 per 1000. Similarly, the birth rate had also doubtless increased slightly and was probably closer to 40 per 1000 than to 45. It is quite likely that globally at the beginning of the 1950s the fertility of the Third World countries was already at its peak, even though it was not reached in a good number of the countries until later.

[7] This expression will be used constantly here according to the United Nations' definition: the countries of Africa, Latin America, and Asia (not including Japan, but including the Caucasian and Central Asian republics of the former Soviet Union).

Thus from 1950–2000, the crude birth rate of the developing countries declined regularly, falling from around 45 per 1000 to 25, whereas the crude death rate fell from 20 to less than 10. Meanwhile the decline in mortality was faster than that of birth rates during the 1950s and 1960s before becoming the opposite in the following decades. As a result the rate of natural increase of the developing countries continued to rise for another 20 years after World War II. At the beginning of the 1950s, it was around 2% per year, and it increased to 2.5% at the end of the 1960s. But at the beginning of the 1970s, the trend was reversed as the decline in birth rates was becoming greater (in absolute variation) than that of death rates. The drop in the rate of natural increase has continued to the present day. At the beginning of the 2000s, the rate was only 1.3%.

Therefore, for nearly 40 years the rate of natural increase of all the developing countries combined remained over 2% per year. This may appear modest considering what was stated about Europe in the previous chapter and all the alarmist talk concerning the Third World population explosion. However, natural growth of 2% per year results in a doubling of the population in 35 years, whereas a rate of 1% would require 70 years in order to obtain the same outcome. But above all we must not lose sight that the global evolution of the developing countries thus described is only the result of trajectories that are extremely variable in intensity and have a significant time lag.

The United Nations' current nomenclature distinguishes a subgroup of developing countries called the "*least developed*,"[8] which as we can see (Fig. 69–10) have followed a very different path to that of other developing countries. At the beginning of the 1950s, the crude death rate was still close to 30 per 1000 and the birth rate was nearly 50 per 1000. In other words, these countries only benefited from medical progress much later, and fertility significantly increased during the first phase of the demographic transition. Fertility then reached a peak and remained there for over a decade before beginning a slight decline, which only really asserted itself at the end of the century. The birth rate only dropped under the 45 per 1000 level, a culminating point for all the developing countries, at the end of the 1980s. Consequently and taking into account the significant and regular decline of the crude death rate (until the 1990s at least), the rate of natural increase, which remained the same as in the other developing countries combined until the trend reversed at the end of the 1960s, continued to increase during nearly a further 20 years until the end of the 1980s. It is only since the 1990s that this growth has started to decelerate. It thus culminated at 2.7% per year and was therefore over 2.5% per year for 35 years, from the mid-1960s until the end of the 1990s. With a growth rate of 2.5% per year, the population doubles in 28 years.

But this group of least developed countries also includes countries with different trajectories. To understand the demographic growth rates that the developing countries have experienced and are still experiencing, the level in each country must be studied individually. At the height of their growth, most of the developing countries reached growth rates of 3%, and those that exceeded 3.5% were not exceptional; some countries even exceeded 4%.

It is, however, difficult to reduce all the trajectories to Jean-Claude Chesnais' transitional multiplier (1986). On the one hand, as we saw in the preceding chapter for the European countries, it is necessary to decide on the initial point, which is often unclear because of the low quality of the data, and on the other hand, the demographic transition has not yet been completed in the majority of the southern countries. However, as a basis for the growth observed since 1950, it is also possible to use the United Nations' projections (see Chapter 77) to take into account the end of the transition as they re-estimate the trends that have occurred in each revision of their projections. By using different sources, it is possible to decide on a initial point and to include growth before 1950. The results are shown in Table 69–3 for the 25 developing countries in which the population was estimated at more than 30 million in 2000.

The first two columns of this table show the total population of each country in 1950 and 2000. The next column shows the cumulated rate of natural increase for 1950–2000. This half century is the period in which all these countries reached the peak of their growth, and this cumulated growth is obviously an important part of the transitional multiplier. Through natural growth, only the population of five of these countries more than quadrupled in 50 years: Kenya (4.7), Tanzania (4.2), and Algeria, Mexico, and the Philippines (4). For 13 other countries, the population multiplied by three to four. In only six cases was the multiplier below three (India, Indonesia, Myanmar, China, South Korea, and Argentina).

But in most cases, these coefficients are far from accounting for the totality of the transitional multiplier. The two last columns of Table 69–3 give an approximate idea by supplying the values obtained for two periods of longer duration: the first, from the presumed starting date of the transition up to 2000; the second, from the same starting date up to 2050, which includes the whole period covered by the United Nations' projections. Not only must the first be used with caution as the initial point is very arbitrary and often depends on the data available, but the second is sometimes too long or too short. Cases in which the period is too long are of little importance because beyond the date when the transition should have been completed, the countries in question are supposed to arrive at a near zero growth; however, in the cases in which the period is too short, the uncertainty of future evolution is too great for it to be useful to take it into account.

For the whole of the period up to 2050, the transitional multiplier of these 25 countries varies from 3 (China, 3.3) to nearly 15 (Ethiopia, 14.7; Pakistan, 14.2). Indeed, for China, which had more or less completed its transition by 2000, the multiplier is barely different in 2050 to what it was already in 2000 (3.0). On the other hand, adding the projection period for Ethiopia and Pakistan considerably increases the multiplier, which was only 5.7 and 5.6, respectively, when stopped at 2000. The contribution of the 2000–2050

[8] This group consists of 34 African countries (Angola, Benin, Burkina Faso, Burundi, Cape Verde, Central Africa, Comores, Congo (DR), Djibouti, Eritrea, Ethiopia, Gambia, Guinea, Guinea-Bissau, Equatorial Guinea, Lesotho, Liberia, Madagascar, Malawi, Mali, Mauritania, Mozambique, Niger, Uganda, Rwanda, Sao Tome, Senegal, Sierra Leone, Somalia, Sudan, Tanzania, Chad, Togo, Zambia), 9 Asian countries (Afghanistan, Bangladesh, Bhutan, Cambodia, Laos, Maldives, Myanmar, Nepal, Yemen), 1 Latin American country (Haiti), and 5 countries in Oceania (Kiribati, Solomon Iles, Samoa, Tuvalu, Vanuatu).

TABLE 69–3 Population Growth in the 25 Developing Countries with an Estimated Population of over 30 Million Inhabitants in 2000

Country	Population		Transitional multiplier				
	in 1950	in 2000	1950–2000	1950–2050	Start	Start–2000	Start–2050

Brazil	53,975	171,796	3.1	4.2	1920	5.9	8
Thailand	19,626	60,925	3.1	3.9	1920	6.1	7.7
South Africa	13,683	44,000	3.0	2.7	1930	4.7	4.3
Vietnam	27,367	78,137	2.9	4.4	1920	4.6	6.9
India	357,561	1,016,938	2.8	4.3	1921	4.1	6.2
Indonesia	79,538	211,559	2.7	3.8	1920	3.9	5.7
Myanmar	17,832	47,544	2.7	3.6	1921	3.8	5.1
China	554,760	1,275,215	2.6	2.8	1920	3.0	3.3
South Korea	18,859	46,835	2.5	2.4	1920	4.2	4.2
Argentina	17,150	37,074	2.0	2.9			

period is obviously significant in the countries in which fertility decline was late in starting, on the condition that they had not been ravaged by the AIDS epidemic in the meantime. Therefore, although fertility decline has only recently started in Kenya, which for this reason has the highest multiplying coefficient in Table 69–3 for the 1950–2000 period (4.7) and one of the highest for the period since the start of the transition up to 2000 (6.7), its coefficient only increases moderately when the projection up to 2050 is included (9.5), far below the multiplication by 14.7 of Ethiopia. Yet at the beginning of the 1980s, Kenya seemed to be destined for one of the greatest population explosions of the planet before the arrival of the AIDS epidemic. The effect of AIDS on the potential growth in south Africa is even more spectacular because its more modest multiplier coefficient before 2000 (3.0 for 1950–2000 and 4.7 for 1920–2000) decreases when the 2050 projection is included (2.7 since 1950, 4.3 since 1920).

Table 69–3 exposes the diversity of the situations in the Southern countries beyond the effect of the AIDS epidemic, which severely curtailed population growth in the African countries in which the most spectacular explosions were expected. Despite the AIDS epidemic, the populations of some African countries have increased by more than 13-fold (Tanzania, Nigeria) or 14 (Ethiopia) during their transition, as did the more dynamic Asian countries (Philippines, Pakistan) earlier and Latin American countries (Mexico). Such high transitional multipliers are a long way from the 7.5 of England and Wales, considered in the previous chapter as exceptional in the European demographic transition. The natural increase of countries such as China, South Korea, and Argentina is comparable to what was observed in Western Europe during its transition. The 600 million (and soon to be 1 billion) Chinese have been the cause of much discussion since the 1950s even though the population of China has increased far less during its transition than the population of Europe did a century earlier. The population of India will soon exceed that of China, although its transitional multiplier is lower than that of England.

In concrete terms, Table 69–4 shows the evolution of the population observed between 1950 and 2000 in the countries that today have more than 30 million inhabitants.

TABLE 69–4 1950–2000 Evolution of World Population by Large Regions and by Countries with More Than 30 Million Inhabitants in 2000

4. The Consequences

a. Population Growth and Economic and Social Development

Thus, at varying degrees Southern countries were or are faced with the difficulties of reconciling population growth with development. Two chapters of Volume III[9] will be dedicated to this very controversial question, and the discussion will not be anticipated here. But it can be understood that the beneficial or inhibiting effects of population growth on economic and social development are likely to be very variable. This is not only because of the diversity of the dynamics but also because of their timing. In particular, the Third World countries that entered first into transition peaked in the 1950s and 1960s, during the "*trente glorieuses*" ("the glorious 30 years") (Fourastié, 1979) of world economic prosperity before the recession caused by the oil crisis in the mid-1970s. Similar to Japan at the beginning of the 20th century, several of these countries—notably in East Asia—managed well and followed in the wake of the developed countries, such as the four "dragons" of the Far East (Singapore, Hong Kong, Taiwan, and South Korea) that were in the news during the 1980s. China itself (although the population growth of this country has never been extravagant) accomplished so many feats that the phrase "Chinese miracle" (Yifu Lin *et al.*, 2000) was born as a result. Thailand, Indonesia, and the Philippines also crossed the milestone of their peak population growth with some economic success. In Latin America the most dangerous period in population growth was also overcome. Countries such as Chile and Mexico had exceptional economic growth rates, which resulted in their rejection of the "developing country" title (which the United Nations' continues to attribute to them) and their creating a free trade zone with the United States (North American Free Trade Agreement[10]).

In contrast, the countries that entered into the demographic transition process later, notably the sub-Saharan African countries, had peak population growth in the 1980s or the 1990s, when the world economic situation had become unfavorable and, in the absence of sufficient financial flow, the International Monetary Fund and the World Bank subjected them to structural adjustment. Public budgets shrunk, the countries disengaged themselves from economic and social action, thus ruining social programs, educational systems, and health policies. And to cap it all, the AIDS epidemic arrived. The last quarter of the 20th century will no doubt be considered for a long time in the history of human population as the period of the highest economic and social disparity, not only between the richest and the poorest countries but also within what was previously called the Third World, between southern countries experiencing real development and those countries with fragile economies that were regressing in relative and sometimes absolute terms.

But beyond this global relation between population growth and economic and social development, two more specifically demographic consequences of the transition should be stressed here that have repercussions just as specific in the economic, social, and political fields: the evolution in age structure and migration (international and internal).

b. The Evolution in Age Structure

Progressively with its generalization in the developing countries, the demographic transition transforms the population pyramid of these countries (Fig. 69–11, upper part).

As was previously the case in Europe (Chapter 68), it is this transformation that will lead to the population aging that is characteristic of post-transitional populations. This change does not, however, lead directly to aging. More so than in Europe, it first of all produced a rejuvenation in the developing countries because of the high population growth caused by the reduction in infant mortality. Therefore, between 1950 and 1975 the population pyramid of the developing countries as a whole started by widening at the base. It was only during a second phase that the population of these countries began to age because of fertility decline: from 1975–2000, the base of the pyramid shrank and the central part widened.

However, in 2000 the process was far from over as can be judged by comparing the upper part of Fig. 69–11 to the central part that illustrates the evolution of the population pyramid of the developed countries over the same three periods: in 2000, the developing countries' population pyramid had not yet achieved the much older shape that has characterized the developed countries since 1950.

All in all, taking into consideration the dominating weight of the developing countries in world population, the same phenomenon of rejuvenation between 1950 and 1975 and the start of aging in the last quarter of the century is seen at the level of the population of

[9] In Chapter 85, Arnaud Dellis and Pierre Pestieau discuss the theories on the association between economic and population growth, and in Chapter 86 Jean Coussy looks more specifically at the links between population and development.

[10] The North American Free Trade Agreement (NAFTA) was signed in January 1994 between Mexico, the United States, and Canada. Shortly afterward, Chile began negotiations to join the free trade zone.

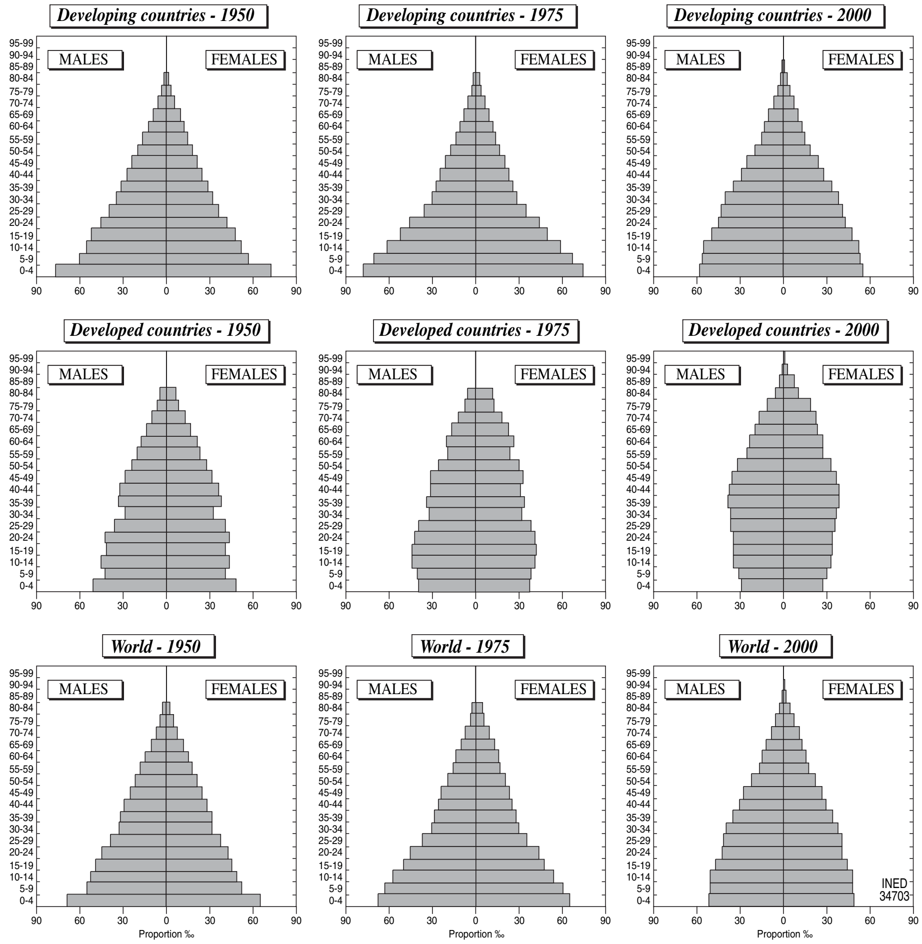

FIGURE 69–11 Evolution of the population pyramid since 1950 in the developing countries compared with that of the developed countries and the world as a whole. (Data from United Nations, 2003.)

the whole world (Fig. 69–11, lower part). The world population was barely younger in 1950 than that of the developing countries, and was a little older in 2000.

But once more, the global trajectory of the developing countries combined is only the result of the considerably different trajectories of the individual countries. Figure 69–12, which illustrates the transformation of the population pyramid for the least developing countries, exposes this clearly: already younger than that of the developing countries combined in 1950, this population continued to become even younger until 1975, and the reflux has started so slowly that the population in 2000 was as young as it was in 1950.

This transformation of the population pyramid is synthesized in Table 69–5 and Figure 69–13, which summarize the compared evolution of the three large age groups, the young (0 to 14 years), working age adults (15 to 59 years), and the elderly (60 years and over). In 1950, 38% of the population of developing countries was under the age of 15. This proportion first increased to 41% in 1975 before beginning its decline and falling to 33% in 2000. But 33% is still higher than the 27% that already prevailed in the developed countries in 1950. In addition, the singularity of the least developed countries is very clear, as 43% for the proportion of the young was still greater in 2000 than was the maximum reached in the developed countries as a whole in 1975 (Table 69–5).

At the other end of the pyramid, the proportion of those more than 60 has only just started to increase: following a slight decrease from 6.6% in 1950 to 6.2% in 1975, in 2000 it was only higher by one point than it was in 1950 (7.7%). During the whole of the second half of the 20th century, it is almost exclusively on the adult proportion that the movement of the young has been added.

This is exposed very clearly in the first graph of Fig. 69–13. Although the proportion of the elderly appears to stagnate at a level that is itself very marginal, a sig-

nificant shift has occurred between the young and the adults. The proportion of adults declined initially with the increase in the young, but since the mid-1970s, it has increased significantly as a result of the narrowing of the population pyramid's base. And although the level reached in 2000 was still considerably lower than was the level reached by the developed countries in 1950, this increase in adults will continue to grow over the next decades beyond the current level reached in the developed countries (see Chapter 77).

Thus, although during a first phase problems associated with rapid population growth in the developing

countries were combined with a specific problem of aggravation of the dependency ratio,[11] during the second phase (beginning in the mid-1970s) growth was accompanied by a distinct improvement in this ratio, which was favorable to an economic takeoff. However, the optimism of such an assessment must be moderated. On the one hand, it is once more based on a very general view that includes numerous exceptions: the least developed countries as a whole have not benefited from any advantage of this kind. But, on the other hand, even in the more numerous cases in which the dependence ratio has become favorable, this is not enough to ensure economic takeoff; it is only one factor among others as it is of little use to have a large working age population if a considerable proportion is unemployed. It is important that the developing countries take advantage of this *demographic window*, as it is open only for quite a short period of time and will be quickly followed by more rapid population aging than occurred in the developed countries.

c. Migration and Urbanization

As in Europe, the exceptional population surplus caused by the demographic transition provoked a double migratory pressure in the developing countries, with a growing proportion of the rural population migrating to the cities and causing a mass increase in candidates for expatriation.

The Urban Explosion

According to the United Nations (2002), of the 1.7 billion people living in developing countries in 1950, 1.4 lived in rural areas and only 0.3 in urban areas; by 2000 from a total of 4.9 billion, 1.9 lived in urban areas and 2.9 in rural zones (Table 69–6).[12] The urban population of developing countries has thus multiplied by six, whereas the rural population has only just doubled. The urbanization rate of developing countries has considerably increased from less than 18% in 1950 to more than 40% in 2000. This level is certainly far from the urbanization level of the developed countries as that was already 55% in 1950 and reached 75% in 2000, but there is a clear narrowing of the gap.

However, the level of urbanization varies significantly even within the group of developing countries, and this diversity can not be clearly associated with the timing of the demographic transition. Although it is

[11] Ratio of the combination of young and elderly (inactive ages) to adults (active age).

[12] These results, like all the results in this section, should be taken with precaution, insofar as the definition of urban population varies from one country to another (see Chapter 61 of Volume II). The United Nations has endeavoured to harmonize the national data as much as possible, but the data still remain influenced by the initial definitions on which they were based.

easy to understand that Africa, which entered later into the transition, is also less urbanized (the urbanization rate increased from 14.7% in 1950 to 37.2% in 2000), the same is not true of Asia and Latin America. Indeed although the urbanization rate of Latin America was already high in 1950 (41.9%) and had by 2000 caught up to the level of the developed countries (75.4%), Asia seems to have experienced a totally different process, with a very low level in 1950 (17.4%) and an identical level to Africa in 2000 (37.2%).

In any case, the second half of the 20th century saw the proliferation of the large cities of the south. In 1950, of 9 agglomerations with more than 5 million inhabitants, only 2 were located in the developing countries: Shanghai and Buenos Aires, each with barely more than 5 million inhabitants. In contrast, New York was on top of the list with over 12 million (Table 69–7), and with London, Paris, Moscow, and Tokyo, was one of the 5 most populated cities of the world. A quarter of a century later, of 22 agglomerations with more than 5 million inhabitants, 12 of them (more than half) were cities in the Third World. Although it is true that the majority of them were still far behind the leader Tokyo (19.8 million inhabitants) and New York (15.6); of the 5 cities with more than 10 million inhabitants, three were located in the Third World: Shanghai (11.4), Mexico City (10.7), and Sao Paulo (10.3). In 2000, more than three-quarters of the agglomerations with more than 5 million inhabitants were in developing countries: 29 out of 37! And although Tokyo remained in

Values are in millions. Cities in developing countries are in bold.
Data from United Nations, 2003.

the lead with 26.4 million, 14 of the 17 cities of over 10 million were in developing countries. Two cities in Latin America, Mexico City and Sao Paulo, have overtaken New York.

In theory, the city is the best outlet for the population surplus of the transition as it is mainly in cities that nonagricultural employment resulting from economic development is created. Nevertheless, taking into account that rural zones are incapable of absorbing the entire surplus workforce from the transition, the city has often attracted more people than it can employ. Urban growth has therefore largely consisted of extremely poor populations squeezed into unhealthy accommodation in slums and other favelas. The situation is more difficult to control when the growth is so fast. Certain authoritarian countries such as China have taken draconian measures in an attempt to stem back the flow (see Chapter 112 of Volume IV), but the suffering caused by these restrictions is hardly less.

The Barricades of the North

International migratory flows have already been discussed at length in Chapter 58 of Volume II. It is therefore not useful to go into it in detail here. Let us say that, despite the very strong demographic pressure exerted on the southern countries by a transition definitely faster and more explosive than the one Europe experienced in the 19th century, the migratory flows from the Third World countries toward the developed countries during the second half of the 20th century are, all things considered, without comparison with the European flows toward the rest of the world in the previous century. The International Organization for Migration estimates that immigrants made up only 2.9% of the world population in 2000 and that this proportion was only slightly higher than it was in 1965 (Table 69–8).

TABLE 69–8 Proportion of Immigrants in World Population

Population	1965	1975	1985	2000
Total population	3333	4066	4825	5882
Immigrants	75	84	105	175
Proportion (%) of immigrants	2.3	2.1	2.2	2.9

Data from IOM, 2003.

The proportion of immigrants in the total population certainly varies considerably from one continent to another. Although it is only 1.1% in Latin America, 1.4% in Asia, and 2.1% in Africa, it is 7.7% in Europe, 13% in North America, and as high as 19.1% in Oceania. Nevertheless, this proportion of the southern countries in the current population of the northern countries is far from that constituted in the past by the proportion of the European population in the populations of large previously poorly inhabited areas such as North America, Australia, New Zealand, and northern Asia. Migration resulting from the European transition submerged local populations and caused some of them to disappear totally, to the extent of transforming these territories into European subsidiaries. But even in Central and South America, historically more populated, the European contribution, with time, more often than not exceeded the population of the now so-called Latin America.

When Europe was exporting its population surplus overseas, no barriers could prevent the arrival of the conquering invaders endowed with military, economic, and financial means superior to those of the locals. On the contrary, when the demographic transition arrived in the southern countries, Europe with its offshoots in North America, North Asia, and Oceania, and stronger than ever before compared to the rest of the world, ensured that it could use at will the population surplus of the Third World. When after World War II there was much reconstruction to do and few hands available, the importation of labor was a widespread practice, continuing as long as economic growth made it necessary. But when the oil crisis of the 1970s and the new direction of the world economy that followed made the importation less profitable and the often inadequate treatment of immigration resulted in serious integration problems, the borders were closed. Certainly there has never been a total closure of borders and it is often bypassed by illegal immigra-

TABLE 69–9 Proportion of Immigrants in Total Population by Continent

Population	Asia	Africa	Europe	Latin America	North America	Oceania	World
Total population	3672	794	727	519	313	31	6057
Immigrants	50	16	56	6	41	6	175
Proportion (%) of immigrants	1.4	2.1	7.7	1.1	13	19.1	2.9

Data from IOM, 2003.

tion, but it was effective enough for this immigration to absorb only a tiny proportion of the potential emigration from developing countries toward developed countries.

II. INCREASING UNCERTAINTY AND THE DEATH OF THE TRANSITION PARADIGM

The evolution of the population of developing countries observed since World War II is assuredly a triumph for the demographic transition theory, but it is a limited triumph that has finally been of short duration. That which has just been described in this chapter is a generalization of the process observed in Europe a century previously. Possibly is could be called a transposition with a general difference (the acceleration of the process) and a wide diversity in application of the founding principle: demographic behavior has evolved owing to the modernization of societies, resulting in mortality decline and in fertility decline. The resulting phase of exceptional growth has only been transitory, and in this sense, the transition theory has had a major role in the explanation of a phenomenon that caused such concern during the 1960s and 1970s. It enabled scientists to propose rational forecasts and the governing powers to establish policies to complement or control the process.

However, the triumph of the theory disguised its limits. The reassuring idea of a convergence of the world population toward a modern demographic system in which low fertility would be sufficient to balance low mortality, thus leading to the absorption of the exceptional population surplus, has helped us forget that rapid population growth was not necessarily the only important issue for the future. The fact that some recent developments such as the fluctuation of fertility in Europe and the eruption of AIDS in Africa raised doubts concerning the convergence principle is not the worst. The main error is to have believed that convergence leads to stabilization. This idea of stabilization did not appear in the work of Adolphe Landry (1934), who was concerned with the risk of depopulation in Europe. It only appeared later in the work of Kingsley Davis (1945) and Frank Notestein (1945) and even later in the work of Thomas Frejka's on long-term population forecasts (1973), as a natural consequence of the fact that the Southern populations would in their turn experience a decline in fertility that would soon result in a near zero growth. It was reinforced by the success of the United Nations' population projections, which were until recently based on this convergence-stabilization principle. From the idea, soon to become reality, that all populations would approach the zero growth level, we progressed to the hypothesis that once this level was attained we would remain there.

The stabilization principle presumes that in a permanent system, fertility and mortality would become stable at a point of balance at which growth is zero and the population is *stationary* in the technical meaning of the term (see Chapter 20 of Volume I). In fact, as soon as mortality before the age of 50 becomes so low as to be nearly negligible, this balance requires a fertility rate of just below 2.1 children per woman.[13] At the highest life expectancy levels, whatever they may be, the first condition is therefore that fertility stabilizes at 2.1 children per woman; the second, that life expectancy itself stabilizes at a high level, whatever that may be. Regarding both of these aspects, the evolution observed in the most advanced countries moves increasingly further away from the demographic transition model, and if convergence is still possible, it is unlikely that it will lead to stabilization.

1. Fertility Crisis or a New Fertility System for Europe?

Although the secular fertility decline resulted in near replacement levels just before World War II in most European countries, nearly all the industrial countries later experienced an increase in fertility, the volume of which surpassed the ordinary effects of recuperation of the birth deficit of the war years. Fertility increased to levels over 2.1 children per woman everywhere, and this occurred over periods of varying duration, not only from the end of the 1940s and during the 1950s but also often in the 1960s and up to the beginning of the 1970s.

Figure 69–14 shows the United Nations' 5-year estimates (2003), which systematically retrace the trends during 1950–2000 of each country in Europe, North America plus Australia, New Zealand, and Japan. Certainly some countries such as Albania, Macedonia, Bosnia, and Malta had not as yet completed their demographic transition with fertility levels between 4 and 6 children per woman in 1950–1955. A few others are different for having not experienced the postwar baby boom and retaining (or reaching) a fertility level very near to 2.1 children per woman at the beginning of the 1950s. This is the case for Sweden and Greece and also countries of the former Soviet Union such as Latvia and Estonia. All the other countries experienced a period of relatively high fertility during the 1950s or

[13] Exactly 2.05 if mortality is zero before the age of 50 and if the sex ratio at birth is 105 boys to 100 girls.

1960s, with over 2.5 children per woman or, in some cases, over 4. However, this phenomenon did not occur in the same way or have the same signifiance everywhere.

In the countries of eastern Europe (Fig. 69–14, first two graphs) and in Japan (Fig. 69–14, seventh graph) the secular decline in fertility was only interrupted by a short baby boom or not interrupted at all, as in Russia, and the decline observed at the beginning of the 1950s is well in line with this secular decline (Chesnais, 1999).

On the contrary, in all the other countries fertility increased well over a mere recuperation of the deficit during the war. Indeed, a significant fluctuation in fertility was observed, which led to its culminating to quite high levels at the beginning of the 1960s and even later in some cases. Although this culminating level was altogether quite modest at around 2.5 children per woman in countries such as Germany, Switzerland, and Belgium, it was close to 3 in France, Austria, Norway, Italy, Spain, and Portugal; it exceeded 3.5 in Australia and the United States and reached as high as 4 in Ireland, Iceland, Canada, and New Zealand. But in an almost perfectly synchronized movement, all these countries then converged in a very pronounced decline in fertility, which resulted in levels below 2.1 children per woman from the mid-1970s.

This large fluctuation of fertility in the Western countries caused much debate. Was it the first fluctuation of the wave toward the fateful replacement level to which the demographic transition was supposed to lead all populations? Or was it an exceptional interlude in the secular fertility decline, which could then continue durably below replacement level? Different interpretations of the decline started to be made in 1965. Roland Pressat (1969a,b), for example, showed

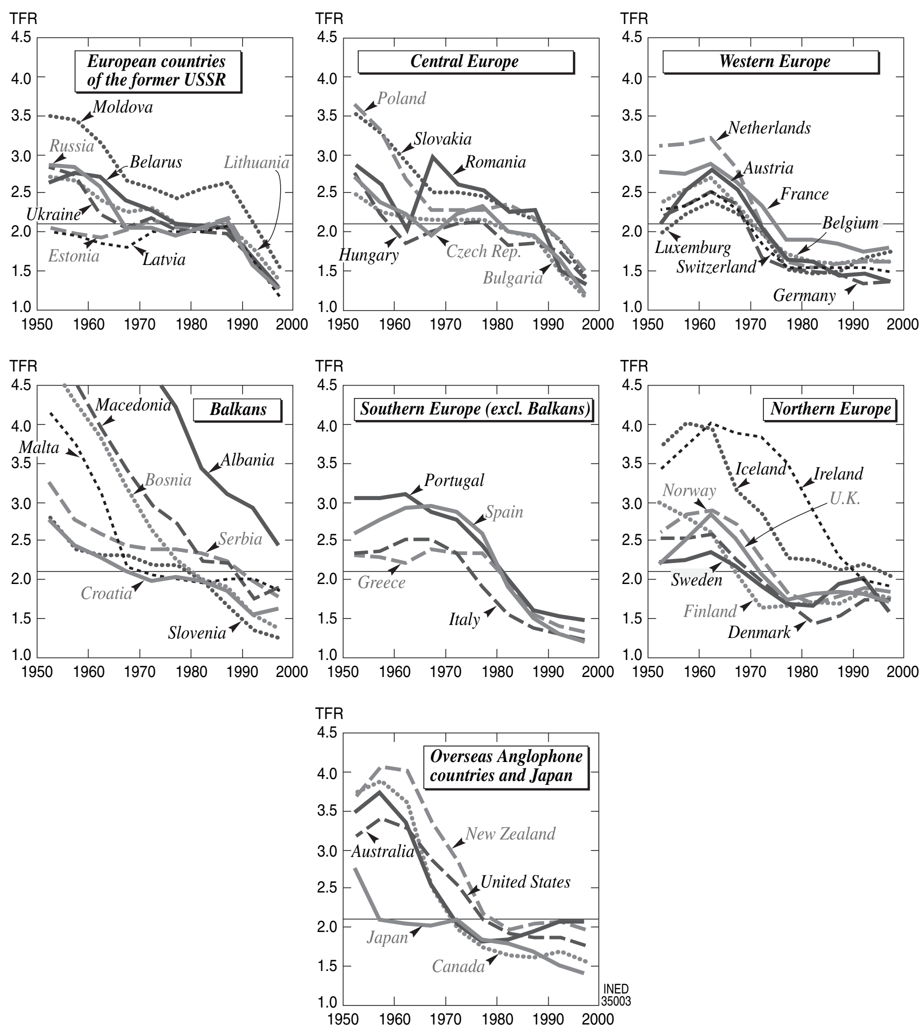

FIGURE 69–14 Evolution in total fertility rate in the developed countries since 1950. (Data from United Nations, 2003.)

that in the case of France, it could only be owing to the direct consequences of an evolution in age at first marriage: it was the reduction of age at first marriage that largely explained the increase in fertility, and the increase naturally caused the reverse to occur. Gérard Calot (1969), however, considered that it was owing more fundamentally to a reversal in fertility trends.

A little later, a demographic-economic explanation based on the ratios between generations was suggested by Richard Easterlin (1976). When the generation of reproductive age arrives on the employment market in greater numbers than did its predecessors, members of the generation experience a problems in the course of their careers that could dissuade them from having as many children as did the previous generation. If on the other hand, the new generation is less numerous, then its members integrate more easily into society and are therefore more likely to trust in the future and have more children. Thus by comparing over a period of half a century the evolution in the ratio of 35- to 64-year-olds to 15- to 34-year-olds to that of the average number of children per woman, Richard Easterlin constructed a model with results that match the reality observed in the United States. In turn, the movement of fertility affects the population pyramid, and it is then possible to imagine a series of self-sustained fluctuations associated with the interaction between age structure and fertility. Of course, this explanation could not be verified simply by observing or matching the fluctuations in a country, and the events that followed did not confirm Easterlin's theory.

More than a quarter of a century has gone by since fertility dropped below 2 children per woman in the majority of European countries without a revival preceding a new fluctuation of the same nature appearing anywhere. Some increase in fertility was observed in the 1990s, notably in the United States, but this phenomenon is rare and nowhere has fertility risen well above the 2.1 children per woman level anywhere. On the contrary, fertility has fallen below this level nearly everywhere, even in countries where it was least expected, such as Canada, Ireland, and Portugal, and even in Eastern European countries, which until the fall of communism had succeeded in maintaining quite constant levels of nearly 2 children per woman.

In 2000 no European country exceeded 1.9 children per woman except Iceland, which has fewer than 300,000 inhabitants. The TFR was between 1.8 and 1.9 only in France, Ireland, Norway, and Macedonia. It was below 1.5 in more than half of the countries and below 1.3 in nearly 20 of them (Spain, Greece, Italy, Bosnia, Slovenia, Bulgaria, Hungary, Poland, Rumania, Czech Republic, Slovakia, Russia, Estonia, Latvia, Lithuania, Byelorussia, Moldavia, Ukraine). Japan was at 1.4. Apart from the notable exception of the United States, developed countries increasingly appear to be established in a long phase of low fertility that is significantly below replacement level.

In a specific analysis of France, Henri Leridon (1987) showed that although a *second contraceptive revolution* did occur (in France from the 18th century to the 1960s, the most frequently used method was coitus interruptus), neither the wide diffusion of modern contraception (pill, IUD, sterilization) nor the liberalization of induced abortion explained the fertility decline observed since the mid-1960s. This revolution certainly resulted in a reduction in the proportion of unwanted children, but it was in no way at the root of the decline in the desire to have a child.

Beyond the benefits of technological developments that make fertility control more comfortable but do not determine its objectives, is there a *second demographic transition* (Lesthaeghe and van de Kaa, 1986; van de Kaa, 1987, 1988, 1994)? Ron Lesthaeghe and Dirk van de Kaa created this term to signify that the fertility decline observed in Europe since the 1960s did not result from the same factors as did the secular decline observed up to the World War II. On the contrary, it is caused by new changes in society that lead to new demographic behavior that could be called *postmodern.* During the past 3 or 4 decades, the family and its place in society have evolved with the reduction in official marriages, the development of cohabitation, the increase in divorces, the appearance of recomposed families, acknowledgement of homosexual couples, and the multiple facets of cohabitation outside marriage, from *couples living apart together* (Villeneuve-Gokalp, 1997) to the *PACS*.[14] At the same time, fertility outside marriage has itself changed completely both in volume and in meaning to the extent that in numerous European countries more than half of births occur outside marriage, and the evolution of these births contribute more to the TFR than does fertility within marriage. However, this does not necessarily mean that fertility decline is motivated by factors other than those that prevailed until the 1960s. Although these factors have certainly evolved since the 18th century, in particular, the evolution in women's role in society has had a growing effect, this phenomenon did not begin in the 1960s or even after the World War II. Rather than a drastic change in the determinants of the decline, one should speak of further developments in

[14] *Pacte civil de solidarité*, a status created in France, with legislation 99–944 of November 15, 1999, for unmarried couples, both heterosexual and homosexual, specifying a certain number of rights and duties pertaining to their conjugal union.

old factors. The necessity for women to have professional careers equal to that of men, one of the key factors in the most recent fertility decline, is only the outcome of feminist campaigns that began during the 19th century.

Whatever the case, whether the demographic transition theory is being replaced by a second transition theory or whether the failure of the paradigm of the stabilization of population numbers should simply be acknowledged, the general convergence toward fertility rates corresponding to replacement levels is as ineffective in explaining current trends in the developed countries as it is in making long-term forecasts for the developing countries.

2. Life Expectancy: Unexpected Divergence, Unknown Limits

If the recent history of European countries has significantly distanced us from a general system of fertility convergence toward near replacement level, the situation is hardly better from the point of view of mortality. Indeed, the unexpected evolution in mortality in several regions has distanced us from the idea of the convergence of life expectancies, but the level at which this convergence was expected has been repeatedly surpassed by reality.

a. Africa's Lateness

Although sub-Saharan Africa has just recently progressed firmly on the path of fertility decline after a long delay, the reverse has occurred in the context of health and mortality. As was the case for fertility, not only has progress been delayed but also, in many cases and notably where it was most rapid, the increase in life expectancy has been seriously affected by the AIDS epidemic.

Figure 69–15 (left) summarizes the evolution in life expectancy since 1950 in the sub-Saharan African countries least affected by the AIDS epidemic and compares these trajectories to Indonesia and Yemen, two developing countries that have followed a path more characteristic of Third World countries during the same period. This figure taken from a recent study (Vallin and Meslé, 2004) also shows, in dotted lines, the extreme values of the evolution previously observed in the developed countries. The rate of progress that all of the African countries have experienced has not been any faster than that previously experienced by the developed countries, despite the time difference. In other words, these countries have in no way benefited from the acquired knowledge that enabled most of the other countries to catch up significantly with the developed countries.

But this is not the only source of African disappointment because, as is shown in Fig. 69–15 (right), the other sub-Saharan African countries, some of which benefited during the 1950s, 1960s, and 1970s from progress nearly as rapid as in Yemen and Indonesia, have been so violently affected by the AIDS epidemic that life expectancy has abruptly dropped. In some cases the decline is such that at the end of the 1990s, life expectancy fell to the levels of the early 1950s and even lower. After gaining 20 years of life expectancy (from 44 to 64 years) between 1950–1955

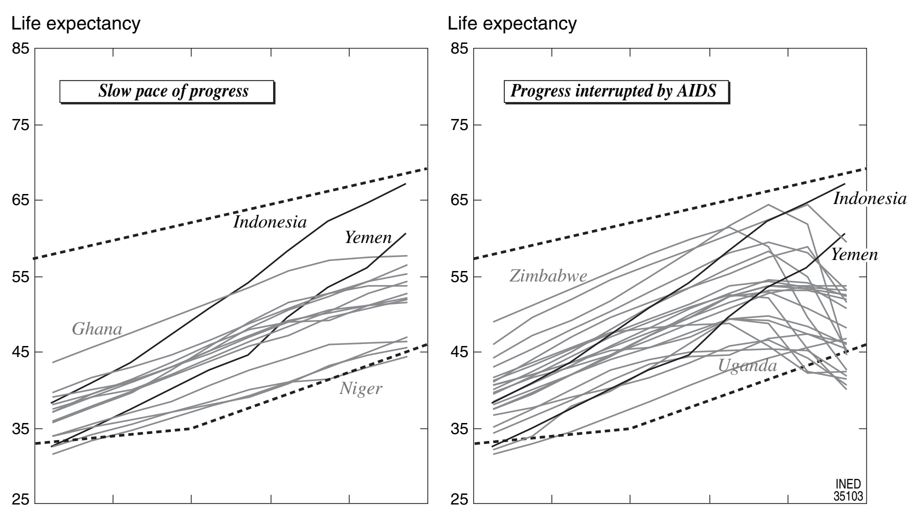

FIGURE 69–15 Evolution of life expectancy in African countries compared to two Asian countries. The dotted lines represent the extreme trajectories observed in Europe at comparable life expectancy levels. (Data from Vallin and Meslé, 2004.)

and 1980–1985, Botswana lost nearly as many years in 1995–2000, decreasing to under 45 years. The increase was less in Zimbabwe (13 years, from 49 to 62), but in 1995–2000 the decline resulted in a life expectancy of only 43 years, 6 years below its level in 1950–1955.

However, this double distortion does not fundamentally call into question the principle of epidemiological transition proposed by Abdel Omran (1971) to explain the mortality decline that is the basis of the demographic transition: if the modernization of society leads to the near eradication of infectious diseases, *a contrario,* some countries can, for reasons pertaining to their history, economy, or culture, be faced with serious obstacles in the attaining of this transition (Caselli *et al.,* 2001, 2002). Sub-Saharan African countries, more permeable than many others to a generalized spread of AIDS as a result of multiple partners and the considerable variability in age differences between partners (Brouard, 1994), were struck in full force by the epidemic at a stage when their still fragile economy was faced with the world economic crisis that had already depleted the meager health services of these countries. Prevention methods and, more recently, treatment methods can be effective, as has been seen in the northern countries, but these remain beyond the financial means of Africa.

b. Crisis in Eastern Europe

The second considerable distortion of the principle of the epidemiological transition according to Omran is that far from ceasing to progress after the victory over infectious diseases, life expectancy has been increasing since the 1970s because of successes on new fronts, such as treatment of cardiovascular diseases. However, it has been possible to reconsider the concept of epidemiological transition to the benefit of the larger concept of health transition (Frenk *et al.,* 1991), taking into consideration health effects of the modernization of society other than the control of infectious diseases in order to better understand the evolution in mortality observed during the demographic transition (Chapter 57 of Volume II). In the light of this, it is that the eastern European countries have been unable to enter into the second phase of the transition that is striking (Vallin and Meslé, 2001). In the mid-1960s, the life expectancy of the countries of central Europe, and even more so of the former Soviet Union, ceased to increase and entered into a long period of stagnation and even a decline of varying severity, notably among Russian men (Shkolnikov *et al.,* 1995a,b) and in the Ukraine (Meslé *et al.,* 2003), leading to a wide divergence between these countries and the other industrialized countries (Fig. 69–16). Communist regimes relied too exclusively on administration from the top of modern medical methods to ensure progress in public health, whereas the second phase of the health transition requires significant changes in individual behavior and thus the active participation of citizens in taking responsibility for their health. On the other hand, the economies of these countries were engaged in a ruinous competition with the West in arms and space programs and were unable to provide the necessary means for a reorientation toward an effective health policy in the area of chronic diseases (Caselli *et al.,* 2001, 2002; Vallin and Meslé, 2004).

c. The New Stages of the Health Transition

In reality, this divergence does not call into question the principle of the health transition itself as much as that of its continuity and uniformity. Like all progress, medical progress associated with economic and social modernization relies on successive inventions, the sequence and the effects of which depend considerably on the history and context of each country and each population. As a result, all major progress—in the past against infectious diseases, today against cardiovascular diseases and cancer, and tomorrow against senescence—is likely to cause an initial divergence to the benefit of the populations best prepared to benefit from it. Then a convergence occurs when the other populations finally succeed in finding ways to enable them to catch up (Vallin and Meslé, 2004). Moreover, Fig. 69–16 shows that some countries of the former communist bloc, such as the Czech Republic, Poland, and Hungary, have experienced an increase in life expectancy during the last decade of the 20th century.

In the same way, some already very advanced countries such as Japan and France continue to make rapid progress and are reaching life expectancy levels (at least its women) that were previously thought impossible, whereas others such as The Netherlands are running out of steam. This is possibly a sign of the beginning of a new phase in progress in the combat against senescence and, with it, a new divergence between pioneering countries and others (Vallin and Meslé, 2004).

In this historic succession of divergence followed by convergence, the pioneering countries are not always the same ones. Retaining for each period the life expectancies of the best-placed countries only, Jim Oeppen and James Vaupel (2002) showed that over 2 centuries the maximum human lifespan is progressing arithmetically. Not only has this progression never stopped, but it has not even decelerated. Without going so far as to follow the investigators in their hypothesis

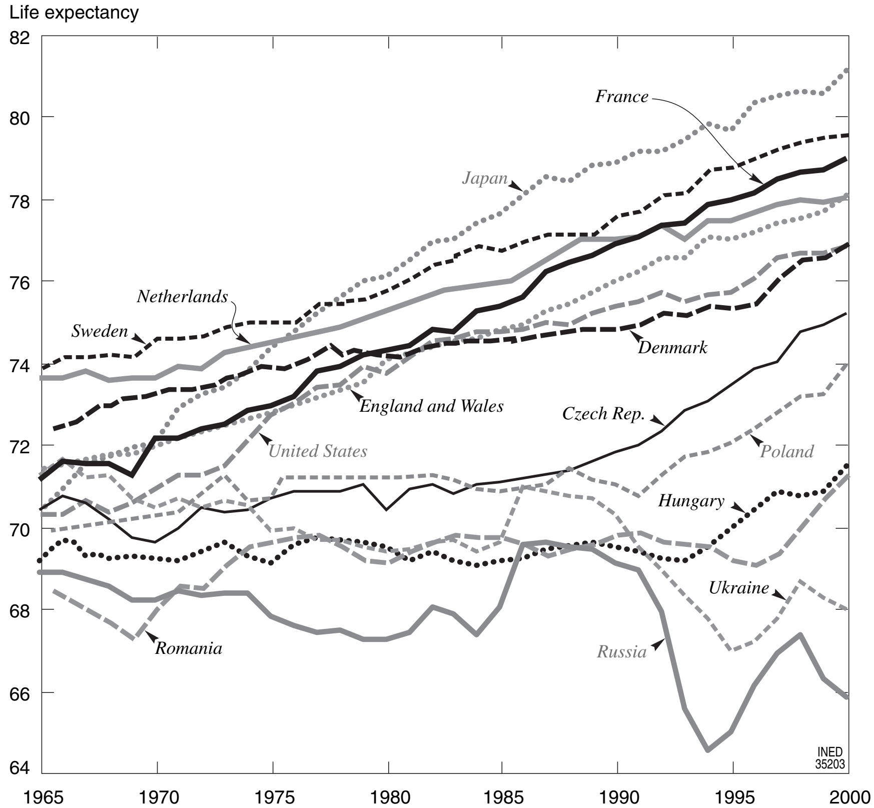

FIGURE 69–16 Evolution since 1965 of life expectancy in some eastern countries compared with some western countries. (Data from Vallin and Meslé, 2004.)

that this could continue for a long time again, the timidity of the forecasts made in the past by the investigators of population projections inspired by the demographic transition theory should be stressed. The United Nations, for example, was in the 1970s still using a life expectancy limit of 75 years as that to which each population should converge. During the 1980s this limit was increased to 85 years. It was only in 1998 that the United Nations ceased to impose an a priori life expectancy limit on its projections, although it nevertheless used mortality tables that did not go beyond a life expectancy of 92.5 years for any sex, even though we know that in a country such as France, a simple extrapolation of recent mortality trends will result in a female life expectancy of 95 years by the end of the century (Vallin and Meslé, 2001). If a limit does exist to the increase in life expectancy, no one knows its level, and the theory of a forthcoming stabilization cannot be retained for mortality any more than for fertility.

CONCLUSION

In reality, as we will see in Chapter 77, if the demographic transition theory has enabled solid world population projections to be made as long as the southern countries (which by their numbers constitute the main concern) were in mid-transition, the fact that the majority of these countries have completed most of the process and therefore have characteristics that more closely resemble those of the Northern countries gives an increasingly global scale to the considerable uncertainties that weigh on the European populations whose demographic behavior contradicts the paradigm of a general stabilization of the world population. As paradoxical as it may seem, at the beginning of the 21st century when population issues seem to be a less major concern for world leaders, the concerns that they raise in the scientific world are much greater now than when the southern countries were at the peak of their growth.

Not only are we realizing that a general and regular convergence of all these parameters is further from the reality of the 20th century than we believed (Coleman, 2002), but more so, we are discovering that the stabilization of population numbers, the *stationary population,* is far from being the most probable model for the 21st century, thereby justifying the most extravagant hypotheses for the long-term future, as we will see in Chapter 78.

THE GEOGRAPHY OF POPULATION AND DIVERSITY OF DEMOGRAPHIC DYNAMICS

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

From history, we move on to geography. Although short, this is a cardinally important section. The cusp of the 20th and 21st centuries is surely the one moment in human history at which demographic situations are most diverse across the world and also at which the distribution of populations across the surface of the Earth is most fluid, less because of international migration, largely halted by restrictive policies in wealthy countries, than because of the diversity of natural demographic dynamics themselves.

Whatever scale and interpretation are used, the world distribution of the population "demonstrates spectacular contrasts between densely populated and totally or nearly-unpopulated areas"[1] observes Jean-Michel Decroly in Chapter 70. After a review of the tools usable to measure this phenomenon, he seeks to explain the reasons for this and demonstrate their nature as broadly historical constants.

In Chapter 71, Bruno Schoumaker, Dominique Tabutin, and Michel Willems, stress that humankind has probably never experienced so many "demographic upheavals as in this latter half of the 20th century"[2] unprecedented growth, a break with the old numerical relationships among people, continents, high-density regions, etc., not to mention the evident radical changes in relationships between age groups and generations. The demographic transition has assumed many different forms and evolved to very different timeframes in different countries and regions of the world. The general dynamic of this has already been referred to in Chapters 68 and 69, but is reconsidered here in a structured way across its very diverse outcomes, observed mainly at the turn of the 21st century. The authors also lay some pointers for the future, and hence for Part III.

[1] "se manifeste par de spectaculaires contrastes entre zones densément occupées et zones où les hommes sont absents ou presque."

[2] "bouleversements démographiques qu'en cette deuxième moitié de XX^{e} siècle."

Distribution of the World Population

JEAN-MICHEL DECROLY

Laboratoire de Géographie Humaine, Université Libre de Bruxelles, Brussels, Belgium

INTRODUCTION

Whatever the scale and analytical framework used, the geographic distribution of the Earth's population displays spectacular contrasts between densely inhabited regions and areas with little or no human presence. Many images immediately come to mind to illustrate this phenomenon, such as the map of world population distribution showing the "full" worlds of Europe, India, and east Asia against the vast empty expanses in the high latitudes and the belt of arid deserts; the satellite image of Europe at night, in which the tight-knit pattern of villages and towns of inner Flanders, the Dutch Randstadt, and the Ruhr basin contrast with the more sparsely populated regions of Limbourg, the Ardennes plateau, and the Eifel; and the map of a city in an arid region showing the stark boundary between the urbanized area and the desert.

Beyond their surprising appearance, these contrasts raise several basic questions: Why are some regions of the Earth so populous? Why are there so few people elsewhere? What role have environmental and social factors played in determining these variations? All these issues are central to the analysis of the relationships between the human population and its habitat.

Addressed by scholars and philosophers since antiquity, these questions became a favorite research topic for the developing academic discipline of geography in the 19th century, at a time when it was seeking recognition. Friedrich Ratzel's *Anthropogeography* (1881–1891) and, above all, Pierre Vidal de la Blache *Les principes de géographie humaine* (1922) showcased the study of the spatial distribution of the population. They saw it as an invitation to examine the respective influence of the natural and human environments on territorial organization. This intellectual fashion would endure, as attested—in the French literature—by the lengthy discussions of settlement patterns by Max Sorre in his treatise on human geography (1948) and by Pierre George (1951), Jacqueline Beaujeu-Garnier (1956, 1958), and Wilbur Zelinsky (1966) in their volumes on population geography. Even today, the analysis of world population distribution remains a prime concern of human geography—more specifically, of population geography. The compilation of a new map of world population distribution by the International Geographic Union (IGU) Commission on Population Geography and Environmental Geography is forceful evidence of this (Fig. 70–1) (Vandermotten and Marissal, 2003). As the interest persists, the analytical approaches are evolving. The study of the impact of unequal spatial distribution is gradually replacing that of its causes (Pumain, 1992).

Rather than attempt a deceptive synthesis of the abundant literature on the topic examined, this chapter has three aims: (1) to highlight the main features of world population distribution, (2) to discuss the origins of the distribution, and (3) to supply a qualitative and historical explanatory framework. Beforehand, we discuss the concepts and tools needed for the descriptive analysis of the spatial distribution of the population. These specifications are useful because the controversies over settlement are partly generated by the ambiguity of the terms used.

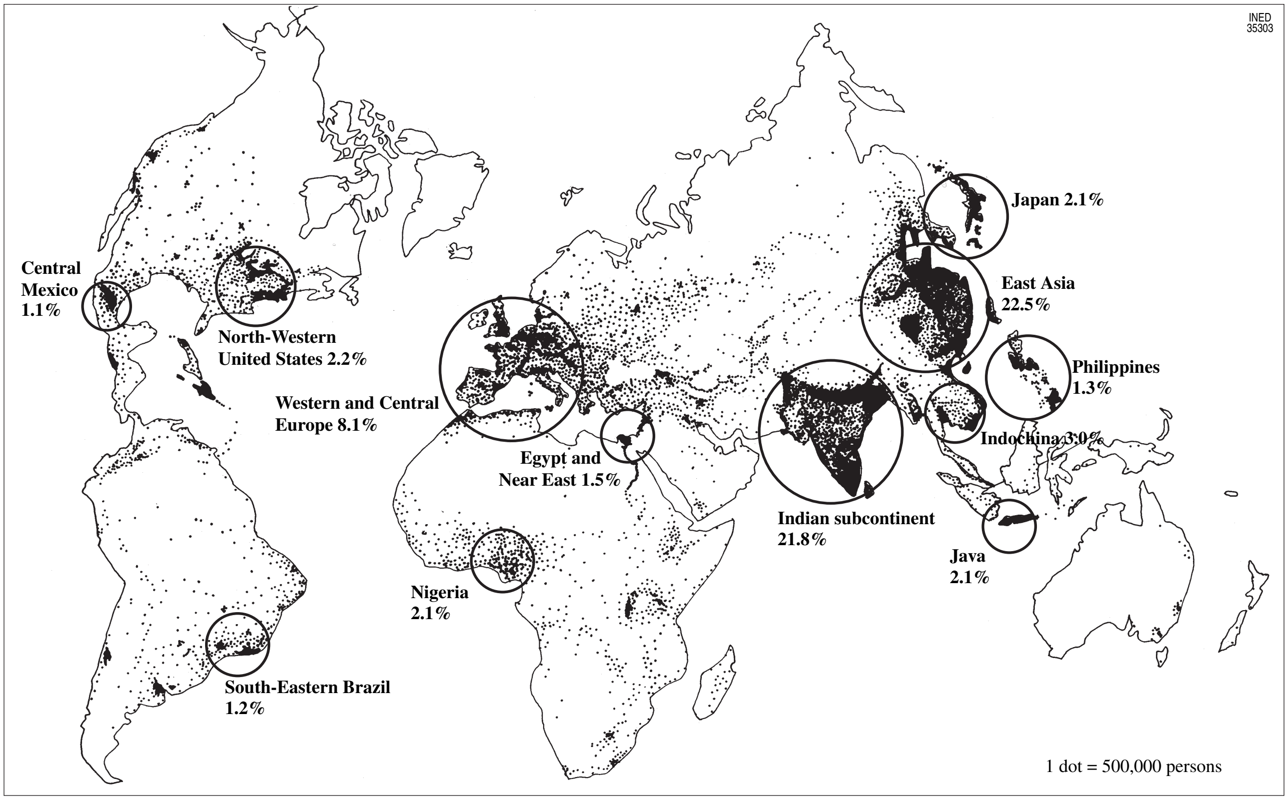

FIGURE 70–1 Map of spatial distribution of world population in around 2000. Demographic weights of population cores have been computed from national statistical yearbooks. (Data from Vandermotten and Marissal, 2003, after Baudelle, 2000 and Dolffus, 1990.)

I. DIFFERENT ASPECTS OF SETTLEMENT

In the social sciences, the term "settlement" has two different meanings. First, it describes the process by which societies establish their presence in a new territory. Examples include the conquest of the West in the United States, Russian settlements along the trans-Siberian railroad, and, more recently, the transmigration that took place in Indonesia from the island of Java to those of Sumatra, Sulawesi, and Kalimatan. Second, the term denotes the forms of land occupation by a population in a given period: presence or absence, occupation intensity, and dispersion or concentration in aggregates of varying size.

The analysis of the spatial distribution of the population specifically addresses this second aspect of settlement, as it seeks to (1) determine the Earth's inhabited area, (2) measure the variations in the intensity of human presence in that area, and (3) describe the geographic pattern of populated localities. This chapter will be restricted to the first two points, the third having been discussed, at least from a demographic standpoint, by Denise Pumain in her chapter on urbanization (Chapter 61 of Volume II).

To meet the objectives of the analysis of the spatial distribution of the population, it is important to establish the location of inhabitants. This self-evident truth conceals two questions. Who should be counted, and where?

The measurement of human presence in a given area relies on the enumeration of the population irrespective of its characteristics, be they demographic (e.g., age, sex, civil status), socioeconomic (economic activity, occupational status), or cultural (e.g., religion, language). This enumeration is usually carried out in the individuals' main place of residence. It is therefore exclusively dwelling related. People are counted in the localities where they live, hence in the structures designed to shelter them and ensure the daily reproduction of their workforce.

The analysis of population distribution at the place of residence does not provide an accurate count of populations that are continuously on the move with their dwellings (e.g., hunter-gatherers, nomadic shepherds, boatmen, gypsies) or groups engaged in seasonal or temporary migrations between several dwellings (seasonal migrants).[1] As a result, it neglects the fact that many acts of everyday life occur outside the home (Hägerstrand, 1973).

As long as transportation was slow, expensive, and difficult, people's workplaces and, more generally, their living spaces were identical to their dwellings: the vast majority of persons spent their lives within a radius of a few kilometers around the family residence. The spatial distribution of the population varied relatively little in the course of the day, the week, and the seasons. The increasing spatial division of work, the specialization of geographic areas, and the acceleration of travel have powerfully undermined the traditional pattern. Today, places of work and exchange are largely separate from places of residence. Daily or weekly commuting, as well as the temporary migration of tourists, characterizes the lives of a sizable percentage of the population, at least in the developed countries.

In consequence, there is often a wide gap between the number of persons who effectively reside in a locality and the number of persons who use that locality for their education, work, shopping, or leisure activities. For example, the resident population of the central business districts of European and North American metropolises does not exceed a few hundred people—but their daytime weekday population runs into the 10s of thousands. Likewise, in some tourist resorts, the peak-season population can be 10 times the number of all-year residents. In terms of local development and environmental impact, the significance of the two figures is, of course, totally different.

Despite its valuable lessons, the spatial distribution of the population by place of education, work, shopping, or leisure is very seldom studied. The task is admittedly complicated by the difficulty of measuring daily travel and, even more so, seasonal travel such as tourist flows (Vandermotten and Decroly, 1990). Nevertheless, further research on the subject would be useful to obtain a fuller picture of world population distribution.

Once the location of inhabitants has been established, we need to answer a third question: At what scale should we analyze their spatial distribution? This is a critical issue in the study of human settlement. The patterns of land occupation by human societies are intrinsically discontinuous: habitats are clustered into aggregates of variable size, located at different intervals from one another. Similar to a galaxy or ant colony, inhabited space therefore exhibits a granular structure, thus generating three major problems. First, such a structure does not have a single envelope but a multitude of potential ones, depending on the precision of the analytical grid adopted. Second, the contrasts inside the structure itself vary sharply with the observation scale. As Hervé Le Bras aptly notes (1993: 115): "to speak of the concentration or dispersion of the population makes sense only at a given observation scale: to say that 50% of the population is concentrated on 5% of the surface area is true only for a given segmentation. . . . The impossibility of determining the concentration of the population is the same as that of solving the famous problem of measuring the length of a country's coastline."

Third, the interpretation of the spatial distribution of the population also depends on the observation level. The processes that explain human settlement vary considerably with the scale of analysis. For example, the contrasts in population density in Belgium between urban agglomerations and their environment, on the one hand, and within the agglomerations, on the other hand, do not have the same causes. The first are largely due to the conditions of urban growth in the 19th century (economies of aggregation for industrial firms, closeness between home and work made necessary by slow transportation). The second are mainly due to the changes in urban space after World War II (shift toward service industries in urban areas, diffusion of the automobile, and promotion of the single-family home as the ideal dwelling).

II. ANALYTICAL TOOLS

The analysis of the spatial distribution of the population has long relied on three well-tested tools: the census as a source, population density as an indicator, and choropleth mapping as a method of representation. Although these tools remain very useful, they have weaknesses, and other less common tools should be mentioned.

1. Sources

A prime source for analyzing human settlement is the population census. In most countries of the world, it provides a comprehensive or nearly comprehensive enumeration of the population within the framework of often detailed administrative divisions. Analyzing the data extracted from this valuable source does,

[1] These groups currently total fewer than 50 million people worldwide. However, they intermittently occupy very large tracts of land, often lacking permanent settlements. The nomadic peoples of the old world's wide belt of arid desert and the Lapp and Siberian livestock breeders travel over territories stretching across more than 15 million km^2, or nearly twice the world's total surface area under cultivation (Debié, 1995).

however, pose two problems. The first is due to the coexistence of two different definitions of the population: (1) the de facto population, that is, the persons present at the census date in the geographic unit examined;[2] and (2) the *de jure* population, that is, the persons habitually residing in the geographic unit, regardless of whether they were present or not at the reference date. Despite international recommendations to harmonize the two concepts, countries continue to use either definition, undermining the comparison of the characteristics of their settlement patterns. In fact, the numerical difference between the de facto and *de jure* populations, which is already significant at the national level, can become substantial at the regional or local level (Decroly and Vanlaer, 1991). For example, in the Greek census of April 5, 1981, greater Athens was found to have a de facto population of 3,025,000 but a *de jure* population of 2,275,000. Barely 55% of the de facto population resided in the capital. Conversely, more than a quarter of Athens residents were enumerated in the de facto population of other geographic units.

The second problem entailed by the census data is the use of the existing administrative divisions as a basis for information collection. The divisions, which express the central government's appropriation of national territory, do not exhibit the same organizational logic or the same degree of refinement from one country to another. The contrasts are sometimes stark, even in Europe, where we find the highly disaggregated division of France (36,433 *communes*, or municipalities, with an average surface area of 15 km^2 and an average population of 1500) and the far cruder division of Belgium (589 municipalities averaging 50 km^2 and 17,000 inhabitants) and of Sweden (282 municipalities averaging 1500 km^2 and 30,000 inhabitants). This heterogeneity is a major obstacle to international comparisons, as the contrasting settlement patterns observed in the finer divisions (e.g., between rural towns and outlying villages) are wiped out in the broader divisions. Spatial smoothing methods (Le Bras, 1993; Tobler *et al*., 1997; Grasland, 1998) provide a way to overcome the obstacle but at the price of sometimes questionable assumptions.

Differences in the size of administrative units also modify the analysis of the spatial distribution of the population in very large countries with sharply contrasting settlement patterns—most notably Canada, Russia, and China. In this case, the size of the administrative units is inversely proportional to the number of persons per surface-area unit. As a result, the spatial distribution of the population is all the harder to determine accurately as the area is sparsely inhabited.

Without a census or population register, the classic way of enumerating the population is through a direct field survey. This information-collection method, however, has the disadvantage of requiring sizable human and financial resources, or it may cover only small areas. When population distribution is the focus of the analysis, the use of alternative sources—in particular, aerial photographs and satellite images—has become increasingly common. Once the dwelling locations have been enumerated and plausible occupancy ratios for the localities have been computed, both of these sources provide a good approximation of spatial distribution of the population at a moderate cost. They also offer the advantage of being suitable for counting populations that make temporary use of an area—for example, a tourist region—or that cannot be captured by standard enumerations, such as refugee camps.

2. Indicators and the Methods for Representing Them

The analysis of the spatial distribution of the population relies on two basic indicators with values that are computed in an administrative or geometrical segmentation: the absolute number of inhabitants and the population density per unit of surface area (Noin and Thumerelle, 1993). In the 19th century, the first cartographic studies of settlement used the abstract concept of density[3]—definitely an expression of that century's naturalistic approach to academic geography. In fact, the notion of density is akin to that of agricultural yields: it measures the number of persons that a given climate or soil is capable of *producing*. As Denise Pumain rightly notes (1992: 442), today "the indicator that possesses a social value would be the measure of the space available to each individual . . . in the same way as one calculates an income per capita." By this yardstick, Belgium would have 0.3 ha per inhabitant; France, 1 ha per inhabitant; and Greenland, 50,000 ha per inhabitant.

Population density should be seen as a descriptor of human presence. We must therefore refrain from giving it an explanatory value. Olivier Dollfus (1990)

[2] As a rule, the de facto population consists of people who have spent the night before the enumerator's visit in a dwelling located in the reference territory. It does not include some categories of persons despite their presence in the area, most notably visitors staying in tourist accommodation.

[3] Respectively, a map of the spatial distribution of the world population published in 1833 by the Englishman George Poulett Scrope in his *Principles of Political Economy* and a series of maps on the settlement of Ireland compiled in 1837 by Henry Drury Harness in preparation for the construction of the island's first railroads (Noin, 1979).

shows the absurdity of equating population density with a measure of the *geographic efficiency* of societies, that is, their capacity to generate yields from their land. Both the denominator (surface area) and the numerator (population) are, intrinsically, heterogeneous variables. The surface of the Earth is anything but uniform, and populations are not equal, if only because their living standards vary substantially from one place to another on the planet. Two identical densities can therefore indicate two very different realities. A comparison of Bangladesh and the Noord- and Zuid-Holland provinces (The Netherlands) is instructive in this respect (Dollfus, 1990). In terms of population density, both entities, located in flood plains and delta plains, would have roughly the same *geographic efficiency,* with 700 and 900 persons per square kilometer, respectively. Yet, on closer inspection, they differ in every way—not only in their living standards, of course, but also in their economic structure, urbanization levels, etc.

Population density is also often used as a measure of overpopulation—another serious error. Overpopulation means that the resources available in a given area are insufficient to meet the basic needs of the local population. In this sense, it is independent of population densities: overpopulated zones may have small populations, just as underpopulated ones may have many inhabitants. Whichever way one looks at it, the region of Brussels, a capital city, is not overpopulated at 5700 persons per square kilometer, despite having to cope with saturated communication infrastructure. By contrast, Mali, whose density barely exceeds six persons per square kilometer, may be described as overpopulated in that its available resources are inadequate for its resident population and its own-account production is preferred to massive imports of subsistence goods.

Even as a descriptor of human settlement, density is somewhat problematic. Its computation rests on the implicit assumption that the population is evenly distributed within each administrative subdivision considered. In other words, it assumes a consistent, homogeneous settlement pattern, which is contradicted by the facts. The discrepancy between representation and reality is not only a theoretical problem. What is the significance of the mean density of Egypt (53 persons per square kilometer) when more than 90% of the country's population is concentrated in the narrow valley of the Nile and its delta? For these different reasons, some investigators prefer to use dot maps, which locate population aggregates with precision.

Despite their being more concrete, population dot maps were not invented until the early 20th century and did not come into widespread use until after World War II. As Daniel Noin notes (1979: 38): "the principle is simple: the population is represented by dots, each of which symbolizes a given number of persons and is positioned as accurately as possible on the corresponding locality. The dots may all have the same value—and so the same surface—or different values." This system of representation offers several advantages. It gives a precise picture of population distribution while displaying certain explanatory factors such as physical features (relief, waterways, etc.) and allowing a reading on multiple levels. However, it does not permit rigorous comparisons in time and space or, more importantly, an effective display of high concentrations of population.

In the second half of the 20th century, many innovative mapping processes were developed to depict population distribution, in particular statistical relief maps, which show densities by means of *reliefs* of different heights, seen in perspective, and anamorphic maps, which display the populations of the geographic units studied by means of surfaces proportional to the number of inhabitants. In most cases, these maps are more valuable as teaching aids than as heuristic devices: they strike the imagination. An anamorphosis of the world population distribution by country shows that Russia weighs little by comparison with China, whereas Australia, which seems so large on a world map, weighs less than Taiwan (Fig. 70–2).

III. THE SETTLEMENT ENVELOPE

The first stage in the analysis of the spatial distribution of the population consists in defining the area occupied by humans. This is a crucial step, for, as Pierre Vidal de la Blache observed (1917: 81): "the area of distribution of a species, whether man or any other living species, is no less instructive for the gaps and discontinuities it reveals than for the tracts it covers." To tackle the issue, we must begin by examining the concept of *oikoumene.*

1. Oikoumene: An Ambiguous Term

The ancient Greeks coined the term *oikoumene* (from *oikos,* "household") to describe the world inhabited by the agrarian civilizations of antiquity. Today, *oikoumene* is one of the most ambiguous terms in the geographic vocabulary: its meaning varies as much as its spelling.[4]

[4] Jean-Pierre Allix (1996) notes no fewer than five different spellings in French alone: œ*koumène, écoumène,* œ*coumène, oikumène,* and œ *cumène.*

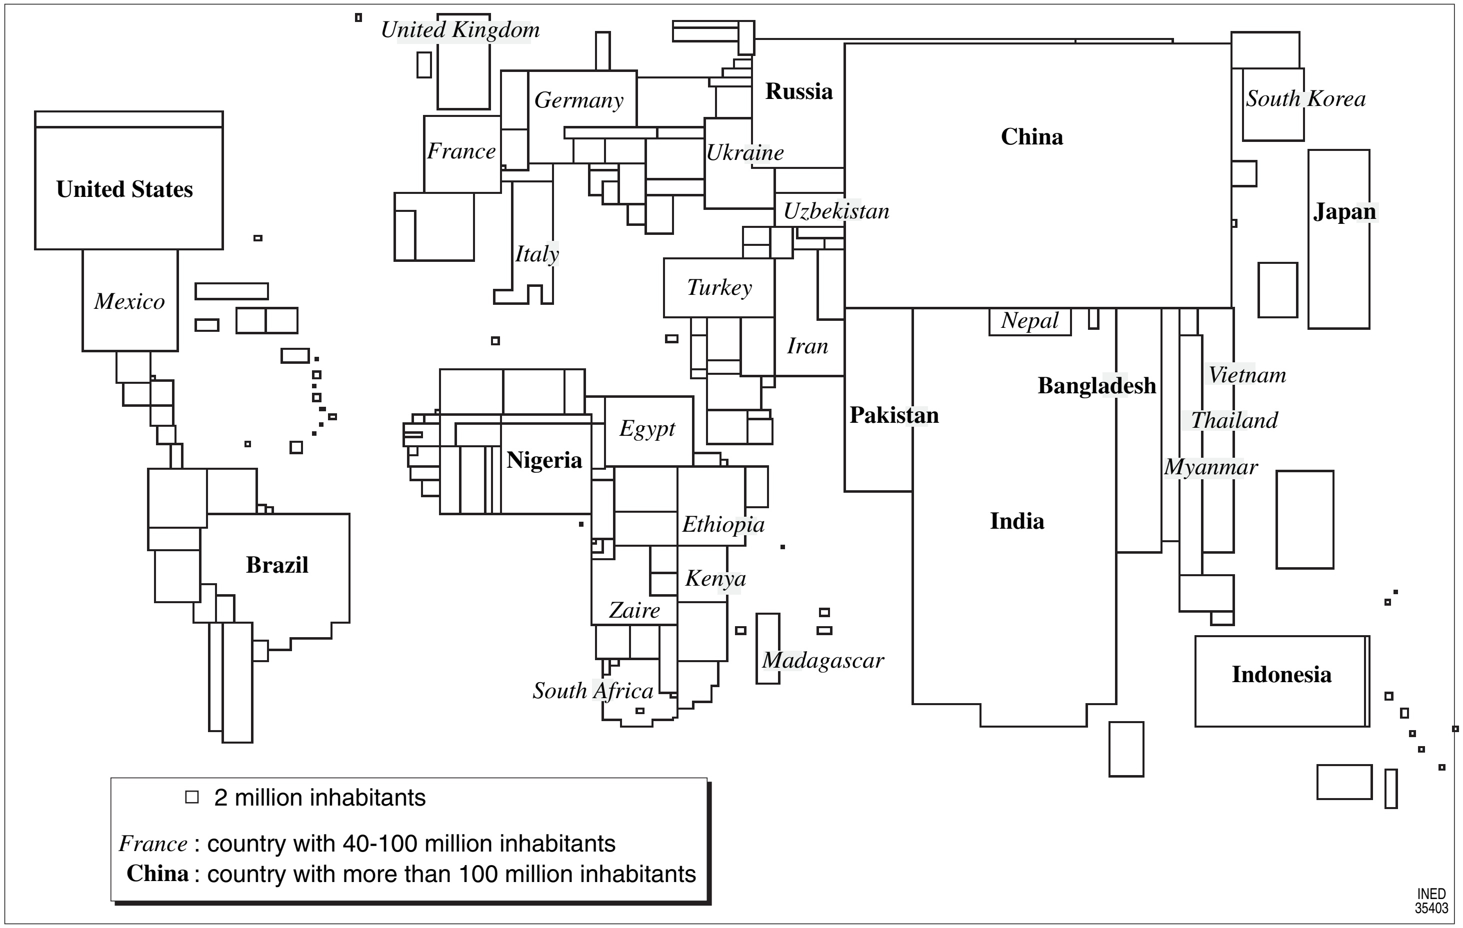

FIGURE 70–2 Anamorphosis of world population distribution. Each country is shown by a surface proportional to its population (Image from Vallin, 2000).

It is sometimes used to refer to the total landmass or, far more restrictively, to designate a market area, that is, a portion of territory in which economic consistency is provided by a network of trade routes (Wilkinson, 1993). As a rule, however, and consistently with its original meaning, *oikoumene* denotes the inhabited world. Following the method of Max Sorre (1948), Jean-Pierre Allix (1996) uses the term to describe the Earth's total inhabited landmass. Franck Debié (1995) broadens the concept somewhat by speaking of *territoire de l'humanité* (territory of humankind). But the basic idea is identical: the *oikoumene* is a concrete reality observable at a given moment. Conversely, Daniel Noin (1979) uses the term to describe the space suitable for long-term habitation by human communities or the total inhabitable areas of the planet.

Inhabited space or inhabitable space? The two notions are fundamentally different. The first is a fact observed at a given moment and on a given scale. The second is both a virtual limit—which complicates matters considerably. Inhabitability is always determined by social factors: it depends on the means of production, development approaches, and social relationships concerning production, as well as a group's representation of its environment. The limits of inhabitable space vary from one society to another, sometimes even radically. Unless we are to fall into the Eurocentric trap, it is vain to seek to define those limits for all of humanity. Consequently, in keeping with etymology, we shall regard *oikoumene* here as referring to the inhabited world as a whole.

2. The Earth as Envelope

Many investigators now regard the inhabited world as coextensive with our planet, and they reject the notion of *human deserts* in the narrow sense of the term (see Dollfus, 1990). Admittedly, the entire Earth has been mapped, explored, and appropriated. First, the successive improvements in surveying methods have made possible an exhaustive cartographic coverage of the planet. Second, the advances in methods for protecting against atmospheric and climatic constraints, combined with the development of transportation, have substantially broadened the area explored by humans. Since the 16th century, for reasons relating to strategy (marking the boundaries of a colony or country), science, or sports, innumerable expeditions have crossed the hot deserts of the old world, the dense equatorial forests, the tundra of northern Canada and northern Russia, the polar ice caps, the major mountain ranges, etc. Third, with a speed of propagation that was fitful but accelerated in the 20th century, all parts of the planet's land mass—including airspace and subsoil—were assigned to the different countries. Today, some 180 nations and 70 not-yet-independent territorial entities share the continental surfaces, forming a complex puzzle.

Although, in practice, the mapping coverage of the world is highly uneven, some areas of Antarctica and the Arctic remain untouched by human exploration, and many territories are still disputed, we have to admit that—at least at a small scale—humanity has taken possession of the entire Earth by use of its *eyes*, *feet*, and *rules*. Does this mean that humanity has extended the inhabited world to the whole planet? Without lapsing into the reductionist vision of 19th-century geography, which restricted the *oikoumene* to the sphere of European civilization and to population groups recognized as sedentary, a large part of the world is empty. In the oceans, in the cold deserts of the upper latitudes, the arid deserts of the tropics, the largest mountain massifs, and the equatorial rainforest, the rare human settlements—permanent or temporary—are separated from one another by vast uninhabited tracts, sometimes up to several 10s of thousands of square kilometers. The inescapable conclusion is that the *oikoumene* is far from covering the entire Earth.

3. The Difficulty of Drawing Boundaries

Because of the discontinuity of human settlement, the *oikoumene* does not have a single envelope, but a multitude of possible limits. On a very large scale, and without resorting to cartographic generalization, it will comprise a very large number of isolated settlements. On a very small scale, and after generalization, it will consist essentially of a few continent-sized populated tracts separated by the large expanses of human deserts. Greenland offers a good example of this. With barely 60,000 inhabitants for more than 2,150,000 km^2, the island, stretching between 59° N and 83° N, has a population density of less than 3 persons per 100 km^2. The human presence is fragmented into 19 isolated coastal settlements, including the U.S. military base of Thule at 76° N. In real life, each of these small agglomerations (the largest has 20,000 inhabitants) may be regarded as a fragment of the populated space—a crumb of the *oikoumene*. By contrast, on a planisphere, we can easily concede that Greenland as a whole is located outside the populated world, its inhabited areas being reduced to a bare minimum. Neither solution is more correct or more wrong than the other; each is correct at a given level of analysis.

The example of Greenland shows that defining the boundaries of the *oikoumene* is not self-evident to the observer but requires a set of prior choices, most notably that of the scale of analysis and the degree of generalization of reality. On a very small scale—the one being addressed here—the first approximation to be adopted may be the proposition that the *oikoumene* broadly comprises the spaces located inside an envelope curve plotted on a dot map of population distribution (Fig. 70–1). The regions outside the envelope curve form the outer limits of the *oikoumene*. They are not totally empty, but their densities rarely exceed one person per square kilometer and are very often zero over large expanses. These limits stretch over a surface area equal to 30% to 40% of the Earth's landmass (including the continent of Antarctica) and comprise less than two-hundredths of the world population.

IV. THE FRONTIERS OF THE OIKOUMENE

A wise observer of terrestrial space, Antoine de Saint-Exupéry, noted in one of his novels (*Vol de nuit*, 1931) that "the universe of fountains and houses is but a narrow ribbon on the surface of the globe; a first error—my plane went astray in the middle of the Paraguayan bush; a second error—it landed in the Saharan sands." Despite massive population growth in the past 2 centuries, the Earth still has wide expanses that are very sparsely inhabited, if at all.

1. Frontiers Shaped by Physical Constraints

The frontiers of the *oikoumene* are divided into four broad subsets shaped by the constraints on agriculture owing to certain characteristics of climate, vegetation, and altitude. To take up Guy Baudelle's (2000) classification, these consist respectively of "white deserts, dry deserts, green deserts, and altitude deserts."

a. White Deserts

White deserts combine nearly permanent cold[5] and meager precipitation. They are mostly situated in a wide band in the northern part of the Eurasian and American continents. They also comprise the Arctic islands and the Antarctic continent. In the northern hemisphere, their southern boundary varies from one continent to another. In North America, it lies consistently between 45° N and 50° N. But on the Eurasian continent, owing to the strong effects of continentality, the boundary shifts southward from west to east—from about 60° N in Scandinavia to 45° N in Siberia and the Far East. These huge territories stretch over more than 20 million km^2 (not counting Antarctica) and account for 10% to 15% of the landmass, but they are inhabited by fewer than 10 million people, or barely two-thousandths of the world population. Except for some large mining towns that are mainly a legacy of the Soviet era (e.g., Murmansk [580,000 people] at 68° N, Arkhangelsk [470,000 people] at 64° N, Norilsk [230,000 people] at 70° N, Yakutsk [190,000 people] at 62° N, Vorkuta [160,000 people] at 67° N), the human communities represent *crumbs of the oikoumene* (Racine and Villeneuve, 1992: 422)—tiny clusters of 100 to 1000 inhabitants separated by wide empty tracts.

The white deserts' low population density owes far less to the physiological effects of cold—against which humans can protect themselves—than to the minimal prospects for agriculture. The main continental glaciers and the permafrost[6] areas are totally sterile, as plants cannot find the water they need for growth. Farther south, periodic topsoil thaw promotes a meager vegetation of lichen and short grass, which can sustain large mammals such as reindeer and caribou, as well as allows hunting and fishing and even extensive livestock breeding. Cereal crops, however, are practically impossible. The mechanisms for producing organic matter are inefficient when the frost-free period does not exceed 150 to 175 days a year,[7] as is the case in white deserts. The importation of foodstuffs grown elsewhere now provides a remedy for this situation and makes it possible to sustain human communities—sometimes large—north of the cereal-growing boundary. But the cost is very high and warranted only by major economic or strategic interests.

b. Dry Deserts

Dry deserts, characterized by a precipitation below the potential evapotranspiration,[8] are dominated by

[5] One or two months with a mean monthly temperature exceeding 10°C in a temperate continental climate; none in a polar climate.

[6] Permanently frozen stratum of the soil or subsoil.

[7] Research by Canadian and Russian geographers has shown a close correlation, in their respective countries, between this climate boundary, the agriculture limit, and the main break in the settlement pattern. In Quebec, for example, the population density falls abruptly north of a line running through Lake Saint-Jean, the Abitibi, and the Témiscamingue: the line marks the boundary of 160 frost-free days.

[8] Evapotranspiration is the quantity of water absorbed by the air either through evaporation (running or stagnant surface water, soil water, and water-tables) or through transpiration by plants and other living organisms. Potential evapotranspiration measures evapotranspiration under the theoretical assumption of a consistently adequate water supply.

the great arid diagonal of Eurasia wrapping the side of the old world from the western Sahara to the Gobi Desert. Among other features, it comprises the Ténéré, the Tibesti, the Sinai, the Rubl'al-Khali, and Nefud in Saudi Arabia; the Lut Desert and Great Salt Desert of northeast Iran; the Kazakh steppe; the Karakum;[9] and the Takla-Makan.[10] In addition, there are the deserts in Latin America (Atacama, Chaco), sub-Saharan Africa (Kalahari, Namib), and Australia (Victoria, Great Sandy Desert, etc.). These arid regions are more populous than are the cold regions of the upper latitudes: covering more than 10% of the world's landmass, they are home to about 1.5% of the planet's inhabitants, with a mean density of about 5 persons per square kilometer versus the 0.5 persons per square kilometer of the white deserts. The gap narrows sharply, however, when one excludes the great irrigated valleys of the Nile, Tigris, and Euphrates, which hold approximately 70 million people. Moreover, similar to the white deserts, most dry deserts have less than one inhabitant per square kilometer.

The main reason for the sparse population of arid regions is inadequate rainfall: similar to the cold in upper latitudes, the lack of rainfall drastically curtails the production of food resources. It is now recognized that rainfall-dependent agriculture has become highly precarious (and subject to large annual variations) when rainfall is under 300 mm/year and is impossible below 150 mm. In these conditions, the formation of sedentary cores is inconceivable without supplementary water inputs—in particular, artesian water-tables and allochthonous rivers—that allow irrigated (often intensively) crops. Settlements accordingly develop as oases with distribution that matches the location of water sources: scattered concentrations around wells tapping into superficial or deep water-tables combined with linear concentrations in valleys of allochthonous rivers (Nile, Tigris, Euphrates, Amu Daria, Syr Daria, etc.) or along the source lines situated in the foothills of mountain ranges.

c. Green Deserts

The third type of *oikoumene* frontier consists of tropical and equatorial rainforests. Their population is often insignificant: 1 to 2 persons per square kilometer in the Amazon and 1 to 10 in the patches of equatorial forest in Africa (eastern Cameroon, Gabon, western Congo Brazzaville, northern Congo Kinshasa), as well as Borneo and New Guinea. Two factors play a key role here: poor sanitary conditions and the difficulty of managing the territory.

[9] Desert covering almost 80% of Turkmenistan, in central Asia.

[10] Desert covering a large portion of Xinjiang Uygur in China.

The moist heat generated by the climate and maintained by the forest cover provides a highly favorable breeding ground for pathogen complexes[11] responsible for specifically tropical diseases (e.g., malaria, leprosy, yellow fever, filariases, bilharziosis, sleeping sickness). This unhealthy environment is as much the cause as the consequence of a low settlement rate. On the one hand, it promotes high mortality and discourages the arrival of new inhabitants; on the other hand, as Pierre Gourou (1982) has clearly shown by using the example of sleeping sickness, it persists all the more easily given the lack of manpower to perform the improvements that would eliminate the vectors' places of reproduction and pathogen reservoirs. Moreover, evidence suggests that when technical resources are primitive, territorial control (e.g. penetration, clearing, extraction of natural resources) is far more difficult in closed forests than in woodlands or wooded savannas (Raison, 1988).

d. Altitude Deserts

The final category of *oikoumene* frontiers consists of the highest portions of large, steep-sloped mountain massifs. Entire sections of the Himalayas, Altai, Karakoram, Qilian, Kunlun mountains, Alps, Rockies, and southern Andes are not permanently inhabited. The same is true of some medium-altitude mountain ranges such as the Pamir,[12] Tian Shan,[13] and Japanese mountains. The upper limit of high-altitude settlements is consistently below the limit of endurance of the human body to the effects of oxygen rarefaction and the decrease in temperature. This boundary is dictated, as in the upper latitudes, by the restrictions on agriculture imposed by cold, in particular the shortening of the vegetative season. The limit therefore varies sharply with latitude: while reaching 4000 to 5000 m in the Himalayas and central Andes, it does not exceed 2000 m in the Alps and 300 m in the mountains of Iceland.

2. A Diversity of Groups Cohabiting on the Frontiers

The frontiers of the *oikoumene* are inhabited by two types of population that are very different both in the size of their settlements and in their degree of mastery and utilization of the environment—as well as the

[11] Each complex combines a micro-organism (parasite or protozoon) responsible for the disease, reservoirs in which it develops, and a vector that transmits it to humans and/or domestic animals.

[12] High mountain range between Tajikistan and Kirghizstan, in central Asia.

[13] High mountain range in Kirghizstan.

resources available to them for the purpose. The first category consists of scattered, often mobile groups that have long occupied these vast tracts; the second comprises groups that have established residence in military bases, industrial towns, or pilot farms built at great expense in recent decades.

Because of their modest resources, the first category is divided into small groups occupying extended tracts, without true territorial control. They include hunter-fishers (Inuit), hunter-gatherers (Pygmies), livestock breeders (Sames and Lapps of the European and Russian Far North), and even (but more seldom) farmers. Some are nomadic (Inuit), others are sedentary, and others combine both modes of spatial occupation (Lapps). To survive in often extreme conditions without sophisticated technologies, all have had to draw on whatever meager resources are available.

The presence of these groups in a particularly hostile environment was often owing to their exclusion (voluntary or forced) from their initial area of residence. The frontiers of the *oikoumene* have thus provided shelter for some endangered minorities (such as Druze and Christians in the Lebanese mountains). In other cases, they have served as "holding pens," where the colonizers confined the inhabitants of the region they had just conquered. In Morocco, for example, during the Arab-Muslim invasion of the eighth century, the Arab nomadic tribes drove back the Berberophones toward the Atlas. Likewise, in the United States, the European settlers steadily drove the Indian tribes out of their traditional hunting or livestock-breeding regions toward the Rockies and their foothills. In the 19th century, the settlement of the most clement regions of northernmost Norway, Sweden, and Finland (valleys and lake shores) drove the Lapps northward, as they were dispossessed of most of their hunting grounds and pastures.

The general shift toward trade-based relations challenged the traditional forms of occupation of the *oikoumene* frontiers. This trend was fueled by the expansion of the European world economy and the emergence of new countries as a result of decolonization. Very often, subsistence activities have been largely abandoned for trading activities. The Lapps, for example, have gradually converted to trading in animal hides. Likewise, in arid regions, long-distance caravan trade gradually gave way to competition from trucking. In a parallel development, political authorities have often encouraged local inhabitants to abandon their traditional areas of travel or residence. In Greenland, most Eskimo groups have been forced to settle in towns; in the Sahara, the Tuareg who moved between Algeria, Niger, and Mali were obliged to adopt a sedentary lifestyle.

These shifts have increased the dependency of the groups involved on the outside world while weakening their social structures (rise in alcohol and drug consumption, higher suicide rates). Where new activities have not generated adequate income, governments have often introduced direct or indirect subsidies. Absent such assistance, economic integration has triggered depopulation, sometimes on a massive scale as in many medium-altitude mountain regions.

For at least a century, the frontiers of the *oikoumene* have been the site of new forms of settlement driven by economic, strategic, or prestige-related motives—or a combination of all three. The extraction of energy resources (oil, natural gas, coal), rare and precious minerals (gold, silver, nickel, etc.), or timberland resources has spawned many urban developments. Some are single-purpose, short-lived, and of modest size, such as the countless small mining ghost towns in the western United States and oil-industry complexes in the Sahara; others are diversified and have become large, such as Yakutsk, a major Siberian natural-gas terminal and a wood- and paper-industry center. From 1950 onward, a drive for effective control of the Arctic led the two superpowers to build military bases and related facilities (e.g., weather stations, radar stations) in the Far North. Some of these bases gave birth to large urban centers, such as the Murmansk naval base on the Kola peninsula. And, in the past 20 years, the settlement of the frontiers of the *oikoumene* has also become an issue of prestige, as witnessed by the pilot farms in the Libyan and Arabian deserts, where cereal and vegetable crops are grown at great expense by tapping deep water tables.

The fruit of costly technological prowess, these new forms of settlement are fragile as they depend closely on changing international economic and political conditions. For example, after the break-up of the Soviet Union and the emergence of new areas of tension in the world, Arctic military bases have been gradually scaled down or simply abandoned (Radvanyi, 1996). Moreover, as Olivier Dollfus lucidly noted (1990: 448), in most of these facilities "a handful of men live in a controlled atmosphere, cooled or heated, consume products from elsewhere, and overcome the isolation and the conditions of a highly artificial and often almost all-male micro-society by frequent trips back to the *oikoumene* for restorative stays."

V. INHABITED SPACES

The spaces lying inside the envelope curve plotted on a dot map of settlements add up to 60% to 70% of the landmass and hold some 98% of the world population. They are not completely occupied, but their densities usually exceed one person per square kilometer. In their midst, where the population density exceeds 50 persons per square kilometer, are the population concentrations. They take up 10% to 20% of the landmass and contain 70% to 80% of the world's inhabitants. Between these concentrations lies the ordinary pattern of human settlement—"areas that are, in a manner of speaking, anonymous, not conspicuous for their excess or shortage of inhabitants" (Pinchemel and Pinchemel, 1988: 45)—covering approximately one-half of the landmass and holding 20% to 30% of the world population.

At the global level, the population concentrations differ in their geographic extension. First, there are three main cores—East Asia, the Indian subcontinent, and Europe—in which areas with a density greater than 50 persons per square kilometer stretch without significant breaks over several hundred thousand square kilometers. The second group consists of about 30 secondary concentrations, with cores that occupy small surface areas and are isolated from one another by large weakly-populated tracts. Both of these *oikoumene* subsets display variable patterns of territorial organization. The forms of spatial appropriation, the arrangement of cities with respect to one another, the formation of communication networks, and other characteristics differ sharply according to the intensity and degree of spatial continuity of settlement.

1. Main Concentrations

The world's three main concentrations hold 50% to 55% of the world population on about 10% of the landmass (Fig. 70–1). They are "*full worlds*" or "*human continents*," to use the expressions coined by Pierre Chaunu (1979) and Frank Debié (1995): they are massively settled, their territory is heavily developed and structured, and these characteristics have prevailed for a very long time. Far from being homogeneous, these concentrations are, in turn, dominated by cores or backbones of stronger concentrations of population, of cities, and of capital and economic activities.

In terms of population size and surface area, the largest of these *full worlds* is unquestionably southeast Asia. Stretching across the entire southeastern rim of the Asian continent, from the Mekong delta in the south up to Manchuria in the north, from the red basin of Sichuan in the west up to the Korean peninsula and Japan in the east, it contains 1.2 to 1.4 billion people on 5.5 million km^2, for a mean density of 200 to 250 persons per square kilometer. Its nucleus consists of the lowlands of northern China between Beijing and Shanghai: areas of early agricultural development and cradles of the main Chinese empires, they now combine very high rural densities—almost consistently in excess of 400 persons per square kilometer—and a uniform fabric of cities of all sizes.

The world's second-largest population concentration is the Indian subcontinent, with 1.0 to 1.2 billion people and a surface area of about 4.5 million km^2—a mean density of 200 to 250 persons per square kilometer. It is dominated by the Indus-Ganges axis and its four main components: the Punjab; the Ganges valley itself, with Uttar Pradesh and Delhi; the Brahmaputra valley; and the lowlands and deltas of both rivers. The area extends into heavy linear concentrations along the coastal plains of the peninsula: Kerala, Tamil Nadu, Maharastra, Andri Pradesh delta. In contrast, the Thar desert, on the western border between India and Pakistan, and the Chota-Nagpur plateau, west of Calcutta, are weakly populated.

The world's third-largest population concentration runs across the European continent, from the Atlantic to the Don[14] and from Sicily to the southern shores of the Baltic. This populated Europe—which excludes Scandinavia and northern Russia—is home to about 600 million people on almost 6 million km^2, which translated into a mean density of some 100 persons per square kilometer. It is dominated by a more densely populated axis that runs from Liverpool to Florence and forms the European megalopolis, a concentration of cities, manufacturing industries, and "command and control" tertiary industries. This large crescent, commonly called the *blue banana,* includes, in its center, the broadly defined German Rhineland and Benelux (apart from the Eifel and Ardennes massifs), central and southern England, the eastern and northern fringes of France, most of Switzerland, and northern Italy (excluding Trentino–Alto Adige).

The Paris basin, the Lyon conurbation, and the Scottish Lowlands to the west of the European megalopolis, as well as greater Berlin to the east, form concentrations that are fairly close to the densest area but separated from it by less populated interstices. To the east of the main axis is a secondary one, oriented west to east, running from Saxony to the Donbass and encompassing Thuringia and the northern borders of Bohemia, Moravia, and Silesia.

In southeast Asia, the Indian subcontinent, and Europe, massive settlement and high-density sprawls are associated with similar patterns of territorial organization that combine a heavy linear concentration of the highest densities; a dense scattering of

[14] River of southern Russia flowing into the Azov Sea, southwest of the Volga.

towns and cities of all sizes; a low gradient of urban density; a long-standing, robust appropriation of land by rural communities and political structures; and old, extensive communication networks with high connectivity (Debié, 1995).

Some investigators, most notably Daniel Noin (1979), link the eastern United States and southeastern Canada with the world's three main population concentrations. This statement is debatable given that, with about 100 million inhabitants spread over more than 1.2 million km^2, the area extending between the Atlantic Ocean and the Mississippi River and between the Saint Lawrence estuary and the Gulf of Mexico comprises a far smaller population than that of east Asia, the Indian subcontinent, or Europe, with lower mean densities—particularly in rural areas. A more detailed analysis also shows that the areas with a density exceeding 50 persons per square kilometer are narrowly confined to the East Coast megalopolis (Boston to Washington), the Midwest steel belt (Pittsburgh to Cincinnati), and the urban rim of the Great Lakes (Buffalo, Cleveland, Detroit, Chicago). By contrast, in east Asia, the Indian subcontinent, and Europe, areas of density stretch over hundreds of thousands of square kilometers. However, some features are comparable to the spatial organization of the *full worlds,* in particular, the linear concentration of high densities, the thick scattering of towns and cities of all sizes, and the high connectivity of communication networks.

2. Secondary Concentrations

Outside of the main concentrations, settlements are fragmented into small, high-density islands. These "*settlement archipelagos*" (Debié, 1995) hold about one-quarter of the world population on less than one-tenth of the landmass. Most are dominated by one or two large metropolises.

Among the 30 or so secondary concentrations enumerated by Frank Debié (1995), the vast majority are coastal or insular. This is true in North America (California and Vancouver–Seattle cores), Latin America (West Indies cores, western plain of Guatemala and Salvador, Venezuelan coast around Caracas, the Nordeste province of Brazil, the Porto Alegre/Sao Paulo/Belo Horizonte "backbone," Rio de la Plata around the coastal cities of Argentina and Uruguay, central Chile around Santiago-Valparaiso), sub-Saharan Africa (coastal cores of the Gulf of Guinea from Senegal to Nigeria, Cape Town and Transvaal cores in South Africa), north Africa and the Middle East (Maghreb "useful core" between Casablanca and Tunis, Levantine coast, Black Sea and Egean Sea coasts in Turkey), South Asia (Irrawaddy delta in Burma, Menam delta in Thailand, southwestern part of the Malacca peninsula, Java Island in Indonesia, Luzon archipelago in the Philippines), and Australia (coastal and urban cores of Perth, Adelaide, Melbourne, Brisbane, and Sidney).

The main exceptions to this pattern are the secondary concentrations associated with major rivers that provide the necessary water for agriculture (Nile, Tigris, and Euphrates valleys in the Middle East, Syr-Daria and Amu-Daria valleys in central Asia, Irrawaddy valley in Burma), those that have developed around Iranian oases, and a few individual concentrations located at the very center of continents, on low-altitude plateaus (Sahel core in Hausa country, northern Nigeria) and in higher-altitude or steep-sloping areas (Mexican core, Colombian Andes around Bogota, Great Lakes core centered on Rwanda and Burundi).

The spatial organization of *settlement archipelagos* differs radically from that of *human continents* (Debié, 1995). Their features are as follows: isolated population concentrations and low spatial extension; strong littoralization (increasing concentration of development on the coast) and scarcity of population enclaves at the center of continents; low density and high concentration of a scattering of towns, often dominated by an agglomeration far larger than the others; sharp contrasts in density between urban and rural areas (high urban-density gradient); recency and weakness of territorial grid; and atrophied communication networks.

VI. HISTORY OF SPATIAL DISTRIBUTION

The spatial distribution of the world population is the product of multiple, complex phenomena and has given rise to highly divergent interpretations. Consistent with the spirit of 19th-century human geography, initial studies emphasized the constraints of the physical environment on settlement. Within this framework, the contrasts in spatial distribution were explained by differences in the ease of living conditions and the disparity in the quality and quantity of available resources. In the wake of the contributions of the French school of geography—in particular, the major studies by Pierre Vidal de la Blache—environmentalist determinism was gradually discarded in favor of a possibilist explanation, largely based on the principle of proof through counter-example that stressed the diversity of production and administration methods. A more systematic approach developed in the 1960s, when population geography emerged as a separate discipline. Largely inspired by demographic methods, it sought to highlight the factors responsible for the observed differences. Accordingly, the approach underscored the history of demographic behavior, in particular, the history of migrations and their influence on settlement (see David Coleman's synthesis in Chapter 67). This type of analysis was very productive as regards the mechanisms of settlement differentiation; however, it led to a fragmentary vision of the formation of densities: the interactions between factors were often neglected, and the socioeconomic conditions in which they occurred were seldom mentioned. In the French-speaking world, it was not until 1990s and the work of researchers such as Guy Baudelle (2000), Frank Debié (1995), Olivier Dollfus (1990), and François Durand-Dastés (1995) that a resolutely cross-sectional approach emerged based on two crucial observations: the stability of the *oikoumene* borders and the persistence of settlement contrasts.

1. Stability of Oikoumene Borders

Archeological research over the past century shows that the human species had already colonized most of its current area of settlement by the Upper Paleolithic (see Chapter 67) (Fagan, 1990). Twenty thousand years ago, humans were present on the five continents, including Oceania, and occupied large tracts of land. According to the evidence available today, the only parts of the world that still eluded humanity's grasp were the high-latitude regions (northeast Canada, Greenland, Iceland, Scandinavia, northern Russia, southern tip of the American continent, eastern Australia) and some islands far removed from the continents (Tasmania, New Zealand, Polynesia, Hawaii, Easter Island, etc.).

These observations corroborate the hypothesis formulated in the early 20th century by Pierre Vidal de la Blache (1917: 241), namely, that the human population *has not broadened its geographic reach so much as it has deepened its localized presence.* In other words, the successive increases in world population since the Upper Paleolithic have resulted in a densification of already inhabited places rather than a spatial extension of the area of settlement through large-scale conquest or clearing: "a crystallization of sorts has agglomerated batches of human population in certain points. These groups have, through their intelligence, increased the natural resources and value of the sites, so that others have come . . . and successive layers have accumulated on the chosen lands" (Vidal de la Blache, 1922). In consequence, the settlement envelope is highly stable, particularly in the main concentrations. In Japan, as in China or Europe, the pattern of territorial occupation has remained basically the same for several centuries. This stability is linked to the spatial logic of intensive agriculture. Improved yields enabled farmers there to reduce working time—a saving that was not used to enlarge the holding but was reinvested in capital to enhance crop performance. This logic, in turn, promoted the accumulation of human inhabitants in the same limited spaces (Baudelle, 2000).

Although the long-term stability of the borders of the *oikoumene* is undeniable on a small scale, the same is not true on a medium or large scale. The successive waves of demographic growth have generally caused a spatial extension of settlement, most notably after the clearing of woodlands or the drainage of wetlands. But this extension usually occurs near already inhabited and developed localities, in already frequented or exploited spaces.

The only significant exceptions to the logic of on-site accumulation of settlement are pioneering frontiers. As a vehicle for the agricultural development of previously low-populated or empty lands, they can change the settlement envelope. Unlike other forms of settlement on the boundaries of the *oikoumene*, they are often charted across vast territories and in a particular direction, mobilizing large populations, and they tend to be more enduring. Pioneering episodes occur in waves, in response to phases of accelerated population growth or political plans. The most significant examples date from the past 2 centuries and took place in the interior or on the peripheral islands of large countries under construction. They include the settlement of the regions west of the Mississippi River in the second half of the 19th century, the pioneering frontiers of the Patagonian pampa in the late 19th century, the colonization of western Siberia along the axis of the Trans-Siberian railroad in the first half of the 19th century, the colonization of Mindanao[15] starting in the interwar years, and the Indonesian transmigration to Sumatra, Sulawesi, and Kalimatan in the last quarter of the 20th century (Pain, 1998).

2. Enduring Contrasts in Settlement Patterns

In the past 20 years, specialists have compiled fairly comprehensive estimates of the population changes since the start of our era by macroregion (Biraben, 1979) or by country (MacEvedy and Jones, 1978). By using these figures, several investigators have emphasized the long-term persistence of major population concentrations. In the first volume of *Civilisation matérielle, économie et capitalisme* (*Civilization and Capi-*

[15] The largest island of the Philippines.

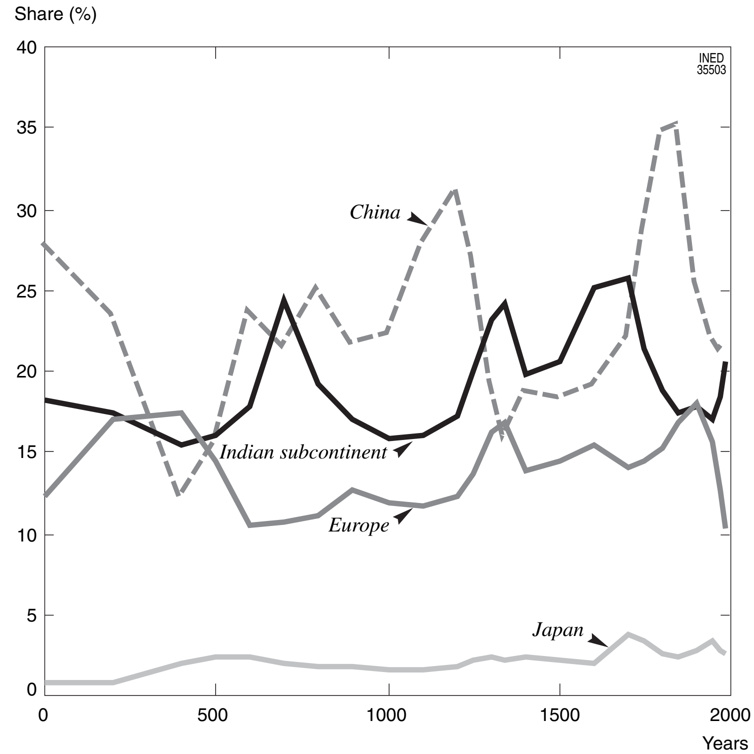

FIGURE 70–3 Changes in relative shares (percentage) of China, Japan, Indian subcontinent, and Europe in the world population since the start of our era (Data from Biraben, 1979).

talism), Fernand Braudel (1979) noted, for example, that the narrow band of high population densities observed in Europe and Asia in the late 15th century has persisted—all other things being equal—in the present geography of the world. Jean-Noël Biraben (1979) points out that, between the start of our era and today, China has consistently held 15% to 35% of the world population; the Indian subcontinent, 15% to 25%; and Europe, 10% to 15% (Fig. 70–3). In other words, for the past 2000 years, between 50% and 70% of the world population appears to have lived continuously on one of the three *human continents,* as defined by Franck Debié (1995) (Fig. 70–4).

We can refine these observations by a systematic comparison of the population distribution by macroregion at the start of our era and at later dates using a temporal autocorrelation method[16] (Fig. 70–5). This shows a slow change in the distribution until the late 15th century. At that date, the contrasts in settlement patterns between macroregions were very similar to those observed more than a 1000 years earlier (r ≈ 0.8). The population distribution then stabilized, roughly until 1750. From that point on, its change accelerated, with the correlation coefficient falling steadily to 0.6 in 1990.

These results show that, inside a rather stable envelope, the spatial distribution of the human population has undergone little change in the past 2 millennia. Until the start of the Industrial Revolution, the proportional relationships between the populations of the world's macroregions remained nearly identical. Afterward, as Olivier Dollfus has already suggested (1990: 457), bursts of sharp demographic growth "altered the existing balances and introduced new distortions between continents" (see Chapters 68, 69). Despite these changes, the broad features of the initial distribution endured, in particular the location of population concentrations. These findings are often valid on a large scale, but for shorter periods of time, as in Europe, many factors in the distribution of high population densities were active by the Middle Ages—for example, the high densities in Flanders and the Po valley in the 13th century. Nineteenth-century industrialization therefore accentuated the density contrasts of the preindustrial period. The centers of industrial development were located in places that had regis-

[16] The principle consists in calculating the correlation coefficient between the initial distribution of the population and later situations. To neutralize the changes in the relative weights of the most populous regions, the value has been computed on the logarithms of the population rather than on the populations themselves.

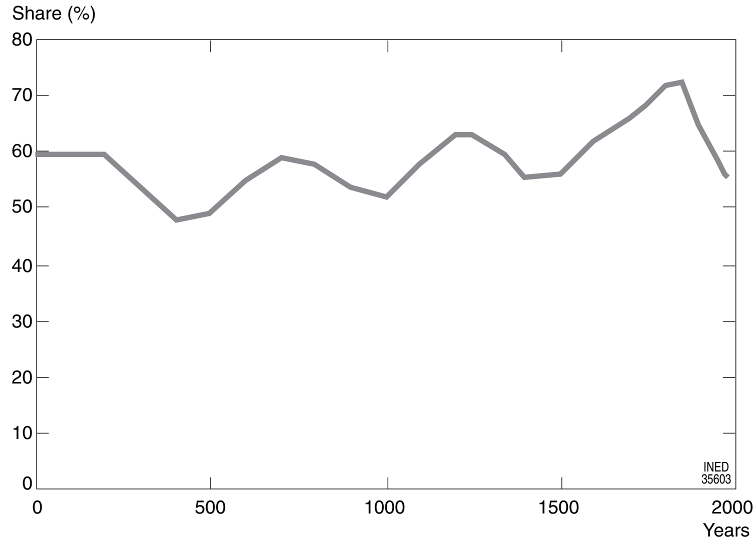

FIGURE 70–4 Changes in relative share (percentage) of the combined population of the three human continents in the world population since the start of our era (Data from Biraben, 1979).

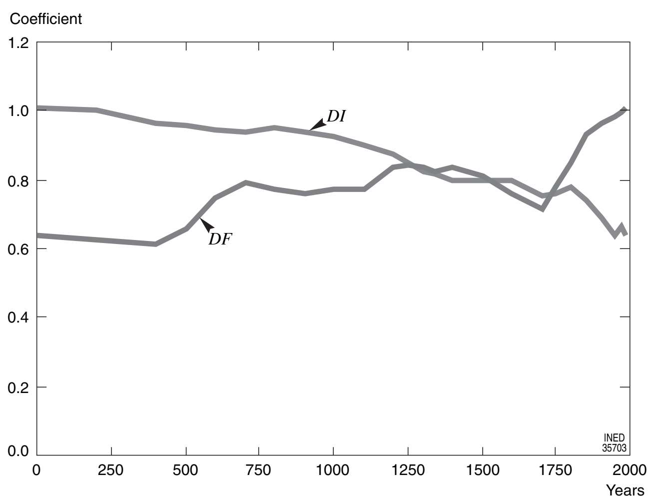

FIGURE 70–5 Change in correlation coefficient for world population distributions (12 macroregions) since the start of our era. DI, correlation coefficient between initial and later distributions; DF, correlation coefficient between final and earlier distributions. (Data from Biraben, 1979)

tered the earliest and most vigorous capital accumulation, where a prosperous merchant bourgeoisie had emerged and where agriculture was already the most advanced and the most closely integrated into the town-centered trading networks (Decroly and Vanlaer, 1991). In short, the areas of population concentration were already potentially present in the shaping of the European merchant economy of the 17th and 18th centuries.

The dot maps of the spatial distribution of world population over 2 millennia, such as the ones prepared by Daniel Noin (1979: 92–93) and Olivier Dollfus (1990: 447), provide a useful complement to this analysis. Admittedly, they rely on highly uncertain and fragmentary data, especially for periods before the 18th century, at least for the areas outside the great empires of the Mediterranean world, India, and China. Nevertheless, they offer a broad picture of the changes in global population distribution (for a detailed analysis, see Noin, 1979 and Debié, 1995).

Of the Earth's 250 million or so inhabitants at the start of our era, almost 60% lived in one of the three human continents. The north China plain, between the Huang-he and the Yangzijiang, is believed to have held alone nearly 50 million people, that is, one-fifth of the world population and four-fifths of the Chinese population. It was thus already the planet's largest population concentration. The rest of China presumably comprised some 20 million people living in small, scattered settlements. The Guangdong region, similar to the middle Chang Jiang valley and Sichuan, was not yet an area of relatively concentrated population.

The Indian subcontinent is estimated to have had nearly 50 million inhabitants, of whom about 30 million were in the Indus-Ganges plain and roughly 10 million were in the Dekkan coastal plain. Europe's approximately 30 million people were concentrated within the borders of the Roman Empire, particularly in the plains and basins near the western Mediterranean (10 million people) and on the Egean coasts (about 3 million people on the European rim).

The most novel aspect of world population distribution at the start of our era was the relative importance of the Middle East. The region, bounded by the

Red Sea and Persia at one end and the Black Sea and Indian Ocean at the other, is thought to have had some 50 million inhabitants, most of them concentrated in four areas: lower Mesopotamia, the Turkish coast, the Levant coast, and the western coast of the Arabian peninsula. If we add north Africa's estimated 15 million or so inhabitants, we find over 60 million people—nearly one-quarter of the world population in that period—living on the confines of the arid zones of the old world and in the oases at the heart of those zones (Nile, Tigris, and Euphrates valleys). In later periods, even at the apogee of the Arab-Muslim Empire, the region's share of the world population never reached these initial levels.

The rest of the world population of the time (about 50 million) was scattered across the vast expanses of sub-Saharan Africa and the American continent, which held about 12 million people each.

As mentioned earlier, the spatial distribution of the world population underwent minimal change between the start of our era and the end of the 15th century. By the latter date, the three *human continents* of the old world contained slightly more than 55% of the planet's 460 million or so inhabitants: east Asia (China, Japan, Korea) and the Indian subcontinent each held 90 to 100 million people, Europe nearly 70 million. Within these human masses, the Huanghe and Yangzijiang plains in northern China and the Indus-Ganges and Dekkan plains in India remained by far the largest population concentrations. However, the areas of high Asian density expanded substantially, both in China (Manchuria, Korea, Chang Jiang valley, Guangdong, and Indochina) and in the Indian subcontinent (central Dekkan). With almost 10 million inhabitants in its southern lowlands, Japan formed a northeastern extension of the east Asian area of high relative density. Although Europe preserved its relative share of world population (about 15%), the geography of its settlement changed significantly. After the center of gravity of high densities shifted from the Mediterranean coast to the North Sea coast, the space between southeast England and northern Italy gradually emerged as the main axis of the Old Continent.

The most important changes in world population distribution occurred in the areas outside the human continents. Between the start of the Christian era and the Age of Discovery, North Africa and the Middle East lost nearly half their population. By 1500, they held just 7% to 8% of the world population. The only dense, continuous demographic core in their midst remained the Nile Valley. Conversely, sub-Saharan Africa and the American continent registered fairly brisk population growth. Sub-Saharan Africa added about 60 million inhabitants to reach 15% to 20% of the world population by the end of the 15th century. The American population grew by some 30 million to nearly 10% of the world total by around 1500. The spatial patterns of growth were very different in the two continents. In sub-Saharan Africa, most of the new inhabitants scattered across the landmass, so that only one population concentration emerged: that of the Hausa, Mossi, and Yoruba countries in west Africa. In America, by contrast, population growth was more narrowly confined. It gave rise to a series of concentrations, in particular the Aztec core at the center of Mexico and the Inca core along the Andes cordillera.

Between 1500 and 1800, during the expansionary phase of Europe's world-economy, the world population doubled to about 950 million inhabitants. This growth mainly benefited the three human continents: in 3 centuries, their population grew 250%, versus only 30% for the rest of the world. As a result, by 1800, east Asia, the Indian subcontinent, and Europe comprised no less than 70% of the world population. Densification was significant in all the concentrations already established by about 1500, in China (northern plain, Chang Jiang plain, Sichuan, Guandong), Japan, Indochina, India (Indus-Ganges plain, Dekkan), northwest Europe, and northern Italy. Meanwhile, new high-density zones were forming, most notably on the Korean peninsula in east Asia, in the Punjab in the Indian subcontinent, and along the Danube corridor and northern Hercynian massifs, between the Ruhr and Silesia, in Europe.

The weak total growth outside the three main concentrations masks highly contrasting regional patterns. On the Asian continent, the demographic momentum was brisk, as evidenced by the massive densification of the island of Java and the formation of secondary settlement cores along the Burmese and Thai coasts. Similarly, Muscovy and the southern Ukraine gradually developed into distinct high-density centers, and the first pioneering frontiers were created in Siberia. By contrast, the population of Africa, deeply affected by the various slave trades, registered modest gains from its 1500 level (15 million or more inhabitants) and actually fell by about 15 million from its 1600 peak of 105 million. The high-density core in Nigeria remained stable and even weakened slightly; no new significant concentration emerged. Meanwhile, the American continent lost almost half of its population during the period. In the wake of brutal European colonization, the settlement cores clearly identifiable in about 1500 were either almost totally destroyed (Maya core in Yucatan) or sharply reduced (Aztec core in central Mexico and Inca core in the Andes).

A comparison of the world population distribution in 1800 and today shows that the massive 2-century growth has caused major changes in the geography of settlement but has not fundamentally altered its pattern. At the global level, the key phenomenon is the decline in the human continents' share, which has fallen from 70% of the world population in 1800 to 55% today. Conversely, the other regions of the Earth, sub-Saharan Africa excepted, have seen their shares of world population rise, some very sharply (North America, Latin America, southeast Asia), others more marginally (north Africa and Middle East). These contrasting trends are owing, of course, to the different paces of population growth over the past 2 centuries and to the resulting changes in the tempo and amplitude of the demographic transition. Since 1800, the population of the human continents has quadrupled, but that of the rest of the world has increased more than eightfold.

Two of the changes during the period deserve special emphasis: the settlement of North America and the formation of several high-density cores, often coastal, in Latin America and Africa.

In about 1800, North America, including Canada, had a combined population of barely 5 million. Two centuries later, the total stands at 280 million, one-third of whom are concentrated in the "*outlined continent*" (Debié, 1995) consisting of the eastern part of North America. The speed of development of this extended population concentration is spectacular. Whereas it took millennia to produce the *full worlds* of Eurasia, a few decades sufficed for the United States and Canada to build a territory with many similarities but of far smaller size. This speed was the result of massive immigration spread out over barely 2 centuries. It also bears powerful witness to the territorial efficiency of American society as regards the appropriation of space (balanced administrative division into *townships*), land use, and establishment of links between localities.

European immigration and the demographic transition combined to multiply the population of Latin America by 20 between 1800 and today. This prodigious growth—the steepest outside the United States and Canada—was achieved in a territory deeply shaped by an extraverted colonial economy and polarized around a few port towns, Mexico City excepted. This explains the formation of a series of concentrations, most of them coastal, that together constitute the backbone of the Latin American settlement archipelago.

Because of the lateness of its demographic transition and the absence of actual settlement colonies, sub-Saharan Africa experienced far weaker growth than did Latin America. From the early 19th century to the present, its population has risen fivefold from 90 million to nearly 500 million. As in South America, demographic growth led to the formation of a string of coastal settlements. But it also contributed to the strengthening of the settlement core in northern Nigeria and the emergence of other high-density cores inside the continent—most notably the Great Lakes region and, to a lesser extent, the Ethiopian mountains.

VII. TOWARD AN INTERPRETATION

1. Environmental Prerequisites for Settlement

The broadening of the ecological bases of inhabited territories in the past 50 years has led to the gradual abandonment of the analysis of the environmental prerequisites for settlement (Pumain, 1992). We believe, however, that these preconditions must be taken into account, as the formation of population densities is ultimately rooted in the capacity of societies throughout history to tap the resources at their disposal.

To begin with, the settlement of a portion of the landmass requires the ability to extract, produce, or introduce sufficient quantities of two commodities essential to survival: food and water (Claval, 1974). The notion has long prevailed that this possibility depended exclusively on the characteristics of the natural environment, with climate and soil determining the quantity and quality of available resources, and terrain and hydrography determining the capability to bring foodstuffs into the area. Today, it is admitted that availability of food and water are jointly determined by biophysical and socioeconomic characteristics. The productive capacity of a cultivated ecosystem depends on the surface area and fertility of land actually under cultivation. These two variables are determined, in turn, by the characteristics of the cultivated ecosystem and by the methods used in the existing agrarian system to restore soil fertility (Mazoyer and Roudart, 1997).

Population volume in a given area therefore depends on the existing local ecosystem and on the performance of the agrarian systems that have been developed there. The characteristics of these biophysical and socioeconomic components of productive capacity are not immutable: they evolve at the slow pace of climate change or the far quicker pace of social, economic, and political change. Moreover, their state at any given moment is influenced by their previous state: an ecosystem's fertility and the method of replenishing it depend, in turn, on the legacy of earlier agrarian systems. Recent research has also emphasized the role of collective perceptions in the relationship that develops between environmental conditions and settlement (for a summary, see Baudelle, 2000). In this interpretation, what matters is not so much the quality or weaknesses of a particular environment but the value assigned to it—by comparison with neighboring environments—by the human communities that have settled there or would like to. This value depends not only on objective social conditions (production methods and relationships) but also on beliefs and habits. These enable us to understand some original features of settlements. In Japan, for example, the sacred value attributed to mountains has shaped a striking contrast between the relative emptiness of high-altitude regions and the dense occupancy of the plains (Gourou, 1984).

Within the framework outlined above, it is not surprising to observe that the relationships between environmental conditions and population densities vary considerably from one part of the inhabited world to another, and that no generalization is possible on this issue. The relationships between settlement and climate and between settlement and terrain provide convincing illustrations of this.

In the early 1960s, Jozef Staszewski (1961) showed that the highest demographic densities (on average, 60 persons per square kilometer) were found in humid temperate climates and humid subtropical climates (monsoon climate); excluding polar, desert, and equatorial climates, the lowest densities were observed in dry tropical climates (8 persons per square kilometer) and humid tropical climates (14.4 persons per square kilometer). Most important, he demonstrated that the population density for a given climate varied widely from one continent to another, and that the climate prevalence ranking changed from one continent to another. He thus demonstrated at the global scale what many monographs had already underlined or would later underline at the local level, namely, that, in comparable climate conditions, human densities can vary across a very broad range of values (Gourou, 1973): the Mississippi plains have 10 times fewer inhabitants than do the Yangzijiang or Huang-He plains, the Congo basin is nearly empty whereas in Java rural densities reach nearly 2000 persons per square kilometer, and so on.

The analysis of population distribution by altitude also leads to nuanced conclusions (Staszewski, 1957; for a summary, see Bähr *et al.*, 1992). Admittedly, at the global scale, 60% of the world population lives below 200-m altitude and 80% below 500 m. Likewise, again at the global scale, density falls continuously with altitude, consistently with the reduction of farming opportunities as the temperature decreases. As with climates, however, there are sharp differences between continents: less than 1% of the population lives above 1000 m in Australia and Europe, but more than 20% does in Africa and South America. On the latter continent, the proportion of the population living above 2000 m averages 11%, but exceeds 50% in Peru and Ecuador and 70% in Bolivia. These variations show that the appeal of mountains depends on their environment: although the contrast between plain settlements and altitude settlements is sharp at high and medium latitudes, it is more modest, or even reversed, at Mediterranean and tropical latitudes (Belbeoch *et al.*, 1986). For the latter, Olivier Dolffus (1990: 454) notes that, "the plains may seem less safe, less salubrious, less fertile or harder to clear. The Andes were less challenging to occupy than the Amazon forest or the deserts below. This difference is partly due to the societies' technological level. Slopes become an ever more costly obstacle to deal with when motors and axles are used in transportation and agriculture. By contrast, in rural societies that rely on basic tools, the work yield on a 15° slope is barely lower than on a flat terrain."

2. A Distribution Whose Origins Go Back a Long Way

The long-term inertia of the spatial distribution of the world population prompts us to look to Antiquity for an explanation of the contrasts observed today. From this standpoint, the uneven diffusion of agricultural techniques in the Neolithic revolution seems to play a key role—far more decisive than the variations in the absolute age of settlements.

As long as transportation remained slow, human societies had to procure the food and water needed for their survival in a narrow radius around their settlements. The intensity of their presence in an area therefore depended on their capacity to find resources in their immediate surroundings. Throughout the Upper Paleolithic, this capacity remained limited, as the prevailing survival techniques (gathering, hunting, fishing) were simple collection methods without restitution. They required human groups to be mobile over large areas and prevented the formation of significant concentrations. As a result, the density contrasts in inhabited regions were presumably weak.

Ten thousand years before our era, the advent of agriculture and livestock raising during the Neolithic revolution brought slow but deep changes in the characteristics of the earlier settlement. By allowing a sharp increase in food production per unit of surface area, it made possible—in places where it took hold—the establishment of the first significant population concentrations. In the Middle East, for example, densities rose from no more than one person per 20 to 40 km^2 among the hunter-gatherers of the Upper Paleolithic to 2 to 5 persons per square kilometer with the advent of the earliest forms of rain-dependent agriculture. This created the first settlement contrasts between preagricultural economies, in which densities stayed below one person per square kilometer, and agricultural economies, in which densities substantially exceeded that limit. Consistently with Ester Boserup's model (1965), the progressive differentiation of farming techniques later broadened the range of possible densities—to the point at which the following patterns were found across the world at the start of the 16th century (Debié, 1995; Grigg, 1996; Mazoyer and Roudart, 1997): a few people per square kilometer for the itinerant agriculture practiced, for example, in the west African savannas and the lowlands of Central and South America; about 10 persons per square kilometer when this form of agriculture, with shorter rotations, shifted toward more intensive forms as on the highlands of west Africa, in the Andes, and in Mexico; from 10 to 50 persons per square kilometer for agriculture with short fallow periods (biennial or triennial rotation), and animal-traction farming in the Mediterranean basin and most of Europe; nearly 100 persons per square kilometer for permanent rainfall-dependent agriculture (without fallowing) in Flanders, Tuscany, and Lombardy; and 200 to 300 persons per square kilometer, or locally more, for irrigation farming in the Indus-Ganges plain, the Gulf of Bengal, the Malabar and Coromandel coast, southern China (Chang Jiang valley, Sichuan, Guandong lowlands), Japan, Java, and the deltas of southeast Asia.

In sum, a long-standing spatial concordance exists between areas of intensive agriculture and dense settlement. This link still harbors many mysteries, most notably because the functional relationship between agrarian structures and settlement is so complex and varies according to the political framework in which it operates. Research on the issue has yielded two important findings. First, the studies by Ester Boserup have shown that the relationship between farming techniques and population densities constituted a system: progress in farming techniques allowed population growth, but, reciprocally, increased densities required or stimulated advances in agrarian structures. Second, archeological studies indicate that, as early as the Neolithic, agricultural progress generated surplus production that allowed work specialization, fostered trade, encouraged the emergence of political control structures, and promoted the birth and rise of towns. Reciprocally, these transformations stimulated technical progress, most notably in agriculture.

François Durand-Dastés (1995) has drawn on these findings to propose a model for interpreting the high overall densities observed in India. He begins by pointing out that rice farming is an agricultural production system characterized by very high yields (quantity of food produced per surface-area unit) but very low productivity (quantity of food produced per labor unit). Rice farming therefore sustains high population densities, which, in return, help to perpetuate and even expand it. Durand-Dastés also identifies three links that have developed between rice farming and control structures. First, high rice yields generated large surpluses, allowing urbanization and the formation of fairly centralized governments. Second, the mobilization of the labor force and the management of large-scale infrastructure development—which only a central government was capable of achieving—played a likely role in the growth of rice farming. Third, organized states have the capability of setting conflicts inside their borders and can thus ensure the existence of *peaceful areas* conducive to population growth. In combination, these three feedback *loops* form a system with an operation that—according to Durand-Dastés—is responsible for the close correlation between rice farming in floodable areas and high population densities observed in India.

The historical developments between the early Neolithic to the Age of Discovery were therefore largely responsible for the differential pattern of human settlement. For the most part, developments in later centuries "strengthened the continents, the high-density axes, and the settlement cores already sketched out, multiplying the densities of the early modern era by five, ten, and sometimes a hundred" (Debié, 1995: 327). They also brought some important adjustments linked to the rise of the European world-economy (Braudel, 1979; Wallerstein, 1980a,b). Examples include the demographic debacles in America and Oceania, population transfers owing to the growth of the slave trade in Africa, but also, more indirectly, to the concentration of the population in the coastal areas of colonized territories. The latter phenomenon was owing to the centrality of ports in the colonial economy and the expansion of "funnel-shaped" transportation networks. Likewise, the economic and demographic disruptions of the 19th century, by triggering trans-Atlantic migrations and fostering the expansion of pioneer frontiers, enlarged the settlement envelope to some extent. But the outcome of the process had already been determined long before—indeed, very long ago.

CONCLUSION

A panel at the main entrance of the Lisbon World Exhibition (1998) dedicated to oceans stated that, at the close of the 20th century, almost 60% of the world population lived on sea coasts. This claim is highly fanciful, as the recent computations by Daniel Noin (1999) found that barely 16% of the Earth's inhabitants live within 15 km of a coast. Nevertheless, the panel—widely quoted in the media—points to a key aspect of human settlement: its pericontinental distribution. Today, more than one-quarter of the world population lives within 50 km of a coast, almost one-half at 200 km, and more than two-thirds at 500 km. Most of the main population centers are located in the immediate vicinity of the sea or communicate with a seaboard; many metropolises with populations in the millions are coastal. As many other aspects of settlement, this concentration seems to be an enduring pattern. It was already observed at the start of our era and was consolidated by the expansion of the European colonial economy from the 16th century onward. However, it may be called into question in the near future. Experts predict that climate change in the 21st century could raise the average sea level and threaten the coastal plains, some of which—such as northwest Europe and the Bangladesh lowlands—are heavily populated. Will the potentially displaced populations find shelter along the new emerging coastal settlement bands, thereby increasing concentration in the lowlands or, on the contrary, will they be forced into new locations, perhaps outside the settlement envelope? Such questions belong to the realm of *geography fiction* for now but could become topical at fairly short notice.

INTRODUCTION

Humankind has never experienced such demographic upheavals as in this second half of the 20th century: a huge growth of the population (which increased from 2.5 billion to more than 6 billion between 1950 and 2000), a new distribution of the population on the planet (with the regions of the south now representing 80% of the total versus 67% in 1950), a concentration of the population in the towns or on the coasts, and consequent changes in the demographic dynamics of most societies. As mentioned in Chapter 69, after and largely in response to the transformations observed in Europe (Chapter 68), a genuine demographic revolution began that is irreversible, although it occurs at different rates in the different cultures or economic systems. Although the transition was quite advanced by the 1950s in the countries in the north, it was just beginning in those in the south, gaining momentum in the 1970s and 1980s. Heterogeneous situations, diverse rhythms of changes, spatial and social inequalities are the dominant features of contemporary demography that will be described in this chapter. The focus is on the 1960–2000 period, in which major changes occurred. First, the patterns of demographic transition and population growths will be explained, fertility, mortality and age structures will be described, and finally a few questions concerning the future will be introduced, including the demographic impact of AIDS.[1]

[1] Migration will not be discussed in this chapter.

I. SOURCES, INDICATORS, AND GEOGRAPHIC DIVISIONS

In an overview of the demography of various regions and countries in the world over 40 years, statistic works of historic compilation and perspectives conducted by specialized organizations such as the United Nations (UN) or the World Bank should be consulted. We will use the database of the UN Population Division (UN, 1996a,b, 2001a,b), which is probably the best known and most detailed. Although it is revised every 2 years, we shall mostly use the 2000 revision, as well as results on fertility and child mortality from recent surveys (such as the Demographic and Health Surveys [DHSs] conducted in the 1990s).

The indicators selected are the usual ones—birth, death, and natural growth rates to examine the transition patterns, the total fertility rate (TFR), life expectancy, and infant mortality,[2] as well as the proportions of population aged under 15 and over 65 years as indicators of the age composition.

We have gathered the above-mentioned indicators on 187 countries[3] and over three periods (1960–1965,

[2] We wish we could have used the 0- to 5-year-old probability of dying, which is a better indicator of mortality at early ages, but it is not systematically published by the United Nations nor is it available from other sources in all the countries.

[3] The United Nations publish them only on countries and territories with a population of more than 140,000. The data on Melanesia, Micronesia, and Polynesia sometimes are not included in the analyses, making a total of 179 countries in certain tables and charts.

1975–1980, 1995–2000).[4] In Appendix Table 71–1, the average numbers are presented in table form according to the 6 major regions and 21 subregions as defined by the UN with a view to synthesis and minimal diversification. UN terminology divides the countries among three categories: developed (44 countries, 20% of the world population), least developed (which we will refer to as the poorest; 45 countries, 32 of which are in sub-Saharan Africa, 10% of the world population), and intermediate (98 countries, 70% of the total).[5] Although these three major categories offer different demographic systems, some heterogeneity can be observed within each of them. Another form of classification is a division of the world into nine major regions: Europe; North America, South America, Central America, and the Caribbean; North Africa; sub-Saharan Africa; the Near East; Central Asia; South Asia; Southeast Asia; and the Far East. These countries are listed in table form according to those geographic classification in Appendix Table 71–1.

All averages, variances and other indices are weighted by population size of the countries under study.

II. THE TRANSITION PATTERNS FROM 1950–2010

The chapter moves from a world perspective, as outlined in Chapter 69, to examine regional patterns, going back to 1950 and using the projection (mean hypothesis, medium variant) suggested as far ahead as 2010, in the framework of the longer-term projections that will be discussed in Chapter 77.

1. The World

The population of the planet has never increased as quickly as it did in the second half of the 20th century. With birth and death rates of about 38% and 20% in 1950 (Fig. 71–1), the population increased at an annual rate of 1.8%, or about 48 million individuals per year. With decreasing mortality in the countries of the south, the growth gained momentum to about 1970 (2.1% a year) before slowing down as a consequence of declining fertility, particularly in China (from the early 1970s). For 15 years (from 1975–1990), growth remained at about 1.7%. In the late 1990s, growth was estimated at 1.3%, with a birth rate of 22% and a death rate of 9%, which meant an annual increase of approximately 80 million people. According to UN projections, the growth rate will still probably be 1.1% in about 2010. The transition takes place by stages, and on the whole, it has been slower than was expected in the 1960s or the 1970s, leading to several revisions of the mid- and long-term projections in the past 30 years.

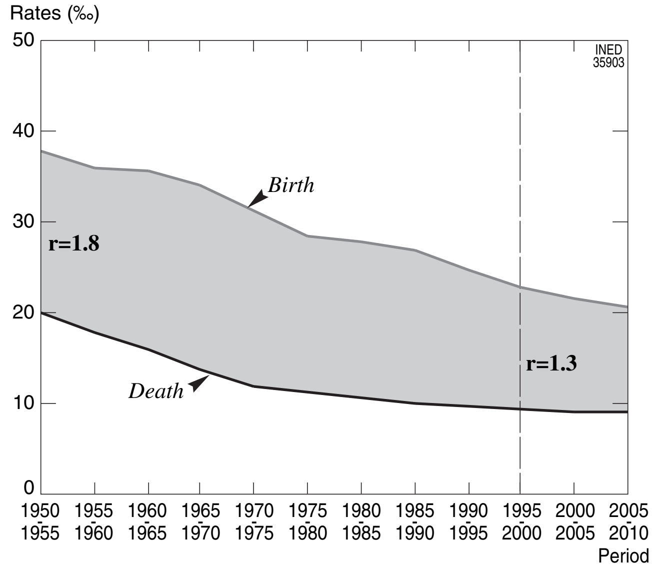

FIGURE 71–1 The transition pattern of the world population from 1950–2010. (Data from United Nations, 2001a,b.)

2. The Three Major Groups of Countries

World demography is an abstraction; in fact, some people doubt that the concept is of any interest. From the distinction between developed, intermediate, and poor countries emerge three major categories of transition histories, which as early as 1950 have been very different from one another (Fig. 71–2; Table 71–1).

The developed, rich countries—In these countries the decline of fertility and mortality dates back to the second half or the end of the 19th century.[6] By the beginning of the 1950s, the birth (22%), death (10%), and natural growth (12%) rates were comparatively low among the countries of this group. Nevertheless, after the baby boom of the 1940s and 1950s, fertility declined again at the end of the 1960s, falling drastically in the 1970s and 1980s and causing the

[4] Sometimes we go as far back as 1950 or 2010.

[5] Those numbers are 55, 48, and 125, respectively, when countries with a population of less than 140,000 are included.

[6] For most of these countries at least, as some had begun earlier (e.g., France, where fertility started to decline as early as the late 18th century) and others later (Southern and Eastern Europe, where the trend really started only in the early 20th century). Those historical discrepancies between the Western countries have been previously discussed, in Chapter 68. Readers may also see the works by Jean-Claude Chesnais (1986) or Patrick Festy (1979).

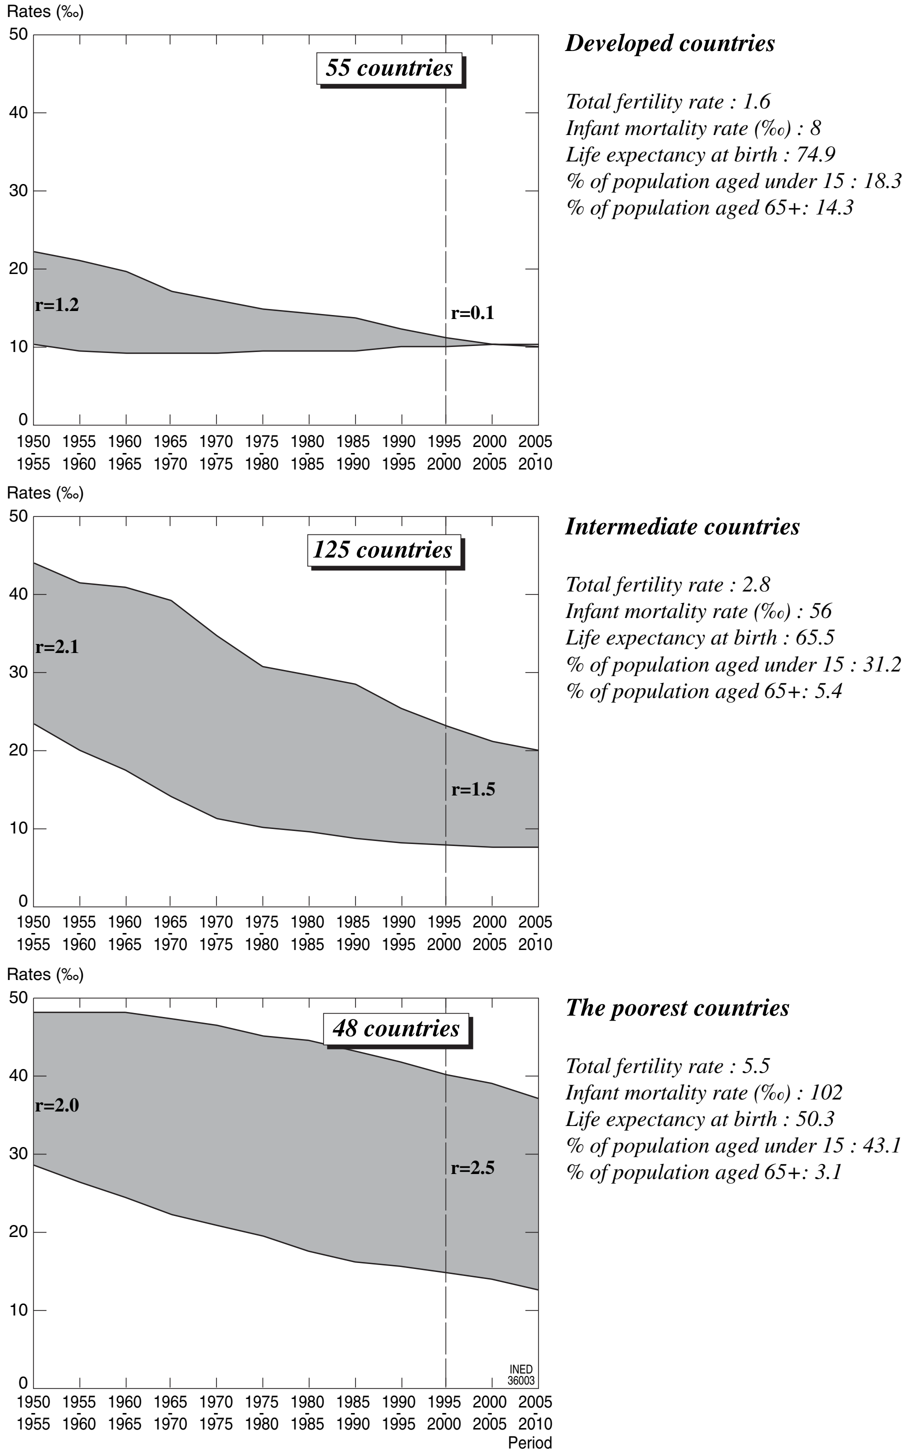

FIGURE 71–2 Patterns of transition from 1950–2010 in the three major groups of countries. (Data from United Nations, 2001a,b.)

growth to cease (or even become negative), as well as accelerating the aging of the population.

The intermediate countries—In this group, which is the largest and most heterogeneous, birth rates have been decreasing by stages (Fig. 71–2), sometimes since the 1950s but mostly since the mid-1960s. Death rates also declined, enough to counterbalance the decline of fertility, so that the growth rates went down only in 1950 (1.5% versus 2.1%). With an average fertility rate of 2.8 children per woman, a life expectancy of 65

TABLE 71–1 A Few Indicators of Structures and Demographic Change in the Three Major Country Groups and in the Countries in Extreme Situations

Indicators	Period	World average (n = 228)	Poorest countries (n = 48)	Intermediate countries (n = 125)	Developed countries (n = 55)	Countries and extreme values: Minima	Countries and extreme values: Maxima

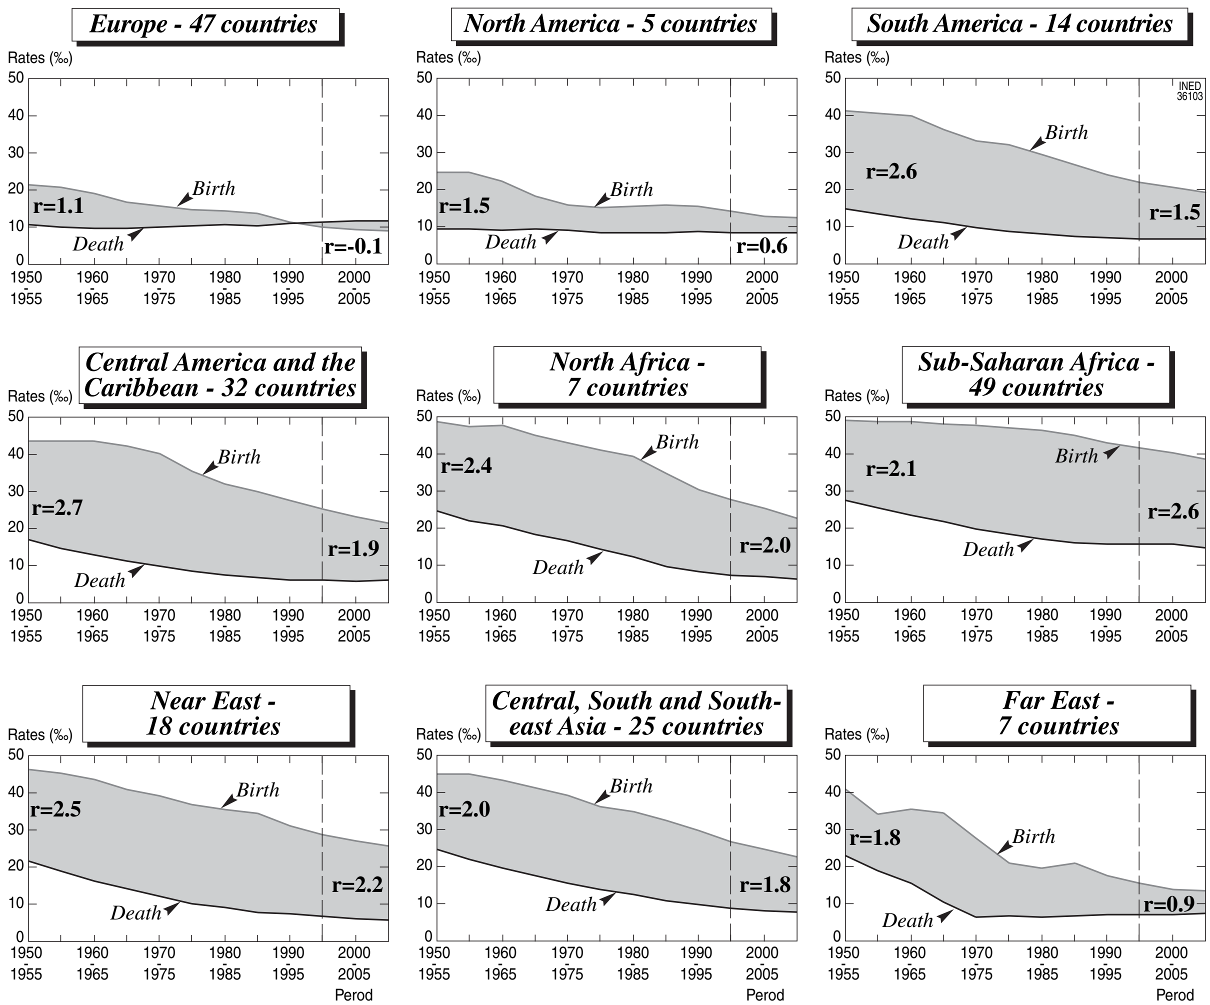

FIGURE 71–3 The transition patterns of nine major regions from 1950–2010. (Data from United Nations, 2001a,b.)

years, and the fast aging of the age structure (the proportion of the population aged under 15 dropped from 45% down to 31%), this group is well advanced on the path of demographic transition.

The poorest countries—Some 50 countries, the poorest ones in the world and those who are excluded from economic and social development, represent over 10% of the world population and 13% of all the developing countries. On the whole, they are still at an early stage. Birth (41%) and fertility (5.5 children per woman) rates have changed little, but mortality has decreased (the crude death rate dropped from 25% to 15% between 1960 and 2000). As a consequence, in the second half of the 20th century, growth increased, going from 2.0% in 1950–1955 to 2.5% in 1995–2000; according to UN projections, growth will reach even higher levels in 2010. However, the age structure will remain as young as it is now (about 43% of the population are aged under 15).

3. The Regional Diversification

In addition to the slowing down of world demographic population growth from 1950–2000, which was rather slow to occur, there is a great diversity in the history and present situations of the 21 subregions selected in Appendix 1, or even of the 9 major regions given in Fig. 71–3.

In the north, two groups of developed countries should be distinguished:[7] (1) Europe, in which birth

[7] On the figure we have not represented the Australia—New Zealand subregion (which appears as such in the table in Appendix 1), nor have we isolated Japan, integrating it into the Far East.

and death rates are more or less equal (about 10%) and growth is virtually nil; and (2) North America, in which growth is still slightly positive and is expected to remain so in 2010.

In the south, seven regions appear to be at different, more or less advanced stages of transition.[8] Within some 40 years, this group, the situation of which used to be comparatively homogeneous, has acquired unprecedented diversity. Although in 1955, all the subregions had pretransition birth rates greater than 40%,[9] the birth rates now range from 16% in the Far East to 43% in sub-Saharan Africa. Death rates, which already were more varied, now range from 5.4% (in Central America) to 15% (in sub-Saharan Africa). Last, growth rates, which in the early 1960s were between 2% and 2.7%, ranged from 0.9% (Far East) to about 3% (sub-Saharan Africa) in 2000. When the 1990s are compared with the 1950s, it appears that everywhere the rates went down, but the decrease occurred at diverse speeds: fast in the Far East and in South and Central America, and more slowly in the Near East, in north Africa, and Central and South Asia, as well as sub-Saharan Africa, where growth is still 2.6% per year.

Although in the 1950s and 1960s it was still possible to refer to the Third World population and quote some average numbers to situate it in contrast with the population of the Western world, that has changed. For some 30 years now, the various regions, countries, and the many diversified societies of which they are made, started their own transitions at more or less early dates and then continued at more or less rapid, more or less steady paces. Except for the Far East, the new balance that was promised or forecast, based on a zero growth with a fertility rate of about 2 children per woman and a life expectancy of 75 or 80 years, is still far from being achieved. Regional diversification and inequalities between the different countries have never been so great, a situation that is likely to persist for a large part of the 21st century.

III. FERTILITY: DECLINE IS WIDESPREAD, THOUGH AT UNEQUAL PACES

Fertility at the world scale has declined since the 1950s, dropping from 5.0 to 2.8 children per woman, particularly in the past 20 years. This decline is gradually becoming widespread, although at paces that vary from one region and one country to another.

As previously mentioned, the developed countries completed their fertility transition after a long process that usually started in the second half of the 19th century (see Chapter 68). The Far East has recently achieved the same rate (1.8 children per woman in 1998), after a decrease of fertility that will probably remain as the most rapid and dramatic of the whole history of humankind. On the whole, the decline was significant in all of the intermediate countries: the TFR dropped from 5.9 to 2.8 children per woman within 40 years (Table 71–1). For about 10 years now, the group of the 48 poorest countries has also been affected by the decline, although at a much slower pace (in these countries, the average TFR is still 5.5 children per woman).

The diversity is still greater when the trends *by region* (Fig. 71–4; Table 71–2) are examined, leaving aside the Western countries and the Far East. The starting point, in the 1950s and 1960s, is high levels of birth and fertility rates, which everywhere are far higher than those in pretransition Europe: about 45% (as against 35%) for the birth rate, and 6 to 7 children per woman (as against under 5) for the TFR. These fertility rates of the 1940–1960 period, at such a level of aggregation, were probably the highest of the history of humankind, as each region later experienced a decline of fertility, each at its own time and pace: first Latin America, as early as the beginning of the 1960s; then Central America and the Caribbean in the late 1960s; South and Southeast Asia in the early 1970s; and, last, the Near East (at a rather slow pace) and North Africa, which started from a higher level (7 children per woman) but decreased comparatively quickly, particularly from the 1980s (3.6 children by 1998). As for sub-Saharan Africa, a region that was long considered a pocket of resistance (some people even called it the African exception), the decline of fertility started in the 1990s (Fig. 71–4).

In fact, regional reproductive behaviors have been experiencing a rapid, deep change for the past 25 or 30 years. This change includes both significant changes in the area of family and marriage (particularly as the age at which women marry has increased) and the extension of contraception. The decline has been substantial on the whole, and it has even been faster than certain observers had predicted in the 1960s or 1970s.

At the *national level*, both the intensity and variability of changes were confirmed by studying the evolution of fertility between 1963 and 1998 in 179 countries (Fig. 71–5). Fertility remained virtually the same, or even slightly increased, in some 30 countries, mostly in sub-Saharan Africa (in addition to Bhutan, Laos, and

[8] For further details concerning those regions, see Tabutin (1995).

[9] It should be recalled that they were higher than in pretransition Europe in the 18th and 19th centuries (30% to 35%) as a result of marriage models that were traditionally earlier and more intense in most of the other societies and cultures.

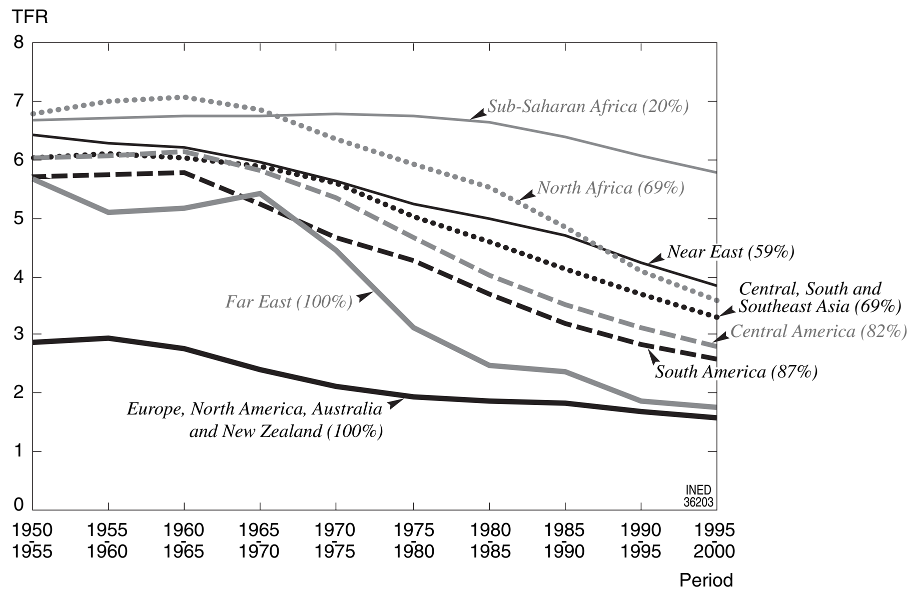

FIGURE 71–4 The evolution of the total fertility rate between 1950–1955 and 1995–2000 by major region. The figures between brackets are the proportions showing how much has been achieved with regard to replacement level (2.1) from 1950–1955 to 1995–2000. (Data from United Nations, 2001a,b.)

TABLE 71–2 Averages, Standard Deviations, and Coefficients of Variation of Total Fertility Rates in 1963, 1978, and 1998 in the Eight Major Regions

Regions	Average			Standard deviation			Coefficient of variation (%)		
	1963	1978	1998	1963	1978	1998	1963	1978	1998
Sub-Saharan Africa (46)	6.8	6.8	5.9	0.51	0.74	1.11	8	11	19
North Africa (7)	7.1	6.0	3.6	0.21	0.72	0.66	3	12	18
Near East (18)	6.3	5.3	4.0	1.24	1.59	1.80	20	30	45
Central, south, and southeast Asia (25)	6.0	5.0	3.4	0.58	0.66	0.84	10	13	25
Far East (7)	5.3	3.1	1.8	1.19	0.48	0.14	23	15	8
Central America and Caribbean (20)	6.5	5.0	3.0	0.84	1.15	0.82	13	23	28
South America (13)	5.8	4.3	2.6	1.21	0.62	0.45	21	14	17
Europe, North America, Australia, New Zealand (43)	2.8	1.9	1.6	0.45	0.30	0.34	16	16	21
Total, World (179)	5.0	4.0	2.9	1.65	1.63	1.47	33	41	51

The figures in parentheses are the number of countries in each region. The averages and standard deviations are weighted.
Data from UN, 2001.

Afghanistan), during that period. In all other countries, fertility has declined, but in different ways.

When the standard deviations and the coefficients of variation of TFRs among the countries in the eight regions in 1963, 1978, and 1998 (Table 71–2) are compared, or when the dispersions are examined graphically (Fig. 71–6), it is confirmed that the situations within regions are growingly heterogeneous. The only coefficients of variation that remain more or less stable are those concerning South America and Europe, and the only one that really decreases is that of the Far East (understandably, as it includes only six countries). At world level (Table 71–2), the standard deviation gets slightly smaller, but the coefficient of variation increased from 1963 to 1998.

Between regions, as well as countries, there is great diversity as to when the decline begins and to its pace, and it will probably remain so for some time yet. “All situations are possible: an early start and slow pace (India); an early start and fast pace (Mauritius); a late start and fast pace (Mexico); a late start and slow pace. Though the process, once irreversibly launched, on the

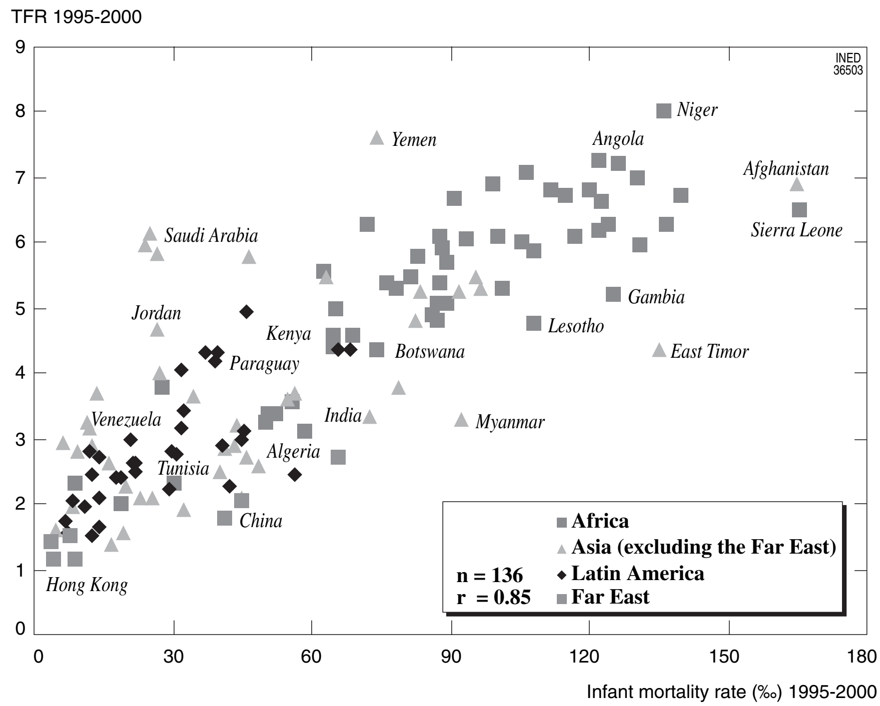

FIGURE 71–7 Relations between fertility and infant mortality in 136 countries in the south in 1995–2000. (Data from United Nations, 2001a,b.)

whole is faster than it was in Western countries in the past, there is no rule, nor general relations between starting levels, period and decline paces. A society's reproduction model is derived from complex dynamics that depend on historical, cultural, social, economic and political factors" (Tabutin, 1995: 46). In other words, every country has is own history, so that within one culturally homogeneous region (e.g., North Africa), the fertility decline processes, which are only one element of the evolution of societies among others, may occur in rather different ways, although they eventually converge.

In the theory of transition, *child mortality* always appears as one of the major variables that account for the variations and evolution of fertility: it is impossible to have very low fertility rates in contexts of high mortality levels or the population would be threatened with extinction. The decline of mortality is often presented as a precondition for the decline of fertility. What is the situation then with these two variables on the international level? Figure 71–7 presents the relation, in about 1998, between the TFR and the infant mortality rate in 136 countries in the south. The relation is clearly a positive one, with a correlation coefficient of 0.85, although some countries differ from the general pattern–for example, a few of the Emirates (which have a high fertility and a very low mortality rate), the India—Bangladesh—Myanmar group (with intermediate fertility but still high levels of mortality), or some countries in which mortality levels are clearly exceedingly high (East Timor, Liberia, Sierra Leone). However, it should be acknowledged that the latter group of countries have very specific contexts of political and military unrest.

Apart from a few exceptions, all countries in which the infant mortality rate is greater than 90% have a fertility rate of more than 5 children per woman; all countries in which mortality rate is under 30% have a fertility level of less than 3.5 children per woman. None of the countries with a fertility rate of 2 children per woman has an infant mortality rate over 25%, except for China (44%). All considered, no society in the south has achieved its fertility transition without its infant mortality first decreasing in a significant and often rapid way.

IV. MORTALITY: IMPROVEMENTS BUT GROWING INEQUALITIES

The health transition started in the late 18th century in Northern and Western Europe,[10] spreading on to North America, Japan, and southern and eastern

[10] For further details, see Chesnais (1986) or the 1989 issue of the *Annales de démographie historique*; also see Chapters 57 (in Volume II) and 68 (in Volume III).

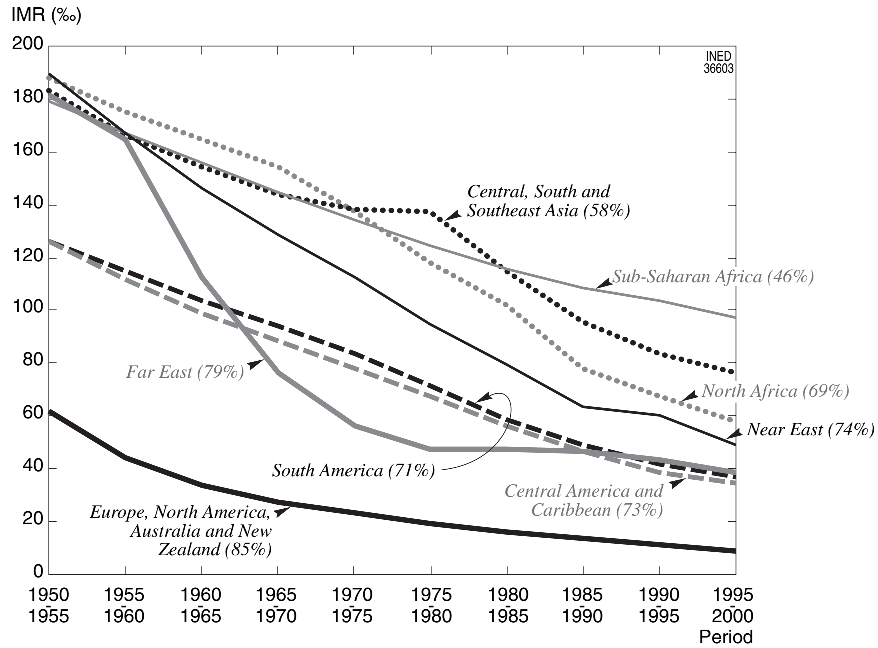

FIGURE 71–8 The evolution of infant mortality rates in 1950–1955 and 1995–2000 by major region. The figures between brackets are the proportions of decline from 1950–1955 to 1995–2000. (Data from United Nations, 2001a,b.)

Europe in the second half of the 19th century. Then it reached South America and a few countries in Asia between the two World Wars, before spreading to the whole of the planet in the 1950s. Just as for fertility, there have been significant differences in the timing and the pace of mortality changes.

As a consequence, just after the end of World War II, the situation was extremely diversified. In the early 1960s (see table in Appendix 1), life expectancy was 70 years in the developed countries, 49 years in the intermediate group, and barely 40 years among the poorest countries; the figures nowadays are 75, 66, and 50, respectively. Infant mortality rates then ranged between 33‰ and 171‰, in 1998 they ranged from 8‰ to 102‰. In the 21 subregions (see table in Appendix 1), life expectancy ranged from 39 to 71 years in the early 1960s; in 1998 the range is from 46 (East Africa) to 78 years (Australia and New Zealand).

It thus appears that the social and health progress that caused mortality to decline has affected every region and every country. Inequality, however, is now as great as it used to be, if not greater: there is a difference of 32 years between the extreme life expectancy figures by region, and infant mortality rates range from 1 to 20 (whereas they ranged from 1 to 8 in the 1960s). The poorest countries have hardly caught up, and in those countries most seriously affected, AIDS now tends to slow down or destroy the progress achieved in the area of mortality. Last, the diversity of situations has never been so great within the regions in the south.

Let us more closely examine this diversity in the area of infant mortality, the best known and probably most reliable at international level. It still represents 30% to 40% of death cases in many countries in the south, its relation to life expectancy[11] remains strong, and the pace at which it changes (on which the pace of life expectancy largely depends), is considered a good indicator of social and health progress.

In the eight regions that we have drawn (Fig. 71–8; Table 71–3), infant mortality has much declined in some 40 years, but at different paces: from 1963–1998, the decline was 76% in the developed countries (starting from a much lower level), 66% in the Far East, 64% in Latin America and North Africa, 54% in Asia, but only 38% in sub-Saharan Africa (where the gap with the other regions in the world has been widening since the 1980s). Just as in the area for fertility, the Far East has experienced an unprecedented health revolution as early as the beginning of the 1960s, although its effects on infant mortality have considerably slowed down in the past 15 years.

[11] Calculated on 172 countries (of all categories), the coefficients of linear correlation between life expectancy at birth and infant mortality are –0.96 in 1960–1965, –0.96 in 1975–1980, and –0.94 in 1990–1995. Calculated on 130 countries in the south, they are –0.94, –0.94, and –0.93, respectively.

TABLE 71–3 Averages, Standard Deviations, and Coefficients of Variation of Infant Mortality Rates in 1963, 1978, and 1998 in the Eight Major Regions

Regions	Average			Standard deviation			Coefficient of variation (%)		
	1963	1978	1998	1963	1978	1998	1963	1978	1998

Total, world (179)	119	88	60	49	45	32	41	51	54

The figures in parentheses represent the number of countries in each region. The averages and standard deviations are weighted.
Data from UN, 2001.

Even at that macroregional level, there is great diversification. The classification in three major groups of regions prevalent in 1955 (Fig. 71–8) has been changed into a four-group classification: Europe and North America (infant mortality rate, 9‰); Latin America and the Far East (38‰); south Asia and the Near East, including North Africa (about 60‰); and sub-Saharan Africa, which is lagging behind (97‰).

What exactly is happening within each region? Figure 71–9, in which the infant mortality rates in 1960–1965 and 1995–2000 for 179 countries are compared, illustrates the diversity of the paces of change at national level. We have drawn the diagonal (no changes) and the straight lines corresponding to relative declines of 25%, 50%, and 75% compared with the 1960–1965 rates.[12] Although the quality of some data must be considered, a few major trends and groups of countries can be distinguished.

The countries in which virtually no progress was achieved—Some 10 countries (situated close to the diagonal line or with a decline of mortality of less than 25%) have mortality rates that are not much different in 1998 from what they were in the 1960s, sometimes after certain periods of decline. These are mostly very poor countries (Sierra Leone, Uganda, Zambia, Mali) or countries that have been through serious armed conflicts (Rwanda, Burundi, Liberia or Iraq, Cambodia, and Afghanistan).

The countries with comparatively slow progress (25 to 50% decline)—There are many of these countries, and they are mostly in sub-Saharan Africa, where mortality rates are highest; in central south Asia, although at lower levels; and in Paraguay and Haiti.

The countries with appreciable progress—These countries form a more heterogeneous group, including north Africa; many countries in Latin America, Iran, and Turkey; and a few African countries such as Senegal, Madagascar, and Namibia.

The countries with exceptional progress—These countries have a far higher than average in the world or in the region to which they belong (more than 75% decline). These are the United Arab Emirates, Reunion island in Africa, and Macedonia in Europe.

All considered, on the whole those countries in which mortality was highest 30 years ago (mostly in sub-Saharan Africa) have also progressed the least. Conversely, those countries in the south that were at the best starting points have made the most remarkable progress in their fight against infant mortality.

Nevertheless situations are diversified within the regions. When the graphic dispersions (Fig. 71–10) or the standard deviations and coefficients of variation by region (Table 71–3) are considered, it seems no reduction of the inequalities between countries within the regions is observed. From 1963 to 1998, all the standard deviations have narrowed down,[13] but most of the

[12] The relative decline of infant mortality in the world was 50% from 1963 to 1998 (table 3).

[13] But at various paces, North Africa's has even slightly increased.

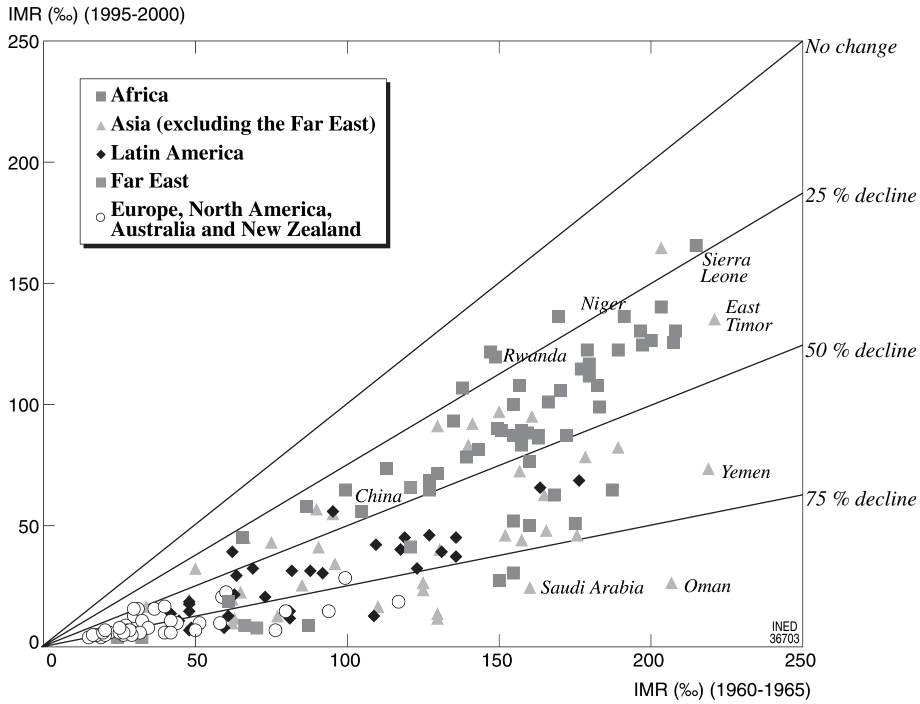

FIGURE 71–9 The evolution of infant mortality between 1960–1965 and 1995–2000 in 179 countries by pace of decline. (Data from United Nations, 2001a,b.)

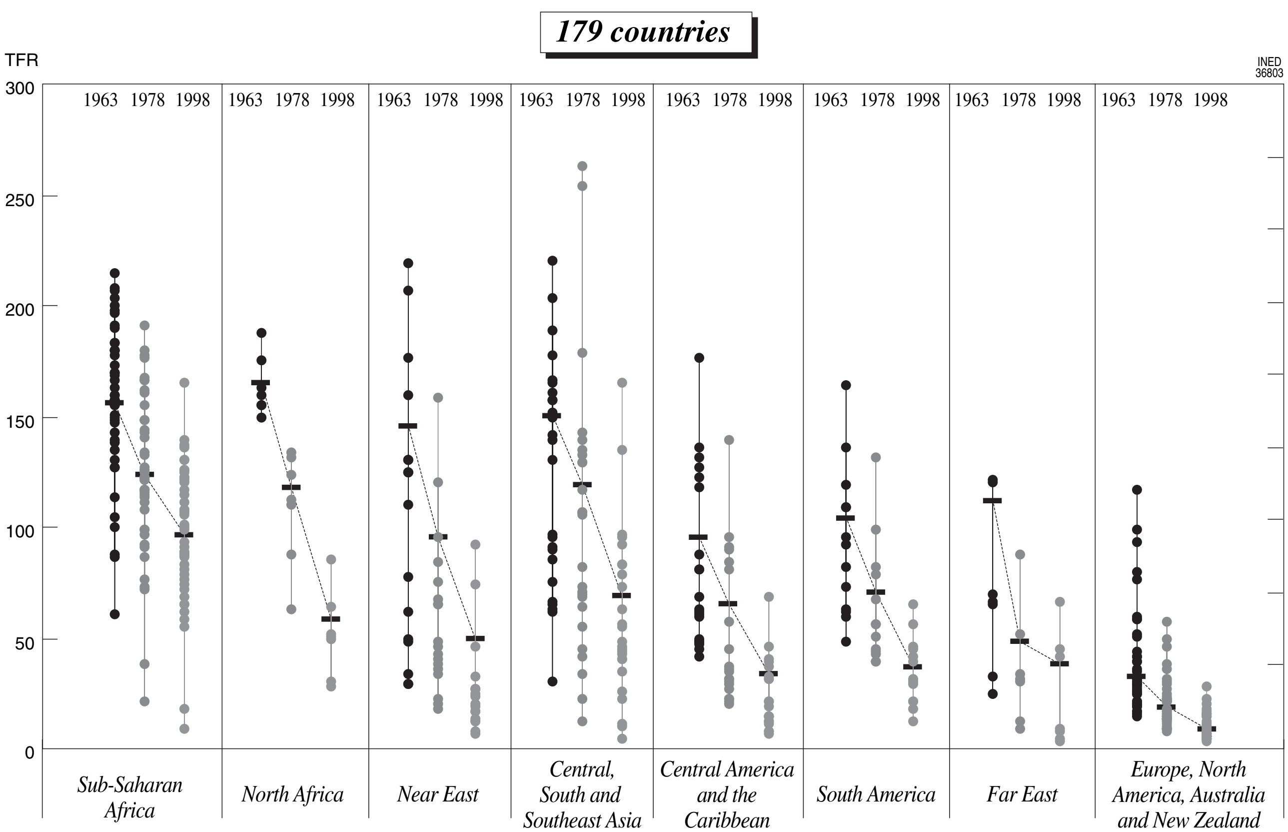

FIGURE 71–10 Dispersion between countries and average infant mortality rates in 1960–1965, 1975–1980, and 1995–2000 by major region. The dots represent countries, and the dotted lines link the weighted regional averages between them. (Data from United Nations, 2001a,b.)

coefficients of variation have clearly increased. They are particularly high in the Near East, Central America, and Europe/North America.

When the persistently high mortality rates, the widening inequalities, and the serious public health problems in many countries in the south are considered, the "health for all in 2000," as promoted by the World Health Organization, is far from a reality. Now AIDS also has a major effect on the evolution of mortality in Africa, which will be discussed later in this chapter.

V. FROM NATIONAL AVERAGES TO SOCIAL OR REGIONAL INEQUALITIES IN THE COUNTRIES OF THE SOUTH

Behind national averages usually lie regional or social inequalities in areas such as fertility and its intermediate variables (Chapters 34, 37 of Volume I), marriage (Chapter 28 of Volume I), or mortality (Chapters 53, 54, 55 of Volume II). There are—or were—differences in pretransition societies, in which demographic systems have never been homogeneous. However, just as on the international level, it is often during the demographic transition that internal disparities widened. The decline of mortality and fertility do not affect all social groups at the same period or pace. There are always groups that are ahead of others, innovative groups, and groups that are kept away from progress or are more averse to change (Tabutin, 1995). It seems that after a phase of rather high homogeneity, a phase of growing heterogeneity usually comes, which is followed by a phase of convergence. Such diffusion, such gaps between social and cultural groups or between living environments, are fairly well documented for Europe but are less so in the countries in the south. Cross-sectional analyses are still often used, in which countries are compared at various stages of transition, although the diversity of political, cultural, economic, and health contexts in those various countries is likely to cause confounding.

However, what do such analyses show? Fertility is now lower in urban than in rural regions and is lower among the more educated groups than among the least educated groups. However, differences, both absolute and relative, vary from one country to another. On the whole, the differences according to the living environment corroborate a dynamic pattern in which a growing heterogeneity, in a first transition phase, is followed by a certain convergence. According to fertility surveys conducted in the 1970s, 1980s, and 1990s (UN, 1987; Muhuri and Rutstein, 1994), the smallest relative gaps are to be observed in high and low fertility countries, whereas the largest gaps are in intermediate fertility countries. Such inequality is also greater in Latin America than it is in Africa or Asia.[14] Differences caused by educational level, which usually creates the largest disparities, are also greatest in intermediate fertility countries; again, the gaps are wider in Latin America than anywhere else (UN, 1995).

Child *mortality* is also lower in urban areas, and the gaps vary from one country to another. In a few countries (e.g., Trinidad and Tobago or the Dominican Republic), mortality levels are much the same in urban and in rural areas, but in most cases, there is a great difference. Relative differences, however, do not depend much on the mortality level. The relation between infant-child mortality and the mothers' educational level is stronger: everywhere, the mortality of children whose mothers have been through secondary education is much lower than that among children whose mothers are uneducated.[15] Absolute differences usually decrease along with the mortality level, whereas relative inequalities either increase or remain unchanged. Again, inequalities are much greater in Latin America than elsewhere.

Table 71–4 illustrates and confirms some of the relations described above for countries at various stages of transition. It also shows the inequalities that may exist for two important intermediate variables of fertility, that is, age at first marriage and prevalence of modern contraception.

In Mexico, for example, the absolute gaps in contraceptive prevalence rates are 30 points between place of residence and about 45 between educational levels, whereas in Indonesia, Sri Lanka, or Trinidad and Tobago, although the prevalence at national level is also about 40%, the gaps between place of residence are very small, a few points only. The gaps between educational levels are larger. It is also between educational levels that differences between median ages at first marriage are greatest—ranging from 2.3 years in Tunisia to 8 years in Senegal.

Even in high fertility countries (where apparently no change is occurring), there may be significant differences between social classes. For example, in Burkina Faso (Table 71–5) the fertility rate is 6.9 children per woman at national level. Three major reproductive models can currently be distinguished in this country (Tabutin, 1997): (1) that of executives, who form a small minority and are ahead of other groups

[14] Except for Trinidad and Tobago, where the urban-rural gaps are some of the lowest in the world.

[15] The ratios are very often one to three, or even four. For a comprehensive view, see Sullivan *et al.* (1994). For Africa in the 1970s and 1980s, see Akoto and Tabutin (1989).

TABLE 71–4 Inequalities in about 1990 in Eight Countries in the Areas of Marriage, Fertility, and Child Mortality

Indicators	Countries	Place of residence			Educational level			National average
		urban (1)	rural (2)	≠ % (1)–(2)/(2)	illiterate (3)	secondary education and over (4)	≠ % (4)–(3)/(3)	
Median age at first marriage (women aged 30 to 34 years)	Senegal	18.3	15.7	+17	16.0	24.0	+50	16.2

Data from the Demographic and Health Surveys national reports. These surveys were conducted between 1987 (Ecuador, Trinidad, and Tobago) and 1994 (Bolivia).

in every respect, with a fertility of 3.1, a postpartum abstinence period extending over 7 months, and a contraceptive prevalence of 33%; (2) that of clerks/traders/industrial workers, who are in the early stages of transition, with contraceptive prevalence ranging from 11% to 17% and a slightly lower fertility; and (3) that of farmers, who have kept their traditional behaviors virtually unchanged (7.6 children, 27-month breastfeeding, a long period of abstinence, and very low contraception prevalence).

Now what is the situation when the evolution of the mortality and fertility inequalities is examined in the countries for which adequate chronological data are available? In Honduras, Paraguay, or Indonesia, from the 1960s to the 1980s, fertility first declined in the more privileged regions or in the more educated urban families, causing disparities to widen. Between 1970 and 1980 in Cuba, Chile, or Thailand, where fertility was already very low, the fertility decline affected all classes of the population before a process of convergence started. In contrast, John Cleland et al. (1992) showed that, over the 1975–1985 period, child mortality declined in the 12 countries in the south they studied (and in all social classes), without giving any

TABLE 71–5 Indicators and Intermediate Fertility Variables by Social Groups and (Extreme) Educational Levels of the Spouses in Burkina Faso (1993)

Social groups	TFR (1)	No. of children at age 45	Desired no. of children (2)	Breast-feeding period (3)	Period of abstinence	Median age at first marriage (4)	% women in polygamous situations (5)	Current modern contraception (6)

The figures in parentheses represent the weight (in %) of each group in the survey.

(1) Ever-married women; (2) ever-married women aged 30 to 39 years; (3) average length of breastfeeding and abstinence periods (ever-married women aged 15 to 49 years), expressed in months; (4) ever-married women aged 30 to 39 years; (5) at age 30 to 39 years; (6) proportion (%) of women who were using a modern contraceptive method at the time of the survey.

Indicators calculated from the 1993 Demographic and Health Survey by Youssouf Langani (Institut de Démographie, Louvain-la-Neuve).

obvious sign of converging. The gaps between the place of residence or the mothers' educational levels even seemed to have widened.

Social, regional, or even cultural disparities are then great, virtually universal, and persistent. Though convergence, or the narrowing of inequalities, has started in many countries in the south where fertility is concerned, it is not a fact yet where mortality and health are concerned. On the contrary, inequality may even worsen concerning the latter.

But before the impact of AIDS and future uncertainties are addressed, we should deal briefly with the structures and the aging of populations, the consequences of the transitions in the past few decades.

VI. AGE STRUCTURES AND DEMOGRAPHIC AGING

The age structures of populations vary considerably from one country or one region to another. At one extreme, in 2000, the population of Sweden, one of the oldest in the world, had virtually as many old people (those aged 65 years and older were 17.4% of the population) as young people (18.2% were aged under 15 years). At the opposite extreme, in Senegal there were almost 15 times as many young (44.5%) as there were old (2.5%). Between the two extremes are countries whose population pyramids have a more or less large base: in Mexico, for example, young people are about 33%, or in China, where people aged under 15 years were only about one-quarter of the total population in 2000 (24.9%). On the scale of the three major groups of countries, the group of the poorest has a very young population: 50% of the population were aged under 18 in 2000, and about 3% were 65 or older. In the developed countries, the structure is clearly older, with a median age of 37, and young people form less than 20% of the population; people aged 65 years and older, 14%. Last, in the intermediate countries, young people are about 31% of the population; people aged 65 and older, 5%.

Those differences in the structures are linked to the evolution of fertility and to that of mortality and sometimes migration (like in such cases as Israel or Burkina Faso). Examining the pyramids (Fig. 71–11), it appears that the structures have remained unchanged in the poorest countries in the past 30 years. For example, in Senegal, where mortality has declined between 1965 and 2000 (life expectancy has climbed from 39 up to 52 years), no aging of the population is observed. In contrast, the population even got slightly younger, owing to the decline of child mortality. The main cause of population aging is the decline of fertility, at least in a first phase, in which fertility and mortality are still comparatively high (Grinblat, 1986). This accounts for the stability of the population pyramids in the poorest countries, most of which have not expe-

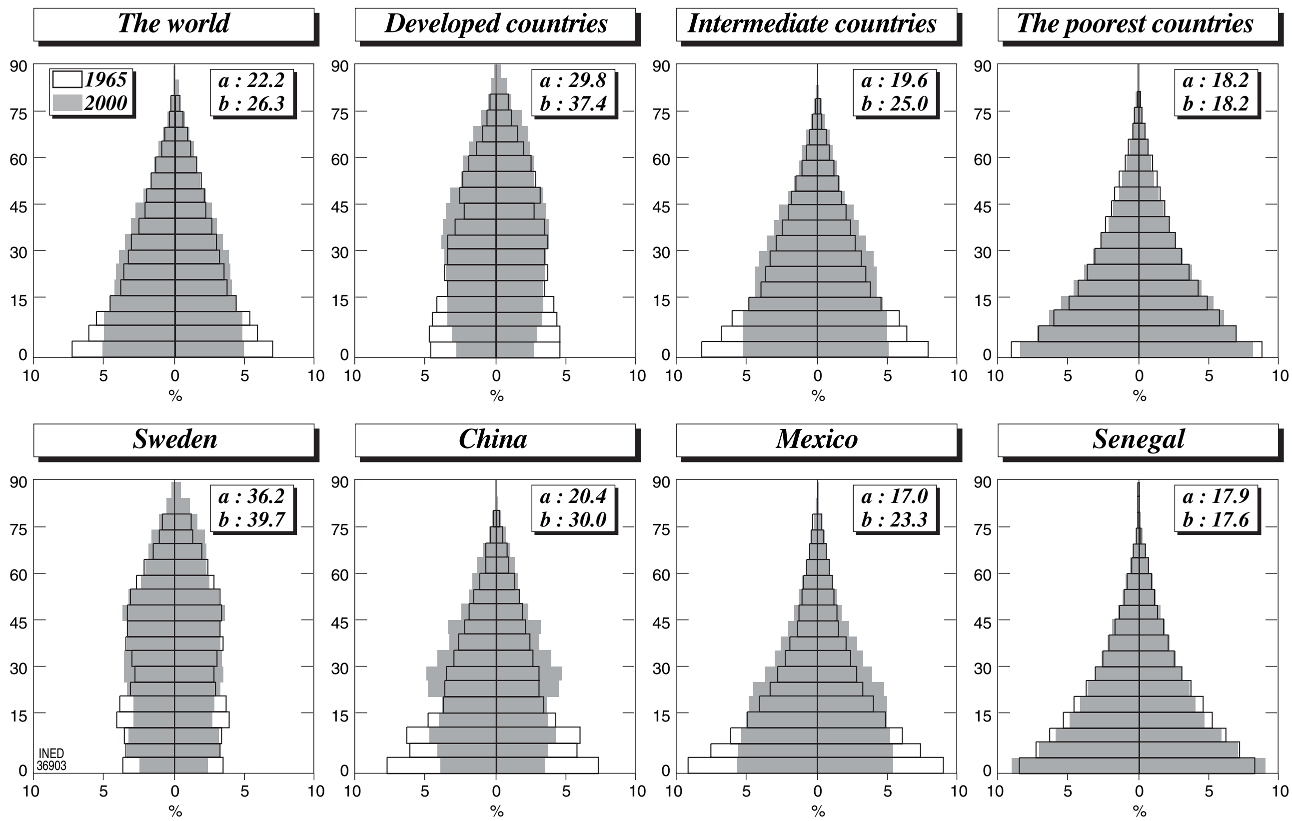

FIGURE 71–11 Relative structure by sex and age of the populations of the three major groups of countries, and in Sweden, China, Mexico, and Senegal in 1965 and 2000. **(a)** Median age in 1965. **(b)** Median age in 2000. (Data from United Nations, 2001a,b.)

rienced any significant decline of their fertility. As for the intermediate countries, they have started the aging process: between 1965 and 2000, the base of the pyramid in the countries taken as a whole has considerably narrowed (41% people aged under 15 in 1965 versus 31% in 2000), owing to the decline of fertility. Although the proportion of people over 65 has not increased in any appreciable way, it is likely to reach 6% in 2010 and 9% in 2025, which means more than 500 million people aged over 65. The developed countries have been experiencing an increase of the proportion of the elderly for a much longer period, starting in 1950 (Fig. 71–12).[16] As for the proportion of youth, it remained the same and then slightly increased in the 1950s before it went on a decline, starting in the 1960s.

Aging, although it has widely affected the developed countries and, to a lesser extent, the intermediate ones, has not really affected the poorest countries. However, one important fact should be kept in sight despite this: the population of those countries will be aging in the coming century. In a first phase, the proportions of young people will go down along with the decline of fertility, as is currently happening in the intermediate countries (Fig. 71–1). The proportion of the elderly will increase only later, as a consequence of the decline of the proportion of youth and through a decline of mortality at older ages, as is now the case in developed countries. However, beyond proportions, it is the total population of people aged over 65 that is increasing already and will keep on increasing in an impressive way. Aging is a problem not only of structures but also of absolute numbers (Tabutin, 1986). Only 20 million people aged over 65 currently live in the 48 poorest countries. There will be 27 million of them in 2010 and some 46 million in 2025. At that date, there will also be 520 million of them in the intermediate countries and 260 million in the developed countries. There are currently about as many elderly people in the rest of the world as in the developed countries. There will be twice as many of them in 30 years. The countries in the south will all be faced with new social and health constraints. And the aging process will be all the more dramatic as fertility has declined faster. In this respect the case of China is exemplary (Fig. 71–11).

[16] Except for a stagnation in the early 1980s.

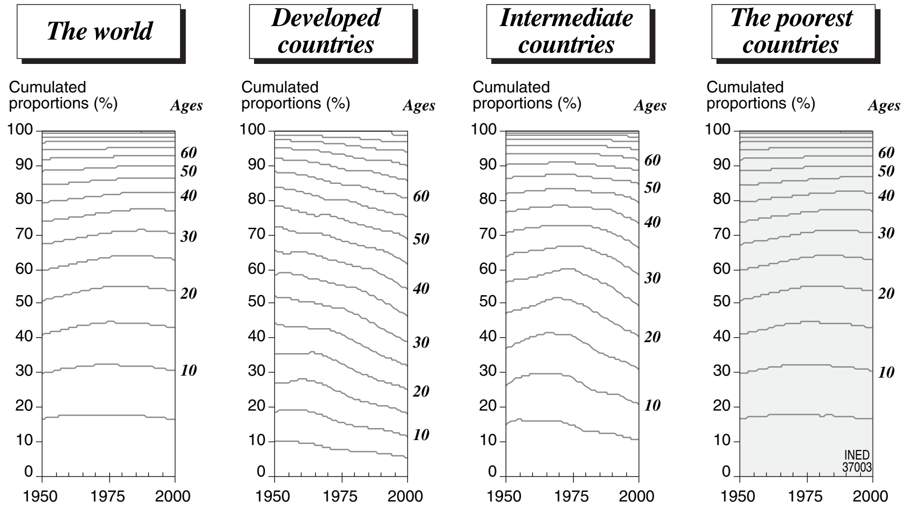

FIGURE 71–12 The evolution of the cumulated proportions (percentage) of the population by age from 1950–2000 in the world and in the three major groups of countries. (Data from United Nations, 2001a,b.)

We should probably worry not so much about any loss of dynamism in society or any aging of mentalities but about the transformations made necessary by such a revolution of age structures, as well as about the lot of those masses of elderly people (Tabutin, 1986). Social security systems are still budding or are nonexistent in many countries, and family solidarity, which was traditionally important, is changing.

VII. AIDS AND ITS DEMOGRAPHIC CONSEQUENCES

As we have seen above, mortality has noticeably declined in all regions of the world since the 1960s. Even in sub-Saharan Africa, where progress has been slower than elsewhere, infant mortality has dropped from 156% in the early 1960s to 100% in the late 1990s, and in the same period, life expectancy has improved from 40 to 48 years. However, since the early 1980s, the evolution of life expectancy has noticeably slowed down or stagnated. It was estimated as 48.3 years in the 1980–1985 period and was still 48.4 years in the late 1990s. This halt in the improvement of life expectancy reflects the tragedy of the AIDS epidemic that many African countries are experiencing.

Sub-Saharan Africa is the region most seriously affected by the epidemic: 70% of the 42 million HIV-infected individuals in the world now live in sub-Saharan Africa (UNAIDS/WHO, 2002), although only about 10% of the world's population live in the region. The prevalence of HIV for the whole of sub-Saharan Africa was estimated at 9% at the end of 2001, far ahead of the Caribbean, the second most affected region, with a little more than 2% of its adult population infected by HIV (UNAIDS, 2002).[17] Last, the 20 countries most seriously affected in the world are all in sub-Saharan Africa, with a prevalence of more than 20% among the adult population in seven countries of southern and east Africa (Botswana, Zimbabwe, Swaziland, Lesotho, Namibia, Zambia, South Africa).

What are and will be the demographic consequences of the epidemic? Although there are still many uncertainties, clearly the AIDS epidemic has and will continue to have devastating effects on mortality in years to come in many countries, particularly in sub-Saharan Africa, where AIDS is now the first cause of mortality (Murray and Lopez, 1996), but also in the Caribbean (e.g., Haiti, Guyana) and a few countries in Asia (e.g., Cambodia, Thailand).[18] In those countries that are most seriously affected, life expectancy has already deteriorated since the early 1980s, falling below its 1960s level in Botswana and Zimbabwe (Table 71–6). Child mortality also seems to be increasing in several African countries owing to the

[17] In all the other regions prevalence is less than 1%, and the prevalence among the 15- to 49-year-olds at world level was estimated as 1.2% in late 2002 (UNAIDS, 2002).

[18] The consequences of AIDS on fertility are not as well known, but it seems that the fertility of HIV-positive women is about 25% to 40% lower than that of noninfected women; such differences might largely be accounted for by the effects of other sexually transmitted diseases associated with HIV infection (United Nations, 2002). The indirect influences of the AIDS epidemics on fertility, particularly through the change in the behaviors of noninfected individuals, are potentially important but have not been extensively studied (United Nations, 2002).

TABLE 71–6 Populations, Life Expectancies, and HIV Prevalence in the 10 Countries Most Affected by AIDS in Late 2001

The 10 countries most affected by AIDS	HIV prevalence (%) in late 2001 (among 15–49 year old)	Life expectancy						Population (in thousand)			
		Past estimates		Estimates with AIDS		Estimates without AIDS		Estimates with AIDS		Estimates without AIDS	
		1963	1983	1998	2008	1998	2008	2000	2010	2000	2010

AIDS epidemic (U.S. Bureau of the Census, 1999). Consequently, the countries most affected, which used to be some of the African countries with lowest death rates, now have some of the lowest life expectancies. According to the UN Population Division estimates (UN, 2001a,b), life expectancy is lower by more than 15 years than it would have been if not for AIDS in several countries, and the gap might be as much as 30 years in the next few years (Table 71–6). As a result, crude death rates are already three times as high as those that would have been observed without AIDS in those countries most affected,[19] and the gaps are likely to widen in years to come.

The impact of AIDS on mortality is already reflected in population growth clearly slowing down in several African countries. The natural growth rate in Botswana between 2000 and 2010 would have been about 2.5% without AIDS; it is now probably about 0.5%. The populations of Botswana and Zimbabwe in 2000 are already fewer by 7% and 10%, respectively, than the populations that would have been observed without AIDS, and these differences are likely to reach almost 20%, if not more, in the next few years. Population growth is thus perceptibly slowing down; however, it is likely to remain positive in virtually all countries. According to UN projections, only South Africa and Guyana (two countries with comparatively low birth rates) may have negative growth rates (UN, 2001a,b).[20]

On the other hand, AIDS affects a majority of young adults and, to a lesser extent, very young children, which causes deep changes in the age distribution of deaths among the populations seriously affected by the epidemic (Murray and Lopez, 1996). This has a particular impact on the age structures of those populations (Stanecki, 2000). By disproportionately affecting young adults, the epidemic also has major economic consequences in the countries most affected. One more consequence is the significant increase of the number of orphans. The proportion of children under 15 years of age who have lost their father and/or mother was estimated 12% in sub-Saharan Africa in 2001, whereas it would have been about 8% without AIDS (USAID/UNICEF/UNAIDS, 2002). At that date in Zimbabwe orphans were about 18%, three-quarters of which were owing to AIDS. Among the main effects of these trends is that children are more vulnerable, and the elderly have a greater part to play in taking care of them.

The demographic, health, social, and economic consequences of the AIDS epidemic in Africa and some countries in the Caribbean and Asia thus appear to be considerable. At the world scale, however, the effect of AIDS over mortality and demographic growth is com-

[19] In the 1995–2000 period, the crude death rate in Botswana was estimated as 17.0%, whereas without AIDS, it would have been about 6%. These indicators are 18% (with AIDS) and 6.4% (without AIDS) in Zimbabwe, and 10.8% and 7.6%, respectively, in South Africa.

[20] Of course, those results depend on the hypotheses on the evolution of the epidemics in the countries involved. Stanecki (2001), for example, shows that, according to the projections of the U.S. Bureau of the Census, Botswana and Zimbabwe are also likely to have negative population growth.

paratively moderate in relative terms. Nevertheless, an estimated 20 million individuals have died of AIDS since the epidemic started, about 3 million of whom died in 2002 alone (UNAIDS/WHO, 2002), which represents more than 5% of deaths in the world during that year.

CONCLUSION

Everywhere in the world, mortality has been declining in the past 50 years. Even in the group of the poorest countries, life expectancy went up from 40 to 50 years between 1960–1965 and 1995–2000, and infant mortality went down from 171% to 102%. But the starting levels in the 1950s, as well as the decline paces, have been variable, and inequality between regions and countries is currently as great as or greater than it was. Mortality remains high and health precarious in many countries, particularly in sub-Saharan Africa, where "an increasing number of countries appear to be kept out of the phase of fast progress which Third World countries experienced before them on the way to epidemiological transition" (Vallin and Meslé, 1995: 18). "Health for all in 2000" unfortunately remained a slogan in many poor regions. Complete control of infectious diseases is far from being achieved, and the dissemination of AIDS contributes to stagnation of life expectancy in sub-Saharan Africa. The epidemic has devastating consequences in some countries, where life expectancy is noticeably decreasing. The economic crisis and its consequences on health care or education systems are also likely to slow down the decline of mortality in the poorest countries.

At diverse periods, most of the regions in the world have also entered a phase of transition to low fertility. The latter was over 5.5 children per woman in the 1950s in 6 of the 8 major regions. That level currently prevails only in sub-Saharan Africa, where the decline began only very recently. There has been—and will be for time to come—diversity in the starting periods and speeds of the decline , between regions and countries, and between social groups within each country. Unlike mortality, the decline of fertility seems hardly reversible; countries, once they have launched in the transition process, continue and will probably continue to experience declining fertility. Some countries, such as China, Thailand, or Sri Lanka, have been through such decline and have currently reached levels close to those of developed countries. Many other countries have started on the same path.

Although it is comparatively clear that all countries will have their fertility rates go down, it remains unknown when the decline will begin and at what pace in those countries that have not yet entered the second phase of demographic transition (some 50 countries in the world, about one-sixth of the world population). The improvement of the populations' living standards, which was long considered a precondition for fertility decline, is now superseded by concepts of crisis-led transition and poverty Malthusianism. It seems that deterioration of living standards would not be incompatible with fertility decline. On the contrary, it tends to give it momentum. However, it is not clear whether the economic, social, and health difficulties in some countries, particularly in sub-Saharan Africa, can be integrated into such patterns in the short term and contribute to the decline of fertility. By limiting girls' education and slowing down the decline of mortality or access to health, they may possibly contribute to delay or slow down the decline rather than accelerate it.

At the world scale, however, sub-Saharan Africa currently represents only a comparatively small part of the world population (some 10% in 2000). Consequently, its transition lag will hardly affect the evolution of the world or of the undeveloped countries. The fertility transition is now largely under way, with an average of 2.9 children per woman in 2000 at world level. The world life expectancy has increased by 12 years in the past 4 decades, and infant mortality has gone down from 119‰ to 60‰.

Although, because of such data, we might think that the demographic transition at world level will soon be completed, Africa and some other countries and regions in the world remind us that huge differences and inequalities persist, that the process will be a long one in some places, and that many things remain uncertain for the future. Among these are the direct and indirect and more or less immediate effects of economic recession, AIDS, civil wars and local conflicts, and resurgent or emergent religious or political fundamentalism.

PART

III

THE FUTURE OF POPULATIONS: DEMOGRAPHIC ISSUES AND PROJECTIONS FOR THE FUTURE

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Having retraced the history of the human population, especially the recent and still ongoing transition in the developing countries from an old to a modern demographic regime reflected–as it still is in the least developed countries–in exceptional population growth, and having remarked on the wide range of current situations–especially the contrast between southern regions of the world, where population growth remains strong, and northern regions, where the decline is increasing in intensity–is it possible to foretell the future?

If we are to produce projections and population forecasts from which to conjecture probable future trends, we must first have reliable estimates of actual current situations and recent trends, but also a set of cogent methods that draw extensively on the range of principles and tools of demographic analysis. But for those projections to be reliable, they must be underpinned by hypotheses of demographic relevance on trends in the main factors of change–fertility, mortality, and migration.

In the first chapter of Part III (Chapter 72), therefore, Christine Wattelar takes a historical look at the methods and basic principles behind the reliable projections made over the past 50 years by various national and international statistical and demographic bodies, chiefly the cohort-component method but also the useful and promising companion methods of simulations and probabilistic models.

But it is not enough simply to forecast population size and age-sex structure trends; one often needs projections for much more specific target groups than the general population: school populations, working population, pension/retirement forecasts, health outlooks, etc. This is where purely demographic studies must be combined with forward economic, social, or medical studies to evolve new hypotheses with which to produce what are known as *derived* forecasts–so called because they are generally derived from existing general population findings made by a set of key projections. But not in all cases. In Chapter 73, Marlène Lamy gives a concise overview of this, exemplified by educational forecasting.

As stated at the outset, however, the most challenging stage of a population projection is formulating plausible hypotheses for fertility, mortality, and migration trends. For that reason, specialists have been enlisted to discuss in three separate chapters how future trajectories in these three components of population change can be conjectured. Luciano Ciucci and Piero Giorgi will consider hypotheses construction techniques for fertility forecasting in Chapter 74, and Graziella Caselli, Odo Barsotti, and Alberto Bonaguidi will do likewise for mortality and migration forecasts in Chapters 75 and 76.

With the tools and hypotheses to hand, it remains to make the projections and assess the outcomes. This section connects up with the chapters in Part I on the history of the human population by focusing on the future of the world population. In Chapter 77, Jacques Vallin and Graziella Caselli take critical stock of the outcomes of nearly half a century's world population projections by United Nations experts compared with actual outcomes and other attempts by other rival authors and organizations. This covers short- and medium-term projections (over about 50 years) and longer-term projections by which to conjecture not only the final outcomes of a general stabilization of all parameters at strict replacement level but also those of selected alternative scenarios and textbook hypotheses by which to assess how material a role behavioral changes now in progress will play.

In the concluding chapter (Chapter 78), the same two authors conjecture what the possible *post-transition* development towards new changes in mortality may be, such as access to a life expectancy of 150 years with the *rectangularization of the survival curve* or conversely the *re-expansion of ages at death* or fertility, with the adoption of new patterns such as the *one-child family, delayed fertility*, or *two-mode fertility*, let alone the impact of changes in the sex ratio at birth. The findings offer much food for thought. Although they set out more to invite reflection than prognosticate the future, what can be said of findings is that they are no less improbable than the absolute all-round stabilization accepted until very recently as the most likely outcome of the demographic transition.

Demographic Projections: History of Methods and Current Methodology

CHRISTINE WATTELAR
Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

INTRODUCTION

As Louis Henry (1973) wrote, "demographic projections enable us to calculate a population's future size and structure, according to any given set of hypotheses." This definition highlights the conditional nature of this type of exercise (see de Jouvenel, 1964: chapter 5); it implies that the hypotheses are as important as the method chosen, if not more so, as the latter is essentially quantitative (Pollard, 1975; Wattelar, 1980).

The term "demographic projection" actually encompasses two very different types of analysis. On the one hand, it denotes population forecasts, the goal of which is the short-term prediction of a population's size and structure based on plausible assumptions about the future; on the other hand, it also refers to longer-term demographic projections that, as simulations, are not constrained by the need for immediate plausibility. For instance, a population projection that extrapolates from tendencies observed during the recent past into the near future is often termed a prediction; in contrast, normative models that push a given dynamic process to its extreme, in order to assess the consequences (e.g., of certain government policies), are more strictly-speaking "projections." This type of model experiments with more speculative scenarios.

Since the late 1970s or early 1980s, however, the term "prospective analysis" is often preferred to "prediction" (Godet, 1977),[1] in the sense that "a prospective analysis aims not at predicting the future . . . but at helping us create it" (de Jouvenel, 1993: 51). Prospective analysis requires a more active involvement on the part of the researcher than does the purely intellectual exercise of prediction, however sophisticated (Romaniuc, 1990). Finally, during the same period and spurred by systemic models, the expression "sectoral forecasts" replaced that of "derived forecasts," thereby stressing the interaction of demographic variables with economic and social sectors (e.g., employment, education, health) rather than assuming that population estimates necessarily precede other predictive models.

This chapter aims to trace the evolution of these various approaches,[2] from the works of earliest pioneers to those developed in the early 1980s, before examining more recent developments, still highly influenced by these earlier methods. New techniques have appeared, but works of pure "futurology" remain rare in demography.

[1] Gaston Berger had already created this new word, prospective, in 1957, in the *Revue des deux mondes* (Cazes, 1986: 337), emphasizing the close link between action and future.

[2] Computer software for projections or population simulation will not be discussed here (Pinelli and Birindelli, 1996), as they will be examined in the specialized chapter of Volume IV.

I. GLOBAL MATHEMATICAL PERSPECTIVES

The history of demographic perspectives[3] is not a long one. The first scientific attempts to extrapolate populations go back barely 2 centuries. Influenced by the physiocrats and the newly developed *mathématique sociale*, the first authors who ventured into the prediction of population dynamics were convinced that, whatever the internal composition of the population, human evolution was governed by mathematical and physical laws.

Thus, by the mid-17th century in England, writers such as Thomas Browne and James Harrington had already attempted a mathematical demonstration of population growth. Nonetheless, the three true forefathers of demographic projection, all writing at the end of the 17th century, were John Graunt, William Petty, and Sébastien le Prestre de Vauban (Hecht, 1990: 290).

Eighteenth-century demographers remained within the tradition of these three pioneers, and Europe became the center of a heated controversy regarding the real or imagined risk of depopulation. Authors such as Montesquieu,[4] Jean-Jacques Rousseau, Condorcet,[5] and Jean-Baptiste Moheau sided with the pessimists or with the optimists, sometimes alternating between the two camps, in their common search for the "optimum" population.

Not before the early 19th century, with Thomas Malthus and his "Essay on the Principles of Population," was population growth expressed in terms of a fixed rate geometric progression, leading to population doubling every 25 years.[6] After Malthus, others introduced a more refined variant of the exponential law: the logistic law. Thus, according to the Belgians, Adolphe Quetelet (1835) and Pierre Verhulst (1845), and, later on (1923), to the Americans, Raymond Pearl and Lowell Reed, human populations do not grow at a constant rate but go through several phases, according to an interplay between the environment and the resources available. According to this law, a population's exponential increase slows in proportion to the square of its volume and cannot exceed a given threshold.

Raymond Pearl and Lowell Reed adjusted this logistic curve to the American population, registered in the 1870 and 1910 censuses. Their method generated satisfactory population predictions for the years 1920 and 1930 (Myers, 1954; Orcutt *et al.*, 1961). Others also used third- and fourth-degree functions to extrapolate the growth of the American population (Myers, 1954; Orcutt *et al.*, 1961).

These first attempts all produced acceptable results because of the long-term stability in population growth in the United States during the 19th and early 20th centuries. The 1930s crisis and, to an even greater degree, World War II, radically disrupted these trends. Since then, no fixed and aggregative law has ever successfully adjusted to population movement taken as a whole. All global mathematical projections failed and were discarded, at least as far as national forecasting[7] was concerned.

II. POPULATION PROJECTION AS FORECASTING: THE COMPONENT METHOD

As early as 1924, demographers such as Arthur Bowley abandoned global methods and drew attention instead to the importance of a fundamental element: population age structure. In 1925, the Americans Louis Dublin and Alfred Lotka demonstrated that the real growth rate of the American population was lower than the rate actually recorded, because of immigration's role in driving up numbers of young people and adults. Louis Dublin even came to envisage a decline in the American population before the end of the 20th century.[8]

1. Origins and Development of the Component Method

In 1926, the Swedish economist Sven Wicksell was among the earliest users of the component method, estimating the evolution of the Swedish population on the basis of hypotheses relating to each

[3] For more details the reader can consult the comprehensive works and articles of Thomas Frejka (1981, 1996), Bernard Cazes (1986), Marcel Lachiver (1987), Jacqueline Hecth (1990), and Éric Vilquin (1996).

[4] Charles de Segondat, baronet of Brède and Montesquieu.

[5] Marie Jean Antoine Nicolas, Marquis of Condorcet.

[6] Even before Malthus, Vauban had already predicted that the population would double every 30 years. He had, in fact, elaborated population or "populating" projections for the period 1730–2000, using 50,000 households from the Canadian colony as his starting point, and assuming four children per household: "Moyen de rétablir nos colonies de l'Amérique et de les accroître en peu de temps," cf. *Les Oisivetés de M. de Vauban* (quoted by Vilquin, 1972).

[7] At the local level, nonetheless, and more particularly for projections of urban growth, mathematical methods, including the logistic one, are still recommended (see United Nations, 1975).

[8] An earlier English author, Edwin Cannan, had proceeded in a similar manner in 1895. Before him, John Graunt had already stressed the importance of immigration in the growth of the city of London (Vilquin, 1977: 84, 87, 110).

component of demographic growth: fertility, mortality, and migration.[9]

In 1928, the American Pascal Whelpton began his long series of American population forecasts. He was the first to take a longitudinal approach to projections, using the cohort-survival method to estimate the future population, cohort by cohort; he was also the first to apply the component method to regional predictions (Thompson and Whelpton, 1934; Whelpton, 1936).[10] In this same year, 1928, Alfred Sauvy wrote his first essay on demographic projection. His later projections (Sauvy, 1932, 1937) demonstrated the importance of this new method through their success in alerting the French public to the risk of declining fertility rates faced by France at that time.[11]

The radical upheavals wrought by World War II[12] and the early postwar years left many highly skeptical about the validity of demographic predictions (Dorn, 1950). Demographic phenomena no longer displayed any regular pattern of development but were constantly fluctuating: deficient cohorts, baby boom, marriage recovery. The World Population Conference, held in Rome in 1954, expressed deep pessimism in this respect (Henry, 1954; Hajnal, 1954; Myers, 1954); at the 1965 Belgrade conference, the ups and downs of demographic projection were still on the agenda (Grauman, 1965: 10–14; Shryock, 1965).

It is since the war, nonetheless, that national statistical institutes have started to carry out regular population forecasts, based on results of 5- or 10-year censuses, depending on the country. Although the methodology is evolving only gradually, the tools used to make the calculations are developing rapidly, making it possible to incorporate multiple hypotheses and alternative scenarios (Calot *et al.*, 1970: 12).

International agencies also regularly conduct vast comparative projections, by continent, region, or country. The first world population projections carried out by the United Nations (UN) go back to 1951; since 1958, the UN has updated these projections on a regular basis, first every 5 years and[13] then every 2 years (see Chapter 77). In 1953, Jean Bourgeois-Pichat published his first European population projections at INED (*Institut national d'études démographiques*). In 1956, the Organization for European Economic and Development (OEEC), since renamed the Organization for Economic Cooperation and Development (OECD), started conducting demographic forecasts for its member states (OEEC, 1956), revising them periodically. Also worthy of mention is CELADO's (*Centro Latinoamericano de Demografia*) work in the field of projection, initiated in the 1960s for several Latin American countries (CELADE, 1960–1968). Finally, the World Bank published its own world demographic projections for the first time in 1978 (Zachariah and Mi Thi Vu, 1978).

2. Refining Component Analysis and Microsimulation

During the same period, demographers sought to achieve increasing precision in their analyses. Within period measures, they strove to identify more fundamental tendencies, contrasting a longitudinal or cohort vision of events to a cross-sectional or period one (Ryder, 1956; Akers, 1965; Hency, 1996) and making use of so-called translation methods (see Chapter 17 of Volume I) (Ryder, 1963; Frinking, 1969) to reconcile the two points of view.

a. *Fertility Perspectives*

The principal objective of the 1955 and 1960 Growth of American Families (GAF) studies (Freedman *et al.*, 1959; Whelpton, 1963; Whelpton *et al.*, 1966) was to find an efficient means of predicting marital fertility by asking couples directly about their projected family size. Results proved interesting in the study of couples' fertility intentions, as long as the necessary qualifications were taken into account when interpreting the data. In the responses given, it was clearly necessary to dissociate the now familiar distinctions between ideal, expected, and completed family size (Ryder and Westoff, 1967; Siegel and Akers, 1969). However, such surveys cannot provide information on couples not yet constituted and are also strongly influenced by period effects.

Meanwhile, knowledge of the biological process underlying human reproduction progressed greatly, thanks to microsimulation models. The REPSIM model, elaborated by Mindel Sheps and her team, is particularly worthy of mention (Perrin and Sheps, 1964). Mindel Sheps' (1971) historical sketch of the evolution of these microsimulation models remains a useful reference. Thus emerged stochastic types of projection models that follow the individual trajectories of a selected sample, no longer using the mean and aggregate indicators of larger populations (Orcutt

[9] See United Nations (1975).

[10] Jacob Siegel (1972: 67) re-examined the series of American projections.

[11] The history of French projections can be found in Nizard (1974), and INED (1987: 63–81).

[12] In 1943, the League of Nations had already conducted international projections in collaboration with the Princeton team (Notestein *et al.*, 1944).

[13] Jacques Vallin (1976) studied the results of successive UN projections in depth (see Frejka, 1981).

et al., 1961). The University of Göteborg developed such models (Hyrenius *et al*., 1967; Holmberg, 1968; Widen, 1969).

New problems emerged, however. From 1965 onward, fertility plummeted in most industrialized nations, with no means of assessing whether this trend was temporary or permanent. It appeared that couples' fertility intentions were themselves influenced by conditions at the time and could lead to serious mistakes when it came to assessing their own reproductive future (Westoff and Ryder, 1977; Monnier, 1978).

b. Regional Forecasts

Regional forecasting, characterized by internal migration, followed a path that closely paralleled that of fertility projection; as the latter, it benefited from developments in fundamental demographic research. Studies of spatial mobility now dissociate the longitudinal from the cross-sectional perspective (Eldridge, 1964). The demographic concepts of frequency, duration, and rank (Goldstein, 1954; Pourcher, 1966; Morrison, 1971; Courgeau, 1980) are increasingly integrated into the very notion of migration and are starting to be used to elaborate projections (Hobcraft, 1977).

Regional perspectives henceforth emphasize gross migratory flows rather than net migration (Siegel, 1954; Schwartz, 1963; Schryock, 1965; Lowry, 1966; Zitter, 1969): as a species, the *net migrant* is virtually extinct! The individual motivations behind aggregate measures are also drawing attention (Wolpert, 1965; Morrison, 1971; Chevallier, 1973). More recently, some have advocated applying event history analysis techniques to the study of migration (Courgeau and Lelièvre, 1989).

After a certain obsession with deterministic, even mechanistic,[14] methods, based on essentially gravitational models within which the notion of distance is pivotal,[15] regional projections are now struggling to incorporate the socioeconomic context within which the migratory movement necessarily takes place; multiple regression methods have come to the forefront (Tarver, 1961; Lowry, 1966). In addition to the more traditional concepts of zones of attraction (or repulsion), often defined by the opportunities available to migrants (Stouffer, 1940), demographers have added those of social distance (Somermeyer, 1961) and life space (Fremont, 1972; Brunet, 1973; Courgeau, 1984).

Here also, regional forecasting has had periods of hope and optimism followed by extended periods of despair (UN, 1954; Hamilton, 1961). Researchers soon realized that the smaller the area studied and the faster the population's growth rate, the greater the inaccuracies at the regional level (Siegel, 1954: 125). According to the most pessimistic, no method was better than any other, and regional demography had progressed no further than the stage of trial and error (Siegel, 1954; Giard, 1973).

If regional forecasts, whatever the methodology, are less reliable than are national ones, it is not only because they deal with smaller populations, more sensitive to the effect of small numbers but also because they are more affected by the evolution of migration than of fertility or mortality. Unlike migration, the latter contain a double inertia, which make them more predictable—a definite advantage for those involved in forecasting. Not only do fertility and mortality generally evolve in a steadier and less extreme fashion than does migration, but their influence on population dynamics and structure is also slower and more diffuse. By contrast, migration fluctuates more acutely in response to political and economic conditions, and the repercussions for population dynamics, and especially structure, can be very swift. It is precisely the weight of this kind of inertia that makes demographic forecasts so much more reliable than are economic ones. The larger the population and the weaker the role of migration, the stronger this inertia becomes. Consequently, world population forecasts are the most reliable of all, not only because errors made about one country can cancel out inverse errors made about another one but also because migration plays no role whatsoever.

Finally, coming back to regional migration, the debate is not over between the advocates of a methodology that could be described as "distributive"—one that distributes national projection estimates between regions in proportion to their population (the ratio, or quota, method)—and the proponents of a disaggregated approach, in which each territorial subdivision has a dynamic of its own, and one that could ultimately affect the national average.[16] From this point on, it became clear that regional perspectives increas-

[14] The study of migrations has long remained under the influence of the laws established by Edward Ravenstein (1885) at the end of the 19th century. Thus, migration between two areas can be determined, among others, by the distance separating them and by the size of their respective populations. This is what George Zipf (1946) called the $P_1.P_2/D$ hypothesis. This type of formulations is often called "Pareto formula."

[15] For a retrospective study of migration models and their importance for demographic projections, see Ter Heide (1963), Termote (1967), and Giard (1973).

[16] Papers presented at the seminar "The improvement of disaggregated methods and techniques of demographic projection" at the General Congress of the IUSSP, in Mexico City, in 1977, are a useful reference.

ingly require the collaboration of various disciplines. However, given the growing complexity of each variable taken into consideration, integrating and reconciling all points of view sometimes raises insuperable problems for projection.

III. PROJECTIONS AND DYNAMIC POPULATION MODELS: QUESTIONING STABILITY

The first mathematical models of population growth were created a little before that of Malthus.[17] Nonetheless, it is really to Alfred Lotka, who provided the most fundamental demonstration of the intrinsic properties of demographic movement, that we owe their definitive formulation (see Chapter 20 of Volume I). His theory has remained the reference for any study connected, however remotely, to dynamic population models; the concepts of stable or stationary populations are alluded to daily in the specialized demographic literature.

All the properties that Lotka established in terms of infinitesimal analysis were integrated, in a different format, into a new projection approach based on matrix calculus (Leslie, 1945; Keyfitz, 1964). The population matrix is often referred to as the *Leslie matrix*, in honor of its author.[18]

New computer technology made it possible to construct gigantic matrices that are particularly well adapted to the analysis and projection of interregional population movement (Muhsam, 1961; Rogers, 1968; Feeney, 1973; Rees and Wilson, 1977). These large matrices are often termed the *Rogers matrix.*

These methodological developments spurred the elaboration of large-scale projection models spanning long periods of time; unlike the microsimulation models described above, these projections received enthusiastic acclaim during this period, and the large systemic world models developed at the Massachusetts Institute of Technology were much talked about (Forrester, 1971; Meadows, 1971; Meadows *et al.*, 1974; Mesarovic and Pestel, 1974). In these dynamic models, populations interact with all the other variables of the surrounding system. The Bachue simulation models, of the International Labour Office, is another example (Blandy and Wery, 1973).[19] Initially, the notion of zero-population growth spread like wild fire and appeared as a miraculous solution to development; it nonetheless soon provoked a heated controversy (Bourgeois-Pichat, 1970; Frejka, 1973; Cole *et al.*, 1974).

From a purely theoretical point of view, Lotka's dynamic model is a process closed to migration. It became imperative, therefore, to find a way of integrating the migration process into macromodels (Tabah and Cataldi, 1963; Le Bras, 1971a). The initial hypothesis of convergence towards an upper limit can even be waived, replaced by notions such as weak convergence (or weak ergodicity) (Lopez, 1961; Coale, 1972), or quasi-stable (Coale, 1963) or even unstable populations (Le Bras, 1971b, 1974; Bourgeois-Pichat, 1994).

Dynamic population models were thus mostly elaborated at the macroanalytical level. Some studies on projection, nonetheless, make more explicit use of probabilities (Pollard, 1966; Sykes, 1969) and endeavor to be less deterministic than are classical approaches. Markovian migration processes (Goodman, 1961; Tarver and Gurley, 1965) belong to this category of models, known as stochastic models. In more recent work, transition probabilities are no longer held constant over time[20] in these models and can even become a function of migrant's personal characteristics; such processes are then labeled semi-Markovian (Ginsberg, 1971). In this way, the new probabilistic population models seek to give more of a place to extrademographic motives, and attempt to get closer to a "predictive process" in the strict sense of the term.

IV. CONTEMPORARY METHODS[21]

1. The Component Method Yet Again

Contemporary textbooks always specify that, "In the present state of projection methodology, population forecasting essentially constitutes an exercise in extrapolation based on the demographic transition model. Hypotheses about the evolution of fertility and mortality from a reference year to the final year of the projection are applied to a given population, divided by sex and age. The computer does the rest" (Tapinos, 1996: 116–117). At first glance, nothing has changed.

[17] It would be even more precise to say that they go back to Leonhard Euler (1760).

[18] For a more complete retrospective study of the various projection matrices and their creators, see Wattelar and Gillet de Stefano (1971).

[19] See René Wéry's retrospective analysis (1996).

[20] The Cornell University team postulated the axiom of cumulative inertia, which expressed the probability not to migrate as an function increasing with the duration of residence (Myers *et al.*, 1967). Seymour Spilerman's research should also be mentioned.

[21] Nico Keilman's (1985b) and Joël Cohen's syntheses constitute useful references concerning recent innovations in mathematical demography applied to models and population projections (see also Hatem, 1993; Lutz *et al.*, 1996).

Its universality is undoubtedly a great advantage of the component method. It can be applied at every level of observation (individual, local, regional, or national). Furthermore, countries with incomplete statistical data can use it as easily as can countries with a permanent population register, compensating for the lack of complete and up-to-date data through the use of indirect methods adjusting age-specific fertility or migration curves mathematically, and model life tables.

Numerous recent studies have nonetheless improved on earlier work on the mathematical adjustment and parameterization of demographic functions developed previously (Heligman and Pollard, 1980; Zaba, 1985; Kostaki, 1992; Wunsch, 1966; Romaniuc, 1973; Brass, 1974; Duchêne and Gillet de Stefano, 1974; Rogers *et al.*, 1978). Others focus on the three dimensions of demographic phenomena—age, period, and cohort (APC models) (Hobcraft *et al.*, 1982; Rodgers, 1982); they apply this three-dimensional approach to projections of fertility (Willekens and Baydar, 1984) and mortality (Osmond, 1985). "Time-series"[22] are back in fashion and have been improved by incorporating the variance that "surrounds" these statistical trends.[23]

Moreover, projections tended to be conducted separately for each sex, giving priority[24] to the female population, especially in fertility estimates; the new projection models, on the contrary, aim at simulating both populations simultaneously (Pollard, 1977; Wijewickrema, 1980; Preston, 1983; Keilman, 1985a; Pollak, 1986).

2. "Multistates" and "Multilevels"

During the 1980s, projections techniques that used large multiregional matrices continued to develop (Willekens and Drewe, 1984).[25] The multistate approach moved beyond the field of regional studies and started to be applied to other dynamic processes, such as marital status projections (Lavoie, 1984; Espenshade, 1985), educational forecasts (Guyot, 1991), and even an attempt at social accounting (Cohen and Tuyl, 1991). Finally, Claude Dionne (1995) used the Leslie matrix to create an intergenerational model of projection and retrojection.

Moreover, some felt compelled to apply their analyses to different levels of observation (multilevel analysis), making it necessary to integrate individual and aggregate approaches simultaneously (Courgeau, 1994; Goldstein, 1995; Pinelli and De Rose, 1997). During the same period, semi-Markovian models remained fashionable (Rajulton and Lee, 1988), and event-history analyses proliferated (Ravanera *et al.*, 1993).

3. Household Projections

Although household projections began as early as the 1930s (Siegel, 1972; Pressat, 1959), especially in the United States with the work of Pascal Whelpton mentioned above, this type of model blossomed during the 1980s (Bongaarts *et al.*, 1987; Keilman *et al.*, 1988). As with classical projections, there are two types of methods: aggregate household projection methods and microsimulation models (van Imhoff *et al.*, 1995; Duchêne, 1996).

Macromodels (UN, 1974) are essentially based on the computation and extrapolation of household headship (or reference person) rates, or household size (Kono, 1981). Micromodels rather draw on individual data in an effort to simulate the family trajectory of each individual (Bongaarts, 1981; Nelissem and Vossem, 1989).

One method, which can be viewed as midway between micro- and macrosimulations, consists in dividing a population by subcategories or multistates (Ledent, 1992), on the basis of geographic locality or household status. This type of approach led to the LIPRO model (van Imhoff and Keilman, 1991; Boulanger *et al.*, 1994). In addition, family reconstitution models (Rallu, 1986) extrapolate to the entire population the family dynamics observed in a reference sample. Certain demographers (Mason and Racelis, 1992) attempted to integrate both sexes within household projections, and in the final analysis, fuzzy logic has entered the realm of household projections (Murphy, 1996): reality is no longer perceived in a dichotomous manner but rather in terms of networks linking people belonging to neighboring configurations, with blurred boundaries.

4. Small Populations

"The projection of subpopulations is strangely lacking in the current debate on regional development" (Banens, 1994). The methodological problems are numerous (Termote, 1980; Ledent, 1995). Several new methods have been proposed; some are deliberately hybrid, such as the "quasi-component method"

[22] For a history of the times series method, and its use in population projections, see Cohen (1985: 182).

[23] Consult Burgio and Frova (1995) and Caselli (1996) for a critical analysis and a comparative application of these methods, particularly to mortality.

[24] In the past, some authors had already dealt with this problem (Goodman, 1953; Keyfitz, 1968; Feeney, 1972).

[25] Following the example of the Netherlands, Canada, and Belgium, national statistics offices increasingly use this approach, particularly for regional forecasts.

(Hakkert, 1985; Smith and Shahidullath, 1995); others make use of new spatial representations (geographical or social), such as fractal scales (Le Bras, 1993; Toulemon, 1991; Frankhauser, 1996).

Here also, the component method remains the rule (Rees, 1994) but introduces other variables of local interest, such as housing (Dittgen, 1995). Methods inspired by thermodynamics (Prigogine's team: Allen and Sanglier, 1981) have been applied to the mechanisms of urban growth (Pumain, 1991). The geodemographic dimension (Tayman, 1996) needs no further proof, and the inclusion of a policy variable (local policy) is an essential element of the predictive process (Thumerelle, 1987).

CONCLUSION: UNCERTAINTY

This short historical review of demographic research in the field of projections shows that, in demography as in other sciences, any progress in methodology relies largely on the results of fundamental research. The time has certainly not yet arrived for population forecasting to find its particular specificity. Its line of reasoning, which could only be autonomous at the risk of becoming sterile, is perhaps taking a new direction.

Finally, it must be acknowledged that researchers who indulge in the perilous practice of projection are well aware of the random nature of what they are doing and regularly and willingly subject their work to a retrospective evaluation by confronting the results of their models with reality. The maxim, to predict is not to explain, remains to the point.

Educational Forecasts

From Derived Forecasts to the Application of the Flow Method

MARLÈNE LAMY

Institut de démographie de l'université de Paris (IDUP), Paris, France

INTRODUCTION

In the majority of countries, the proportion of public spending on education, often already considerable, is increasing. In Third World countries, the phenomenon is associated with the establishment of compulsory education, which affects particularly large school-age populations; in countries where the education system is older, public demand for pre- and postcompulsory education continues to increase and, taking into account the economic and social issues involved, governments are striving to respond positively.

For example, in France—where education is compulsory between the ages of 6 and 15–in the beginning of the 1990s nearly all 3- to 5-year-olds attended school, and since 1987, approximately 35% of all 2-year-olds attended nursery school. Moreover, few adolescents left school at the age of 16. The rate of school attendance among 20 year olds more than doubled between the beginning of the 1980s and the beginning of the 1990s. In 1995–1996, 57% of young people between the ages of 6 and 15; in 2001–2002, 65.9% were currently pupils or students. Thus, in 1995–1996 and in 2001–2002, nearly 15 million youngsters in France were attending school or university.

Educating such large numbers requires considerable budgets and planning for student needs. Planning is mainly based on forecasts of the pupil population, which in addition to demographic variables, take into account the future demand for different types of education, the rules that give access to it, and political environment that determines the availability of the education.

There are basically two types of educational forecasts. The first is based on population projections (which is why it is called "derived") and the enrollment rate. The others come from analyses of pupils' progress within the education system and apply flow rates to the number of pupils in attendance. These two methods are not interchangeable as they often have different objective and use different data, but they can complement each other.

The derived forecast method is usually used to shed light on general long-term trends and to make international comparisons. The flow method is used for more short-term forecasts, such as ascertaining the grade at a local level or within an educational establishment.

I. DERIVED FORECASTS

Derived forecasts can be used to evaluate the school-age population and to distribute them by grade. The principle consists of estimating the school-age population by applying the enrollment rate to the projected population by sex and age. Therefore, for the year n,

$$E_{x,n} = P_{x,n} \times T_{x,n}$$

where $E_{x,n}$ represents the total number of pupils aged x;

$P_{x,n}$, the projected population aged x; and

$T_{x,n}$, the enrollment rate at the age of x.

Technically, the calculation is simple, but it implies the respect of certain hypotheses, and the required data collection is not always easy.

On one hand, the formula assumes that there is independence between the rate and the size of the population; on the other hand, it assumes that there is concordance in the definition of ages relating to the population forecasts and to the enrollment rate.

For population size not to affect the enrollment rate, the supply must meet the demand for education without delay. In countries where the educational system is old and where the objective of forecasts is to fulfill the spontaneous demand for education, this hypothesis for the future seems obvious. However, as future rates are determined from past values, it must be verified that they have not been influenced by a lack of elasticity in the supply. For example, in France, the enrollment rate of 2-year-olds in is greater when the number of 3- to 5-year-olds is less, and vice versa. This association is obviously caused by the number of places available in nursery schools. In such circumstances, it would be risky to base future rates on the most recent ones; it is therefore recommended to use series that are sufficiently long to reduce the impact of these period variations.

This kind of competition between several demands that, in the example in question, relate to spontaneous education exists on the level of compulsory education in countries where the educational system is recent. Unless the rules of access to education are applied in a draconian manner and all the children who are not eligible are excluded, the school enrollment rate at the legal age is not likely to immediately match the unit value. Indeed, the desire of older children to take advantage of the new system will compete with the obligation of those who have reached the required age; if the supply is not increased to match the demand, the rate will remain lower than the unit value until the overall demand is satisfied.

To avoid the influence of numbers on the determination of the rates, it is also preferable to use rates by age in years rather than rates by age groups that vary with changes in population structure.

The second verification to make before applying the above formula applies to declared age. Apart from the appropriate censuses and surveys, demographic statistics and educational statistics do not originate from the same sources and are not collected at the same dates. The former are generally collected at the end or in the middle of the year, whereas the latter are collected at the beginning of the school year. Unless the data is sorted by cohort and the ages under consideration are ages reached during the year (see Chapter 6), it is not easy to establish rates that differentiate children enrolled in school from within the total population at a given time. Data comparisons are made easier if information is collected according to the age the pupils reached during the year or by birth cohort; completed age at the beginning of the school year, which depends on when the school year begins, should not be used. If total population and school population are estimated annually, then the gap between the two dates of collection will be 6 months at the most. At a national scale, if mortality and migration levels are low, the corrections may not be needed to compare both statistical series; however, corrections are required if both levels are high.

The reliability of derived forecasts is related to the reliability of the population forecasts, on the one hand, and the quality of the evaluation of the enrollment rates on the other hand. At ages at which compulsory education is effective, the uncertainty of education forecasts depends only on the uncertainty of population projections. At a national level, in the absence of significant variations in mortality and migration, the forecast is accurate if the cohorts concerned have already been born. If they have not yet been born, the degree of uncertainty will depend on future fertility.

At the ages of pre- and postcompulsory education, demographic uncertainty is compounded by spontaneous school attendance, which is more or less variable according to the level of education.

The accuracy of the projections is therefore not the same at these various levels. At university level, it depends almost entirely on changes that occur in the desire of young people to continue their education or on the wish of governments to steer the active population toward certain sectors. At the pre-elementary level, parents' wish to have more or fewer children and to place them earlier or later in school must be taken into consideration.

Long-term forecasts by level of education are essential for planning the recruitment of teachers and the creation or reorientation of educational establishments. Here again, educational forecasts will be based on population projections. The distribution of the population by level of education is obtained by applying an indicator of school enrollment to a specified projected population figure. This indicator, which is also called a *crude school enrollment rate*, is calculated by applying the number of pupils at a certain educational grade to the number who, according to legislation, are of the age to be in that grade. Thus, in a country where children start school at the age of 6 and where primary education lasts 5 years, we would have for the primary level the following crude rate Tp:

$$\mathrm{Tp} = \frac{\text{Number in primary education}}{\text{Population aged 6–10 years}}$$

In France, for example, the number of pupils enrolled at elementary level are compared to children aged 6 to 10 years, those in the first cycle (junior secondary school) to children aged 11 to 15 years, those in the first short cycle to the 14- to 17-year-olds, and the first long cycle (junior and senor secondary school) to the 15- to 19-year-olds.

Such rates can surpass the unit value if the number of pupils repeating a grade is significant; it decreases if measures are implemented to reduce academic failure. These measures should be integrated into the underlying hypotheses of the projections.

In developing countries, crude rates are likely to be even higher as pupils entering the system late are added to higher numbers of pupils repeating a grade. The resorption of the demand for education from older pupils reduces the crude rates by level of education, whereas the reduction in the dropout rate over the course of a cycle causes an increase. Moreover, any change in the policy relating to repeating a grade (regression or even suppression) during a cycle is likely to have repercussions on the distribution of pupils of other cycles; any innovation at a given grade should be integrated into the forecasts for all the grades.

Grade repeating, dropping out, and progression are terms found in the majority of flow model variants on which shorter-term educational forecasts are based. This type of model is preferred in evaluating the number of pupils per year, or the grade of study at a local level and within individual schools or universities.

II. THE FLOW METHOD

At the end of a school year, pupils can either proceed to the next grade, repeat the grade, or drop out. If there is no external contribution, the numbers present during a given year at a certain grade are equivalent to what has become of the pupils enrolled at the preceding grade during the previous year. It is therefore through the comparison of two successive stocks that the flow is estimated. This is how real, imaginary, or apparent educational progress is evaluated.

If only the numbers by year of study are available for two consecutive school years, then the *retention rate* (*rg*) is calculated as the number of pupils in a grade (g) at the beginning of the school year compared with those of grade $g - 1$ at the beginning of the previous school year. These rates are then applied to the number present in one grade at the beginning of the school year t, ($E_{g,t}$), and by iteration, the number of pupils at the beginning of the following school years is obtained:

$$E_{g+1,t+1} = rg \times E_{g,t}$$

The *rg* rates vary under the influence of school results and demographic events such as mortality and migration. In the case of external contributions being greater than departures, their value can be greater than one. These are also called *apparent flow rates* and are used in schools to evaluate the number of pupils per class in the very short term, such as the beginning of the next school year or the year following. In developing countries, they are used at the national level as little data collection is required.

When possible, it is nevertheless preferable to differentiate, at each grade, those pupils that are repeating a grade from new entrants. Thus, by difference, the net balance between entries and departures of one grade are obtained, and the succeeding flow rates calculated are less global than the are previous ones:

Grade progression rate (P_g)—proportion of pupils of grade g during the school year t who will be in the next class in the following year

Grade repetition rate (R_g)—proportion of pupils of grade g during the school year t who will still be in g in the year $t + 1$

Grade dropout rate (A_g)—proportion of pupils of grade g who will drop out during or at the end of the school year t

The outcome for pupils at grade g is calculated by the following:

$$E_{g,t} = P_g \times E_{g,t} + R_g \times E_{g,t} + A_g \times E_{g,t}$$

with

$$P_g + R_g + A_g = 1.$$

And in the absence of external contributions, the following equation makes it possible to obtain the number at grade $g + 1$ at the beginning of the school year $t + 1$:

$$E_{g+1,t+1} = P_g \times E_{g,t} + R_{g+1} \times E_{g+1,t}$$

However, it is not possible with this flow method to forecast the number of entries into the educational system, which must be estimated by using population forecasts.

The analysis can be even more precise. For a given grade (if the data are available), those passing to the next grade and those repeating the grade can be esti-

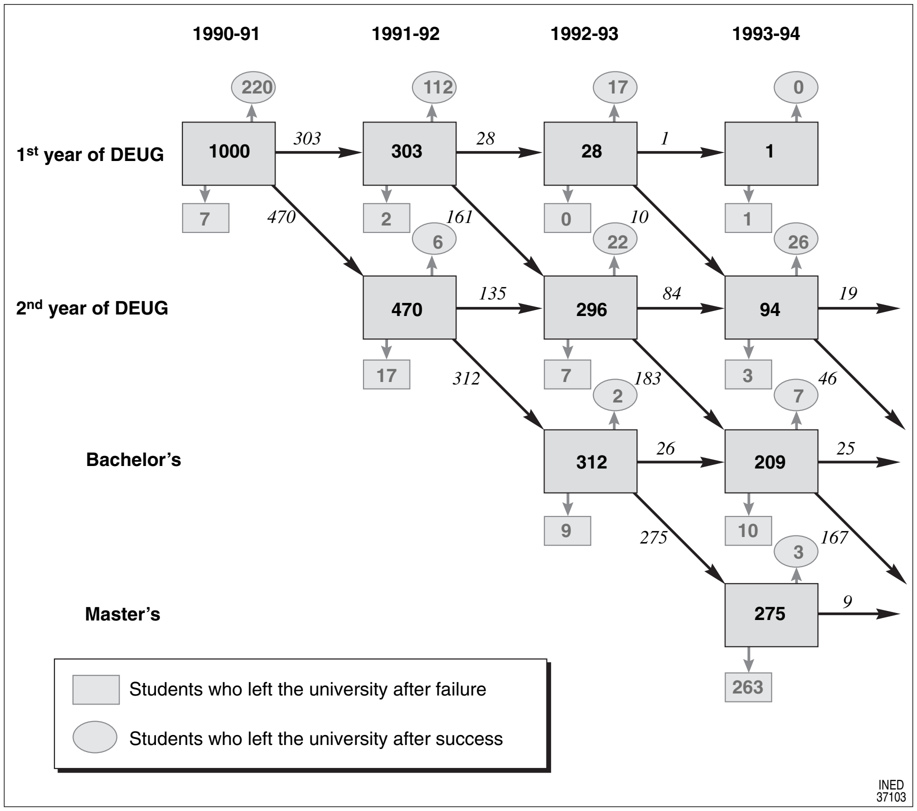

FIGURE 73–1 Cohort study at the *Université de Paris I Panthéon-Sorbonne.*

mated according to whether the pupils were enrolled for the first, the second, or even the third time. Cycle and grade repeating can be matched with dropout rates; transfer rates between regions or educational institutions can also be introduced.

The possible influence of one level or cycle on another must also be taken into account. A restriction on entries at one level can provoke a surplus of repeating pupils waiting to enter the cycle, and the preceding level as well as the adjacent levels will be affected by its repercussions.

Although they are more precise than are the previous analysis, these variants remain based on period data analysis; information relating to two consecutive years is sufficient to establish the required indicators.

An analysis of behavior, based on real case studies is by far preferable. But collecting the required data is an onerous task. At the national or local level, it requires the existence of panels of pupils. These pupils are studied on their arrival at primary level in order to evaluate the rate of passage to the next grade and the repetition rate, or they are studied in the French system on their arrival at *collège*[1] in order to estimate the distribution of pupils between the short and long cycle. Progression can be traced from secondary school to show the proportion of holders of the *baccalauréat* and of pupils dropping out during the cycle.

The issues vary according to education level and become more complex when schooling is no longer compulsory. These issues can often be treated in a differential study according to social and family environment. This latter variable, which is important for the future of pupils, is also important in the design of the hypotheses on which the forecasts are based. However, it loses impact as pupils progress through the educational system and can be replaced by the age reached and the diplomas received.

Educational institutions, because of their size, prefer studying entire cohorts to samples. They attract a more homogenous population compared to the one at the national level because of their geographic and social localization or the selection process that they operate. As a result, they can often dispense with an internal sociological differentiation in establishing their projections. Moreover, the smaller population size would probably make this impossible.

Cohort studies within an establishment can be very informative. In the following example based on the French educational system, for readability the distri-

[1] Junior secondary school that French children attend between the ages of 11 and 15.

bution of those who passed one level at a given grade is shown, as well as their characteristics: age reached, *baccalauréat* type, social and family environment, and place of birth and residence. One can take these factors into account by retracing the educational history according to them, thereby refining the forecast. Such detailed data collection even makes projections by simulation of individual trajectories possible.

The degree of detail contained in forecasts depends on their objectives. A mayor who wishes to know the number of meals to provide in the school dining hall is only interested in the total number of pupils. Academic inspection departments need to know the distribution of pupils per class in order to create new classes or close down some according to predefined criteria of numbers per class. The Education Department needs to be able to plan the recruitment of teachers. These different forecasts require educational projections.

In the long-term, it is preferable to use the derived projection method, which requires the design of population projections beforehand, for which the risks of error at each stage are independent. In the more short-term, the flow method is better, but it has the disadvantage of increasing the size of any potential initial error when the projection period is long. The choice of objectives is at least as important as the choice of methods for projections, including educational forecasts.

Hypotheses for Fertility Forecasts

LUCIANO CIUCCI AND PIERO GIORGI

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

INTRODUCTION

The advances made in the description and interpretation of reproductive behavior have often provided the hope of increasing the capacity to forecast the future of fertility. However, reflection on forecasting tools (Lee, 1978; de Beer, 1992) as well as the ex post evaluation of earlier results have periodically led researchers to increasing pessimism about the possibility of being able to anticipate future fertility trends with any certainty at all.

It is true that forecasters rarely aim to predict what will really occur. Instead, they usually suggest possible scenarios for fertility trends without taking the risk of predicting which scenario is most likely to occur; however, the results are hardly satisfactory as the anticipation of trends is rarely based on clearly stated theoretical presuppositions.

The reason for this uncertainty is owing to insufficient understanding of the individual and collective determinants of reproductive behavior, which makes it impossible to predict whether the couples of the future will make different reproductive choices compared with those of the couples of today.

A review of currently available forecasting tools and possible methodological developments cannot, however, be based on this single premise. To understand what can reasonably be imagined and what can reasonably be accomplished, it is not possible in forecasting fertility, even when methods are based on the most recent expertise, to disregard objectives or targets assigned to *knowledge of the future* of fertility.

This knowledge of the future can only be understood as an intellectual construction or conjecture on the probable future, or even of several probable futures because the directions in which the trend can develop are multiple and what will actually occur will depend as much on spontaneous factors as on political and social decisions and choices, without mentioning possible innovations that are difficult to predict. The modern mind cannot accept the hypothesis of a determinist future, and a future that is not controlled by human decisions and that depends only on spontaneous evolution is unimaginable. The political, economic, and social implications associated with the progressive aging of populations of the developed countries and the rapid demographic growth of the developing countries should also be taken into consideration insofar as they can lead to interventions or population policies likely to modify current trends.

Yet, in the short and medium term, the essential operational needs of administration and management require knowledge of the future, which is equivalent to an *anticipation of what will occur.* In this case, indeed, such a requirement can be satisfied by supposing that the near future is, at least partly, already written in the present and past trends and that possible changes are, barring major upheavals, limited. In addition, it is assumed that retroactive effects likely to modify spontaneous trends are improbable.

I. APPROACHES AND METHODS OF FORECASTING FERTILITY

Traditionally, among fertility forecast methods, it is possible to make a distinction between those based on extrapolation, which consider the future as a continuation of the past and can only be evaluated through an accurate analysis of past experience; those based on desired fertility expressed by couples; those based on explanatory fertility models; those based on the opinion of experts; and those that are based on the construction of scenarios.

Various authors have already evaluated the problems of forecasting fertility and also drawn up exhaustive assessments of the different approaches and methods used (Lee, 1978; Willekens, 1990; de Beer, 1992). In this chapter, we will restrict ourselves to a rapid examination, essentially critical, of the different approaches before discussing the potential of these various methods according to the aims of the forecast.

1. Extrapolation

The extrapolation of past fertility trends is based on more or less detailed measurements of the phenomenon: intensity and tempo, age-specific rates, order-specific rates, parity-specific rates, etc. (see Chapters 12, 14 of Volume I).

The independence of measures, the number of variables, and the related logical and operating choices are the difficulties in the application of these various methods. Moreover, empirical evidence exists that supports more or less disaggregated methods, and the choice of various operators is not univocal.

The complexity of the issue is owing to the interdependence of these two aspects and their relation to the choice of a longitudinal (Chapter 12 of Volume I) or period approach (Chapter 14 of Volume I). In other words, the choices made on one of the dimensions of the issue necessarily engender repercussions on the other dimensions. For example, using a parametric curve, the tool most often used to make a dimensional reduction, transfers the problem of the independence of specific rates to the parameters of the model used to represent them. Attempts have been made to overcome the problem of variable interdependence, but these have not yet resulted in projection methods (Thompson *et al.*, 1989).

In addition to the problem of independence that rises nearly exclusively from logical coherence, the problem of the consistency of projected variables must also be dealt with, if only in terms of the coherence of the profiles of the extrapolated fertility rates.

Various authors have studied the consistency problem. Some have tried to solve specific stages such as that of the dimensional data reduction. This is the case for the procedure based on the factor analysis of the fertility rate matrix (Bozik and Bell, 1987). In other cases, the consistency problem has been automatically solved by using approaches in which the main objective is not consistency itself or dimensional reduction as a basis, as is the case in approaches based on the multivariate *Arima* models adapted to cohorts (de Beer, 1985). The main objective of these models is to extrapolate period indicators up to a level already attained in terms of cohorts or, as in the application of age/period/cohort (APC) models—be it at their simplest (Lee, 1974) or more complex (Willekens and Baydar, 1984; Giorgi and Viola, 2003)—to take into account the analysis of the effects of age, cohort, and period. More recently, the consistency problem was tackled by the representation of the fertility process through a model that, by associating the parity progression ratios, the time elapsed since the preceding event, and the age of the mother at the time of the preceding event, directly produces a consistent set of age-specific rates (Martinelle, 1989, 1993).

In addition to the above-mentioned methods that produce age-specific fertility rates or other measures from which they are directly deductible, there are also other methods based on the extrapolation of fertility indicators that are nonreducible to age-specific rates, such as methods based on fertility measures by age and parity (Al-Osh, 1986), by parity and the time elapsed since the preceding event (Feeney, 1985), or by parity only. In all cases, however, these methods require the construction of appropriate population projection models capable of producing the female population distribution necessary for the application of the indicators used. This construction can introduce problems in incorporating mortality and migration, which produce the number of births to be inserted in the classic forecast of population by sex and age. These methods are only useful if birth order is one of the objectives of the forecast.

2. Methods Based on Desired Fertility

For short- and medium-term forecasts, some authors rely on models based on the observed desired fertility of women (Lee, 1980; de Beer, 1991; Van de Giessen, 1992). Although some official organizations use this type of application, the real usefulness of such data for fertility forecasts remains largely controversial.

The particularity of this strictly microapproach is the use of intrinsically predictive variables that are based on women's replies to questions regarding their future fertility. However, although fertility intentions are highly predictive from a theoretical point of view, in reality they cannot be directly used, as actual births do not generally match the intentions expressed (van Hoorn and Keilman, 1995).

In actual fact, fertility intentions only represent potential reproductive behavior if the individual and structural aspects of the socioeconomic situation remain unchanged. Some authors see only purely conjectural indicators in these fertility intentions and believe forecasts based on desired fertility depend too heavily on current conditions to be of any use (Westoff, 1981).

On the other hand, other authors attribute a real predictive value to this approach, even if they do not directly use fertility intentions to estimate future fertility, as fertility plans will not be carried out in the same way or in the same terms implicitly or explicitly predefined by the women. This is why the transformation of intentions into actual forecasts requires the development of adjustment methods (van de Giessen, 1992; van Hoorn and Keilman, 1995) that are based on the use of two conceptual approaches that can, moreover, be combined: the *limiting factors* model and the *partial adjustment of the projection*.

The limiting factors model consists of weighing the declared intentions with individual variables, identified beforehand, directly or indirectly associated with factors that obstruct the achievement of these goals. The partial adjustment of the projection is based on the inverse relation between age and desired fertility empirically observed within the cohorts, and evaluated from successive surveys.

Data on desired fertility are mainly used to complete the fertility of female cohorts who have not yet completed their fertility, or to develop fertility hypotheses to use in other projection methods. A significant example of the use of data on desired fertility can be seen in the fertility forecasts of The Netherlands' Central Statistical Office (Statistics Netherlands) (de Beer, 1992).

3. Methods Based on Explanatory Models

Models based on an explanatory approach to fertility use the results of regression analyses of the time trends in variations of fertility and other variables, particularly economic ones. In general, they do not rely on a very solid theoretical basis, so much so that often variables that appear correlated to fertility levels are accepted, even if there is no logical association between them. Moreover, these models do not simplify the issue of forecasting, insofar as they only substitute the problem of fertility forecast with that of predicting the phenomena, premonitory or explanatory, which are associated with it. This is the case of two models proposed by Ermisch (1992) that are based on the relation between certain economic variables (particularly female employment) and (1) the trend in age-specific fertility and (2) and the parity progression ratios by age and parity. This type of approach obviously comes up against the possibilities of actually predicting the trend of explanatory variables (Long, 1985), and of validating the explanatory models adopted, particularly with reference to their invariance with time, either in terms of relative weight of the different variables or in terms of the explanatory variables taken into consideration in the model. Social and economic variables are indeed subject to rapid changes, and their development is often more difficult to predict than is that of the demographic variables with which they are associated (Keyfitz, 1982). However, in developing countries where the trends of certain variables are sometimes easier to predict, it can be useful to base fertility forecasts on those of their explanatory variables. Thus, the development of female education has become a solid base for fertility forecasts in some countries.

In Richard Easterlin's model (1976), which directly produces series of future births, explanatory mechanisms of a highly economic nature are in actual fact represented by variables that are exclusively demographic (Ahlburg, 1986). In substance, this model's subjacent theory is that individuals belonging to a birth cohort, or to a group of cohorts, that is larger (for whatever reason) than the preceding one suffer greater stress owing to the imbalance between their aspirations and the resources to achieve them. This stress, which is expressed, for example, in terms of entry into the employment market or economic and social progress and which is therefore associated with an objectively disadvantageous situation, encourages individuals to reduce their number of children because they are unable to cope with the costs related to the arrival of children. On the contrary, the cohort of their children, fewer in number, will experience an objectively more advantageous situation with less imbalance—or even none at all—between their actual resources and their aspirations, an advantage that, according to the theory, should lead them to have more children.

Such a cyclicity, although resulting from essentially economic mechanisms, can be seen through the periodic oscillations of the population structure observed at the level of birth cohorts, with an amplitude of fluctuation double the interval between two generations, and, from there, can easily be transformed into a predictive instrument.

4. Methods Based on Objectives/Hypotheses and Expert Opinion

Population forecasts by official bodies are often based not on actual fertility forecasts (which, on the contrary, appears to be the case for mortality) but according to objectives promoted to the rank of hypotheses, even if they are not always presented as such by their authors. A critical analysis of the fertility hypotheses employed by the various bodies responsible for official forecasts show to what extent, in reality, such objectives have been frequently adopted and how they have often conditioned, albeit only implicitly, forecasts theoretically based on extrapolation (Lutz, 1991; Keilman and Cruijsen, 1992). The most frequent focal point was initially the *replacement* level under which period fertility should not fall; followed by the level of 1.5 children per woman that no generation was supposed to cross; together with alternative trends toward fertility decline, a hypothesis set aside a priori for a long time, even when it appeared clearly in the extrapolation of current trends; and, finally, the return to the replacement level, which continues imperturbably, despite all odds, to fascinate.

5. The Scenarios Method

The word *scenario* has quite varied meanings, and to understand the content of fertility forecasts based on the scenario method, a precise reference frame must be specified. These forecasts are in no way, unlike population forecasts, simulations of the future resulting from the presumed trend of fertility dynamics without reference to a clearly defined theoretical framework.

The method is based on the construction of pertinent alternatives for the future, none of which are considered to be more likely but which are seen as "a coherent group of realistic trends for the future" (Cruijsen, 1991). It thus aims to build an instrument for analyzing the future and is particularly useful in evaluating possible consequences of political decisions, leaving the field clear for creativity while not reducing it to a purely academic exercise. That is, it supplies images of the future based on a meticulous quantitative analysis of processes that, by hypothesis, could lead from today's situation to that of the future.

The scenario method is therefore meant to be very different and innovative compared with the extrapolation of the past. It seems to be closer to the view of forecast not as an anticipation of the future but rather as prospect or conjecture, that is, as an intellectual construction of the future or as an exploration of the various possible, although sometimes contrasting, futures. It is a long-term projection method aimed at showing the effect of potential structural changes.

Careful examination of the past is once again an essential factor of validity, but extrapolation of past trends is not in itself proof of a good definition of future trends and it is not justified by the application of analogous methods. It aims rather to interpret trends in terms of the internal structural relations within the system under observation and to respect major changes in order to avoid discontinuity between the current situation and future scenarios. In this sense, as well as the synchronic approach, used to construct representations of the future, a diachronic approach is also used to define the direction to follow in order to link the present with the future.

The definition of reliable logical rules and clear procedures is needed to limit the arbitrary values in this method that can produce sufficiently operational projections, insofar as it succeeds in translating qualitative evaluations of future trends into quantitative terms. Using appropriate quantitative methods is therefore also important, even if it is likely to reduce the scope of creativity available with this method.

In an interesting application of this method (de Jong, 1995), scenarios of future fertility were obtained by imposing deviations on an observed trend to extrapolate the fertility of cohorts of women. The direction and scale of these deviations were derived from the analysis and theorization of the relation between developments in socioeconomic and cultural systems and fertility trends.

II. FORESEEABILITY OF FERTILITY AND CRITICAL ANALYSIS OF THE METHODS

Table 74–1 presents a classification of available methods, some of which are simple tools, according to whether they are based on the observation of past trends of the reproductive process or, on the contrary, on theoretical or explanatory models of reproductive behavior. A residual category assembles the approaches that do not fit exactly or completely into the two main categories.

We have singled out some important characteristics in order to better distinguish between the different methods:

Use of measures of past fertility trends
Ability to anticipate trend reversals
Degree of subjectivity
Longitudinal or period approach
Quality of the estimate
Significance of the ex-post evaluation
Content of the projection

Short-term methods based on neutral projections, and therefore on extrapolation, are characterized by a complete and systematic use of the past, a minimal degree of subjectivity (reference period, trend model),

TABLE 74–1 Characteristics of Fertility Forecast Methods According To Whether They Are Based on Past Observations or on Theoretical or Explanatory Aspects

Classification elements	Approaches based on:					
	Past observations	**Theories and paradigms**		**Others**		
Basis	observed results of the reproductive process in terms of event and measure	interpretative theories of reproductive behavior		partial or mixed		
Product	"projection" of the past	"anticipation" of the future		"projections" partially associated with the past and dependent on other criteria		
Methods	extrapolation of (1) measures, (2) model parameters (historical, age/period/cohort)	use of expressed desired fertility	construction of scenarios	reference to analogical schemes	realization of objective or reference hypothesis	expert evaluation
Use of past trends of fertility indicators	total	nil	nil	partial	partial	partial
Ability to anticipate trend reversals	nil in cases of direct extrapolation but some models (age/period/cohort) can produce reversals	yes	yes	yes	yes	yes
Degree of subjectivity	weak and limited to (1) the reference period, (2) the trend model	weak (choice of impeding factors)	high	high	high	high
Longitudinal/period	promotes the evaluation of trends (disregarding the logical contents of the longitudinal approach)	longitudinal	both, but mainly longitudinal	longitudinal	longitudinal (the objectives are expressed in longitudinal terms)	longitudinal (but often the criterion is period related)
Quality of the estimate	depends on (1) identification of the trend, (2) its variability; method fails if there is a break in the trend (need to work on disaggregation to increase inertia and flexibility)	ability to recognize the associations between the wishes (goals) and their achievement	depends on the ability to process the theory and its ability in anticipating the future	not assessable		
Significance of the expost evaluation	reduced or nil	important as a knowledge base of relations in expectations and achievements	important in verifying the ability of a theory in anticipating the future	useful for revisions		
Predictive content						
Short-term	good	high	nil	limited (difficulty in evaluating the gap)	nil (by construction)	limited (no logical frame of reference)
Long-term	nil	nil	limited			

the production of estimates whose quality depends (because of the significant short-term inertia of disaggregated indicators) on the identification of trends and the parameters to be projected and their variability. For an improved identification of trends, the longitudinal perspective is often adopted. Such methods cannot generally anticipate trend reversals unless they result from cohort effects that are detectable in complex models such as APC models (Chapter 18 of Volume I) or translation models (Chapter 17 of Volume I).

Using data on desired fertility in short-term projections is characterized by its more or less complete lack of recourse to the past, a strictly longitudinal perspective, and a low degree of subjectivity in the choice of factors limiting the achievement of desired fertility. When used for short-term forecasts, these data help to complete the fertility of cohorts currently of reproductive age, and their main asset is the theoretical capacity to predict trend reversals absent in other forecast methods.

The advantage of this type of approach depends largely on the stability of desired fertility and the extent to which it can be achieved, taking into account the obstacles that couples could encounter as well as current events that could have affected the estimates. Indeed, some authors maintain that desired fertility depends largely on the socioeconomic and cultural climate of the time and, as a result, can only be conjunctural. The concept of cohorts' fertility plans is being challenged today with the return of the idea that cohort fertility, its intensity, and tempo are caused by a dynamic process of interaction among desired fertility and the obstacles, limitations, and constraints imposed by the circumstances at the time. Despite theoretical uncertainties, these methods are still used to a great extent by official statistical institutes in their forecasts.

The construction of long-term scenarios is characterized by the absence of recourse to the past, integrated use of longitudinal and period dimensions, and a large dose of subjectivity. There does not as yet seem to be sufficient knowledge on the complex mechanisms that associate, on one hand, the collective and structural factors and individual factors with, on the other hand, fertility trends in order to produce the certainties necessary for evaluating the degree of likelihood of the constructed scenarios. Numerous obstacles that prevent the theories and the interpretation frameworks from being transformed into efficient forecasting tools (Keyfitz, 1982) actually occur, even when we simply wish to extract likely future scenarios from the theories.

If imagining future changes in behavior is beyond the actual cognitive possibilities that exist today, the static, comparative, and conditional nature of current theories impede the simple translation into trend scenarios, as does the fragmentation and partiality of the various theories. Often two theories are applicable or better, their mode of action on behavior occurs jointly but without it being possible to determine their relative weight. The qualitative nature of a number of theories is not helpful in constructing scenarios. One cannot say that the possible availability of a complete theory of reproductive behavior (a possibility that some authors challenge) can be transformed into a tool both useable and manageable for normal human intelligence.

Furthermore, even by presupposing the credibility of conjectures on future trends of reproductive behavior according to the dynamics of the socioeconomic context, the technical tool for constructing quantitative scenarios does not seem to respond to precise rules and thus imposes a large dose of the arbitrary in the actual construction of scenarios for the future.

III. PROSPECTIVE

To evaluate what might occur in the short-term, in other words to make a real forecast, it is possible to use different tools that are, whatever happens, capable of making short-term forecasts. It is possible to use all those methods based on the results of the reproductive process, expressed in terms of event/measure that base the forecast entirely on the analysis of past trends in fertility indicators and their projection into the future with the aid of a neutral extrapolation method. Still in the short-term, variables on desired fertility—which by their very nature are intrinsically predictive and can, theoretically at least, anticipate manifestations of reproductive behavior—can also be used.

For long-term forecasts, on the contrary, the tools rely mainly on the development of theoretical knowledge, both qualitative and quantitative, to be used not for making forecasts but for constructing scenarios that can prefigure various possible futures, none of which, however, might actually occur. As previously stated, these scenarios are reasoned conjectures that, although based on theoretical presuppositions, do not claim to be forecasts, as it is impossible to control the complexity of the theoretical relations and difficult to control all the dimensions of the phenomenon's variability. In the abstract, scenarios could also anticipate change processes that lead to new forms of behavior and are therefore not foreseeable, a prospect that should certainly not be excluded in the long term. In concrete terms, however, giving theoretical justifications to possible but unforeseeable trend reversals, such as a rise in fertility in the European countries, does not seem easy if we consider that in the very rare cases in which it has been verified (e.g., Norway), either it cannot be explained or explanatory factors of contrary effects have been adopted (a favorable economic development that results in fewer relative costs of children and more women undertaking an economic activity).

Disregarding, in any case, the desirable development of the theoretical knowledge and techniques necessary for increasingly more effective applications of the scenario method, progress is still needed particularly in optimizing the use of the more traditional methods and their capacities, always in the context of their effective possibilities of forecast.

According to these considerations, the only real forecast would be to explore the short term only. And for projection methods, methods of demographic analysis aimed at separating the demographic mechanisms of reproductive behavior should be promoted in order to better determine the trend of their elementary components by eliminating the effects of structural factors from the measure. Recent or future progress in the field of fertility analysis by birth order or by parity (Martinelle, 1989; Rallu and Toulemon, 1993) could therefore be used to study the effects of age, period, and cohort (Willekens and Baydar, 1984) and to examine the translation mechanism beyond the traditional model of event frequencies (Keilman, 1994; Keilman and van Imhoff, 1995).

A more detailed description of reproductive mechanisms does not necessarily improve the quality of short-term forecasts and is of no value for long-term forecasts, but it reinforces our knowledge and assumes a fundamental importance when it comes to associating reproductive behavior with its determinants, as fertility scenarios attempt to do.

Evidently, the trend is to abandon or at least to go beyond the constraints that constitute, on one hand, the use of probabilities by age that integrate measures of another nature into their forecast (Martinelle, 1989) and, on the other hand, the use of completely different approaches aimed at directly predicting births that thus become an exogenous component of the system of population projection by the component method. Recourse to multistate models would make it possible to directly insert fertility indicators by parity, accompanied, however, by a significant increase in the complexity of the whole system.

In terms of fertility projections, progress in the analysis and the identification of the most basic components of reproductive behavior can be favorable to a new method of constructing *conditional forecasts*, understood not as the results and consequences on the population of hypotheses concerning the trends in fertility (and mortality) but as the trends of aggregate fertility indicators within a set of possibilities identified by analyzing what is considered as improbable or incompatible at the level of basic components. This presupposes that the disaggregated methods can distinguish a group of associations that help to define this set of possibilities.

The possibility of relating the fertility measures adopted in the projection or forecast model to the reproductive processes attributed to cohorts becomes more important to give greater demographic significance to the input of the model by attaching it directly to hypotheses of reproductive behavior, to make rational predictions on the reproductive behavior itself, to associate the fertility forecasts with the desired fertility observed at an individual level (de Beer, 1991). In other words, we refer to the diversity of the possibilities provided by these models to translate the hypotheses on the *input* into underlying hypotheses or objectives on reproductive behavior, or (in light of what has been stated) refer to the capacity that such measures have of representing the evolution of the reproductive process, if they are analyzed on a temporal basis, and enabling the forecast to be based on actual knowledge of the phenomenon.

The association of the variables of the model to the subjacent reproductive process can also have repercussions on the possibility of correctly using statistical methods capable of identifying and quantifying dependency between the variables. This is only possible if the measures under consideration are not ambiguous as a result of a lack of control over certain variables. Thus only the relationship with the subjacent reproductive process allows effective explanatory models to be produced.

Moreover, the forecast procedure, be it mathematical or statistical, would produce the best results if the associations between the variables of a purely demographic nature have already been eliminated and if techniques do not require an internal method of control (Giorgi and Viola, 2003). This last case is equivalent to the hypothesis that even with measures that do not control the population's age structure, the forecast method could grasp and distinguish, in a way that we cannot be aware of, between the evolution of components relating to the measure itself, in the sense of reproductive behavior, and trends of component, which are owing to structural elements. We can understand why such hypotheses have never been attempted and that, even in a case in which the method had this possibility, it would work better particularly in the dynamic model if the series of measures were not influenced by structural elements but could be directly related to changes in reproductive behavior.

The possibility of translating the hypotheses of the model's parameters in a bi-univocal manner into hypotheses on the reproductive process and on cohort behavior makes it possible to interpret the *input* of the models and to clearly formulate forecast hypotheses; once again, models with variables that are essentially reducible to the reproductive process are the most promising.

In conclusion, it would appear that, in purely demographic terms, the most frequently applicable methods, disregarding the availability of raw data, are the Martinelle model and the probability model (Giorgi, 1993).

In the case of desired fertility, the logical frame of interpretation that associates it to individual reproductive behavior can be improved, particularly by identifying the obstacles and constraints (collective and individual) in a theoretical-behavioral, and not exclusively mechanical, context that can stop desired fertility from being fully realized.

It is more difficult to give indications on the direction to follow in order to improve the capacity to produce probable scenarios. The transition model would seem to be a useful structural reference, within which we can place theoretical contributions that explain each partial aspect in the context of a more general and comprehensive explanation of fertility trends. This would help to reduce the present mechanical character of the transition model. However, it seems impossible to obliterate the difficulty of explaining the changes in fertility by the action of the social and economic factors to which fertility determinants are attributed.

For interpretative theories to be useful in producing probable scenarios, they must be intrinsically dynamic; that is, they must be capable of taking into account the association between the past and the present in order to project into the future. These theories, particularly economic theories, are essentially static, with the exception of those that use the concept of life cycle in the wake of Easterlin's macro theory. The possibility of creating probable scenarios depends largely on the ability to produce explanatory theories with a high dynamic content.

In any case, it is indispensable to avoid the intellectual isolation of forecasters who limit themselves to the statistical extrapolation of the past to formulate long-term hypotheses. One can also wish for a greater sensitivity among those who deal with the interpretation of reproductive behavior in their comparisons for the aims of forecast, as these aims require dynamic models and possibly univocal management.

Mortality Forecasts

Hypotheses and Methods

GRAZIELLA CASELLI

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

INTRODUCTION

Because demographic phenomena respond to and reflect long-term changes in society and the economy, forecasts of future demographic behavior can usually be based on past behavior. This particularly applies to mortality forecasts, even more so for countries for which long series of data disaggregated by sex and age are available.

Mortality forecasts often hypothesize gradual convergence of rates toward a specified target that will be attained by the end of the forecast period. The target usually coincides with the mortality rate observed for another population, or a subpopulation, taken to be further along with regard to health achievements (Olshansky, 1988). The target could also be mortality rates by age with level and structure that describe ideal mortality schedules that the population could expect to achieve. For example, 1994 United Nations (UN, 1995) forecasts were based on the assumption that countries would achieve the same life expectancy levels worldwide by 2020–2025: the rate of improvement for the most advanced countries would slow while those farthest behind would rapidly catch up (for UN forecasts, see Chapter 77). As opposed to other approaches, targeting is often applied to populations for which the data are incomplete or not very reliable, and recourse is often made to standard life tables or to those for more developed countries (van Poppel and de Beer, 1996).

It could be said that targeting leaves more scope for the imagination whereas other approaches are primarily tied to the past. The approach chosen largely depends on the statistical data available.

This chapter looks at the various approaches, indicating the hypotheses and methods most widely used in demography. Ex post data comparisons will be used to assess the ability and potential of each method to affect forecast results.

I. FROM SIMPLE TO MORE COMPLEX MODELS

This section covers methods based on extrapolations of the past. When a forecast is based on the hypothesis that past trends will continue into the future, it is crucial to define not only the method used to estimate trends but also the length of the data series involved and the year selected to start the forecast. These choices greatly influence the final outcome (Beaumont and Isserman, 1987), so much so that they overshadow even the efficacy of more sophisticated methods. Particularly in recent times when elderly mortality has declined both considerably and unexpectedly, the choice of whether data for the past decade or the past 2 or 3 decades is used, or of whether the starting year is the current year are not arbitrary. Although at a theoretical level, these observations may appear obvious, empirical verification is always needed to assess their effect. For this reason, after a brief introduction of the most widely used forecast methods, later sections focus on applications that clarify the various methods and hypotheses used in estimating future mortality trends.

There are numerous examples of mortality forecasts based on extrapolation methods, from simple graphic extrapolations to analytical extrapolations of an indicator or a mathematical equation modeling the survivorship of a population. What is important is that the selected indicators have an easily recognized underlying trend; that is, they are not subject to strong perturbations and at the same time are sensitive to variations in observed mortality levels. The choice of indicator is usually either the probability of death or age- and sex-specific mortality rates.

At its simplest, a *graphic extrapolation* plots the data by time with the aim of identifying trends. This type of extrapolation often suffices because, although it may appear to be subjective and nonscientific, the results often do not differ very much from those obtained with more objective, complex mathematical approaches.

Analytical extrapolations project trends for a demographic indicator by using a mathematical equation that describes changes over time (McNown *et al.*, 1995). The equation can incorporate the dynamics of one or more dimensions of the chosen indicator: that is, age (A), period (P), or cohort (C).

Among the equations used, John Pollard's (1988) is the most frequently applied and models an exponential drop in mortality in time for each age (with varying P):

$$q_{n,x} = b_x(c_x)^n, \tag{1}$$

where

$q_{x,n}$ is the probability of death at age x in year n,

b_x is mortality at age x at a particular moment in time, and

c_x (ranging between zero and one) expresses the decline over time of mortality at age x.

By applying the logarithmic transformation of Eq. 1 we have

$$\ln(q_{n,x}) = \ln(b_x) + n\ln(c_x). \tag{2}$$

If we wish to fix a lower limit a_x for the mortality decline at age x, we use

$$q_{n,x} = a_x + b_x(c_x)^n. \tag{3}$$

Once representative ages of the mortality model by age are chosen, the corresponding values c_x for different calendar years is estimated with the ratio $(q_{n,x}/q_{m,x})^{1/(n-m)}$, (where $n > m$); then the values of c_x are calculated to obtain those forecasts. The results, applied to one of the three formulas above, yield the probability of death at the selected age. By interpolation, q_x for ages in between can be obtained.

During the late 1970s and 1980s, *parametric models* were popular in making mortality forecasts. Over the past century, mortality experts have tried to infer mathematical laws through a combination of a certain number of parameters (where A varies, fixed P) from regularities in mortality by age. There is, for example, Gompertz's law (1825), named after the mathematician and later modified by William Makeham (1867) and Wilfrid Perks (1932). The main defect of these functions is that they only model mortality beyond 30 to 35 years of age, that is, to a mortality curve that increases with age and thus not to the mortality curve for infancy and youth. Larry Heligman and John Pollard overcame this drawback in 1980 with a three-component model. Their equations, with eight parameters, are

$$q_x/(1-q_x) = A^{(x+B)c} + D\exp\{-E[\ln(x/F)]^2\} + GH^x \tag{4}$$

or, alternatively,

$$q_x = A^{(x+B)c} + D\exp[-E(\ln x - \ln F)^2] + GH^x/(1+GH)^x] \tag{5}$$

The first component of each function models infant mortality, the second models youth mortality from violent causes, and the third follows mortality trends among the elderly.

Thus, parametric models gradually adapt to the age-specific mortality curve as the number of parameters to be estimated increases. Although ensuring greater similarity between theoretical and observed values, this has generated such complex analytical functions that their use has been limited. This helps explain the success enjoyed by the two-parameter Brass model (1974)—particularly in countries where data are lacking—which uses the logit of the survival functions of a life table:

$$L_{x,n} = 0{,}5\ln[(l_{0,n} - l_{x,n})/l_{x,n}]^s. \tag{6}$$

This models the logits of a given life table as a linear function of the logits of a standard or reference life table, or

$$L_x = a + bL_x^{(s)}, \tag{7}$$

whose parameters a and b are independent of age x (where P varies, fixed A). Its application thus depends of the availability of sufficiently lengthy series of the probability of death, so that the survivorship of a cohort may be reconstructed. If this is possible, survivors for certain selected ages x of the cohort born in the calendar year n can then be calculated and the corresponding logit can be linearly extrapolated. The values obtained, applied to the inverse of the logit transformation—that is, $l_{x,n} = l_{0,n}/[l + \exp(2L_{x,n})]$—yields the estimated survivorship ($l_{x,n}$). Where cohort data are missing, a frequent occurrence, period life tables are used. In their absence, as happens in developing countries, standard UN or Ansley Coale and Paul Demeny tables (1966, 1983) are employed, using subsequent series through a longitudinal reading of mortality at different ages.

In summary, the application of parametric models for forecasts comprises three steps: an estimation of the parameters, an extrapolation of the relative trend over time, and the subsequent integration of estimated values of the parameters into the original mathematical equation. Parameters are estimated by fitting to the data, often by least-squares methods, by chi-squared methods, or by examining the maximum likelihood function (Wilmoth, 1983). The corresponding values forecast for a given year are attained by substituting these values into the model so that mortality at each age can be calculated.

Among the many drawbacks arising from the application of parametric models, we focus on two. First, there is a possible inconsistency of the results obtained by extrapolating the parameters independently of each other. For example, when fitted over age for a fixed period, it should be verified that for every cohort that the number of survivors at age x is greater than at age $x + 1$. Second, it may be difficult to identify the trend of parameters characterized by large variability, so that the choice between the many possible solutions becomes subjective.

Since the 1980s, demographic forecasts have turned with increasing interest to methods based on the analysis of economic time series.[1] The simplest of these is a deterministic linear model, where the dependent variable is mortality in age group x (expressed by rates or logarithms of rates), and the independent variable is time t:

$$X_t = a + bt. \tag{8}$$

A simple stochastic model is

$$DX_t = DX_{t-1} + e_t \tag{9}$$

where the change in X_t (i.e., DX_t) depends both on variations in previous time periods (DX_{t-1}) and on a random term (e_t). This formulation is included within a wide class of models called ARIMA (autoregressive integrated moving average) models. McNown and Rogers (1988) experimented a method combining parametric models with time series analysis. In practice, an ARIMA model is often used to extrapolate from "pure" George Box and Gwilym Jenkins (1970) time series methods, which are theoretic and make the introduction of additional substantive information difficult. Robert McNown and Andrei Rogers applied their model to mortality data for the United States by performing an ex post forecast: based on the historical series for the period 1941–1970, they checked whether forecasts matched observed data for 1971–1983. Although the results obtained were not completely satisfactory, this study still represented a stepping stone in the potential offered by ARIMA models in interpreting and making mortality forecasts.

However, ARIMA models are frequently unable to capture changes in the latter years of the observation period, so during the extrapolation step they have less influence than do overall longer-term trends in the time series. This is a major drawback in demographic research and particularly in the analysis of mortality in the near past, which has been distinguished by a sudden and marked decline among the elderly. However, as all variations in mortality must be accounted for—and, in particular, those in the last years of the reference period—a mathematical function is needed that can interpret these and provide the best indications of possible future change. Numerous attempts have been tried, particularly in the economic literature, where the principal time series techniques have been developed. The most recent of these are based on linear regressions. Simple linear relationships do model mortality well as long as there are no underlying variations in the trend. If not, which often occurs when studying mortality for a given cause of death, more complex mathematical functions are needed. Thus, although still dealing with time series, the probabilistic component has been replaced by a deterministic model. The data are interpreted by models like Eq. 8, where the dependent variable is mortality at age x (expressed by logarithms of mortality rates) and the independent variable is time t. The linear relationship is denoted by

$$\ln(m_{x,t}) = a_x + b_{x,}t \tag{10}$$

or by the quadratic relationship:

$$\ln(m_{x,}t) = c_x + b_{x,t} + c_{x,t}{}^2 \tag{11}$$

By using least-squares methods, coefficients can be estimated and the extrapolation begun. As far as forecasts are concerned, however, the disadvantage of these functions is that they fail to impose limits on the time trend, so these are only valid in short- or medium-term forecasts.

Among *stochastic models*, Ronald Lee and Lawrence Carter (1992; Lee, 1998) proposed what is today the

[1] In the standard definition for an historical time series (X_t, $t = 1, 2, \ldots, N$), what is intended is the finite realization of a stochastic process X_t, where t is time, that describes the trend.

most well-known and frequently used method. Their analysis focused on stochastic variations within a single model of mortality change. The procedure "combines a rich yet parsimonious demographic model with statistical time series methods" and relies on a simple model of past mortality trends. Their model is

$$\ln(m_{x,t}) = a_x + b_x k_t + (e_{x,t}), \tag{12}$$

where

$m_{x,t}$ is the mortality rate at age x for time t;

a_x, b_x, and k_t are the parameters of the model; and

$e_{x,t}$ is an error term, with expected value $E(e_{x,t}) = 0$ and variance $V(e_{x,t})$. Although Lee and Carter fit their model by ordinary least squares, other methods can be used (Lett *et al*., 1995, 1998). The interpretation of the parameters is quite simple: the fitted values of a_x are exactly equal to the average of $\ln(m_{x,t})$ at age x over time, b_x represents the age-specific pattern of mortality change, and k_t represents the time trend (Wilmoth, 1996). The advantage of mortality trends obtained by using this model is that it provides a confidence interval range within which the results can vary.

The Lee-Carter method can be expanded to include age and period, by adding additional parameters to be estimated (Wilmoth, 1993). Gomez de Leon (1990) tackled these aspects in an exploratory analysis of Norwegian mortality data for 1846–1988.

The Lee-Carter method presumes that mortality variations are a function of the components of age and period (where A and P vary); however, particularly when forecasts are made for cause of death, it may be of interest to consider the third component of mortality, cohort (C). In such a case the model becomes increasingly complex but formally more accurate in analyzing cause-specific mortality trends in which variations are strictly linked to changes in generalized behavior patterns.

Age-period-cohort (APC) models have been widely applied to past mortality time series (Osmond and Gardner, 1982; Hobcraft *et al*., 1982; Caselli and Capocaccia, 1989; Wilmoth *et al*., 1989), but they are not frequently used in forecasts (Caselli, 1993, 1996; Burgio and Frova, 1995), and even in those cases, they are usually used only to forecast cause-specific mortality (Osmond, 1985). In a recent article, Alessandra Burgio and Luisa Frova (1995) hypothesized that the logarithms of mortality rates can be interpolated by using a polynomial function of the age, period, and cohort covariates, based on the fact that the mortality rate can generally be expressed as a smooth function of factors and parameters. Their model is

$$\ln(y^*_{t,x}) = a + a(x) + p(t) + c(t - x) \tag{13}$$

or

$$\ln\left(y^*_{t,x}\right) = a + \sum_i b_i x^i + \sum_j c_j t^j + \sum_k d_k (t-x)^k, \tag{14}$$

with $i = 1, \ldots, h_1$; $j = 1, \ldots, h_2$; and $k = 1, \ldots, h_3$,

where $y^*_{x,t}$ is the theoretical mortality rate at age x and time t, and $b_1, \ldots, b_{h1}, c_1, \ldots, c_{h2}, d_1, \ldots, d_{h3}$ are the parameters estimated with the least-squares method.

This model may be acceptable if used to describe past mortality trends. For projections, however, the use of a period effect curve may be inadequate owing to the volatility of short-term factors. Thus, the period curve is subdivided into two additional contributions: the trend underlying the period component is given by the straight line uniting the first and last year of the observation, and deviations from this average trend. An additional hypothesis supposes that the underlying trend holds for the future with no fluctuations from this trend. This is possible by transforming the period function $p(t) = c_0 + c_1 t + \ldots + c_{h2} t^{h2}$ so that the new function $p^*(t)$ results as $p^*(t_1) = p^*(t_n)$, where t_1 and t_n are, respectively, the first and last year of observation. Subsequently, as long as the mortality rate remains unchanged, age and cohort functions all undergo a comparable transformation. By these transformations, it is possible both to identify the model (Caselli and Capocaccia, 1989) and to control the period effects.

II. TARGET FORECASTS

Unlike an extrapolation approach, targeting allows for a larger number of hypotheses about future mortality. As a method it is more flexible; however, it tends to favor the influence of subjective elements, which could compromise the results. Moreover, once the end target has been set, an additional problem arises: how to get there from here (Keyfitz, 1981; Alho and Spencer, 1985). This will depend in part on the completeness of mortality data. Where data are missing, model tables are used or reference is made to those for other countries. When sufficiently detailed data are available, an approximation to the final value can be obtained by means of ad hoc functions that have been constructed based on the information at hand.

An approximation to targets using model tables carries the implication that the system of tables can be adapted to fit the mortality structure. A table having the value of the desired parameter (e.g., infant mortality or life expectancy at birth) is chosen that is suited to representing the new mortality model and is thus able to provide the targeted probabilities of death. Additional hypotheses are then made, or interpolation methods are employed, which determine the other values of the parameter so that the remaining model tables will be representative of different phases in future mortality trends.

A similar approach may be used for mortality forecasts for developed countries. To illustrate this point, let us recall the health transition in Europe: overall mortality patterns, especially for causes of death, were similar for the majority of countries, although with individually varying time schedules and some variations in pattern (Caselli, 1993, 1994): some countries forge ahead while others lag behind, experiencing the same phenomena but with a certain phase displacement.

A good example is provided by mortality trends for lung cancer in adult men (although the same applies to other causes of death). Incidence has tended to increase with time, and until quite recently, it was thought impossible to bring this trend to a halt. Following major antismoking campaigns, dating from the 1950s in England and Wales, male mortality from lung cancer began to decline. At the same time, lung cancer mortality in other Northern and Central European countries continued to rise, a trend that was not reversed or halted until the late 1980s. Naïve trend extrapolation for these areas might not take into account more recent trends elsewhere, although it might be reasonable to expect the England/Wales experience to be replicated elsewhere but with a time displacement.

A crucial aspect of such an approach is assessing the potential for phase displacement, such that it would be possible to link mortality trends across countries. Naturally, both the theoretical and operational problems are numerous and would necessitate solutions specific to each country, for each cause and for each age.

Less sophisticated approaches would include those in which hypothesized mortality trends are extreme, the aim being to achieve ideal values expressed by an "optimal" mortality table. In this case one must establish how and when an approximation to the ideal table is to be achieved. For this type of forecast, Eq. 3 is generally used, where q_x represents the probability of death in the ideal table.

Targeting models also include *cause-delay models*, which foresee the elimination, either partial or total, of one or more causes of death in order to assess their impact on the population's survival levels (Olshansky, 1987, 1988). When formulating the hypotheses, the researcher attempts to identify intervenable risk factors so as to gradually abolish the cause or causes of death directly linked to these risks. It is then possible to express a particular cause of death in terms of cost in life expectancy. Cause-delay models are particularly desirable in long-term forecasts if it is possible to intervene on one or more risk factors.

III. DIFFERENT METHODS COMPARED

Figure 75–1 compares mortality rates for English males aged 60 to 84 years for the period 1971–1988; the forecasts are for the same period and are made by applying three different models to the series of mortality rates by age observed for the years 1950–1970. The

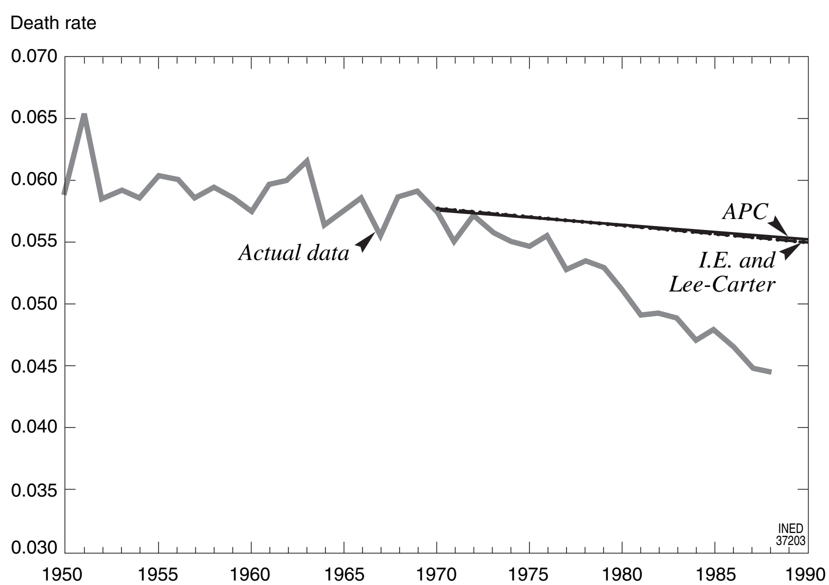

FIGURE 75–1 Extrapolations for 1971–1988 of trends for 1950–1970, according to three models, compared with actual trends. Direct extrapolation of total mortality rates (data on England and Wales, males).

three models are (1) interpolation and extrapolation as expressed by the Eq. 10 or 11, hereafter referred to as model I.E.; (2) "Lee and Carter"; and (3) APC. First, observe that when the reference data present an easily identified underlying trend, the use of any of these models, or even a simple graphical extrapolation, largely generates the same result. Second, note that none of the forecasts was able to capture the sizeable decline in mortality among these age groups from the 1970s onward. Could a mortality forecast, obtained from single forecasts of mortality for the major causes of death, be capable of it? We know that changes in trends after the 1970s, especially for the ages considered, are the outcome of modifications in mortality levels for certain causes of death, particularly cardiovascular diseases and lung cancers. As can be seen from Fig. 75–2, regardless of the model used, the outcome of forecasts for the five major groups of causes, although quite different from the levels observed in recent years, are without doubt better than anything else previously obtained (Caselli and Vallin, 1999).

In this case, the reason why the fit between the forecast and the actual was so poor must be traced back to certain cause-specific mortality trends, particularly car-

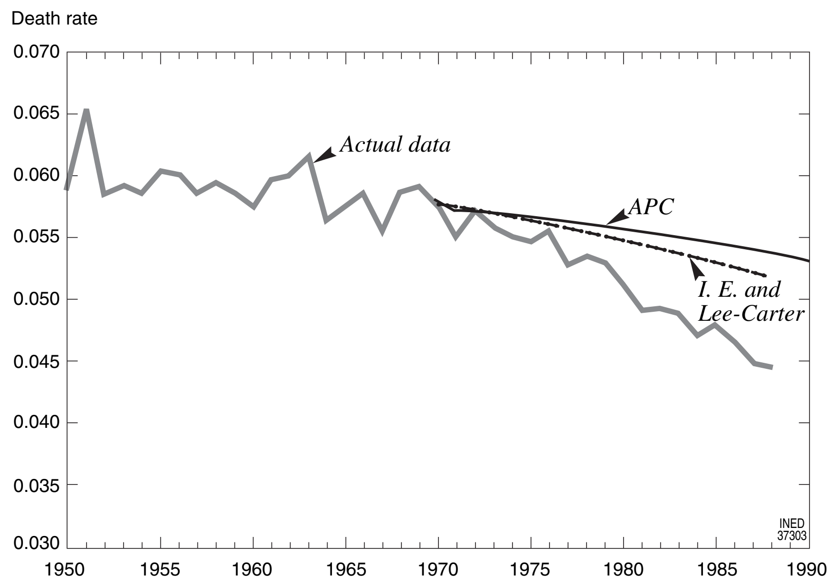

FIGURE 75–2 Extrapolations for 1971–1988 of trends for 1950–1970, according to three models, compared with actual trends. Sum of extrapolations of rates by cause (data on England and Wales, males).

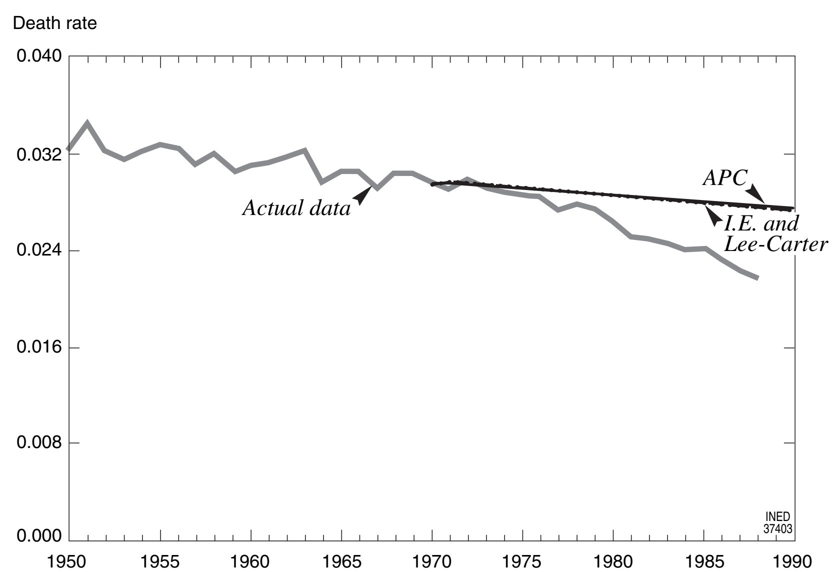

FIGURE 75–3 Extrapolations for 1971–1988 of trends for 1950–1970, for mortality by cardiovascular diseases according to three models, compared with actual trends (data on England and Wales, males).

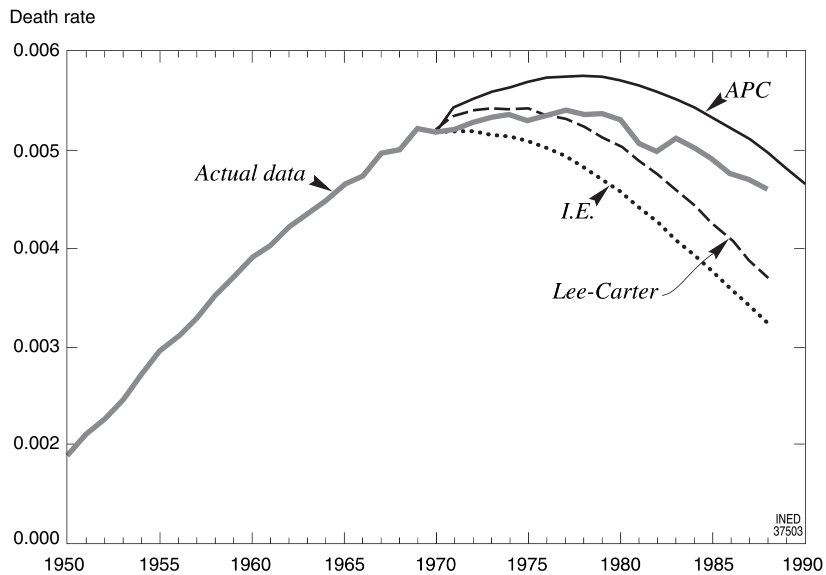

FIGURE 75–4 Extrapolations for 1971–1988 of trends for 1950–1970, for mortality by lung cancer, according to different models, compared with actual trends: Males, 60–84 years (data on England and Wales).

diovascular diseases (Fig. 75–3). These trends have the same form as that for total mortality, and no model was able to isolate it. The quick pace of this decline was unexpected and coincided with major therapeutic advances in the early 1970s. Thus, the "period" effects had an important role to play on trends in mortality rates.

The decline in lung cancer mortality was much more gradual and was lagged in time as the age of the population increased. First, this involved generations who throughout their adult lives could benefit from antismoking campaigns, either moderating or avoiding smoking altogether (Fig. 75–4). It was only later that other generations, who had been smokers and thus exposed for a lengthy period, began to be involved. Mortality trends by age for this cause clearly illustrate this process (Fig. 75–5). It is interesting to see that, at least with regard to lung cancer, the APC model offers the best insight into mortality trends because this approach, at the extrapolation stage, emphasizes the importance of the cohort component in mortality trends.

IV. HYPOTHESES FOR MEDIUM AND LONG-TERM FORECASTS

We now turn to critical hypotheses, the baseline data series, and the starting date of the forecasts. Figure 75–6 compares the results of forecasts made for English males aged 60 to 84 years between 1989 and 2050 based on two different data series: 1950–1988 and 1970–1988.

As may be expected, mortality levels to 2050 are fairly similar for each of the models used when based on the same reference period. Perceptible differences arise, however, depending on the length of the data series: mortality levels are lower when based on 1970–1988 data, coinciding with the date when a marked decline in mortality for these ages first began.

As further proof, and to focus on the importance of the starting date set for forecasts, we present a summary of forecasts made in the late 1980s in certain European countries (Table 75–1). First, let us consider the forecasts for the 1980s by national statistics bureaus, beginning with a comparison of the forecasts made by France's National Institute for Statistics and Economic Studies (INSEE) and Italy's National Institute of Statistics (ISTAT). Both these bodies adopted a "trend" hypothesis of changes in the mortality rate. ISTAT, which made its forecasts in 1989, took as the point of departure the year 1988, whereas INSEE began with 1985. This difference of only a few years, together with the different lengths of the baseline series (in France, 1950–1985; in Italy, 1980–1988), meant that the French forecast could not fully reflect recent mortality trends, and thus, their results were more pessimistic (Fig. 75–7).

Figure 75–7 helps to provide a focus on the problem of what baseline period to choose when making a forecast, by providing a global overview of mortality trends from 1900–2020; the effect of different assumptions on the results can be observed. For the middle age groups, French data show a steep decline in rates for adults and the elderly, although it is not even

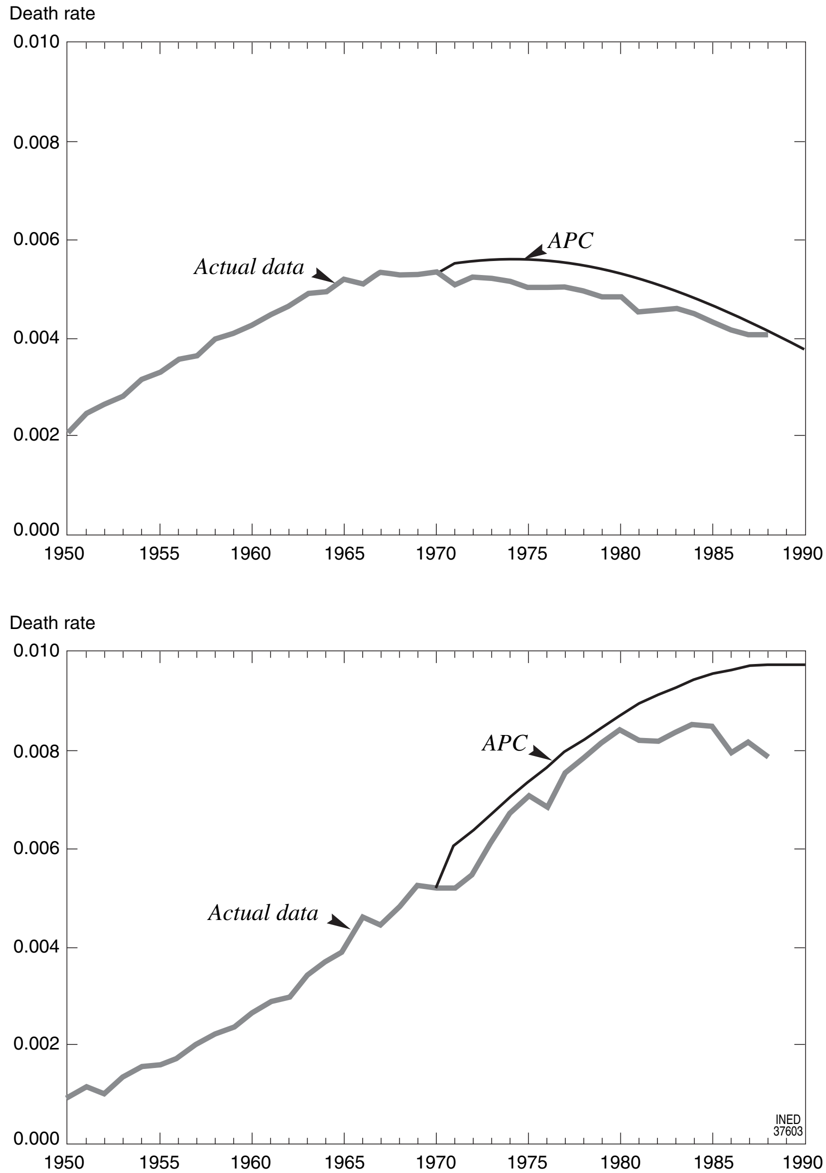

FIGURE 75–5 Extrapolations for 1971–1988 of trends for 1950–1970, for mortality by lung cancer, according to different models, compared with actual trends: Males, 65–69 and 80–84 years (data on England and Wales).

slightly apparent in the Italian forecast (Caselli, 1993–1994). An ex post assessment of these results is that the elderly mortality drop after the 1980s was not foreseen for either of the two countries. Moreover, this drop has recently involved the upper age limits, for both men and women (Vallin and Meslé, 2001).

Thus, it is not surprising that each country has entirely different life expectancies for the year 2020: 74.0 years for French men compared with 76.3 years for Italian men (the latter had an advantage of 1 year in 1985), and 82.4 years for French women compared with 83.7 for Italian women (who had roughly a 6-month advantage with respect to French women in 1985). If we consider the fact that in 2001 French men already enjoyed an average life expectancy of 75.5 years, it is extremely pessimistic to believe that over the next 19 years 1.5 years of this would be lost. The same consideration applies to women, whose estimated life expectancy in the 1980s for 2020 is the same as that already achieved in 1999. Survival gains already achieved at the dawn of the 21st century in Italy and France are far removed from those estimated in the 1980s for the year 2020. These figures show that, although theoretically tractable, the extrapolation of

past trends risks being disproved each time a sudden change occurs as was the case in the 1980s.

Apart from the prudent attitude generally shown by most European countries (Table 75–1) when the forecasts were made (some maintained that mortality levels were to remain constant, whereas others fixed a threshold which could not be surpassed), recent mortality trends have rendered obsolete all estimations made in the 1980s, as none of these were able to anticipate the present decline. In 1981 and 1988, respectively, the Finnish and Swedish statistical bureaus made forecasts to the year 2020. Finnish women would have had no further advance after 1987, the year in which they achieved survival levels foreseen for 2020

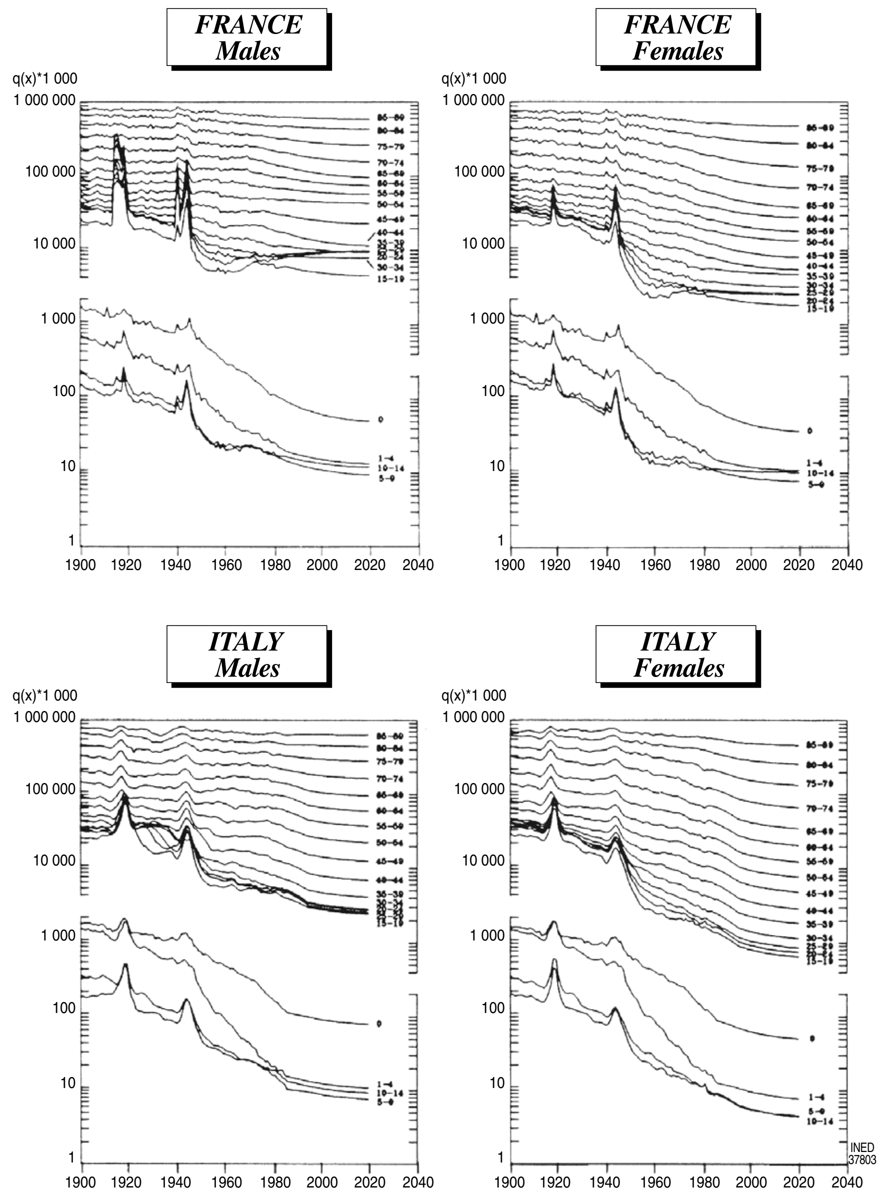

FIGURE 75–7 Changes in mortality rates for different age-groups, observed and forecast, from 1900–2020 in France and Italy.

(79 years), which was easily surpassed by 1999 with an 81-year life expectancy. Likewise, Swedish women were forecast to achieve a life expectancy of 78.9 by 2020; by 1999 they had achieved 81.9. Generally speaking, Table 75–1 shows that for most countries, the figures forecast for the year 2020 were already either reached or surpassed for both sexes by 1999.

In recent years forecasts of future European mortality levels across all ages have become more optimistic. This is the trend referred to by national statistics bureaus in their most recent estimations, such that they now proclaim a much higher life expectancy than was previously the case (Table 75–1), beginning in the 1980s and prolonging mortality trends observed in 1980s and 1990s. At a quick glance, there is about a 3-year difference in forecasted life expectancy to the year 2020 when using more current baseline data than when data from before the 1980s only is considered. The widest gap between both estimates is in Sweden, with a difference of 6.5 years for men and 5 years for women.

CONCLUSIONS: FACT OR FICTION?

At this stage it is impossible to say whether Eurostat forecasts for 2020 will in fact become a reality or whether, as in the past, they will be unable to capture latent trends that will emerge over the next few years. An approach that makes use of cause-specific mortality may be able to yield more satisfactory results because it uses more dynamic indicators. On the other hand, such an approach can generate quite volatile outcomes, as is seen in Fig. 75–2 for English males. In the early 1980s, Bernard Benjamin and Elizabeth Overton (1985) made forecasts for England and Wales, taking into account trends in mortality for eight major causes of death, which were much more optimistic than those contained in Table 75–1. They estimated a life expectancy of 81.3 and 87.1 years for males and females, respectively, for the year 2017, 3 and 4 years higher than foreseen in the 1990s for 2020.

The life expectancy values forecast by extrapolating the changes in cause-specific mortality might appear too high were it not for the comparable results obtained by Ward Kingkade (1994), who has calculated the lowest mortality figures ever observed in the developed countries in his life tables corresponding to the mortality rates based on age and major groups of causes of death. This table, although purely theoretical, has the characteristic of being based on the minimum values observed in practice of 81.6 years for men and 87.2 years for women, figures that come astonishingly close to those obtained for England and Wales by projecting recent trends in the mortality rate disaggregated by cause of death.

By altering the controlling hypothesis, forecasted results may be completely changed. Only the future can tell which will be the most accurate. Thus, no assumption should be taken lightly: even clear and well-established trends can change, as they did in the developed world in the 1980s. Experience has shown the arbitrariness of preimposing limits to mortality trends, so perhaps we should begin to seriously consider the hypothesis that in the long term the only acceptable limit is that mortality will all but disappear until the end stage of the life course, resulting in a full rectangularization of the survival curve. Nor should this goal be seen as too distant on the horizon as far as developing countries are concerned.

Many experts suggest that the hypothesized rectangularization of the mortality curve for the wealthier nations may be accompanied by even greater longevity at the tail-end of the human life cycle (Vaupel *et al*., 1979, 1998; Duchene and Wunsch, 1994; Valkonen, 1994; Caselli and Vallin, 2001a,b). These aspects of human survival are covered in Chapter 21 (Volume I); Chapter 78 covers long-term future trends. For the time being, the question belongs to the realm of fantasy and not of forecasting. At this stage it would be advisable for demographers to begin a discussion with colleagues in other fields, particularly biologists and epidemiologists, so as to reach a better understanding of extremely complex processes that could be increasingly influenced by new discoveries in the field of biogenetics (Walford, 1984; Fries, 1989; Dulbecco, 1995; Vaupel *et al*., 1998).

Hypotheses for Migration Projections

ODO BARSOTTI AND ALBERTO BONAGUIDI

Dipartimento di Statistica e Matematica applicata all' Economia, Università degli Studi di Pisa, Pisa, Italy

INTRODUCTION: CAUSAL MECHANISMS, FORECASTING METHODS, MIGRATION

Demographic forecasts have been developed primarily through the search for regularities in previous trends and improvement in the quality of available data.

"Demographic forecasting is seen as the search for functions of population that are constant through time, or about which fluctuations are random or small," wrote Nathan Keyfitz (1972: 347). It is in fact an approach that is essentially "guided by the data" (Willekens, 1991). Even the impetus to improve the corpus of methods and models adapted to the work of forecasting was provided by the need to make the best possible use of past trends in order to forecast the future.

It has nevertheless been proved that the growing quantity of available data and the increasing effectiveness of analytical tools have hardly improved on the quality of population projections, and their precision depends more on a real understanding of demographic behavior than on the sophistication of the methods used (Keilman, 1990). Forecast quality can only be improved if we increase our ability to define the causal factors and the processes that determine the level, the sequence, and the timing of demographic events, and we improve our understanding of the mechanisms of the determining factors of observed population dynamics (Willekens, 1990, 1991).

After considering the manner in which knowledge can improve demographic forecasting, Nathan Keyfitz (1982) concluded that research on population tends above all to show conditioned causal associations (if . . . , so . . . , all other things being equal), which are useful in understanding the past but inadequate for making forecasts. Such associations are necessarily based on partial theories, namely, theories that explain one or several of the associations that make up the whole system that determines population dynamics. If, to improve forecast quality, we were to move from forecasts based on data trends to those based on causal processes, demographic research should progress from quantitative associations between variables to the causal mechanisms that produce these associations. Research of this type implies that demographic events that occur at different periods are linked as much with the characteristics of the social context, with the successive phases of the development process of which these events are a part, as with the individual characteristics of those experiencing them.

The new generation of population projection models should show explicitly how contextual changes (socioeconomic, cultural, technological, and legal) are mediated by the characteristics of the process at the microlevel (individual and family). All this calls greater attention to life cycle transitions and the influence of exogenous factors on these transitions. In other words, an association between the most advanced conceptual framework of demographic analysis (i.e., the age-period-cohort approach), and the dynamic behavioral theories should be established. The shift in the focus from observed data and trends toward subjacent processes constitutes a considerable challenge. "The data we have traditionally been working with may prove to be inadequate and the models need to be revised or need to be developed anew. The real challenge is to develop simulation and forecasting models that are based on theories which reveal the casual mechanisms determining human behavior and which explain demographic change in terms of these mechanisms" (Willekens, 1991).

The search for subjacent processes is far more complicated for migration than for natural events, as migration is more sensitive than are fertility and mortality to the variations, even in the short term, of economic, social, and political variables. Furthermore, migratory phenomena interact more directly with the same phenomena that influence them. In reality, migration is by nature closer to a *process* than to a simple event, such as a birth or a death. This obviously results in it being less foreseeable. The difficulty in forecasting migration results fundamentally from the limits and the uncertainty of our theoretical knowledge of the complexity of the factors affecting the phenomenon and its manifestations. Beyond this uncertainty of the concepts and nature of the data is the added complication of the *instrumental* character that surrounds the migratory event, different to other events in the life cycle.

These difficulties concern internal migration as much as international migration, but there are particularities in each case that lead us to discuss the two phenomena separately.

I. INTERNAL MIGRATION FORECASTS

1. Problems

The difficulties in formulating hypotheses on the evolution of internal migratory movements stem from the fact that the propensity to migrate from one geographic area to another depends on a complex set of variables acting and interacting at the macrolevel—such as the general economic and social conditions of the country, characteristics specific to the departure zone and to the destination zone (labor market, housing market, quality of the environment)—and on the microlevel, such as the individual characteristics of the potential migrants and the current phase of their personal and family life cycle (see Chapters 59, 60 of Volume II). Formulating a hypothesis by taking into consideration the different aspects of the variables involved (or at least a considerable number of them) and their interrelations requires the reorientation and investigation of the concepts on which forecasting migratory processes is based.

However, at the present, we are too far from an ideal theory of migration—that is, a series of logically arranged concepts that can explain the entire constellation of the migration phenomena at different scales—to be able to account for past and present trends and forecast the future. We have to be satisfied with many partial theories that give preference, according to the case, to a particular approach to the phenomenon: a historical or economic approach, a sociological or psychological approach, a macro approach that gives priority to explanations by variables acting at an aggregate level, or the micro approach that associates individuals' migratory behavior with their personal characteristics, their past experiences, and their expectations for the future.

The current theoretical corpus on migration owes much to the pioneering work of Edward Ravenstein (1885), who greatly influenced subsequent theoretical approaches with his *laws* (see Chapter 59 of Volume II). The most important law is the one inspired by a well-known law of physics, according to which the number of persons moving between two geographic areas is directly proportional to the size of the population in the departure and destination zones and inversely proportional to the distance between them. Another fundamental contribution to the study of internal migration comes from the more recent work of Everett S. Lee (1966), who provided an interpretation method in which four categories of factors intervene: factors associated with the departure zone, factors associated with the destination zone, obstacles to movement, and personal characteristics (e.g., age, sex, level of education) of potential migrants.

Another very important contribution was made by Wilbur Zelinsky's *mobility transition* theory (1971), according to which the migratory phenomenon is situated in a perspective of historical evolution. According to this theory, during the most advanced phase of economic and social development, traditional rural to urban mobility gives way to other forms of mobility, such as interurban and intraurban migration, which become the most important components in the process of population distribution.

The micro point of view transfers the focus on to the individual and the reasons that incited him/her to migrate (e.g., improvement in economic and social conditions, construction of family ties, the search for a certain lifestyle). According to Larry A. Sjaastad's *human capital* theory (1962), the decision to migrate is taken when the current value of the gain expected in the destination zone, less the costs (financial and psychological) of migrating, exceeds the net gain of staying in the zone of origin. The instrumental nature of migration implies that the decision whether or not to migrate is conditioned by other decisions through which the individual attempts to satisfy all of his/her aspirations. Migratory behavior is the outcome of a decision-making process comprising various phases, during which all of the consequences of the decision are evaluated. Gordon De Jong and James Fawcett's "value-expectancy model" (1981) proposes a conceptual model for studying the reasons for migrating and the decision to migrate. This approach is even more useful when it is considered from a dynamic perspective, that is, when it is linked to the context in which the individual lives (Willekens, 1985).

To illustrate the complex interweave of variables on which migratory behavior depends, we can refer to the phenomena of context (the coexistence of significant surpluses in the supply and demand of work in different regions of the same country), which, considered in isolation, could be deemed key determinants of large internal migratory movements but, which under the influence of other factors (increase in family income available through public transfers, role of the family in estimating guarantees, cost of moving in to new accommodation) and the social and cultural characteristics of the new generations (increase in level of education, refusal of migration as a solution to employment problems), may not determine any of these internal movements that, in a partial vision, would have been considered inevitable.

The main limitation to formulating hypotheses on internal migration is owing to the impossibility of defining all the variables which affect this phenomenon. The variables most often considered in selecting hypotheses for the future evolution of internal migration are, as we know, the differential growth between sections of population of working age, territorial imbalances in the supply and demand of work, industrial implantation policies, development of infrastructure and services, and the consequences of past movements. These are undoubtedly extremely important factors, yet they only represent a partial vision of a far more complex system of interaction.

Moreover, the instrumentation of migration in relation to other key life events, such as marriage, entry into the labor market, and the birth of a child, has obvious consequences on their future evolution. Therefore, forecasts made without reference to other life events may go against the existing relations between migration and the life cycle. There are phases in life when the propensity to migrate is greater than in others. These phases are precisely those during which other important choices are made (e.g., to work, get married, have a child). The changes occurring in the development of the life cycle that are translated by postponement or prescheduling of the most important milestones in life (e.g., completion of education, finding work, marriage, birth of a child) undoubtedly affect migration projects.

Among the specific problems that forecasting internal migration poses with regard to the two other components of population dynamics (mortality and fertility) is that of definition and measurement. Migration is generally considered as the transfer of the place of residence from one administrative unit to another. This reference to crossing administrative borders introduces the spatial dimension of the migratory phenomenon, which in itself constitutes an extra element of complication. It is then duplicated by a supplementary problem: the occurrence of the event depends strictly on the administrative division of the territory.

The second large problem is that of measurement. The migratory event can, as we know (see Chapter 13 of Volume I), be directly observed through the data in population registers (registration and removal of individuals on population registers), or indirectly by comparing the place of residence observed at two different dates during surveys or censuses. In this latter case, the period of time between the two dates is generally fixed (often 1, 5, or 10 years). The first source, called *anagraphic*, collects data on the migratory *event*; the second, called *censitary*, records the migrants *status* and not the migratory event. For the second source, the difference between migration and migrants is negligible only if the time lapse is short. The two sources obviously need to be processed differently. Contrary to appearances, the anagraphic source is not necessarily more accurate than is the censitary source: a migratory event only becomes such once the new place of residence has been declared, but this declaration can naturally be made with a more or less significant delay; conversely, some declarations can be purely fictitious.

2. Methods

The methods for forecasting internal migration vary according to how the three fundamental characteristics are considered: level (number of migrations during a given period of time), calendar (distribution of the migrations in the interval), and direction (departure and destination zones) (Willekens, 1990). If the interval is defined in terms of calendar years, by *period*, the *cross-sectional* approach is adopted, as is the case in most forecasting models. If, on the contrary, the interval is defined in terms of years of life, by *cohort*, the *longitudinal* approach is adopted. The forecasting methods that take the relation between the migratory event and other life events into consideration are naturally situated in a longitudinal perspective. The age variations in the propensity to migrate can be modeled on profiles, which have proved to be relatively stable in time and space. This applies to the *migration schedule model* (a mathematical model that linearly combines double-exponential functions), the parameters of which are useful for description and for interpretation and forecast (Rogers and Castro, 1981). In Great Britain, for example, this model was widely used for the projection of internal migration between localities (Bates and Bracken, 1987). In the Netherlands, it is an integral part of the mltiregional demographic analysis (MUDEA) model that was adopted for subnational population projections. However, this model complicates the formulation of hypotheses of the evolution in the relation between migration and age, as specific demographic significance cannot be attributed to its parameters.

Forecast methods also change according to the way in which the *direction* of the flows are treated. Whereas traditional methods were mostly based on *net balance*, the most recent studies more frequently consider the *flows*, thus distinguishing the direction of migration from the departure zone to the destination. Indeed, it is only in the case of flows that the issue of causation makes any sense (the balances have no direct cause). The flows are determined by behavior, and it is on these that the formulation of evolution hypotheses should be based. The systems of flows are the basis for multiregional models for forecasting by cohort, which have greatly reformed national and regional population projection methods. To make population projections, one can also usefully resort to methods that express, in terms of the parameters of log-linear models, the system of internal flows by geographic zone (region) of origin and destination (e.g., in the recent projections of the National Institute of Statistics [ISTAT]). These methods enable a reduction in the complexity of the data and an indirect estimation of the missing data.

The extrapolation of historical series as a projection method of the origin-destination flow system is hardly used owing to the limited availability of historical data and the complexity of the data. However, the original and interesting method of treating and projecting historical series proposed by Frans Willekens and Nazli Baydar (1986) should be mentioned. This method has several phases. First of all, the internal flow system is separated into three distinct components: a *level* component (total number of internal migrations), a *sending* component (the proportion of a given zone within the total emigration flow), and a *distribution* component (the proportion of emigration from the zone for each of the destinations). Each of these components is weighed and then subjected to an exploratory analysis with a view to locating constants and irregularities in the data structure. The structure is described by using a generalized linear model, which enables the parameters dependent on time, that is, the variable components of the migratory system, to be identified and then extrapolated.

For projecting the spatial dimension of internal migrations, it is also possible to resort to explanatory models, notably spatial interaction models or gravitational models. The most modern version of these models was formulated by William Alonso (1978) in his general mobility theory. Alonso's model has proved to be very useful in studying internal migration and has also shown its validity for forecasting the origin-destination flow system (Ledent, 1986).

II. INTERNATIONAL MIGRATION FORECASTS

1. Problems

In (national) population projections, international migration is generally treated as a subsidiary of fertility and mortality. The reasons given for this are as follows:

1. Low intensity of the phenomenon in many cases—"For most countries, the volumes of immigration and emigration are either too small, or the balance of the two (net migration) is too insignificant to justify separate treatment." (George and Perreault, 1992: 87).
2. Inadequacy and paucity of data that are difficult to compare owing to the nature, the plurality, and the heterogeneity of the sources used: "The administrative nature of the data sources used is the factor largely responsible for the lack of international comparability." (United Nations, 1998: 6).
3. Uncertainty in the definition of an international migrant: "The slow progress made in enhancing comparability coupled with a worldwide trend toward the stricter regulation of international migration and the expansion of migrant categories considered policy-relevant suggests that a new approach must be taken. International comparability may be enhanced by recognizing that, from the policy perspective, there is a set of migrant categories that can be distinguished statistically on the basis of administrative sources because they are subject to distinct treatment in terms of admission and residence rights." (United Nations, 1998: 6).
4. Low foreseeability of flows that are more affected by the economic, social, and political situation: "Recent immigration trends in Western Europe clearly demonstrate the volatility of migration trends. During the

early 1970s West Germany had an annual net migration gain of more than 300,000; 5 years later this number had declined to only 6,000 and 3,000 during the early 1980s. During 1985–1989, however, the annual net gain increased sharply to 378,000, 100 times that of the previous period. Few other countries have these extreme fluctuations, but the traditional immigration countries (USA, Canada, and Australia) show remarkable ups and downs." (Lutz *et al*., 1996: 369).

5. Difficulty in formulating hypotheses on the future dynamic of international migration as a result of the profound changes in its nature: "International migration therefore concerns nearly all the countries of the world, and recent changes have overturned the traditional classifications between countries of emigration and countries of immigration . . . In a parallel direction with the globalisation of the international movement of people . . . we are also observing a multiplication in the different forms of migration."[1] (Guengant, 1996: 110).

Whatever the reasons leading to minimizing the issue of international migration in population projections, the most recent developments in demographic analysis have, on the contrary, clearly highlighted its importance:

1. The number of international migrants and refugees is currently estimated at approximately 120 or 130 million, and the phenomenon has increased considerably over the course of the past 30 years, as the estimated number at the beginning of the 1960s was 70 million (Guengant 1996: 107–108). In the 1985–1990 period, the net rate of international immigration of the most developed regions increased to 1.6 per thousand, which was equivalent to more than a quarter of population growth (6 per thousand). In the 1990–1995 period, it increased to 1.8 per thousand, or 45% of population growth which itself had fallen to 4 per thousand (United Nations, 1998: 14).

2. The significance of the phenomenon in the industrial countries is reinforced by the idea that it could thwart the effect of fertility decline (often well below the replacement level) on the size and composition of the native population and labor force.

3. The influence of migration on the social, ethnic, and cultural structures of the receiving countries has been increasing (George and Perreault, 1992).

4. Through the services, material or intangible, that migrants render to their country of origin, international migration plays an important role in the development process of a growing number of countries that export manpower: "At the macrolevel, remittances are usually a major source of foreign exchange earnings for countries of origin and, in some cases, contribute a sizeable share of GDP. For the world as a whole, the level of remittances estimated on the basis of data compiled by the International Monetary Fund (IMF) rose from US$ 43 billion in 1980 to US$ 71 billion in 1990 (Russel, 1992). In 1989, the estimated remittances amounted to US$ 61 billion worldwide, a figure that compares favourably with the US$ 47 billion provided as official development assistance by Organisation for Economic Cooperation and Development (OECD) member States to developing countries that year (Russel, 1992; IOM, 1994)." (United Nations, 1998: 154–155).

The total integration of the international migration component in projection work is naturally confronted by problems of uncertainty in definition, heterogeneous data sources, erratic movements, and, consequentially, the above-mentioned phenomena that are difficult to foresee.

These problems are even more acute for international migration, but even for internal migration, the fundamental issue that needs to be resolved in order to make reasonable hypotheses on their future evolution remains the comprehension of its causal determinants.

Various theories have been proposed to explain why international migration occurs and how migratory flows grow with time and spread into space. Each of them tries to explain the same thing, although through concepts, hypotheses, and analytical frameworks that are often radically different. The various interpretations are not necessarily contradictory, but their results are only partial and considerably influenced by the angle of approach adopted (economic, sociological, political, systemic) and the method used (micro, macro) (Massey *et al*., 1993: 432; United Nations, 1998: 141–147).

Their complexity and their multiform nature require, on the contrary, "A sophisticated theory that incorporates a variety of perspectives, levels, and assumptions. . . . We are skeptical about both atomistic theories that deny the importance of structural constraints on individual decisions, and of structural theories that deny agency to individuals and families." (Massey *et al*., 1993: 432, 455).

If we look closely, the theory on which research for an explanation of international migration is based is

[1] "Les migrations internationales concernent donc désormais la quasi totalité des pays du monde, et les évolutions récentes bouleversent les classifications traditionnelles entre pays d'émigration et pays d'immigration. . . . Parallèlement à la globalisation des mouvements internationaux des personnes . . . on assiste également à la multiplication des formes de migrations."

not substantially different from that which explains internal migration. The explanatory variables are essentially the same; even if some of them, notably demographic, political, and geopolitical variables, have a more important role in international migration. Contrary to internal migration, international migration is not always a voluntary choice; it can even be forced or can constitute a way of fleeing from political persecution, ethnic conflict, serious environmental crises, or intolerable poverty.

The macrostructural factors responsible for international migratory pressure are numerous and interconnected: economic imbalances, demographic and social imbalances, political crises, ethnic conflicts, ecological deterioration, revolution of the communications system, standardization trends in the content and structure of education systems in countries with different levels of development, increasing levels of education, and inappropriate development strategies and policies, often resulting in privileges for tiny social categories. Macrostructural attraction factors also have an important role to play in the migratory choice of the potential migrant: a request from the most industrialized countries for workers to immigrate, varying degrees of accessibility, the degree of permeability of borders, the stringency of controls and rigidity in expelling irregular or illegal immigrants, and the development of formal or informal reception and support networks (Stahl, 1995).

The problem then becomes more complicated because it is not sufficient to try to interpret current events only, but future trends must also be explored. We should, in fact, try to imagine the specific weight of each structural push and pull factor; if and how the interaction between these factors can be modified; the effect they will have on migratory pressure; and how, through the mediation of individual and family factors, they could be interpreted as a migratory option and, consequently, as a flow.

2. Methods

The paucity of data, the uncertainty of definitions, and the complexity of the phenomenon that makes the simplification in one global explanatory model difficult have generally impeded the formulation of hypotheses on the future of international migration based on sophisticated models and extrapolation techniques. The aforementioned work of M. V. George and Jeanine Perreault (1992: 99) illustrates the results of a survey carried out in 30 industrial countries that show that nearly all the developed countries apply rather simple methods to measure and extrapolate external migration: the vast majority of countries assume that future migrations will occur at the same level as previous ones, unless they believe that the level will be zero. Nevertheless, the two authors draw attention to the need for a general framework of analysis and interpretation of international migration, as a result of the scale of the problems raised by the phenomenon at different levels of public action (national, regional, local).

The estimation of future international migratory movements should take the following events into consideration: (1) the past evolution of the phenomenon and current trends, (2) the migratory policies in the host country and the country of origin, and (3) the push and pull factors that determine migratory pressure and the propensity to migrate (Oberg, 1996; Zlotnik, 1999).

There are three fundamental types of error in population forecasts (Lutz *et al*., 1996: 35). The same types of error, considerably accentuated, also apply to international migration:

1. *Measurement errors*—As we have already stated, basic data on international migration are by their very nature uncertain (much more so than data on births and deaths and more than internal migration data), and the category of international migrants, for which in practice these forecasts are made, often only consists of the most visible component made up of the migrants authorized to stay for a prolonged period or permanently in the host country (on the contrary, temporary, clandestine, and illegal migrants are excluded, even though usually, a wider definition of migrants is theoretically used) (Oberg, 1996: 339).
2. *Trend misevaluation*—International migration is characterized by great fluidity and considerable fluctuation from one year to another, much more so than other demographic events; the extrapolation of past trends can therefore lead to erroneous predictions of future changes.
3. *Unexpected events*—Each event, such as a particularly severe and prolonged food shortage, the explosion of war, the blaze of ethnic conflicts, or a drastic change in migratory policies in the host or departure countries, can provoke severe changes in trends and therefore cause the extrapolated image of the future to be inconsistent.

In Europe, various international organizations have endeavored to fill the gaps in the information on the scale and volume of migratory flows. The primary objective is to harmonize the data sources; to reexamine the practical concepts, definitions, and measurements used in order to improve the comparability of migration statistics; and to assemble into one international database the data collected in each country (EUROSTAT, 1992, quoted by Willekens, 1994: 20).

All this, with the utilization of techniques that are increasingly capable of combining data sources, and the use of increasingly sophisticated forecasting models, should make it possible to reduce the first two types of error (measurement and trend evaluation) that international migration is subject to.

But although these improvements are important, they only slightly affect the third type of error, which concerns unexpected events. To reduce this type of error, it may be useful to exploit a source of information that has remained in the shadows for a long time: that which is constituted by the various experts and practitioners who for various reasons work directly or indirectly on the issue of international migration and who for years have been observing and interpreting the flows and study national migratory policies. Their judgment, opinions, and intuitions can capture signals of changes and can foresee transformations in behavior and models that are difficult to record objectively, and therefore provide a more concrete view of reality than that which statistical measurements can supply (Willekens, 1994: 25).

The estimation of future international migration, based on this type of expertise, has benefited from the development of new techniques and projection methods, in a probabilistic approach.

One of these methods was used by International Institute for Applied Systems Analysis (IIASA) (Lutz, 1996) to calculate world projections (see Chapter 77). The approach (by scenario), based on hypotheses proposed by experts, enables hypotheses on the effect of unexpected events to be made and seems to be the best method of evaluating the influence of structural changes on the dynamics of demographic parameters, taking into account the uncertainty caused by random factors. The opinion of experts can indeed be based on recent experiences that incite them to investigate unexpected but possible alternative trends and allows them to be converted to parametrically specific hypotheses (Lutz *et al*., 1996: 37).

The predictive distribution of probabilities is entirely based on the subjective opinions of the practitioners, opinions that are rooted in their understanding of past trends; their knowledge of the determinants of fertility, mortality, and migration; and the ability of these experts to imagine potential future changes at the level of the determinants themselves. By combining the subjective distribution of probabilities of a sufficient number of experts, an aggregate predictive distribution of probabilities can be obtained, which makes it possible to produce reliable confidence intervals for estimating demographic parameters (Lutz *et al*., 1996: 37).

In the area of migration, a matrix of interregional migratory flows (the world having been divided into 13 regions defined on the basis of geographic proximity and socioeconomic criteria) was constructed based on practitioners' opinions. Three levels of annual net migratory balance were identified (high, low, and intermediate), and it is presumed that the distribution is normal and that 90% of the cases are situated between the high and low levels. To determine the age distribution of migrants, age-specific rate profiles of Rogers and Castro's migratory model were used (Lutz *et al*., 1996). With this type of method, an evaluation of the degree of uncertainty of the estimated demographic parameters can thus be obtained, taking into account the possibility of unexpected events.

CONCLUSIONS

The main conclusion of this short review of possible hypotheses for migration projections is doubtless that the conceptual device developed to study internal migrations can be used for international migration. Moreover, this is an argument that has for a long time been supported by migration specialists and that appears increasingly realistic today. On the one hand, local factors that are at the root of internal migration are increasingly influenced by the international and even global context; on the other hand, local factors themselves have more and more influence beyond national borders.

Finally, the distinction between internal and international migration has less and less meaning; both forms of migration are now expressions of phenomena governed by the same logic. The remaining differences, which mainly relate to the greater influence of political and geopolitical factors on international migration and which naturally should be taken into consideration in formulating evolution hypotheses, are not of a nature to justify treating them separately.

In contrast, international migration has characteristics that reflect, above all, the action of regional factors. First, more so than between countries, migratory flows are formed between a given region of a departure country and a given region of a host country. Second, foreign immigrants are concentrated in certain specific geographic zones of the host countries. Third, international migration supplies internal migration, either because foreign immigrants substitute locals in the labor market or because their presence incites certain elements of the local population to migrate as they refuse to reside in close contact with the foreign immigrants.

All these characteristics of international migratory movements increasingly reinforce the hypothesis according to which this form of mobility can be taken to the same conceptual scheme as internal migration. Ultimately, in a context such as Europe on the path to integration, the disappearance of national borders even causes the idea of international migration being distinct from internal migration to disappear.

The United Nations' World Population Projections

JACQUES VALLIN AND GRAZIELLA CASELLI

Institut national d'études demographiques (INED), Paris, France

Dipartimento di Science Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

INTRODUCTION

According to Thomas Frejka (1981), the first attempt at projection of the world's population dates more than 300 years ago, when Gregory King (1695, 1973), drawing on William Petty's (1682) political arithmetic at the end of the 17th century, forecasted that the total world population, which he estimated at 630 million in 1695, would reach 780 million in 2050. However, the question was of little interest to the scientific community at the time. In fact, Gregory King's manuscript, which was published for the first time in 1973, was largely ignored by his contemporaries as it did not provoke any debate or critique. Yet the questions asked by both William Petty and Gregory King are recurrent ones: How many men can the world feed, and when will humanity reach its sustainable limit?

William Petty wrote: "The present 320 millions . . . will within the next 2000 years . . . increase . . . to give one head for every 2 acres of land in the habitable part of the earth" and will then "exceed . . . 20,000 millions" (Petty, 1682:19).[1] Gregory King, for his part, calculated that "If fully peopled, [the World] would sustain 6,257,000,000 which is 10 times the number of people now in being, and it is not possible to maintain more than double that number or 20 times more than the number of people now in being . . . and if it were possible to sustain 20 times the number of people now in being, it could not increase to that number till about the year of Christ 10,000, which is above 8,000 years to come." (King, 1973:2).

Although the debate concerning the nature of population growth has always been of interest to the scientific community, especially from the end of the 18th century, we know of no other attempt at a world population projection until the 1920s, when the issue returned to the forefront. In 1924, Edward East, a geneticist of vegetables who converted to the social sciences, declared that having made a thorough study, he was able to conclude that "A reasonable maximum for the world's future population is one person for each 2.5 acres on 40% of the land area of the globe. This gives a figure of 5.200 million, a population which at the present rate of increase would be reached in just a little over a century." (East, (1924) 1977:69). In fact, as Thomas Frejka mentions, Edward East used George Knibbs' estimate of a doubling of the population every 80 years, a doubling that would lead rapidly to intolerable population numbers: 3.9 billion in 2008, 7.8 billion in 2089, 15.6 billion in 2169, 31.2 billion in 2250, and 62.4 billion in 2330. According to George Knibbs (1928), at this rate, the sustainable limit would be reached before the end of the 21st century. However, these population projections were based, as was Gregory King's, on the rough application of a

[1] Although Gregory King used William Petty's work as a basis, he significantly revised the world population estimates upward at the end of the 17th century, as he calculated that this figure was twice the size William Petty had thought.

doubling rate; as a result, they were rather anachronistic and far removed from the numbers one would expect to find with a modern demographic approach that had been enlightened by considerations of carrying capacity.

Raymond Pearl attempted to improve on East's projection by applying a logistic model that was used widely in zoology. This method took into consideration the initial size and carrying capacity according to production methods and consumption at the time, population increases at a variable rate, and that fact that the population tends to stabilize as the maximum is approached. In 1924 Pearl calculated a curve that, according to him, made a world population projection possible. This study was later revised in collaboration with Sophia Gould (1928). Of course, such an approach depends entirely on the supposed compliance between the logistic curve and the population limit imposed by the carrying capacity. Although this compliance is verifiable at some point, it changes with time, and as the Pearl himself suggests, the projection should be revised with each significant change in the relation between the carrying capacity and the available technological resources.

The modern era of world population projections actually began with the League of Nations' belated initiative, which was picked up and developed by the United Nations (UN) after World War II.

In 1941, the League of Nations asked Princeton University's *Population Research Office* to undertake a broad analysis of demographic trends and world population problems, and it was through this program that a first volume on Europe and the Soviet Union (Notestein *et al.* 1944) was published in 1944. Even though this first volume does not give a world population projection in the strictest sense, it does reveal all the ingredients that Frank Notestein (1945) then used to form the basis that would later result in the UN projections: as reliable a database as possible, a summation of independently obtained data for each country or region, and national and regional projections calculated according to what is generally known as the "component method" (see Chapter 72). As Thomas Frejka (1981) wrote, "The actual size of the world population in the year 2000 will—absent catastrophe—certainly be much larger than the then projected 3.3 billions, but the ideas, approach and methods Notestein applied provided a valuable base for a generation of world projections to follow." (Frejka, 1981:512).

Indeed, since the beginning of the 1950s, the UN's Population Division has regularly published world population projections based on the principles proposed by Frank Notestein. The endpoint of the recent projections[2] (UN, 2001) is no longer the year 2000, which is now the starting year, but 2050. World population growth should continue and result in an increase from the 6.06 billion reached in 2000 to 9.32 billion in the middle of the 21st century if the medium-scenario hypotheses are confirmed.

The results of this projection are presented in this chapter. We will then see—by analyzing their development and the underlying hypotheses and raw data—if the history of the UN projections teaches us anything about their plausibility and reliability. We will also compare the results obtained by the UN with those of other projections developed at the same time, either by independent researchers or by rival institutions. Finally, we will briefly discuss the possible repercussions of these world projections in terms of specific categories, such as large age groups or urban and rural populations.

We conclude that the endpoint (2050) of the UN regular projections is too soon to supply a correct projection if all the variables (e.g., demographic transition) are to be taken into account. Because of this problem, and notably following the work of Thomas Frejka, at the end of the 1970s the UN published longer-term projections that forecasted as far ahead as 2100 and even 2150.

I. BETWEEN 8 AND 11 BILLION IN 2050?

The aforementioned figure of 9.32 billion for 2050 is the result of the medium hypothesis in the last UN projection. This is accompanied by other scenarios and is bound by low and a high hypotheses of 7.9 and 10.9 billion, respectively, at the same date.

1. Source Data

One of the most difficult tasks of the UN experts in charge of population projections is assembling, evaluating, and sometimes even completing the necessary source data. This task is also one of the most decisive elements for the projection's credibility, at least in the short and medium term. Ideally, it consists of an

[2] Since this chapter was written (autumn 2002), the United Nations' Population Division has produced a new version (United Nations, 2003b,c,d). However, it seemed futile to delay the publication of this volume in order to update the chapters on the basis of this new version. The only major innovation of this new version is that it includes a hypothesis of an extension in fertility decline under the replacement level in certain developing countries. Nevertheless, the resulting global difference does not in any way affect the reasoning of this chapter.

accurate estimate of population by age on the January 1 of the starting year (in this case, January 1, 2000), as well as a comprehensive estimate of the trends in mortality, fertility, and migration by age observed during the previous decades. The former obviously constitutes the starting point for the projections, and the latter enables the formulation of hypotheses on the future evolution of mortality, fertility, and migration. In reality, the first is often lacking, except in countries that regularly produce annual population estimates by age and sex based on reliable observations. More often than not, notably in the least developed countries, the most recent population estimates date from the last census, which may sometimes precede the starting date of the projection by several years. In such cases, recent mortality, fertility, and migration estimates are crucial to estimate the initial population.

These are all the data that the UN Population Division strove to systematically collect for the 2000 projections, as it did for all the preceding projections, for each country or at least for the 187 countries and territories (out of 228) with a population over a certain level (140,000 inhabitants for the last projection). Below this level the benefits of a projection using the component method are low because of the risks affecting age-specific rates.

The source data collected in this manner are of variable quality and accuracy in different countries. For example, when the initial population is estimated, nearly all the developed countries have not only a recent census but often a good estimate of population by age at January 1, 2000. On the contrary, very few developing countries have such estimates and a recent census or the necessary fertility, mortality, and migration estimates to produce one. Only 135 of the 173 developing countries held a census during the 1990s.

Whether it is a question of the retrospective data used to make hypotheses of future developments (traditionally, the UN endeavors to retrace the trends since 1950) or the more recent data necessary to evaluate the population at January 1, 2000, the fertility, mortality, and migration estimates are subject to even greater disparity. Since 1950, the developed countries often have nearly complete series of age-specific mortality and fertility rates since 1950. However, there are significant gaps in migration data. As for developing countries, a significant number of them still have only fragmented recent data, which is often crucial to consolidate the starting point, As an example, only 63% of Africa's population lives in countries that have an evaluation of fertility by age for 1995–1999. Yet this score should be considered a valuable asset compared with the one observed for infant and child mortality (57%) and particularly for adult mortality (11%). In this latter case, the total lack of information is the lot of the majority of the African population (73%). The situation is better in Asia and Latin America, where the majority of the population resides in countries that have recent information on fertility. Knowledge of infant mortality is much more widespread in Latin America than in Africa (but not in Asia), and there is more information in Asia than in Latin America for adult mortality (UN, 2002).

Hardly any country supplies data by age and sex on migration entries and departures. The best that one can expect, with some very rare exceptions, is an estimate of net migration. In many cases, one must be satisfied with often not very recent net migration data obtained by subtraction of the natural balance from growth between censuses.

Added to these gaps is that the estimates available are not always exempt from major errors, as internal and external consistency analyses show. Preliminary analysis and reconstruction work is therefore essential as much for constituting the basis of the projections as for helping with reflection on hypotheses of the trend factors in population change.

After half a century of experience and the remarkable progress of national and international statistical institutions, the UN Population Division now produces a demographic database by country for the 1950–2000 period, which, although far from perfect, has the unique advantage of being exhaustive and comparable. This prerequisite in the production of world population projections is in itself a very valuable tool in the comparative analysis of past global trends, provided that we do not lose sight of the heterogeneity of the quality of the estimates behind it.

2. Method

The projection method used by the UN has hardly changed since the 1950s. It is based on the dual principle already recognized as essential by Frank Notestein: an independent study of each country (or, if this is not possible, of each region) and the use of the component method by cohort (using an age structure at the start and projections of fertility, mortality, and migration by age). In fact, as we have just stated, countries with less than 140,000 inhabitants are not subject to the second principle, as the conjunction of errors related to small numbers with the paucity of essential information may make this refinement counter-productive. In these cases, rough projections based on no less rudimentary hypotheses of the trend in the global growth rate are the best that can be done and certainly do not affect the world projection.

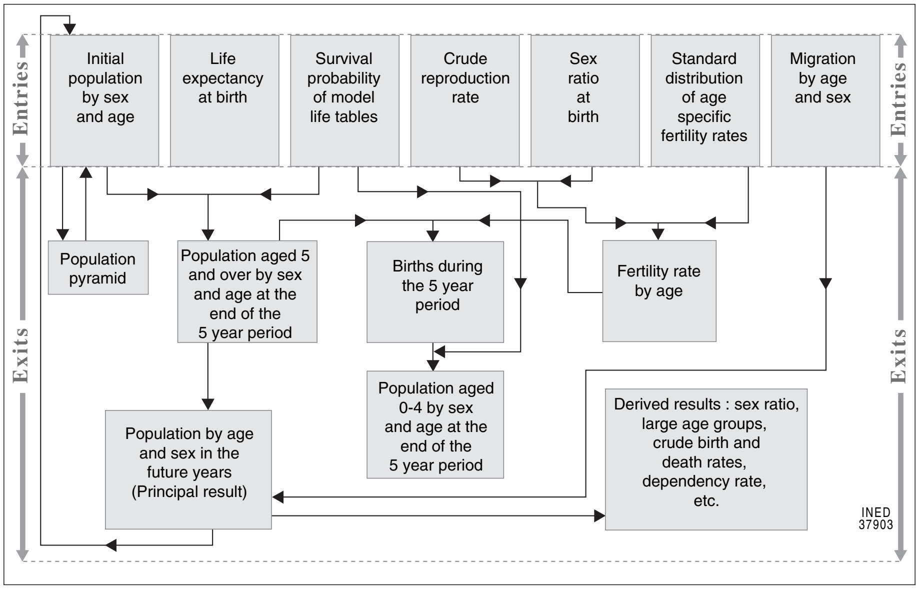

FIGURE 77–1 Major stages of the United Nations' projection for the countries where the mortality and fertility hypotheses are formulated in terms of age-adjusted indicators (life expectancy at birth and total fertility rate) (Data adapted from United Nations, 1971).

A comprehensive description of the algorithm used to transcribe the component method was given at the end of the 1950s (UN, 1957). Even though, computers make further refinements possible and the UN takes studies made by the national statistical institutes of the different countries into consideration, the process remains more or less the same. Figure 77–1 summarizes the progression of one frequent case in which model life tables and fertility models are used to translate into age-specific rates the hypotheses of trends in life expectancy and total fertility. This process is obviously simplified if mortality and fertility have been initially projected directly by age (and by sex for mortality).

3. Hypotheses and Scenarios

The choice of the hypotheses of the trend of the three factors of population dynamics (fertility, mortality, migration) is crucial. During the first years of the projection, the estimate of the initial data, particularly the population's age structure, is an essential factor, but in time this factor is erased and becomes nearly negligible and the evolution of fertility, mortality, and migration rates by age make their mark. Because of the generalization of Lotka's theory (see Chapter 20 of Volume I), we know that the initial age structure disappears completely and that two populations with entirely different age structures converge into one, sometimes new, structure when they are subjected to the same fertility, mortality, and migration rates for a sufficiently long period. The main concern of investigators of relatively long term population projections is therefore that of making the right choice, which is unfortunately, as we have seen in the previous chapters, far from easy.

It would be ideal to refer to a theory to anchor the hypotheses for the three components of demographic change. However, an investigator must simply make the most reasonable choice possible. One classic measure of caution consists of establishing several scenarios by combining different hypotheses for each component of change. The UN gives the "medium scenario" (or medium hypothesis), a scenario that, if not the most probable, is the least improbable.

In the context of the UN projections, these hypotheses, as we will see below, have varied. In the 2000 projection, the hypotheses reveal a subtle combination of reasoning, pragmatism, intuition, and the arbitrary, never really leaning toward one theory in particular. The UN experts have adopted five fertility hypotheses, of which three are currently used; two mortality hypotheses; and two migration hypotheses. Of the mortality and migration hypotheses, only the one called "normal" is currently used.

a. Fertility Hypotheses

The first choice made by the UN experts is to consider that the main possible source of error relates to fertility. There are three main fertility hypotheses that determine the difference between the three scenarios currently in use; they are called high, medium, and low as they are a direct result of the high-, medium-, and low-fertility hypotheses. Each of these scenarios is based on the same "normal" mortality and migration hypotheses. In addition to these three major fertility hypotheses, the 2000 projection includes "constant" and "instant replacement" fertility hypotheses. These last two hypotheses are only used as demonstrations to better define the evolutionary target in fertility behavior, do not depend on a preliminary data analysis, and do not require any particular choice. They are self-defining.

Constant fertility hypothesis—For each country the age-specific fertility rates are kept constant during the whole projection phase at the level estimated for the 1995–2000 period.

Instant replacement fertility hypothesis—For each country and each 5-year period of the projection, the total fertility rate is fixed at a level that, taking into consideration the mortality rate, ensures a net reproduction rate of one, or an intrinsic growth rate of zero (see Chapter 19). This does not mean that the resulting growth rate for the 5-year period will be zero but that the corresponding stable population will have a growth rate of zero; in other words, it will be stationary (see Chapter 20).

The three main fertility hypotheses require the most attention, especially the medium hypothesis as it determines the way the other two frame it. The choice is made in a complex way, beginning with distinguishing three categories of countries, by referring to the demographic transition theory (the only theory that is explicitly evoked) or, more exactly, to fertility transition, one of its components. Referring to the theory does not, however, mean that it is followed blindly. Different countries of the world are at different stages of their fertility transition, and the rate of fertility decline that is likely to be observed during the coming decades depends on this fact. The UN therefore distinguishes three categories of countries: the high-fertility countries (the fertility level estimated for 1995–2000 remains close to the highest level reached between 1950 and 2000), the medium-fertility countries (the fertility decline has already begun but still remains above the replacement level), and the low-fertility countries (fertility is lower than replacement level).

Medium-fertility hypothesis—In the countries with high fertility (Fig. 77–2A), the medium-fertility hypothesis supposes that the total fertility rate will decline at a rhythm of one child per woman per decade. The starting point of this decline, however, has a variability of 5 years. It is supposed that fertility will remain constant during the first stage (2000–2005) if no sign of decline has been detected at the start, but it is applied at the beginning for countries in which a slight decline has already been identified. In most cases (13 countries out of 17), these countries will still be above the replacement level in 2045–2050, at the end of the projection. However, whether they start from a lower level or whether they have started a minor decline, the other countries (4 of 17) will attain this replacement level.

In the countries with medium fertility (Fig. 77–2B), the medium-fertility hypothesis supposes that the replacement level will be reached before the end of the projection and that from then on fertility will remain constant until the end of the projection.[3] Everything therefore depends on the date at which the objective of 2.1 children per woman is reached and the rhythm of decline that enables this objective to be reached. Each case is treated in a reasoned manner according to the country's context, but while fertility remains quite high (with rare exceptions), it is presumed that it will decline rather rapidly (at the rate of one child per woman in 15 years) and this rate declines significantly with the approach of the replacement level. For these two groups of countries, the fertility rates by age[4] are interpolated between the rates observed at the beginning of the period and the rates combining 2.1 children per woman with three fertility schedules by age (early, late, or medium) chosen according to the national context.

For the low-fertility countries (Fig. 77–2C), the medium hypothesis forecasts that fertility will rise but will remain, barring exceptions, under the replacement level. This result is obtained in every country for which data are available by assuming that the targeted fertility level attains the levels reached by the cohorts born at the beginning of the 1960s. In countries where these data are not available, fertility is supposed to increase up to 1.9 if the starting level is more than 1.5 and up to 1.7 if the starting point is below 1.5. The idea of a systematic return to replacement level has been rejected as unrealistic for the duration of the projection, but the idea of a systematic rise has

[3] However, in the 2002 revision of its projection, the United Nations for the first time retained the idea that the decline could continue below 2.1 children per woman in some developing countries. (United Nations, 2003a,b,c).

[4] To be precise, the distributions of fertility by age are interpolated, not the rates; these distributions by age are then multiplied by the total fertility rates (themselves interpolated) to determine the fertility rates by age, which comes to more or less the same.

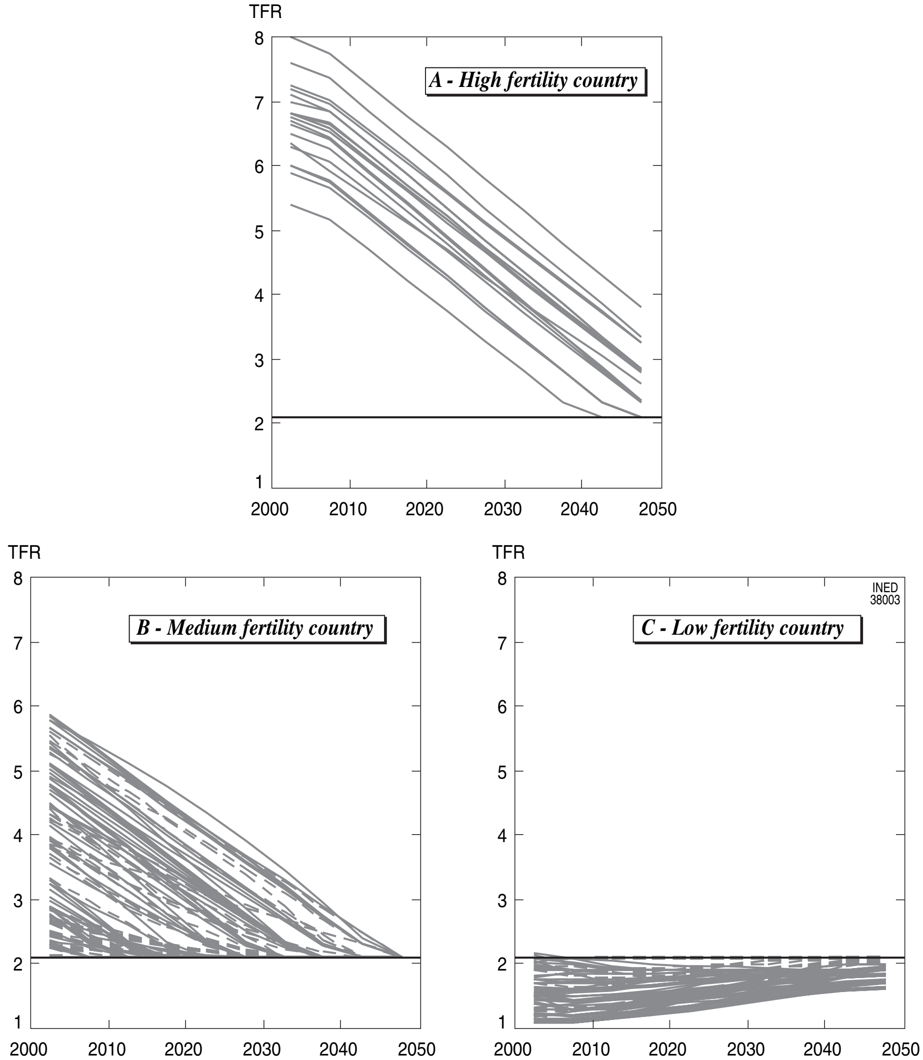

FIGURE 77–2 Hypotheses of the trend in total fertility by country in the case of the medium variant hypothesis according to the category of initial fertility.

nevertheless been accepted over the hypotheses of a deepening in the decline or of variable case by case trends.

High- and low-fertility hypotheses—While the criteria for choosing the medium hypothesis are varied and complex, the high- and low-fertility hypotheses are simply deducted from the first. In countries with high fertility, they evolve systematically at 0.5 children above or below the medium hypothesis. In countries with low fertility, the same occurs, but with a gap of 0.4 children.

b. Mortality Hypotheses

The 2000 hypothesis includes a so-called normal mortality hypothesis and a constant mortality hypothesis.

In the constant hypothesis, mortality is presumed to remain for the duration of the projection at the levels observed in 1995–2000 for each country.

The normal hypothesis is based on an estimate in the evolution of life expectancy at birth. This is estimated in different ways, according to the public health context of each country. For most countries it was considered that life expectancy would increase regularly during the whole period. However special attention has been given to the 45 countries particularly affected by the AIDS epidemic.

For the countries where mortality is expected to decline regularly, the rate of increase in life expectancy has been determined according to three reference models (rapid, medium, and slow increase). In each of these models, it is supposed that the rise in life expectancy will be accompanied by a decline in its rate of increase

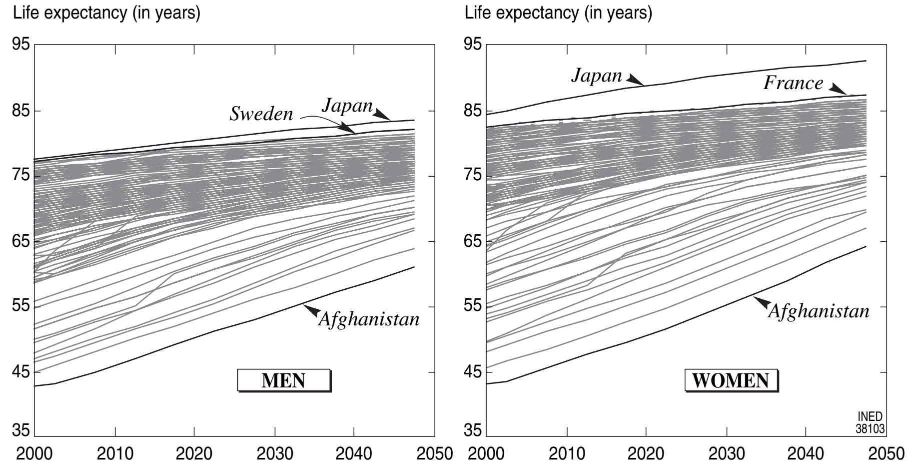

FIGURE 77–3 Trend by country of expected life expectancy at birth in the context of the "normal" hypothesis, in countries where AIDS has no major incidence.

and that this rise will become almost negligible at a certain threshold of life expectancy. In fact, this threshold, 82.5 years for men and 87.5 years for women, will not be reached by any country (except Japan) during the projection period. In the rapid or medium mortality decline models, if life expectancy does not yet exceed 60 years, it will increase by 2.5 years every 5 years for both sexes; this increase is only 2 years in the slow decline model. Afterward, the rate of decline decreases more or less rapidly according to the model and in different ways according to sex. Thus, when life expectancy is between 67.5 and 70.0 years, it is supposed to increase by 1.5 years every 5 years for men and by 2.3 years for women in the rapid mortality decline model, but it only increases from 1.2 to 2.0 years in the medium model and 1.0 and 1.5 years in the slow model. Finally, with the approach of the aforesaid maximum, the increase is only between 0.5 and 0.3 years per 5-year period, according to the model.

The authors of the projection nevertheless do specify that they are not opting for the theory of an absolute limit on life expectancy (see Chapters 48, 57), stating in their report that: "These life expectancies were not meant to represent a ceiling for human longevity, but they were high enough so that no country was expected to achieve them before 2050." (UN, 2002:213). This precaution in language is not only a little hypocritical, as everything leads to the belief that the evolution models appear to have been created to set a limit, but also incorrect, as according to published figures, Japanese women should already have a life expectancy that slightly exceeds the 87.5 years in 2015 and should even reach 92.4 in 2045–2050. Thus, the hypothesis really selected for Japan seems to be more likely than that which this report would suggest, as Japanese women have already surpassed the 85 years, and there are no indications that this progress will cease in the near future. What is most surprising here is that only Japan benefits from this unspoken preferential treatment. For example, the gap between Japanese and French women (the second country in terms of life expectancy for women), which was only 1.8 years, will reach 5.1 years in 2050 (Fig. 77–3). There is no justification for this choice.

Although less spectacular, the same anomaly is observed for men; Japanese men are the only ones to exceed the "limit" by reaching a life expectancy of 83.5 years, thus increasing the gap with Swedish men, their closest challengers (0.2 years of gap in 1995–2000 and 1.4 years in 2045–2050).

The mortality rates by age were obtained by interpolation between the estimated life table for the 1995–2000 period and the theoretical table accepted for maximum life expectancies of 82.5 and 87.5 years.[5] These rates are defined in age groups of 5 years from 5 to 100 (however, childhood mortality rates under 5 years were separated into infant mortality before age 1, and child mortality at age 1–4).

For the countries most affected by AIDS (35 African countries; 4 Asian countries, including India; and 6 Latin American countries),[6] the UN proceeded with country by country evaluations of the anticipated consequences of the epidemic according to available esti-

[5] The report does not specify how the rates were obtained for Japan beyond these limits.

[6] Countries where HIV prevalence at 15 to 49 years was more than 1.9% in 1999 plus India and Brazil, where the prevalence is significantly lower (0.7 and 0.6%) but where the absolute number of infected persons is very high (United Nations, 2002:215).

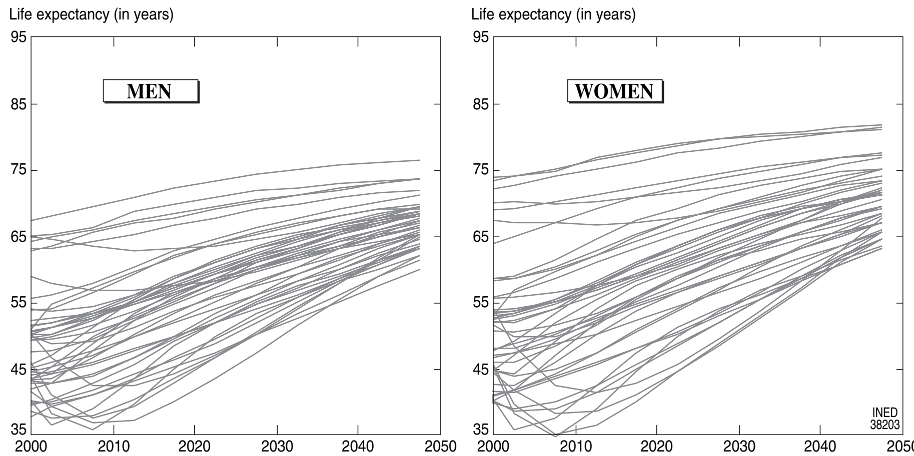

FIGURE 77–4 Trend in expected life expectancy at birth by country according to the "normal" hypothesis, for the 45 countries most affected by AIDS.

mates of the prevalence and incidences of HIV and a probable increase in the development of the epidemic. These evaluations are the subject of a special chapter in the report (UN, 2002:chapter 3). It is expected that in the most affected countries not only will life expectancy decline significantly during the coming years but also the epidemic will soon be suppressed and that all countries will experience an accelerated increase in life expectancy, which will enable many of them to catch up (Fig. 77–4).

c. Migration Hypotheses

The 2000 projection includes a normal migration hypothesis and a zero migration hypothesis.

The zero hypothesis does not mean a total absence of migration, but a zero net migration for each age over the whole of the projection period.

The normal hypothesis is based on a case by case estimate of past net migration and on currently known or predictable future policies regarding international migration. No explicit reference is made to any particular theory. The hypotheses are quantified in terms of absolute numbers of net migrants by 5-year projection period. The report does not specify age distributions of these totals.

In concrete terms, these hypotheses are basically translated by an extremely large inflow toward the United States, a share that is actually meant to decrease during the first decades before becoming constant from 2015 onward (Fig. 77–5). For most of the other countries, the inflow and outflow are supposed to remain constant (in absolute numbers) during the whole of the projection period. The only spectacular changes owing to national political contexts are those for countries that are currently experiencing exceptional circumstances, such as Afghanistan (return of refugees) and Pakistan (departure of the Afghans). The largest negative net migration is forecast for China, but it is three times lower than the positive net migration forecast for the United States.

d. Combination of Hypotheses Used for the Seven Published Scenarios

From these various hypotheses, $5 \times 2 \times 2 = 20$ scenarios are conceivable. However, the UN has explored the results of only seven of them, of which three are meant to realistically forecast the possible future; the others only serve to illustrate the importance of ongoing changes in behavior.

The three main scenarios combine the three principal fertility hypotheses (*high, medium, and low*) with the normal mortality and migration hypotheses. The first two illustrative scenarios combine the *constant* fertility hypothesis and the *instant replacement* hypothesis with these same mortality and migration hypotheses. Inversely, the latter two successively combine the *constant* mortality hypothesis and the *zero* migration hypothesis with the *medium* fertility hypothesis, and with the *normal* migration and *normal* mortality hypotheses (Table 77–1).

Priority Given to Fertility

The priority given to fertility is such that only one illustrative scenario appears in the publications, that of *constant* fertility, destined to show the gap between the three basic scenarios and what would occur if fertility remained fixed at its current level. It is however possible to obtain the results of the last

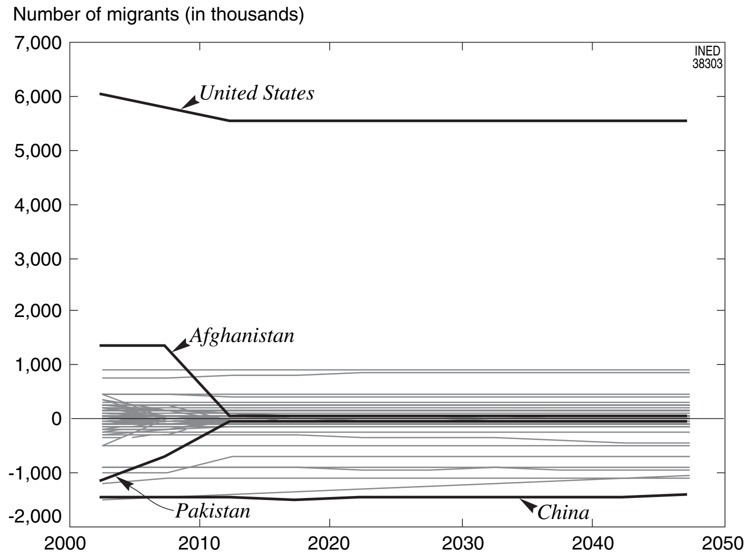

FIGURE 77–5 Trends in total net migration (absolute numbers) by 5-year period, projected according to the "normal" migration hypothesis.

TABLE 77–1 The Seven Scenarios Used for the Publication of the 2000 Projection Results

Scenarios and variants	Hypotheses of:		
	Fertility	**Mortality**	**Migration**
Principle scenario			
Low variant	Low	Normal	Normal
Medium variant	Medium	Normal	Normal
High variant	High	Normal	Normal
Illustrative scenarios

Constant mortality scenario	Medium	Constant	Normal
Zero migration scenario	Medium	Normal	Zero

Data from United Nations, 2002:9.

three scenarios on a computer file from the UN's Population Division.[7]

Figures 77–6 and 77–7 illustrate the results obtained for the total population, in the prolongation of the trend observed since 1950, according to the five fertility hypotheses: high, medium, low, constant, and instant replacement, which are combined each time with the *normal* mortality and *normal* migration hypotheses. Fig. 77–6 represents the population of developing and developed countries on the same scale as world population, and Fig. 77–7 shows only the results of the developed countries, which are crushed in Figure 6 by the disproportion with the rest of the world.

Figure 77–6 shows that when viewed from a global perspective, the demographic situation and change in the developed countries are of little importance. This fact has had a considerable effect, as we will see below, on the extraordinary success of the UN projections.

In the central scenario, world population will increase from 6.06 billion in 2000 to 9.32 billion in 2050. Despite the deceleration in growth rate already established for several decades, a deceleration that is supposed to continue and even increase in the central scenario, an even greater growth in numbers should be expected between now and the middle of the century. It is a real possibility that the leaders of the planet have an tendency to forget that the great demographic scare of the 1970s no longer exists. The stake is even more considerable as the total burden of this future growth will be carried only by the developing countries, as is shown in the second part of Fig. 77–6, which according to the medium hypothesis would see their populations increasing from 4.86 to 8.14 billion (an absolute growth greater than that of the total world population) as, at the same time, the population in developed countries will decrease from 1.19 to 1.18 billion. In other words, the relative growth of the developing countries (67%) is significantly greater to that of the world as a whole (54%).

Furthermore, this burden that weighs so heavily on the future of the developing countries is far from being fairly distributed as the population growth will be

[7] Our thanks to Hania Zlotnik for kindly supplying these data.

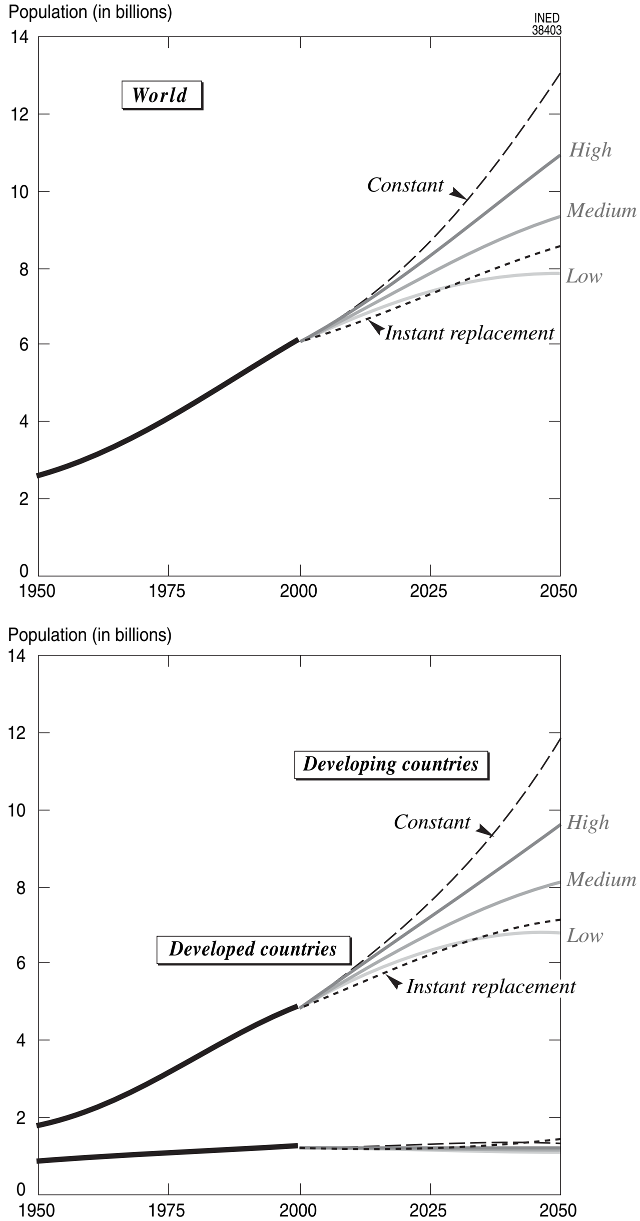

FIGURE 77–6 World population projections according to the five fertility hypotheses combined with the *normal* mortality and *normal* migration hypotheses.

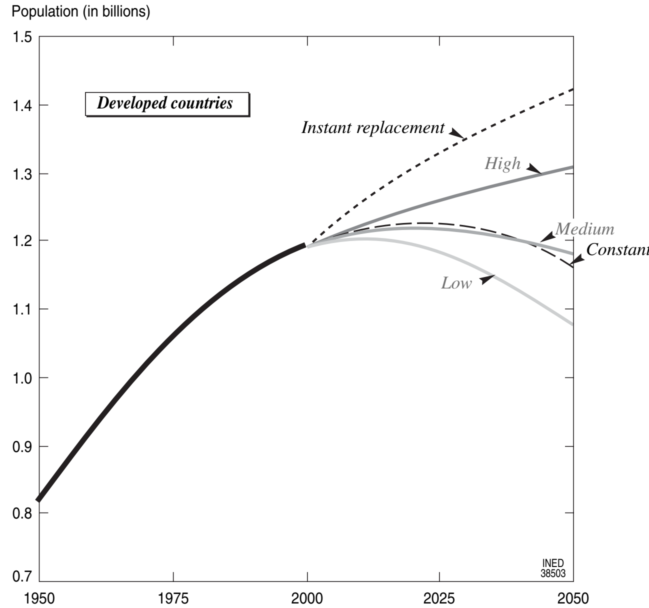

FIGURE 77–7 Zoom on the population projection for developed countries according to the five fertility hypotheses combined with the *normal* mortality and *normal* migration.

much faster among those who are economically the poorest and politically the most vulnerable. In their categories, the UN has for some time distinguished between the least developed countries and the other developing countries. According to the central scenario, the population of the least developed countries will increase from 660 million inhabitants to 1.8 billion, an increase of 178%, or nearly tripling. Demographic growth thus remains a major concern for the coming half century. But who is concerned with such destitute populations that have today, it must be admitted, become a minority at the global level and even at the level of that which used to be called the Third World?

What is the likelihood (or the risk) that this medium scenario occurs? We will be better placed to judge at the end of the following section. Let us say at this stage that in the UN projection system, the high- and low-fertility hypotheses are supposed to cover the plausible reality. In other words this system supplies us with a rough margin of error. In 2050 the world population will probably be between 7.9 and 10.9 billion. In absolute numbers, the margin is quite wide, as the gap between the extremes is more than 3 billion, but the relative error (±16%) is a very modest number for a 50-year forecast. And there is no comparison with other economic and social forecasts. Which economist would dare to make such a long-term forecast? Only the inertia of demographic phenomena gives this type of exercise a respectable credibility.

The two supplementary illustrative hypotheses make it possible to judge both the considerable impact and the limits of behavioral changes taken into account in the UN's population projections. The constant fertility scenario shows that if fertility had suddenly stopped declining in 2000, then the world population would exceed 13 billion in 2050: 2 billion more than in the high hypothesis and nearly 4 billion more than in the medium hypothesis. Instead of a growth of 50% expected in this central hypothesis, the projected population will double in the absence of fertility decline.

This shows the strength of the growth deceleration represented by current changes. Here again, let us emphasize that most of this change occurs in the south: without fertility decline, the population of developing countries will multiply by 2.5 and that of the least developed countries by nearly 5.

But the instant replacement fertility scenario also makes it possible to measure the limits of this type of change. Even with a drop in fertility resulting eventually in a strict replacement of generations all over the world from the year 2000, the world population would not immediately stop growing. On the contrary, it would continue to increase for several decades, reaching 8.6 billion in 2050, an increase of 40% from the year 2000. This is why, owing to past trends, the structure of world population is still young, and even with severely reduced mortality, the mothers of tomorrow, who are more numerous than are their elders, will have more children than their elders did (see Chapter 4). Of course, what is true for the world population is even more so for the population of developing countries, which despite an immediate transition to replacement fertility will grow by nearly 50%; the population of the least developed countries will grow even more, increasing by 60%.

If, seen from the world level of Fig. 77–6, the population projection of the developed countries appears particularly lacking in flavor, this does not mean that they do not need to be concerned with future demographic trends at their level. On the contrary, as Fig. 77–7 shows, the future is most uncertain for them. If only the fertility variants are looked at, the future of their population is open to evolution in the opposite sense. Although the central hypothesis clearly shows the threat of a general population decline in the second quarter of the century, the low hypothesis would introduce this decline during the first decade. In contrast, the high hypothesis would ensure that a significant population growth is maintained, which would enable the population of developed countries to reach 1.3 billion in 2050 instead of the current 1.2.

In the case of developed countries, strictly maintaining fertility at its year 2000 level would hardly change the result shown in the central scenario. This is because the expected changes in the latter would compensate each other, with fertility declining in the countries where it is still close to replacement level (more than 1.9 children per woman) and increasing where it is already below. On the contrary, the instant replacement fertility scenario would provoke a significantly greater population growth than that of the high hypothesis, whereas in the rest of the world, it would give a similar result to that of the low hypothesis as average fertility in developed countries is so low that a sudden increase would be necessary in order to reach replacement level.

The Importance of Mortality Decline

By comparing the constant mortality scenario to the medium variant of the principal scenario, mortality decline in the growth forecast for world population can be seen clearly, as the only difference between the two scenarios is the expected decline in mortality.

With constant mortality, world population would reach only 8.1 billion in 2050 instead of 9.3 (Fig. 77–8). In other words, in the expected growth of 3.3 billion between now and 2050, a little more than a third is owing to mortality decline.

This phenomenon obviously massively affects the developing countries, which in absolute numbers would benefit from the most of the bonus associated with mortality decline, but relatively speaking, the developed countries would be decisively affected. If their mortality stopped declining, the population of the latter would fall to 1.08 billion rather than 1.18. Instead of a slight decrease of −10 million in 50 years, they would lose 100 million inhabitants. In other words, according to the principal scenario hypothesis, it is only through mortality decline that the developed countries would succeed in maintaining their population at more or less the current numbers. But migration also affects the principal scenario.

The Role of International Migration

The future of world population as a whole is obviously indifferent to the UN migration hypotheses, although they could change the growth dynamic of the regions of the world (Fig. 77–9). In reality, they have little effect on the developing countries, as the expected flows are marginal in comparison with the size of the population, but they weigh heavily on the future of developed countries. In the absence of migration, the population of developed countries would only be 1.05 billion in 2050 (instead of 1.18), that is, 130 million less. In other words the anticipated net immigration weighs more than does mortality decline. The UN has not yet explored a scenario without mortality decline and without migration, but barring any interference effects, it can be said that without these two factors the population of developed countries in 2050 would be lower than the 230 million expected in the medium hypothesis. This signifies a loss of nearly one quarter of the current population.

4. Toward a New Demographic Pattern

The geographic distribution of world population has already changed much during the past half century

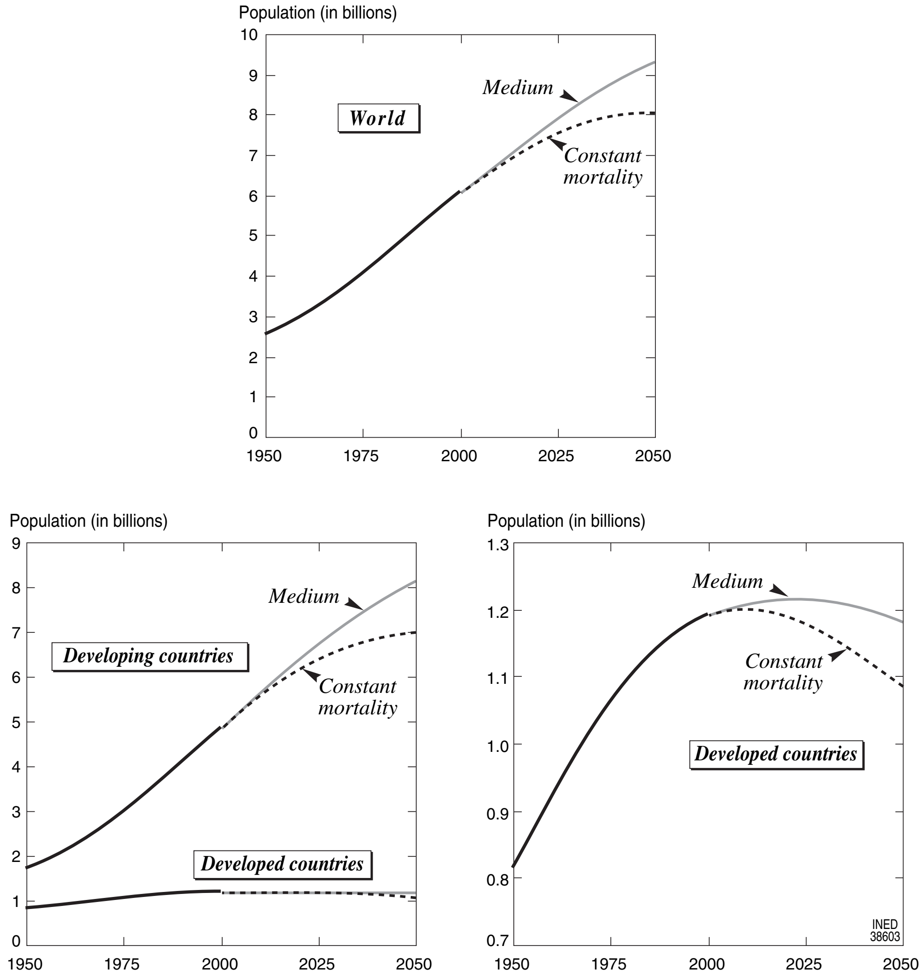

FIGURE 77–8 Comparison of the medium variant of the central scenario with the constant mortality scenario hypotheses.

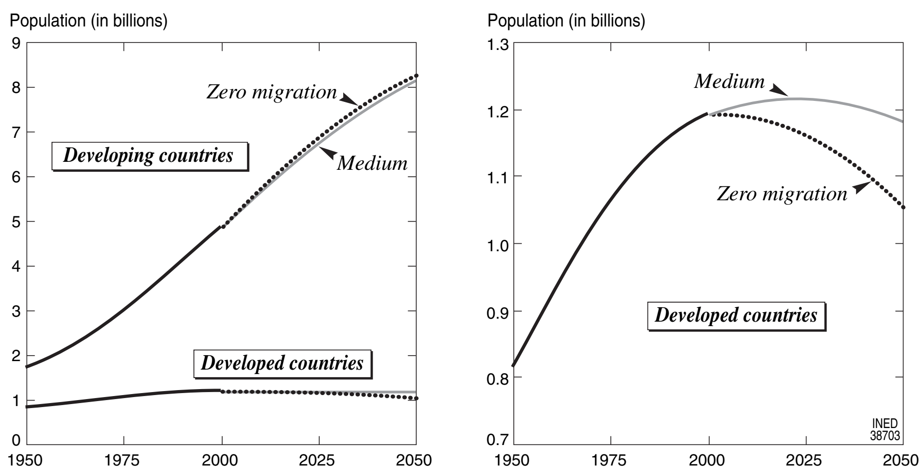

FIGURE 77–9 Comparison of the medium variant of the central scenario to the scenario without migration.

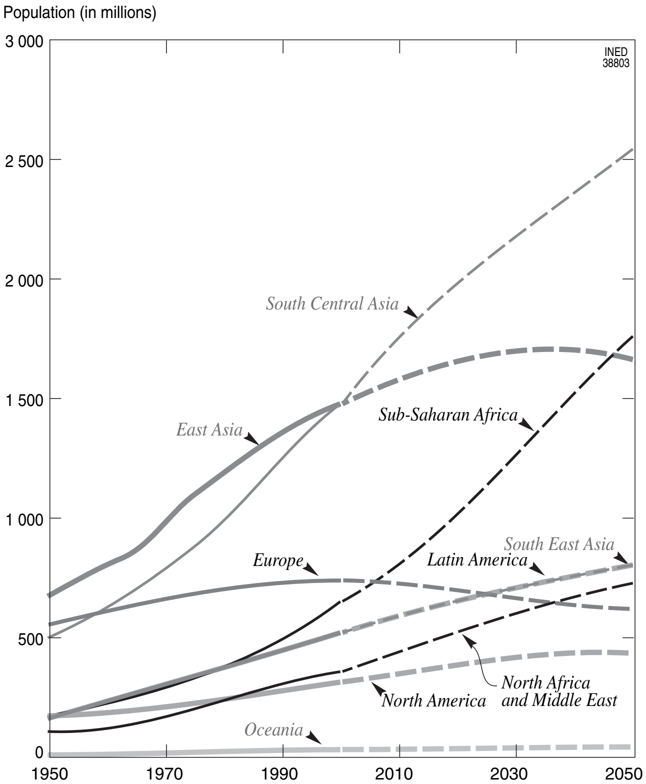

FIGURE 77–10 Trend since 1950 and projection up to 2050 of population by large world regions according to the United Nations' medium scenario (2000) (From United Nations 2001.)

(see Chapters 69 and 71). The redistribution will again be accentuated. To be convinced of this, one should simply look at the UN medium scenario results. Figure 77–10 traces the 1950–2050 trajectories of eight large regions, closely following the UN demarcation.[8]

a. The Large Regions

Despite AIDS, it is sub-Saharan Africa that will witness the largest increase in relative population as, although it will experience a severe loss in life expectancy at the beginning of the period, it will experience a more rapid growth rate than any other region between now and 2050. Consequently, a little before 2050 the population of sub-Saharan Africa will have overtaken that of western Asia. According to the UN central scenario, before the middle of the century, there will be more sub-Saharan Africans than Chinese, Japanese, and Koreans together. In absolute numbers, however, the growth of south central Asia (India, Pakistan, Bangladesh, etc.) will be nearly as spectacular. Although the rate of growth will certainly be slower than in sub-Saharan Africa, the initial population is so high that the increase in population will be almost as spectacular. Sub-Saharan Africa, which in 1950 had only 177 million inhabitants, will increase from more than 600 million in 2000 to 1.8 billion in 2050, whereas south central Asia, which had nearly 500 million inhabitants in 1950, will increase from 1.5 billion in 2000 to 2.5 billion in 2050. It will therefore gain only a billion inhabitants compared with the 1.2 billion gained by sub-Saharan Africa.

On the contrary, if east Asia is about to be overtaken by sub-Saharan Africa, it is also because it should experience a reflux in the second quarter of the century according to the UN central scenario. If the rapid fertility decline, below replacement level, that the entire region has experienced has not yet reversed population growth, it is because of the potential for growth that remains within its age structure. This phenomenon will soon be over, and the region's population could drop to 1.6 billion in the middle of the century after reaching 1.7 during the 2030s.

Latin America and southeast Asia's trajectories are almost perfectly identical during the hundred years from 1950–2050. Both these regions are due to experience growth rates comparable to that of south central Asia and should soon overtake Europe, Russia included. Later, a similar situation should be seen in the north Africa–Middle East block. The future dynamism of these regions contrasts violently with the reflux forecast for Europe. Because of a surprising reshuffle, the current population of Europe will be nearly that of Latin America (or southeast Asia) in 2050, whereas the population of Europe in 2050 will be close to that of Latin America (or southeast Asia) today.

North America should maintain a moderate growth rate, although with a slight deceleration, during the whole of the projection period, increasing from 315 to 440 million in 50 years.

Two supplementary observations clearly expose the demographic change in the large regions. In 1950 five of the eight large regions—sub-Saharan Africa, southeast Asia, Latin America, north Africa—Middle East, and North America—had a population of very similar size, around 170 million inhabitants. Since then, major differences have occurred, but this divergence is only the beginning of a spectacular explosion expected in 2050, from the 440 million in North America to the 1.7 million in sub-Saharan Africa. Yet more remarkable is the expected divergence between Europe and south central Asia. While these two units were the same size in the middle of the 20th century, central Asia is twice more populated than Europe today (1,400 million against 700) and will be four times in 2050 (2,500 against 600).

[8] For obvious reasons (cultural community, comparable demographic situations), we have regrouped the United Nations' North African subregions and western Asia, under North Africa and the Middle East, in order to isolate sub-Saharan Africa. For the rest of the world, UN subregions were used for Asia only.

b. *At a National Level*

The expected recomposition in the large regions is often more obvious at a national level. However, here we will only hint at it by mentioning the trajectories of 23 countries that currently have more than 50 million inhabitants.

Of the three most populated countries of the planet, two belong to the developing world (India and China) and the third to the developed world (United States). It is therefore not surprising that the aforementioned divergences should have such an impact on the top three (Fig. 77–11). China and India are currently rivaling for first position, but India will finally overtake China around 2040. The United States, despite its unstinted growth, lags far behind and will continue to do so. Although in 1950 the 160 million inhabitants of the United States could be compared to the 360 in India and the 550 in China, in 2050 it will not, with 400 million, be comparable to the 1.5 billion Chinese, themselves overtaken by 1.6 billion Indians. As to the other 20 "large" countries, the scale must be changed in order to spot their trajectories (Fig. 77–11b) as they are crushed by the first two giants (Table 77–2).

But the recomposition is even more obvious with the ascending trajectories crossing the descending trajectories. Thus, a large country such as Russia, currently numbering a little more than 150 million inhabitants will have no more than 100 million in 2050, whereas Brazil, which was at exactly the same level as was Russia 10 years ago, will have 250 million by the middle of the century. Another spectacular example is Italy, which was more populated than was Pakistan in 1950 (47 million against 40 million) and will have only 43 million inhabitants in 2050 (less than in 1950), whereas Pakistan will have more than 340 million (eight times more, and nearly as many as the United States). The Congo, which was the least populated of the list in both 1950 and 2000, will overtake 15 countries of this short list in 2050, including reunified Germany, Japan, Russia, and Mexico. In 2050 the two "large" European countries (France and the United Kingdom) with permanent places on the UN Security Council are likely to be among the last on this list (just ahead of Italy).

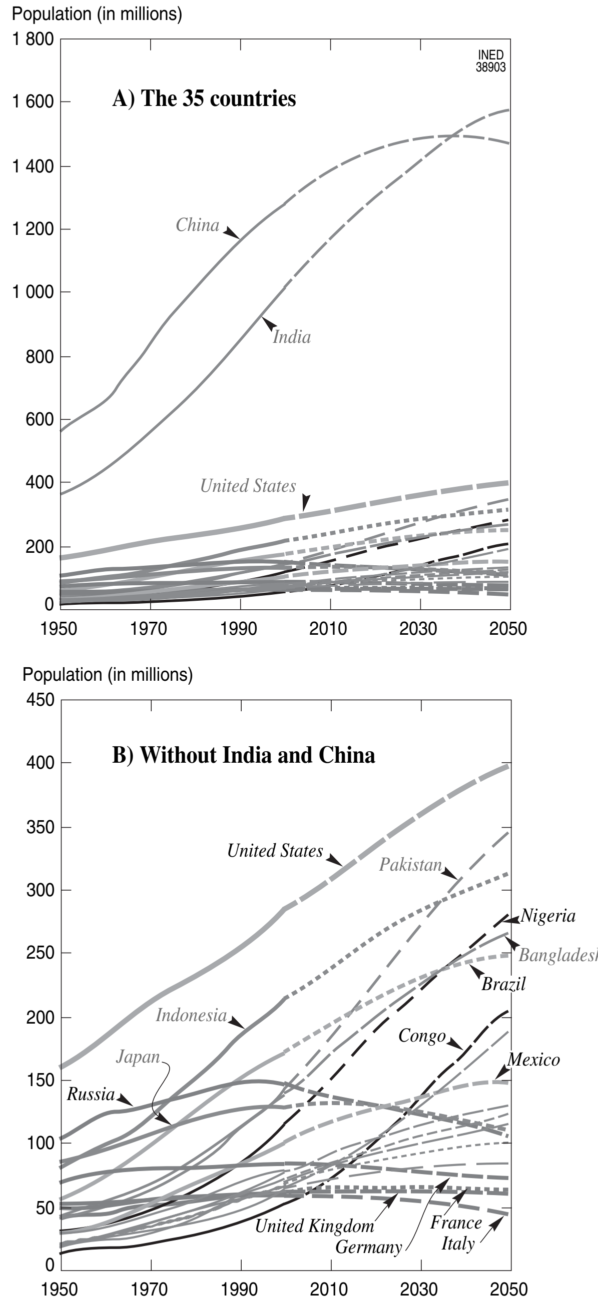

FIGURE 77–11 Population growth since 1950 and projection up to 2050 (medium hypothesis) of the population of 23 countries with more than 50 million inhabitants in 2000 (From United Nations, 2001).

II. DATA IMPROVEMENT, TECHNIQUE REFINEMENT, AND EVOLUTION OF THE HYPOTHESES

To fully appreciate the robustness of the UN projections, we can look at previous projections and compare them to the scenarios that actually occurred. By doing this, we are immediately struck by the success of the forecasts for the year 2000: at the end of the 1950s, the central scenario of the Population Division had forecast the 6 billion that was actually reached. Yet the data quality and techniques were far from the standard of today, and the hypotheses have significantly changed with time. But paradoxically, despite this early success and despite the improvement

Data from United Nations, 2001.

in methods, it must be admitted that the future is more uncertain today than it was in the past.

1. The Extraordinary Success of the 2000 Forecast

Table 77–3 lists the results of the 16 successive world population projections published by the UN since 1958. The first ones were based on data estimated in 1955, 1963, 1968, 1973, and 1978, after which this exercise has been repeated regularly every 2 years. In 1958 (on the 1955 database), the Population Division forecast a population of 6.27 billion for 2000 in its central scenario; since then, in each successive projection, this result has fluctuated a little but never greatly from this initial vision, which is close to today's reality of 6.06 billion for the year 2000. It must be emphasized that the high point of 6.5 billion corresponding to the 1968 calculation could be considered an accident, the experts of that period having given in to slight but unfortunate pressure from the apocalyptical talk of the time on the population explosion of the Third World (Vallin, 1986). Except for this high point, the trend revealed in Fig. 77–12 is eloquent. At the end of the period, a slight reduction in the estimates leading to the reality observed in 2000 is just visible.

Of course, the closer the limit the more likely that the range straddling the estimated final result is reduced; the most remarkable fact is that the range appears today as being nearly excessively cautious. Only in 1968 did the result of the medium hypothesis really vary from the center of any of the preceding estimates. In retrospect and taking into account the difficulties currently faced in formulating good hypotheses of a population projection, this result is hardly believable and cannot be put down to sheer luck as, although repeated 18 times with increasingly effective methods, the exercise has never contradicted the first attempt.

2. The Evolution of the Projections

It is true that the 1958 attempt was not exactly the first. It was preceded by two attempts, the results of which appear decidedly less brilliant. The first was published in 1951 based on 1946–1948 data; the second in 1954, on 1950 data. At the time, they did not dare to examine the 2000 horizon, but this caution was certainly genuine in the context of the fragility of the data (and also the hypotheses). At the end date of these first projections, 1980, the world population was estimated to be at 3.3 billion in the 1951 projection and barely

[a] The 1958 projection does not present results for all of the developed and developing countries. To estimate the population in the first category, we have regrouped the results given for North America, Europe, the Soviet Union, Japan, and Australia—New Zealand and obtained that of the developing countries by the difference with the world total.

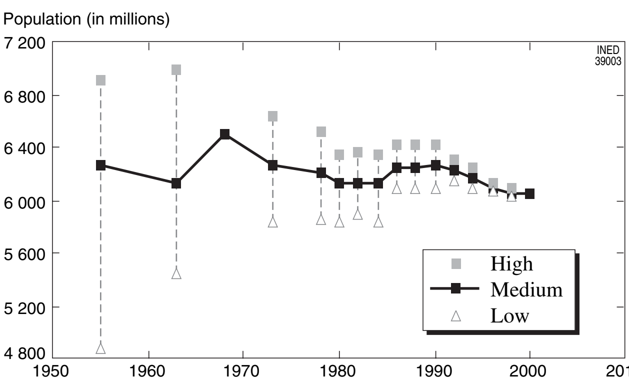

FIGURE 77–12 Estimates of world population on January 1, 2000, according to successive projections published by the United Nations since 1958. High, low, and medium variants of the principle scenario.

higher (3.6 billion) in the projection from 1954. The population actually observed in 1980 was 4.4 billion. Although the trajectories suggested by the central scenario of the following projections are close, nearly exactly superimposing any estimates made today using real data, these two first attempts appear as failures (Fig. 77–13). Not only were the available data terribly fragmentary and often deficient, but in particular (and this partly explains the failure), the importance of the ongoing mortality decline and real fertility levels in the Third World had not yet been taken into account.

Significant progress has been made in several directions since then. The projection method and the technical tools for producing it have improved, but in particular, the quantity and quality of the data have greatly progressed and the hypotheses have become more reliable.

a. Technological Refinement

There is no need to discuss the technical aspects in detail. We have already mentioned that with the adoption of the component method, the basics were in place since 1958 in terms that hardly differ from the algorithm currently used, even though the efficient use of computers has greatly facilitated its application. Even the failed attempts of 1951 and 1954 were basically using the same method. The essentials are shown in the two following points.

b. Improvement in Basic Data

Considerable efforts have been deployed since World War II in the direction of the developing countries (as much by international organizations as in the context of bilateral cooperation) for collecting data aimed at providing information on the demographic situation in most of the Third World countries (partic-

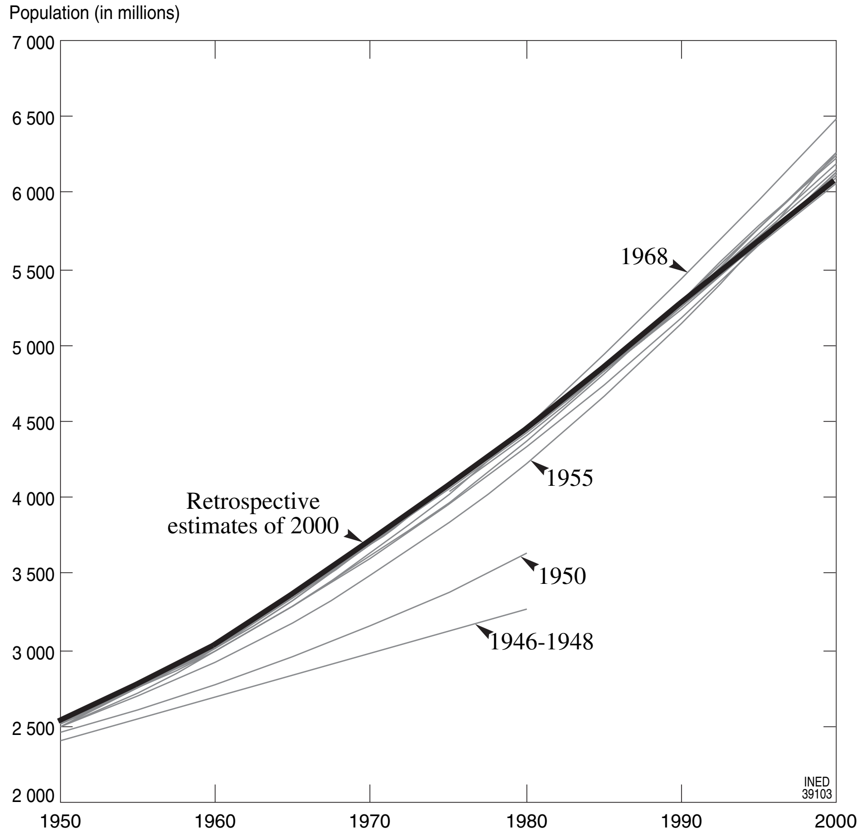

FIGURE 77–13 Trajectories of the first attempts of 1951 and 1954 compared with those of projections made from 1958 and with estimates made today for the 1950–2000 period (The projections are marked by their starting year).

ularly those of sub-Saharan Africa and several countries in Asia and Latin America) owing to the paucity of censuses and civil registration systems enabling births and deaths to be continuously followed. From the 1950s the United Kingdom and France tried to fill these gaps with a series of retrospective surveys in their African colonies, in which more sophisticated approaches were used such as multiround surveys and in-depth studies into women's fertility histories (see Chapter 121). At the same time, indirect analysis and estimation methods were perfected in order to get the best of deficient and fragmentary data (see Chapter 127). From the 1960s, significant efforts were also made by the UN so that the majority of countries could conduct a census every 10 years. This is how numerous Third World countries were able to hold their first population censuses at the beginning of the 1970s and the 1980s. From the 1970s, the World Fertility Survey program, succeeded since the 1980s by the Demographic and Health Survey program, has supplied an invaluable wealth of data on fertility and child mortality, as well as on their determinants. Let us also remember the huge effort of training statisticians and demographers that has enabled southern countries to contribute increasingly to the production and analysis of this demographic data.

Very rapidly, these efforts bore their first fruit, which were decisive in understanding the demographic situation at the start of a population projection, and here no doubt is one of the main sources of the impressive qualitative leap observed between the 1954 and the 1958 projection. Of course, in 1958 there were still enormous gaps that have only since been progressively filled, but in less than 5 years much had been learned about the mortality decline that had started in the poor countries and their levels of fertility. However, the correct trend hypotheses had yet to be made.

c. The Transition Theory

The experts were greatly assisted in this by the emerging theory of demographic transition (see Chapters 68, 69). As soon as the first data announcing this formidable population dynamic that would develop in the Third World countries began to take shape, the authors did not fail to hastily commit themselves in the description of apocalyptic perspectives based on the simple extrapolation of growth rates, themselves in full growth, as Edward East and George Knibbs had already done in the 1920s. The component method in itself gave the experts more confidence, but in order not to give in to the pressure of catastrophism, they needed to be able to formulate reasonable hypotheses not only on the progress of mortality decline but also on the approaching fertility decline in the countries in which fertility had been high and was likely to increase under the effects of progress in health and behavioral changes regarding breast feeding and *postpartum* sexual intercourse (see Chapter 69).

This is what enabled the demographic transition theory to be applied (which seems to us to be nearly a truism today): with the modernization of societies and behaviors, nearly all populations experience a phase of rapid growth that is not permanent, as mortality decline ends up being followed and even overtaken by fertility decline, which restores the balance between the two components of natural growth.

Of course, the authors of the UN projection in 1958 were careful not to refer to a future generalization of the demographic transition theory model or even to deduct the future stabilization of the world population that could result from it (this would appear with the first long-term attempts at population projection), but they used it to imagine the starting dates and the rates of fertility decline, which made it possible to announce such a reasonable population number for 2000 that it indeed became reality.

It would obviously be naïve to believe that all the starting dates and all the rates of decline chosen (varied according to country categories) were correct, but two major phenomena gave a consistency to the whole. On the one hand, the component method enabled a balance between errors of opposite signs (whether it be on the estimate of initial population or on the evolution of fertility and mortality), thus limiting the global error. On the other hand, limiting the exploration to a 40-year period meant a reduced global error was less likely to have a major effect.

But the third reason for the success of the 1958 projection was that the proportion of the world population likely to suffer from extremely erroneous hypotheses was also the population that was about to experience a considerable reduction in weight as a result of the ongoing evolution.

3. A Future More Uncertain Than Ever

Figure 77–14 shows how poor the quality of the 1958 projection would have been if it had forecast the future of the developed countries only. The result finally

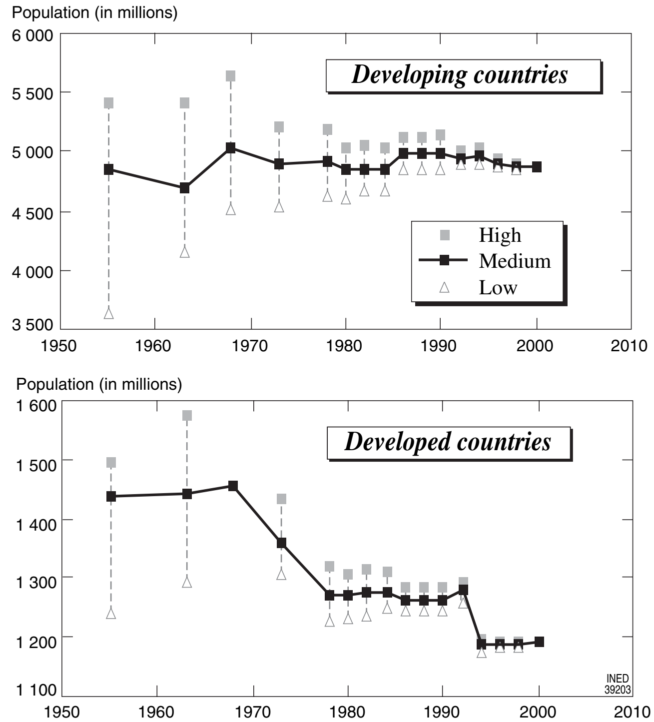

FIGURE 77–14 Population estimates of developing and developed countries on January 1, 2000, according to successive projections published by the United Nations since 1958. High, low, and medium variants of the principal scenario.

observed in 2000 for these countries at 1.2 billion is lower by 300 million than the expected figure in the medium hypothesis—exactly a quarter less! Although it was easy to predict the fertility decline of developing countries through the demographic transition theory, this theory was incapable of predicting the fertility trends observed in developed countries after 1970. On the contrary, at that time everything seemed to indicate that far from being a simple short-term phenomenon associated with the war, the *baby boom* era of the 1940s reflected a permanent behavioral change, in other words, the end of secular fertility decline and its near stabilization around the replacement level.

From the end of the 1970s, the UN experts attempted to adjust their aim, but it was insufficient. It was only with the 1994 projection that they finally approached the reality of 2000 as closely as they had done for world population from 1958. Since 1958 the projection for the developing countries has been consistently very close to the final result.

This observation calls for great caution concerning projections made today for the coming half century. If for a certain fraction of the world population that is still experiencing relatively high levels of fertility and therefore quite far from achieving its demographic transition the theory of the same name continues to provide quite

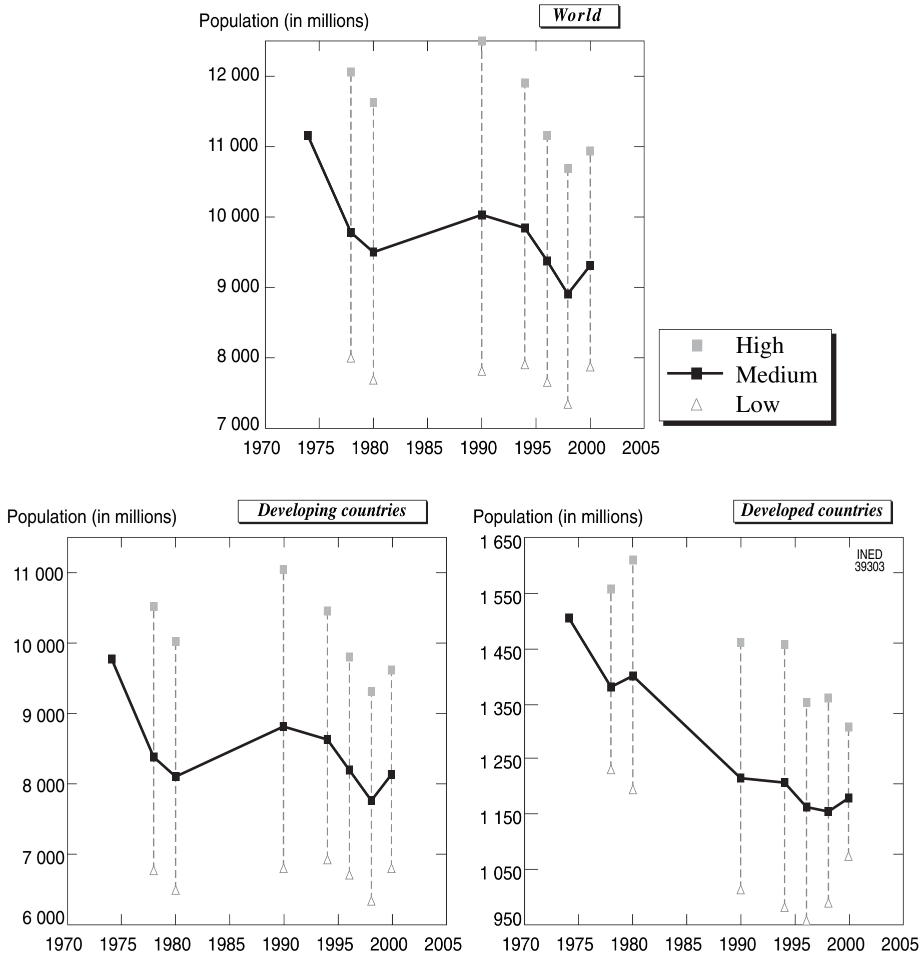

FIGURE 77–15 Population estimates for January 1, 2050, according to successive projections published by the United Nations since 1975. High, low, and medium variants of the principle scenario.

a reliable framework for proposing realistic fertility hypotheses that largely override all other considerations, the section of the world population that it represents is increasingly dwindling, so much so that the future of the greatest numbers tends to depend more and more on the same uncertainties that previously affected the so-called developed countries. Not only is there no longer a general theory capable of indicating the direction in which fertility should significantly evolve, but the future of mortality, which as we have seen weighs heavily on the projections, is the subject of a lively debate, without mentioning migration.

It is only since 1994 that the UN has been systematically exploring the 2050 horizon in their biannual projections. We can, however, connect the results published for the same period in their various long-term projection attempts, which we will discuss below. Table 77–4 assembles the available data; the first United Nation publication announcing a world population for 2050 dates from 1975.

We obviously do not know what the real result will be, but the evolution in numbers successively announced in the context of the medium scenario has already been significantly revised downward, from the 11.1 billion announced in 1975 to the 9.3 billion resulting from the current 2000 projection (Fig. 77–15). We can certainly consider that the 1975 projection was too long term and that slight errors in the increase of the fertility and mortality trajectories were enough to cause significant gaps in the forecast numbers. What is most worrying is that during the 1990s only the forecast had to be reduced by nearly a billion (despite the upward revision of 2001, which thus appears a little artificial). One wonders if the UN is not seriously underestimating the potential fertility decline beyond the replacement level, not only in the European countries for which a recovery in fertility is systematically expected but also in the numerous developing countries close to this level for which a drop below the replacement level is never forecast (in the medium

[a] The 1994 to 2001 projections are the current ones on the 2050 horizon. The preceding projections are long-term projections, which will be discussed in the following point.

[b] The 1974 projection does not distinguish a northern group (3084 million); therefore, east Asia (1760), not including Japan (130), must be subtracted in order to find the developed countries and a southern group (8079), which must be inversely increased to obtain the population of the developing countries.

[c] The 1990 projection does not distinguish the developed countries from the developing countries but a group I and a group II assemble the entire continents. For comparison, we have excluded Japan from group II and added eight Asian republics of the former Soviet Union and inversely for group I. The 1990 projection does not include results per country; we have therefore taken the 1994 projection estimates for these countries.

scenario).[9] But nothing prevents us from making a radically opposite criticism of this scenario tomorrow as we are currently incapable of devising a reliable theoretical framework to support a medium-term prediction.

III. DO ALTERNATIVE APPROACHES EXIST?

Another way to judge the pertinence of the UN work on projections is to look at the competition. During the 1950s and the first half of the 1960s, the UN's Population Division was the only producer of world population projections. However, at the end of the 1960s, two authors, Aron Boyarsky and Donald Bogue, took up the issue and were each emboldened to produce a potential alternative to the UN's work, even though they never really convinced anyone. Shortly afterward, Thomas Frejka picked up the torch, not only proving that it was possible to usefully explore the future beyond 2000 but also conceiving extremely long-term projections, based entirely on the idea of a generalization of the demographic transition conducted to the very end, and attracting in his wake the first attempts of the same type by the UN experts. During the 1970s and 1980s, institutions other than the UN also attempted to compete with the Population Division's projections.

1. Boyarsky and Bogue

Aron Boyarsky's (1965) and Donald Bogue's (1967) approaches differed significantly from that of the UN. The quality requirement of the source data used and the calculation procedures are much less elaborate.

Aron Boyarsky worked at the level of large regions, dividing the world into 12 more or less homogenous areas with respect to their political and social systems and their degree of economic development. He estimated growth coefficients for each region for the 1960–2000 period based on the idea that mortality and fertility depended largely on the economic and social

[9] In its last revision, the United Nations' projection (2003bc,d) acknowledges the possibility of a decline in fertility below 2.1 in some developing countries.

context. He thus estimated, for example, that the expected growth in the advanced capitalist countries would be less than that in the socialist countries, benefiting from better conditions for a reduction in mortality and the maintenance of higher fertility. Of course, he estimated that the growth capacity of developing countries was greater where the potential of mortality reduction was much higher and the perspective of controlling fertility more distant. By combining the results thus obtained by region, he estimated that in 2000 the world population would be between 4.2 and 5.0 billion, significantly less than the 6 billion forecast in the UN's medium perspectives, which turned out to be correct. Besides this obvious error of appreciation, the major fault in Aron Boyarsky's attempt was to follow a path that rejected the component method and lent itself much more to the rough growth rate projections of the past. The only improvement with regards to past projections was that he adopted a regional rather than a global approach, but it still remains far behind the UN's methodical approach by country.

Donald Bogue (1966, 1967) based his work on the general principle that the observed mechanisms that determine fertility in developing countries would soon be subject to a rapid change. He believed that the large majority of these countries' citizens wished to reduce their births, that the national elite and the political leaders were increasingly in favor of developing programs to limit births, and that modern contraception methods—soon to benefit from new technological progress—would easily spread among the population and be adopted by the majority. He also thought that further reductions in mortality would be increasingly difficult to obtain. He concluded that the population growth rate would decrease so rapidly that zero growth could be attained by the year 2000 and that the problem of rapid population growth would only affect a few small backward regions. According to his projection, world population would only reach 4.5 billion in 2000. Even less so than Boyarsky's work, Bogue's attempt could not compete with the UN projections: not only was his prediction of the future no better, but the arguments used were quite naïve and based on an equally coarse method. Donald Bogue, with Ami Ong Tsui, took up the question again in 1979 with more vigor and the same desire to expose the UN overestimate and did not hesitate to write, "We predict that by the year 2025, the world will have nearly achieved zero population growth. It is estimated that this equilibrium will be achieved with a world population of about 7.4 billions." (Bogue and Tsui, 1979:99). This new publication attracted a lot of attention and incited a certain controversy. Giving an estimate of between 5.75 and 5.97 for the year 2000, far below the final result and only 20 years before that date was not particularly perspicacious.

2. Thomas Frejka

Thomas Frejka's contribution (1973) was much more decisive. He convinced the UN to look beyond the year 2000 for the first time, and he exposed all the potential advantages of a very long term logic to better base the hypotheses useful to short- and mid-term projections.

Even though they more or less integrated the teachings of the demographic transition theory, the UN's projections have always given priority to the analysis of past trends confronted with the current political and social context in order to deduct the most reasonable possible future trends of mortality and fertility without too many theoretical apriorisms. On the contrary, Thomas Frejka began with the idea that the demographic transition theory could usefully be applied up to its supposed limit, a stabilization based on a generalized convergence toward zero growth. Instead of considering the future toward which such and such an evolution considered plausible of components of population dynamics could lead us, he considered which trends of these components could lead to this stabilization and in what time limit. Thomas Frejka also accentuated the benefit of producing one or more scenarios considered very plausible side by side with extremely improbable scenarios, this made possible the illustration of the force of current changes and the unlikely results of hypotheses sometimes retained by politicians or public opinion. By describing the improbable as plausible, his intention was for each person to be able to form a considered opinion on the demographic future of the planet. In concrete terms he showed that in the year 2000, which is of interest here, the world population could be 4.7, 5.1, 5.9, 6.4, or 6.6 billion if the net reproduction reached 1 in 1970 (his projection beginning at 1965), in 1980, in 2000, in 2020, or in 2040. It was up to each person to determine at what point reaching this objective was most plausible in order to deduct the estimated populations at the chosen year (2000 here, but it could as easily be 2050 or 2100 as the exercise was resolutely based on the long term, as we will discuss further below). This was doubtless less comfortable than the UN scenarios and no doubt the author can be reproached for this excess of freedom to the reader, but it is perhaps more stimulating because of it. Thomas Frejka's work is a complement to the UN's work and an encouragement to widen the field rather than a real alternative.

3. The World Bank, the Census Bureau

The attempts made from the end of the 1970s by the World Bank and the United States Bureau of the Census to compete with the UN projections are entirely different. Indeed, they are more variations on the same theme than truly original contributions.[10] The repetition of the same type of protocols on the same data produced very similar results, which from a scientific point of view was not without interest. In a slightly more impertinent interpretation, one could say that although the World Bank (Zacharia and Vu, 1978, 1980; Vu, 1985) did good work in predicting 6.02 billion in 2000, the Census Bureau (1979) exaggerated a little with their 6.35 billion in a medium hypothesis for reasons that were perhaps not totally innocent.

The contemporary work of G. Littman and Nathan Keyfitz (1977) was no more innovative and concluded with a result for 2000 that was a little further from reality than that of the UN (5.88 billion).

Table 77–5 and Fig. 77–16 synthesize the results of population projections for the year 2000 published before 1980, according to author and hypothesis. The medium hypothesis of the UN projections have always been closest to reality, with one exception, the World Bank's 1975 projection, which did barely more than pick up on the basic estimates of the UN's hypotheses.

Donella Meadows *et al.* (1972)[11] and then Mihajlo Masarovic and Eduard Pestel (1974) attempted a radical innovation by developing complex models that combined demographic projections with economic, social, environmental, and political trends, with the objective of revealing that the population trends predicted by the UN would necessarily lead to an explosion of the world system during the 21st century, causing an increase in mortality and a rapid population decline. The authors concluded that if this explosion did not finally occur, it would be because fertility would have declined far more rapidly than predicted by the UN. Although the holistic approach deserves to be emphasized, the ideological presumptions significantly reduce its scientific interest.

[10] The U.S. Bureau of the Census (McDevitt 1996; McDevitt *et al.*, 1999) was the first to retain a hypothesis of an extension in fertility decline below replacement level for Arab and Muslim countries (Morocco, Tunisia, Turkey, Iran, etc.), even before the United Nations decided to take this type of hypotheses into account in its last revision (United Nations, 2003b).

[11] See also Delaunay (1972; in French).

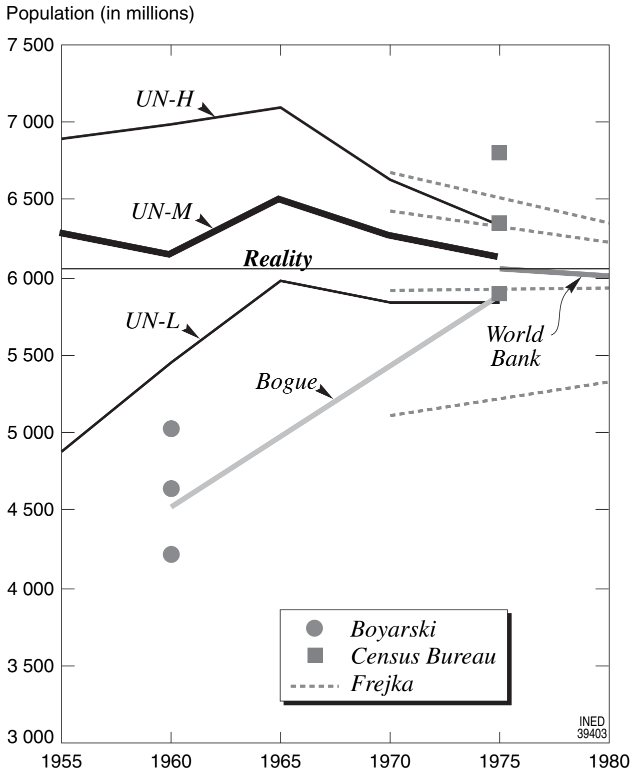

FIGURE 77–16 Comparison of the results for 2000 from the various projections published between 1950 and 1980.

4. International Institute for Applied Systems Analysis

In 1994 International Institute for Applied Systems Analysis (IIASA) published world population projections based on a multiregional model of components by cohort (Lutz, 1994). One of the advantages of these projections is no doubt that a larger number of scenarios was explored by combining different migration, mortality, and fertility hypotheses. Table 77–6 summarizes the results for 2050 published in 1994. By taking the central scenario and combining it with the central hypotheses of migration, mortality, and fertility, a total world population of 11.3 billion was found, against 14.9 billion in the scenario of high fertility and mortality and low mortality and against 8.3 billion in the inverse scenario. The central estimate is much higher than what the UN predicted in its medium scenario in its 1994 projection (11.3 billion instead of 9.8).

Two years later, IIASA (Lutz, 1996) published a new version of these projections, giving clearly different results in which the central scenario (9.9 billion in 2050) was considerably closer to the medium scenario of the UN 1996 projection (9.4 billion). The declared margin of uncertainty was greater as the high fertility scenario (with constant mortality and migration) gave a much higher result than did the preceding scenario (19.0 billion); the low-fertility scenario (still with constant mortality and migration) gave an even lower result (5.1 billion).

More recently, IIASA revived its projection work on a new foundation aimed at completely reforming projection methodology based on an approach of probability (Lee and Tuljapurkar, 1994; Alho, 1997; Lee, 1998; Lutz and Scherbov, 1998; Lutz *et al.,* 1998). The first results were featured in an article published in *Nature* (Lutz *et al.*, 1997) and are available on the Web (*www.iiasa.ac.at*). The previous results were also revised downward significantly: this time the central scenario gives an estimate for 2050 (8.8 billion) that is significantly lower than that of the UN's 2000 projection (9.3 billion). This promising work is, however, too recent to be compared retrospectively to reality, as has been done here with the UN's projections.

IV. FROM MEDIUM TO LONG TERM

As stated above, the credit for showing the benefit and feasibility of long-term world population projections goes to Thomas Frejka (1973). Immediately after the publication of his work, the UN integrated this new dimension into their projection work and published their first attempt in 1974 (UN, 1974a,b 1975). The Population Division then repeated the operation several times, but less regularly than for mid-term

TABLE 77–6 Summarized Results of the International Institute for Applied Systems Analysis's World Population Projection (1994) for 2050

	Hypotheses

All figures are in millions.

projections (UN, 1981, 1982a,b 1992, 1998). In 1974 and in 1982, the targeted year was 2100, the end of the 21st century; in 1992 and 1998, it was extended to 2150.[12]

The priority is no longer to propose as realistic a view as possible on the short- and mid-term future of world population but to illustrate the consequences of a more long-term extension of current trends or those expected in the coming decades. As Thomas Frejka demonstrated, this exercise enables us to imagine what could be the end of the current demographic transition currently generalized at a global level (see Chapter 69).

This is to some extent the role played here by the medium scenario, which shows all the countries of the world toward their maximum life expectancy, with fertility stabilizing at a level close to replacement in 2050–2055 at the latest and supposing that all net international migration would be zero after 2025.

The projection contains seven scenarios that only differ in their fertility hypotheses. In all countries mortality should fall and life expectancy is supposed to increase to the maximum level of 87.5 years for men and 92.5 years for women, at the rate already established in the medium scenario of the projections for 2050. Let us note in passing that for long-term projections, the reference limits of the projection for 2050 (82.5 and 87.5 years, according to sex) were increased, which is proof that the limit is not considered as an absolute but as a pragmatic reference point in order to converge life expectancies. Similarly, there is only one migration hypothesis, which is the application of the trends chosen in the projection for 2050 until 2025 and afterward a constant balance of zero.

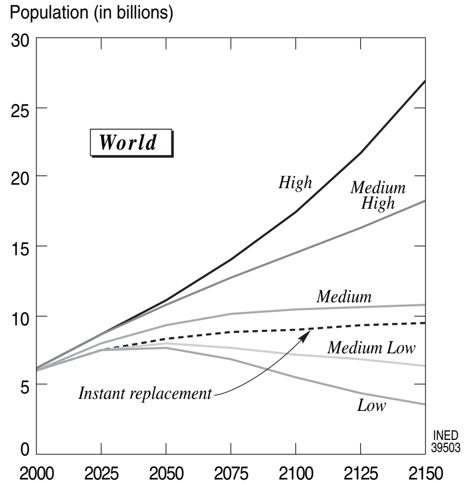
In contrast, fertility is the subject of seven different hypotheses. The medium, high, and low hypotheses are a prolongation of those established for the projection to 2050 in the context of the *1996 revision.* In this case the medium hypothesis differs significantly in this aspect from the *2000 revision*, which was presented at the beginning of this chapter, as it supposes that all countries will converge toward the replacement level in 2050–2055 at the latest and that fertility will then remain constant until the end of the projection period (UN, 1998:8). This provision results in the medium scenario forecasting a direction of *stationarity* (see Chapter 20 of Volume I), in other words toward complete stabilization in the number and the structure of the population. In addition to these three basic hypotheses, the 1998 long-term projection included four other hypotheses. Two of them (called medium-low and medium-high) were justified by the fact that in time the divergence would have increased so much that it was interesting to look at the intermediate trajectories. There are thus five exploratory hypotheses of potential future realities. The objective of the two last hypotheses, as in the 2050 projection, is pedagogic, enabling a comparison of the results of the first five either with fertility maintained constantly at the initial level or with fertility reaching the replacement level immediately (at the beginning of the projection period).

In the context of the medium scenario, the world population would be 10.8 billion in 2150, a period at which it would be practically stable, 10 billion having been exceeded in 2075. The range between the low and high hypotheses obviously widens exponentially (Fig. 77–16). In 2150 it would rank from 3.6 billion to 27 billion, the intermediary hypotheses for the same date being 6.4 and 18.3 billion, respectively. Thus, it is clearly seen that, with time, relatively modest differences in fertility[13] can produce huge gaps in terms of population. But this range, large as it may be, is negligible compared with the result if current fertility was held constant: 296 billion in 2150, including 295 billion for Asia, Africa, and Latin America and only 1 billion for the rest of the world. This number is entirely unlikely but is nevertheless of great pedagogic value: it shows the huge importance of the changes currently occurring. Yet, the calculation is based on fertility levels from 1990–1995 when average world fertility was already only 2.96 children per woman. The same exercise carried out by the UN in 1992, with a slightly higher world TFR (3.45 children per woman) gave a result of 700 billion human beings in 2150 (UN, 1992). The other lesson of such a perspective is to raise awareness of the vast disparities observed in demographic behavior. If the medium growth rate of the world population observed at the start of the projection (1.7% per year in 1985–1990, for 1992) had been forecast, world population would have certainly increased exponentially but would have reached only 70 billion in 2150 and not 700. This results from the fact that, with time, the most fertile proportion of the population increases considerably and the average world growth rate increases, progressively approaching the rates observed in the most fertile countries (Vallin, 1994).

Inversely, the instant replacement fertility scenario reminds us, as we have already stated regarding projections to 2050, of the existence of the growth potential concealed by a relatively young world population,

[12] The United Nations' Population Division (2003a) is currently planning to explore the demographic future of humanity over 3 centuries. A first meeting of experts was held in New York in June 2003.

[13] It results from the fertility hypotheses forecasting that in 2050–2055 the maximum observed gap between total fertility rates would only be between 1.6 and 2.6 children per woman.



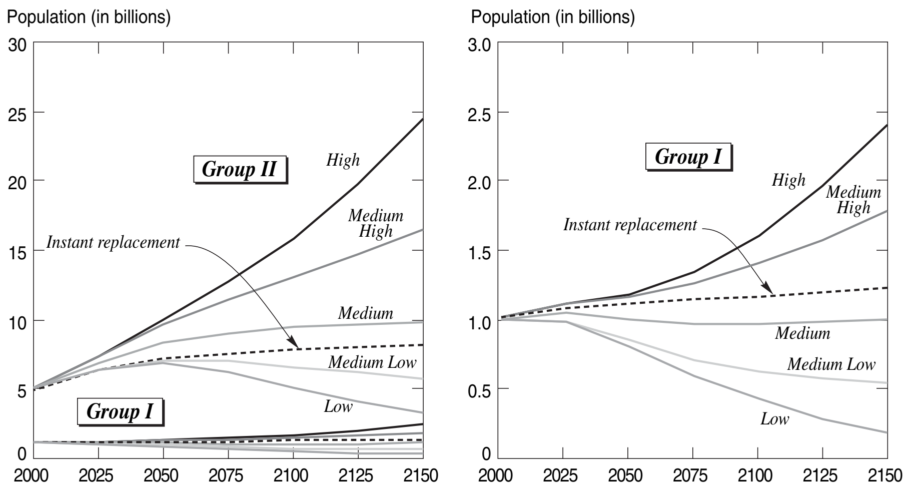


FIGURE 77–17 Population projection up to 2150 for the world and for country groups I and II, according to the United Nations' 1998 projection (group I: Europe, North America, and Oceania; group II: Asia, Africa, and Latin America).

but from this viewpoint, the long-term projection does not yield any more than does the projection to 2050, which is enough to deplete most of this potential.

Contrary to its usual practice, the UN did not divide the world into developed countries and developing countries in this projection but distinguished two groups: group I, which included Europe, North America, and Oceania; and group II, which included Asia, Africa, and Latin America. This does not facilitate comparison,[14] but the general idea is the same: to obtain a classic division between present-day developing countries and developed countries all that is needed is to transfer Japan from group II to group I and do the opposite for Melanesia, Micronesia, and Polynesia.

Figure 77–17 shows the evolution in total population from 2000 to 2150 for both groups according to the six first fertility hypotheses. In the context of the medium-hypothesis, the population of group II would stabilize at around 10 billion inhabitants in 2150, thus doubling its current number, but most of this would already have been acquired by 2075 with more than 9 billion. Group I would just about preserve its current population level of 1 billion, after a slight decline followed by an increase.

More striking than the huge demographic imbalance that will exist between these groups is its susceptibility to fertility hypotheses. Indeed, in the

[14] Not only with mid-term projections but also with the preceding long-term projection, which includes the whole of the former Soviet Union in group I, whereas in the 1998 projection only the European republics of the former Soviet Union were included in Europe.

context of the high hypothesis, group II would reach a population of 24.5 billion in 2150 compared with 2.4 billion for group I. The relative gap is the same in the preceding case, but in absolute numbers, the difference increases from 8 to 22 billion. In the low hypothesis, the population of group II would be reduced to 3.3 billion in 2150, whereas that of group I would literally crumble to 270 million. This time the relative gap widens slightly, but the absolute gap is much less (3 billion). But because all these scenarios are considered as being possible, cases in which both groups follow different scenarios must also be considered. At the extreme case therefore, a group II population of 24.5 billion (high hypothesis) in 2150 next to a group I population of 270 million (low hypothesis) could be imagined, as well as a world in 2150 consisting of a group II population of 3.3 billion and a group I of 2.4 billion. In other words, the so-called north–south demographic ratio of the planet could equally be 1 to 1.5 as 1 to 100 in the middle of the 22nd century.

Beyond these two groups of countries, the UN has also published results by large geographic areas, including India and China as the two largest countries in the world. Figure 77–18 illustrates population trends from the medium hypotheses for each of these large areas.

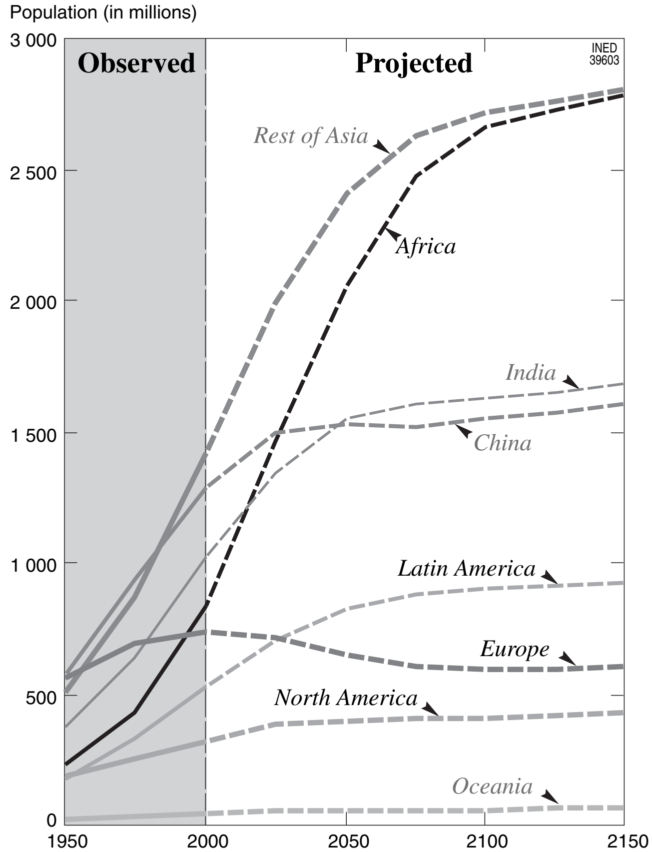

FIGURE 77–18 Trend since 1950 and projection up to 2150 of the population of eight large geographic areas of the world in the medium hypothesis of the United Nations' 1998 long-term projections.

If the general stabilization presumed by this hypothesis occurs, it is clear that all, or nearly all, of it would have taken place in the majority of these areas by 2050. Only Africa and, to a lesser extent, Asia excluding China and India will still experience a substantial growth after that. The population of Africa would increase by another 800 million inhabitants between 2050 and 2150, and Asia excluding China and India would increase by 400 million, with the two latter countries both reaching 2.8 billion inhabitants each.

As previously done for the projections to 2000, Table 77–7 and Fig. 77–19 compare the results for 2001 of the five long-term projections produced by the UN with the various projections published by other authors and organizations.[15] It is obviously not as yet possible to compare them to the real results awaiting us nearly a century from now.

Thomas Frejka's results can not be compared to the others as they do not provide one central scenario that is more probable than the others. The World Bank's results, which were limited to only one scenario (except in 1994) appear once more to be nearly a copy of the UN's medium hypothesis, a little shaky, however, if we judge by the fluctuations surrounding the trend indicated by the Population Division. In its central scenario IIASA's result is, as we mentioned earlier, significantly revised downward. But what is most striking here (Fig. 77–18) is that the range of imprecision varies enormously, notably under the effect of the strong fluctuation of the high hypothesis. All things considered, this comparison reinforces the idea that barring proof to the contrary, the UN's projections give the most complete and reliable context to speculations regarding the future of world population.[16]

[15] Two results from Thomas Frejka (Frejka, 1973; Frejka and Mauldin, 1980), six from the World Bank (Vu, 1984, 1985; Zacharia and Vu, 1988; Bulatao *et al.*, 1990; Bos*et al.*, 1992, 1994), and three from the International Institute for Applied Systems Analysis (Lutz, 1994, 1996; Lutz *et al.*, 1997).

[16] At least at a global level. Indeed, these projections are subject to significant errors at the level of countries considered individually, the global result depending largely on the compensation of opposing local errors.

V. PROJECTIONS BY AGE AND SEX AND DERIVED PROJECTIONS

Population projections obviously do not only aim at imagining the total population at a particular point. Reflection on the demographic future or, further still, using population projections for economic and social planning requires, for example, consideration of the sex and age structure, place of residence, and social and occupational category of this future population. The production of "derived perspectives" that enable these results to be reached requires work in the prolongation of the production of principal projections. When it is used, as is the case here of the component method, the projection of the age and sex structure is in fact a direct result of the main projection as it passes by the application of fertility, mortality, and migration data to population by age and sex calculated during successive stages of the process. To derive the principal projection toward other differentiation criteria, a special program must be developed according to new hypotheses, as was done in Chapter 73 by Marlène Lamy with regard to projections of population schooling. Here we will merely give an outline of the results by age and sex of the UN's projection and mention the specific projections that the UN develops quite regularly concerning urbanization.

1. Age and Sex Structure

After some examples of the possible transformations of the population pyramid between the present day and 2050, we will illustrate some hypothetical trajectories by large age groups up to 2150.

a. Evolution of the Population Pyramid by Age and Sex Up to 2050

Figure 77–20 compares the population pyramid of the world population in 2000 with what it could become in 2050 according to which of the three fertility variants of the principal scenario of the UN's 2000 projection occurs. While the world population in 2000, dominated by the developing countries that are still experiencing high growth, presents a young pyramid, wide at the base and tapering at the top, its profile would change completely in the medium hypothesis and even more so in the low hypothesis. With medium fertility the structure of the pyramid does not disappear entirely, but at its base the frequencies of the young age groups are only slightly higher than those of the adult age group; the top of the pyramid is considerably reinforced. In the context of the low hypothesis, fertility no longer ensures a replacement of the generations, the young age groups are on the contrary smaller than the adult age groups and only after age 70–74 years do we find frequencies lower than that of the age group 0–4. In the context of the high hypothesis, the pyramid structure becomes even clearer than the one for 2000, which is already very marked at the base by the decline in fertility. It is, however, wider at the top, becoming nearly triangular. Even though the hypothetical fertility for 2050 is lower than it currently is, it would actually be higher than the replacement level and nearly constant for several decades, which produces this structure of a nearly regular triangle.

All the following pyramids are based on the medium hypothesis to show that even in this scenario in which preference is given to a general stabilization, a wide variety of different situations will be observed in 2050. All these pyramids illustrate populations of unequal size[17] and are drawn on a relative scale (population proportions and not total frequencies by age group) in order to highlight the structural differences.

Figure 77–21 begins by comparing the world to the two large traditional groups, namely, developing countries and developed countries. Although the developing countries would have a pyramid hardly

[17] Including the pyramids in Figure 77–20 in order to be able to compare them with the ones following.

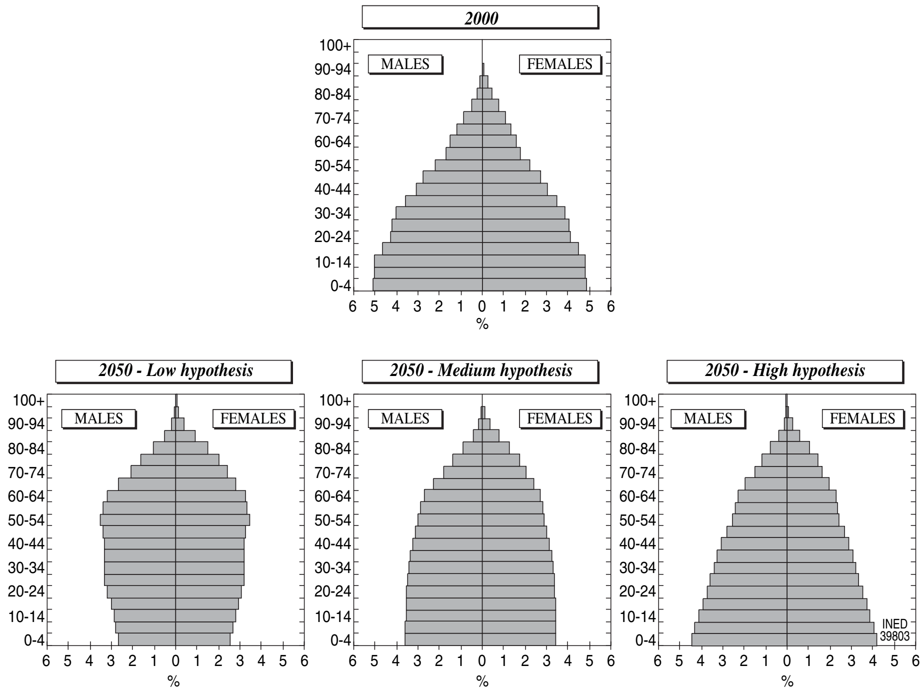

FIGURE 77–20 Transformation of the world population's age pyramid from 2000 to 2050 according to the three fertility variants of the United Nations' principal scenario.

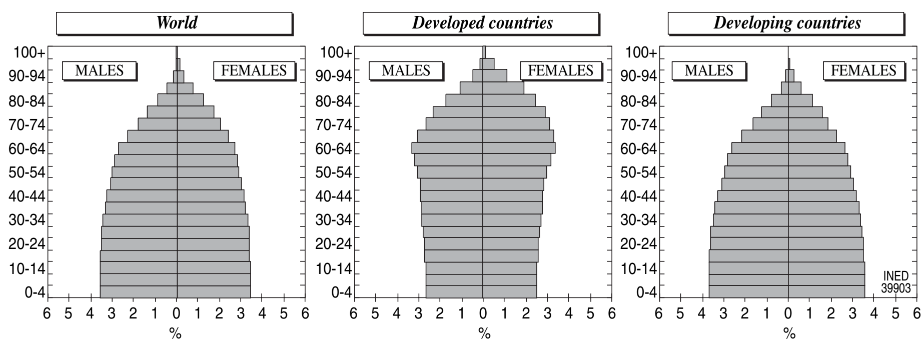

FIGURE 77–21 The world population pyramid in 2050 and those of the developed countries and developing countries, according to the medium variant of the United Nations' principal scenario.

different from the world pyramid (barely wider at the base), which is not surprising in view of their comparative weight, the developed countries would have an age structure dominated by the 50- to 75-year age groups. This population aging may cause serious economic and social problems.

However, this distinction between developing countries and developed countries will not make much sense in 2050 as the diversity of the first group will be so wide. This can be seen by comparing the continents or the large continental regions (Fig. 77–22). Although Africa would still have a very young pyramid, that will not be the case of any of the other subgroups of developing countries. Furthermore, organizing them according to profile as in Fig. 77–22 shows that the developed countries alternate with the younger structures of some developing countries; east Asia (which, although it includes Japan, is massively dominated by China) can be inserted between North America and Europe.

Figure 77–23 illustrates the population pyramids of seven countries that in 2050 will in the hypothesis (as Fig. 77–11 shows) become the most populated countries in the world (India, China, United States, Pakistan, Nigeria, Bangladesh and Indonesia), to which the European Union and Russia were added.

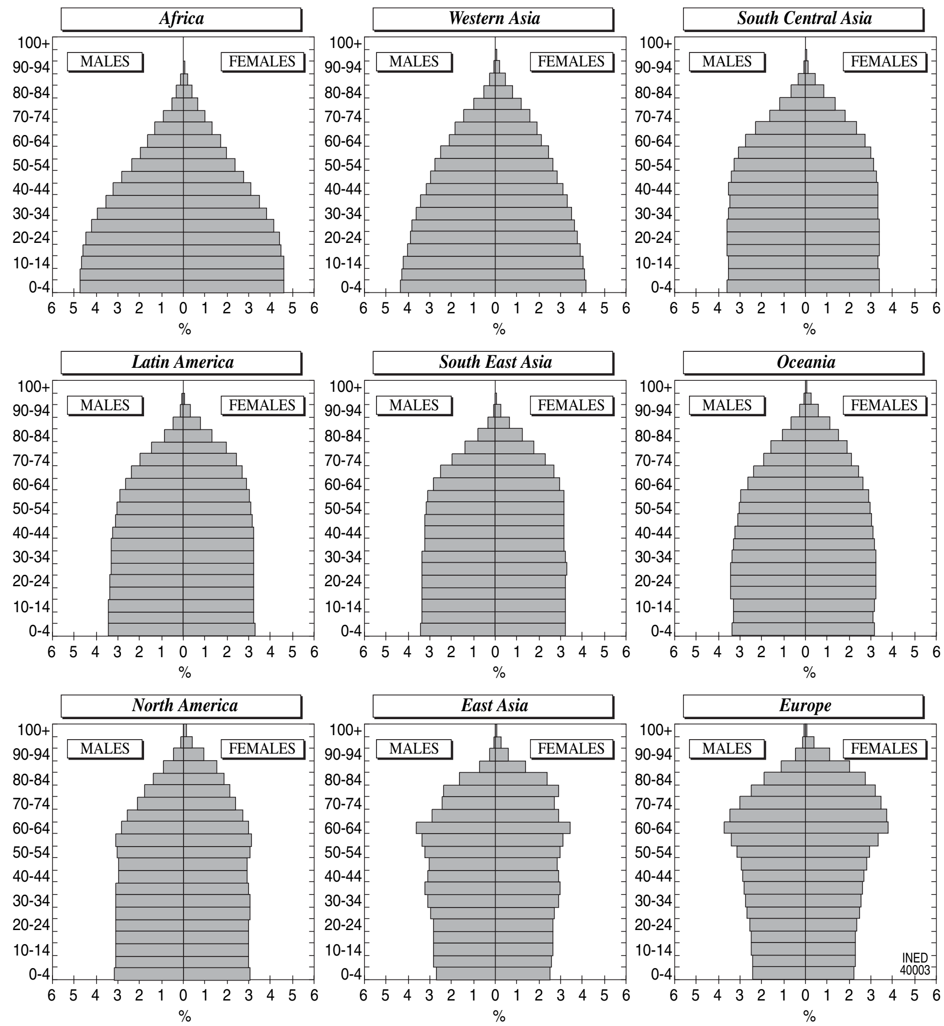

FIGURE 77–22 Population pyramid in 2050 of the population of the large regions of the world, according to the medium-fertility variant of the United Nations' principal scenario.

From Nigeria, which yet presents quite a different profile to the typical African one, to Russia, the diversity is even greater. Here again there is no systematic border between developed countries and developing countries: China is more similar to Europe than to India, whereas the United States resembles Indonesia more than it does the European Union.

b. Evolution by Large Age Groups Up to 2150

The UN does not publish the results of its very long-term projection by 5-year age groups. However, these results by large age groups are at our disposal and thus enable us to visualize the various possible trajectories for the young (0 to 14 years), adults (15 to 64 years), and the old (65 years and over). Table 77–7, illustrated by Fig. 77–24, presents the results of the three variants of the principal scenario.

In all three cases, the proportion of the young declines significantly, whereas that of the old increases rapidly. This general phenomenon is so strong that only in the high hypothesis does the proportion of the 65 years and over group remain constantly below the under-15 group to the end of the projection period. In the medium hypothesis, the two proportions become equal shortly before 2080, each consisting of 20% of the total population. In the low hypothesis, this would occur from 2045; the proportion of the young would fall very rapidly to 15%, whereas the proportion of the old would not yet have had the time to exceed this level (Fig. 77–24).

At the end of the projection period, the world population would be made up of 25% old people to 18% young people in the medium hypothesis, and these proportions would reach 35% against 12% only in the low hypothesis.

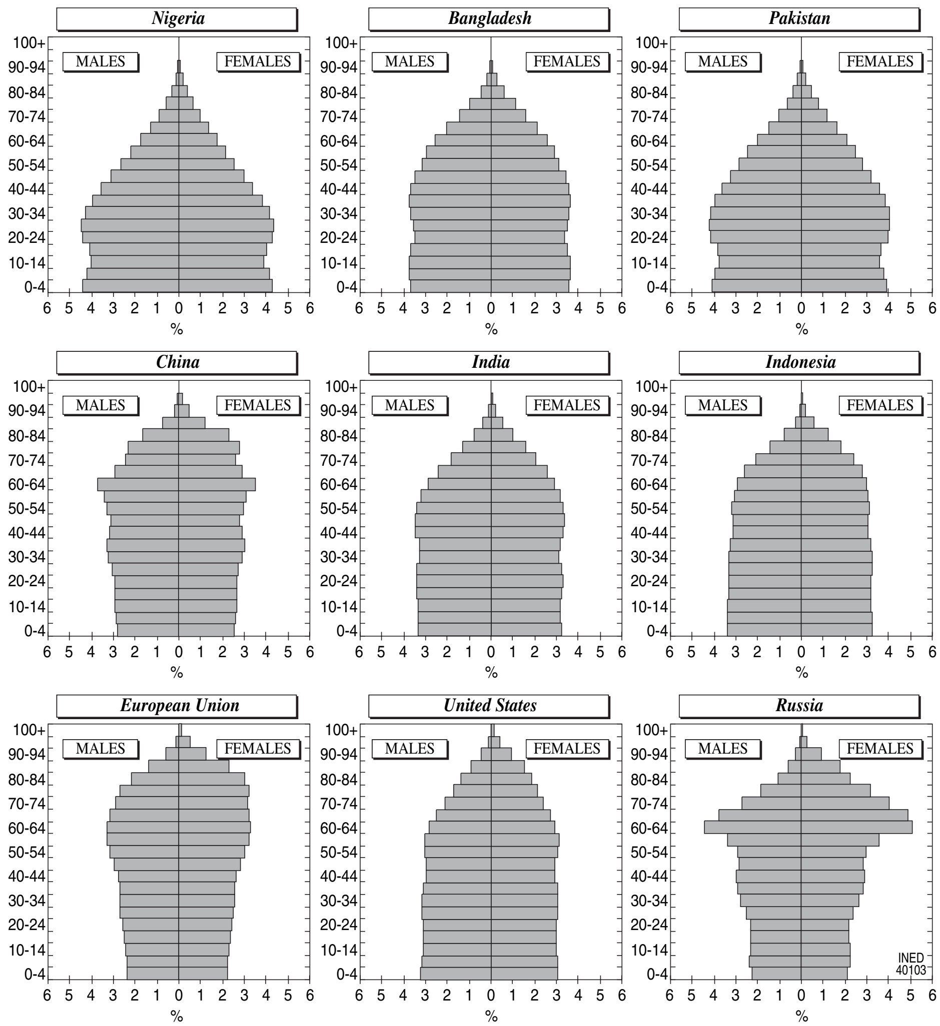

FIGURE 77–23 Population pyramid of the seven countries that will be the most populated plus the European Union and Russia in 2050, according to the medium-fertility variant of the United Nations' principal scenario.

Paradoxically, regardless of the hypothesis, the near symmetry in the evolution of these proportions of the young and old are accompanied by a strong fluctuation within the adult population (Fig. 77–25). With population aging it begins by increasing more or less strongly depending on the selected scenario, opening the way to a kind of golden age of population in which a high proportion of adults creates an excellent opportunity for economic development. In the medium hypothesis, the proportion of adults would reach nearly 66% in 2025 before falling relatively rapidly below the starting level and arriving at 58% at the end of the projection period. This phenomenon would obviously be less significant in the high hypothesis but much more marked in the low hypothesis, with a maximum of 69% around 2025 followed by a drop to 53%. This would apply to the developing countries in particular, of course. In the developed countries, whatever the scenario, the proportion of the adult population decreases from the beginning to the end of the projection period.

This phenomenon is similar to an oxygen supply for the developing countries, giving them an opportunity to invest today in social protection systems that will enable them in future to cope with the problem of population aging with less difficulty. But this is only an interlude, a window of hope that must not be missed if the coming risk of failure is to be avoided. It is even more important to build on it if the fertility decline is rapid. China is a typical example in which this demographic window of economic opportunity is large, as the proportion of adults will soon beat records, but the golden age will not last long since fertility declined very rapidly.

TABLE 77–8 2000–2150 Projection of the Proportions (%) of Children (0 to 14 Years), Adults (15 to 64 Years), and Old People (65 Years and Over) in the World Population and by Country Groups, According to the Three Fertility Hypotheses of the United Nations' Principal Scenario

2. Urbanization

To deduct urban and rural population projections from the main projection, a definition of the border between these two categories must be available (see Chapter 61), as well as estimates of their current size and hypotheses of the specific dynamics of their trends. To do this, in its most recent projection the UN (2001) made some very rudimentary choices, admitting that any attempt in this field is risky and that it is better not to project too far into the future or to overly refine the data or the hypotheses.

The definition of an urban population retained for each country is simply the one used by statistical bodies. In other words, data that are often of a different nature from one country to another are added up on a world level. Moreover, the starting point is also one estimated by each country, at least in terms of the proportion of the urban and rural population; these are then applied to the Population Division's estimated total initial population. Finally, urban and rural population projections are obtained by applying future proportions to the principal projection (in this case the 1998 projection), estimated by using a very simple hypothesis. This hypothesis states that the evolution of the urban population will continue in each country at the same rate as that observed between the two most recent estimates available from census data. Yet again, the conditions for the projection are heterogeneous for all countries. It is not too much to say that the care taken with this type of derived projection is far from the efforts made for the principal projection. It can only therefore give very approximate results, just the general size. It is true that the projection is relatively short term, only up to 2030. We will only show three very basic tables here.

a. Evolution Up to 2030 of the Proportion of Urban Population

The first table (Table 77–9) shows the evolution since 1970 and the projection up to 2030 of the urban population proportion in the world and by continent. In the developed countries, it is already very high (76% in 2000), but according to this projection, it will continue to increase until it reaches nearly 84%. In the developing countries, it was only 40% in 2000 but should increase even more rapidly to reach 56% in 2030. However, the situation in Latin America is closer to the situation in the developed countries than in the other developing countries, with 76% in 2000 and 83% expected in 2030. In contrast, Africa and Asia are far less urbanized (around 37% in 2000) and could each remain separated in this context from the rest of the world (barely 55% in 2030).

b. The Large Cities in 2015

The last two tables describe the very large cities. However, the results for these are given only up to 2015, no doubt to avoid the failures of previous projections that were bolder but completely contradicted by the facts.[18]

Table 77–10 gives the number of agglomerations that have over a million inhabitants according to three size categories, their cumulated population, and their

[18] In their 1990 urban projections, the United Nations (UN, 1991b) had predicted an incredible growth for Mexico City that would increase the population from 14.5 million in 1980 to 25.6 million in 2000. However, the 1992 urban projections (UN, 1993) quickly corrected this, predicting a more modest increase from 13.9 million in 1980 to 16.2 million in 2000 and was guilty of underestimation. In the 2001 urban projections, the UN (2002) estimated the population of Mexico City at 18.1 million in 2000.

TABLE 77–10 Number and Population of the Agglomerations with 5 Million or More Inhabitants in 1975, 2000, and 2015

Agglomeration size	Number of agglomerations			Population (in millions)			Proportion (%) of total population

Data from United Nations, 2001c.

proportion in the total population for 1975, 2000, and 2015. In 1975, only five cities had over 10 million inhabitants. There are currently 19, and that number could increase to 23 in 2015. These cities would then have 375 million inhabitants, 10% of the total urban population. If agglomerations of more than 5 million are considered, then 59 cities, 600 million inhabitants, and a quarter of the urban population would be counted in 2015.

Table 77–11 gives the list of the agglomerations that could number more than 10 million inhabitants in 2015 and their size in 1950, 1975, 2000, and 2015. It gives an idea of the diversity in the growth rates of the large agglomerations. Cities that in 1950 had hardly more than a million inhabitants (Karachi, Istanbul, Hyderabad, etc.), others that had already more than 5 million (Tokyo, Shanghai, Buenos Aires) and even over 10 million (New York) are found in this list. There is not one European agglomeration included in this table, not even those that approached 10 million inhabitants during the 1950s such as London or Paris.

TABLE 77–11 Agglomerations that Could Have More than 10 Million Inhabitants in 2015 and the Number of Inhabitants in 1950, 1975, 2000, and 2015

Data from United Nations, 2001c.

CONCLUSION

Like any projection, the World Population Projections published by the UN give hypothetical results. Since the end of the 1950s, however, they have always given surprisingly reliable results for the 2000 horizon. Initially, this was made possible only by the improvement in the source data and the adoption of a method capable of taking into account the diversity of situations (projection by country) and the principles of population dynamics (component method). But it is also owing to the existence of a general theory (the demographic transition) robust enough to express most of the current trends, at least in the mid term. In fact, no other rival attempt has produced better results.

This is, however, not the case for very long term projections, which predict very different futures because slight variations in the evolution of fertility and mortality can have radically different consequences when they are projected over a century or over a century and a half.

But without even going as far as exploring the long-term future, the mid-term future is today as difficult to predict as it was in the past. In an era in which the great historical change, called the demographic transition, is coming to an end, the paradigm of the same name is of no assistance in predicting what will follow. As to what will follow, we can imagine multiple scenarios leading to consequences that, as extravagant as they may seem, are no less plausible than the improbable prediction of a permanent stabilization.

The Future of Mankind

Looking Ahead after the Transition

JACQUES VALLIN AND GRAZIELLA CASELLI

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

INTRODUCTION

As we have seen in the previous chapter, the hypothesis of widespread and conclusive stabilization of the world's population, which in the mid-1990s still remained the focus of projections of the United Nations (UN, 1995), is of course no more than a reference model—that of the *demographic transition.* It is fairly plausible that, initially, populations will tend to follow this model. However, this is not certain, and it is unlikely that after this transition, things will continue as before. Regarding the first point, the UN projections comprise, on both sides of the average hypothesis, low and high hypotheses (the difference with the former lies in the level to which fertility would tend), with mortality remaining unchanged (UN, 1995). The UN was studying the consequences of a convergence of fertility levels toward 1.7 children per woman and toward 2.5 as an alternative to the 2.1 that ensures strict generation replacement. Of course, in both cases the assumption that the size of the world's population will stabilize is no longer valid. Over the very long term, a level of 2.5 children per woman corresponds to infinite growth, whereas with 1.7 children, growth would soon give place to decrease and the population would tend to become extinct. Toward the end of the 1990s, the UN, within its central hypothesis, dismissed the assumption of a systematic return to the fertility level necessary to ensure replacement in all northern countries, where fertility has already reached even lower levels.

However, whether we are dealing with the central hypothesis of a population size stabilization or the hypotheses of continuous growth or decline, the world's population would become a stable population in the strict sense, that is, a population with constant parameters and an invariable age structure. In other words, even if the size of the population keeps changing, it would be, at the end of the transition, only under the effect of completely frozen behaviors. Of course, this second postulate can also be questioned; in fact, it is very likely that it will be questioned.

Not only is it unlikely that some day human behaviors might definitely freeze, but it does seem to us that we can already observe the early beginnings of new changes that might be the sign of new demographic revolutions to come. Indeed, some authors have already formulated the idea of a second demographic transition (see Chapter 69) in order to account for the changes recently observed in northern countries in terms of marriage and fertility (van de Kaa, 1987). On the one hand, the recent changes in the mortality of the very old reinforces the idea held by a number of researchers that human life expectancy could increase far beyond the limit of 85 years adopted in the 1994 UN projections.[1] On the other hand, the current variations observed in fertility, particularly the recent changes in its tempo, could lead to the adoption of fertility models by age that are completely different from those that have been referred to up to now. In other words, not only is the current transition probably not

[1] In more recent UN projections, this threshold of 85 years (82.5 for males and 87.5 for females) is no longer a strict limit, since the UN foresee that some countries could overpass it. Indeed female Japanese life expectancy already reached 85 years as soon as 2002.

the only foreseeable demographic trend, but new trends might appear even before the generalization of the current transition referred to in UN projections. Thus, it is not wholly ludicrous to suggest that the ostensible limits to the main population parameters of life expectancy at birth, average parity, or sex ratio at birth may not be fixed as they seem. The underlying idea is that there may be some value in exploring the demographic impacts of biological or social behavior that could extend some of these limits sufficiently to give rise to demographic regimes that are radically different from those referred to in the UN's current long-term projections.

However, we do not mean to assert that the social and biological behaviors of our species can endlessly change. Although this exercise requires some imagination, it remains within strict limits, compared with scenarios of infinite life expectancy, zero fertility, or hermaphroditic reproduction.

Tempting as it may be to imagine situations wildly beyond things as they are or even beyond what is generally allowed as possible, we have no wish to take the exercise further than stretching a few more or less established facts or trends. For the same reason, we will limit our investigations to changes in fertility and mortality, because although migratory scenarios can modify the trends observed for a given population, they do not have an impact on the world population as such, not unless we begin to consider interplanetary migrations, which are far from likely to happen in the imaginable future. Let us thus consider a few unconventional but not completely unthinkable possibilities for each of our three indicators of natural increase (fertility, mortality, sex ratio at birth). What would then happen in terms of population size and age structure?

But before moving on to wild conjecture, we must set the baseline.

I. THE BASELINE: WORLD POPULATION IN 2050

The baseline itself has to be resolutely probable. Unlike what follows, however, it will be set in the most conventional possible way: at that mythical cusp when the entire world population will have completed its demographic transition. So mythical is that moment, in fact, that it requires some ingoing massaging of the facts.

The planet's various populations are today at very different transitional stages. Most countries in the northern world completed this long historical process over half a century ago (see Chapter 68), although no precise point in time can be pinpointed. The restored fertility–mortality balance of the interwar years was thrown out of kilter by the baby boom, and it was not until the 1970s or 1980s that it evened up again, or, more accurately, temporarily redressed, as a protracted fertility decline has brought it well below replacement level (see Chapter 69). At the same time, the southern world displays a wide mix of situations: some countries have already joined the northern world in an early post-transitional stage, whereas others remain in high fertility, rapidly rising life expectancy scenarios. Granted, transition theory is borne out by across-the-board, and in most cases rapid, fertility decline; but it will still be some decades (perhaps close to a century) before what is still a large percentage of the world population chiefly in sub-Saharan Africa will achieve the stabilization predicted by transition theory (see Chapters 69, 77).

Strictly, then, we should wait on this culmination of demographic globalization when all the world's populations have completed their transition. But the rub is that no evidence points to a general, post-transition stabilization. Although all the world's populations seem likely to adopt increasingly convergent demographic behavior (which vindicates our world approach), there are no grounds for suggesting that such behavior will meet the stationary population criteria. On the contrary, recent 10-year trends in northern and some southern countries show sharp deviations from this model, which could soon exceed anything we plan to hypothesize.

Our baseline, then, will be the year 2050 a point when the UN *medium variant* population projection estimates that the overall world population will more or less stabilize with fertility of 2.1 children per woman and a life expectancy of 78 years. This is cheating on two scores, because not only do we know that this transition point will not in any sense be a baseline for stabilization but, for practical reasons, we are taking the 1994 projections,[2] which, at the time, were still projecting an early return for the northern world to fertility of 2.1 children per woman (UN, 1995). In the 1998 projections, this hypothesis has itself been dropped in favor of a less unrealistic variant of below replacement fertility for several decades to come (UN, 1999, 2001, 2003).

This baseline is read subject to trend projections for our three key indicators. Average parity will remain indefinitely fixed at 2.1 under the UN age-specific fertility model. Life expectancy will continue to rise at its

[2] We could have also used the 1996 projections, which are based on the same hypothesis, but they were not yet available at the time we were working on the paper for the Siena seminar (Vallin *et al.*, 1996). Because there was very little difference at this level between the 1994 and the 1996 projections, we did not consider it necessary to make an entire new set of computations.

current rate to 85 years for both sexes combined (i.e., 82.5 years for men and 87.5 years for women), which is regarded by the UN as the uppermost limit toward which all the world's populations are moving (see footnote 1, page 235). Lastly, the sex ratio at birth will remain unchanged at its initial value of 1.05 males per female. Fortunately, taking the whole world population as our baseline lets us off factoring in migration projections, as this exercise in science fiction will not be pushed as far as interplanetary flows.

The UN 1994 medium variant projects a world population of 9.8 billion inhabitants by 2050. By then, however, although stationarity may be on the way to being achieved, two population growth factors will continue to have an influence for some time. On one hand, past developments mean that the age structure still contains a significant growth potential. On the other hand, as long as life expectancy increases, the population also continues to grow. So, the total world population would rise to 12.2 billion by 2150 and even to 13 billion in 2250 and 13.4 billion by 2300 (Appendix 1). But its age structure would flatten quite quickly once the rapid aging process begun in past decades had completed (Fig. 78–1). Whereas the UN projection gives 28% aged under 20 years, 52% aged 20 to 59 years, and 20% aged 60 years and over in 2050, the almost final age structure of 24% "young people" to 46% "adults" and 30% "older people" is reached by 2100 (Appendix 5).

II. FROM GENERATION REPLACEMENT TO THE ONE CHILD WORLD

The recent long-term trends observed in the northern world prompt two types of questions about where the fertility trend is heading. First, far from following the (until recently) UN consistent scenarios of a return to the crucial 2.1 children per woman, fertility rates have stayed resolutely below it or continued to decline. Today, Italy and Spain are below 1.2 children per woman (Council of Europe, 1999). Some northern Italian regions have even fallen to 0.8 (Liguria) or 0.7 (Emilia-Romagna) (Santini, 1995; Zanatta and De Rose, 1995). Instead of a two-child family, are we not heading toward the one-child world? Is the one-child model that Chinese leadership has been trying to impose on its people for the past 20 years now being willingly embraced as the European ideal and perhaps spreading worldwide? This is not beyond the bounds of

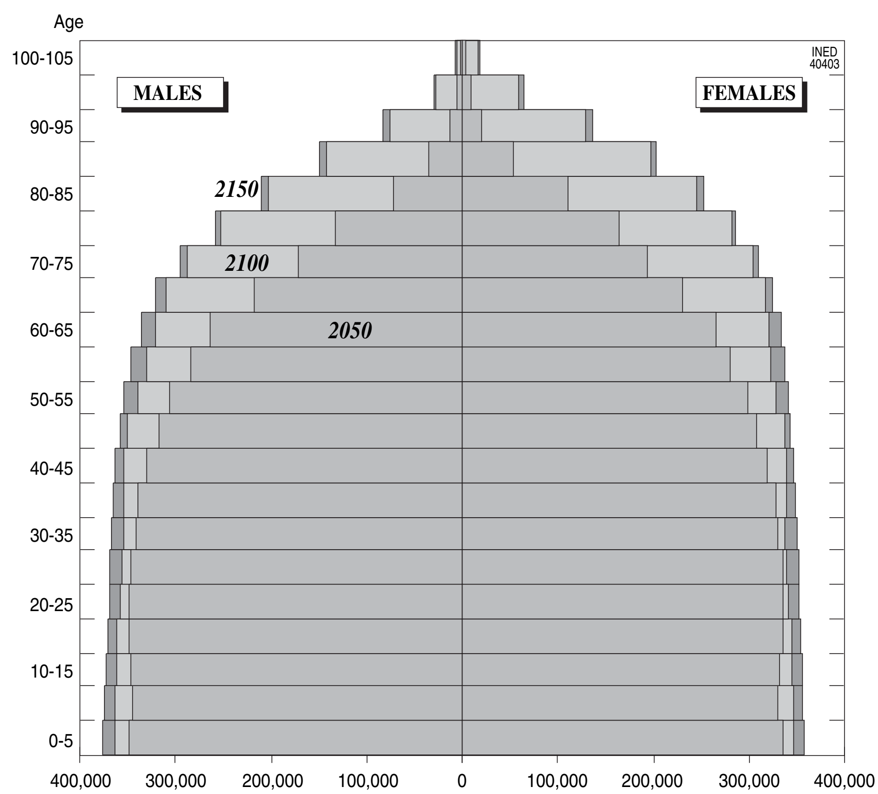

FIGURE 78–1 Age structure of the world population in 2050, 2100, and 2150 in the baseline variant (population in thousands; 2.1 children per woman, life expectancy of 85 years, and sex ratio at birth of 1.05 males per female).

possibility, and it deserves to be explored. But it would be pointless to explore anything below that level, which would just exacerbate a situation already amply catered for by the one-child model.

But recent decades have also seen a slower, more unobtrusive general trend emerging toward postponement of childbirth. In Italy, for example, mean age at first birth rose from under 25 years in 1976 to nearly 28.2 years in 1996 (ISTAT, 2000). So very low fertility may simply result from this later family formation. Delayed motherhood may drive period fertility very low by combining the now very low fertility of women who achieved their desired family size when younger with the still very low fertility of younger women who have put off family formation until later. Overall, desired family sizes may have remained unchanged, but period fertility could in these circumstances actually fall to very low levels. To take this reasoning a step further, if the age of menopause could one day itself be deferred, a new fertility transition might occur that ultimately returns to replacement level. However, the shift from an early model with a normal age around 25 years (UN model) to a late model with a normal age nudging 50 years takes period fertility into a very low phase, possibly even sinking to zero for the space of a few years.

Mean age at motherhood is not only rising, but age at childbearing is also growing more diverse. Some women are still having their children very young, others increasingly later, whereas others are testing out a two-stage fertility, perhaps foreshadowing a model postulated by Jean Bourgeois-Pichat back in the mid-1960s, although admittedly in an altogether different context. Later-onset menopause, he thought, ought to allow women to spread out family formation over a longer time. The day might even come when couples could have two children first between the ages of 25 and 30, then a later pair around the age of 50 after raising the earlier family. That, he said, would create the serious problem of over-rapid population growth, putting society in the position of having to apportion the right to this latter stage of reproductive life (Bourgeois-Pichat, 1966). Twenty years on, Jean Bourgeois-Pichat revisited this idea and updated it to reflect the declining European fertility. The issue was not now fear of overpopulation, but using this two-stage fertility as the means of minimum generation replacement (Bourgeois-Pichat, 1987). It is this last possibility that will be explored below.

1. The Transition to the One-Child World

Many one-child fertility models are clearly possible. We have deliberately chosen here to use a relatively early model, patterned on the tempo referred to by the

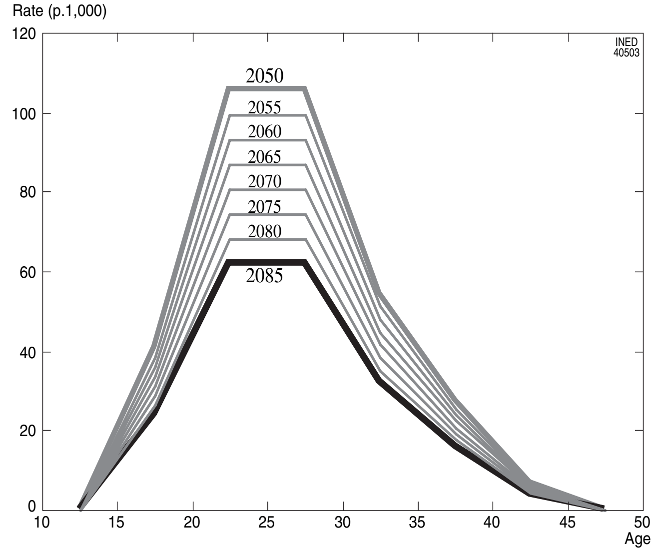

FIGURE 78–2 Age-specific fertility rates in the transition from the United Nations' low fertility variant (1.7 children per woman) to the one-child model over a period of 35 years.

1994 UN's fertility hypothesis at 1.7 children per woman. Thus, the transition to the one-child model imagined here spreads over 35 years, on the basis of the latter UN model. The intermediary stages are obtained through linear interpolation (Fig. 78–2).

For consistency's sake, our baseline in this case is the UN's (according to the 1994 projection) *low variant* world population by 2050 of 7.9 billion inhabitants (instead of the 9.8 billion of the medium variant).[3] A transition to the one-child world with constant fertility at that level over the long-term clearly widens the gap with our baseline variant to a staggering extent. The world population would decline after a century to 2.4 billion by 2150. A century later (2250), it would be no more than 200 million, barely higher than the end of the Neolithic era (see Chapter 66). In 200 years, humankind would have regressed down the same population road along which it had advanced over the past 6000 years. At this rate, of course, total extinction would not be far away. Like a supernova, after flaring up in a breakneck 20th century growth spurt, world population would die out with the same speed.

Meanwhile, it would obviously have aged to a considerable extent (Fig. 78–3). By 2150 the age structure would have stabilized at 8% under 20 years of age, 36% aged 20 to 59 years, and 56% aged 60 years and over (Appendix 5).

[3] Rather than projecting long-term population stability by tending toward stationarity (United Nations' medium scenario), the low scenario provides a more suitable baseline for the transition to the one-child world in 2050 by assuming a drop in fertility below the generation replacement level of 2.1 children per woman.

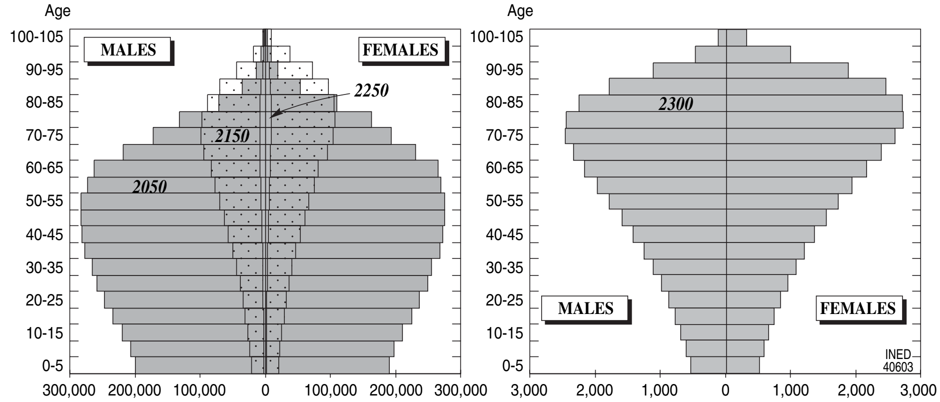

FIGURE 78–3 Long-term age structure trend (in thousands) in the one-child world scenario (1 child per woman, life expectancy of 85 years, sex ratio at birth of 1.05 males per female).

2. Toward New Constant Replacement Level Fertility Scenarios

But the transition to the one-child world is far from the only possible extrapolation of recent trends observed in the northern world. Consider the other two scenarios mentioned above: the bimodal timing of family formation and postponed childbirth, both of which would in the long term restore the balance of births and deaths.

a. Two-Stage Fertility?

Here again, there are an infinite variety of possible bimodal scenarios and many ways of moving from the current scenario of 2.1 children per woman (UN medium scenario) to whatever new model is chosen. We hypothesize that women's lifetime births occur by combining an initial period of reproductive life, with a mean number of 1.4 children born per woman at a modal age of 25 years, and a second period, 30 years later, with a mean number of 0.7 children ever born; the slight deferral of the menopause allows a modal age of 55. Around each of these two modes, the timing of family formation is patterned on the age distribution taken from the UN medium scenario.

The transition from the baseline scenario (in this case the UN medium variant) to the new bimodal variant is based on an assumed gradual take-up of this new schema by younger generations.[4] So earlier reproductive life fertility starts to decrease before the second period of later reproductive life begins (Fig. 78–4). Thus, the total fertility rate first decreases sharply, and then after a period of 50 years (Table 78–1), it reaches its level of equilibrium (set here at 2.06 to settle at the

[4] A more detailed exposition of the fertility scenarios used here can be found in our earlier article (Vallin and Caselli, 1997).

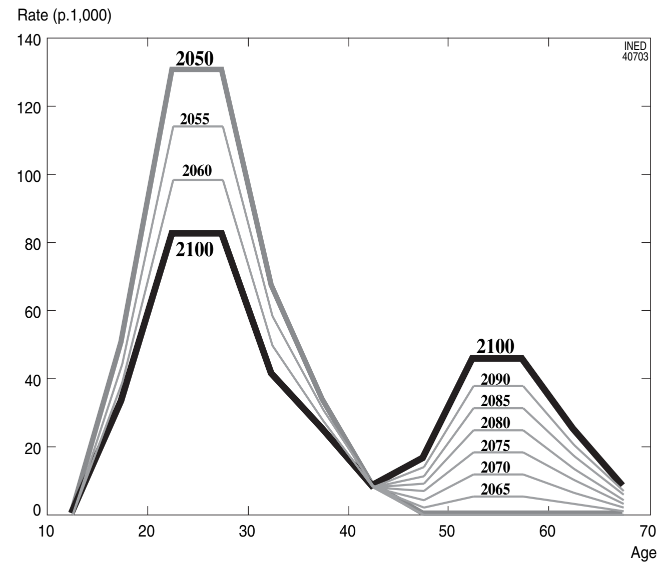

FIGURE 78–4 Age-specific fertility rates in the transition from the United Nations' medium variant (2.1 children per woman) to a bimodal model.

virtual disappearance of mortality below the reproductive ages). From its putative 2.1 in 2050, the total fertility rate drops to 1.4 by 2065, before rising again until 2100, where it stabilizes at the generation replacement level then set at 2.06 to settle at the virtual disappearance of mortality below the reproductive ages entailed by a life expectancy of 85 (Vallin and Caselli, 1997).

Far-fetched as may seem, the transition to this bimodal fertility would not produce major demographic upsets. On the contrary, it would act as a sort of regulator on the total world population beyond 2050 by absorbing the surplus growth expected in the baseline variant. Starting from 9.8 billion human beings in 2050, this would give us 9.4 billion instead of 12.2

billion by 2150, and 9.2 billion rather than 13.4 billion by 2250. This should not come as a surprise, as what is being projected is the long-term stability of fertility at replacement level, whereas the shift between scenarios involves a transitory decrease in the total fertility rate. This low fertility period simply allows the twofold potential inherent in the age structure by 2050 and the transition to a life expectancy of 85 to be absorbed without increase.

It is clear that, ultimately, the age structure will be identical to the baseline variant, the only difference being the less consistent path taken to achieve stability. Population aging will first exceed long-term expectations and then rejuvenate to settle at the proportions indicated above. The proportion aged 60 years and over, in particular, rises sharply from 20% to 34% in 50 years before ultimately slipping back gradually to 30% (Vallin and Caselli, 1997).

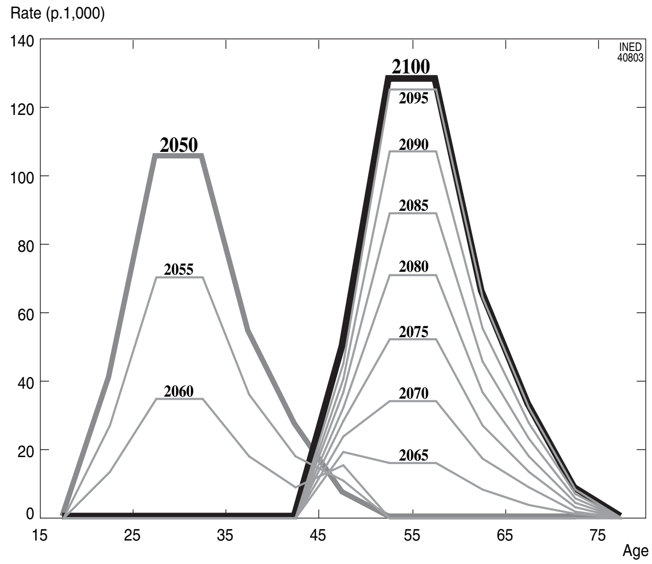

FIGURE 78–5 Age-specific fertility rates according to the United Nations' low variant (1.7 children per woman) in the transition to a postponed childbirth model ensuring equilibrium (2.06 children per woman).

b. Or Postponed Childbirth?

Suppose that recent fertility decline in the northern world—or, more generally, the convergence of the different populations worldwide toward the UN low scenario (1.7 children per woman for the world as a whole in 2050)—is the result only of delayed motherhood rather than a reduction in the number of desired births, and take the reasoning to the extreme by positing later-onset menopause, a much later reproductive life with a mode at age 45 to 54 years instead of age 20 to 29 years. Taking as our baseline the UN low scenario of 1.7 children per woman in 2050, we would again, as in the preceding model, end up 50 years later with the rate of 2.06 children, which will ensure equilibrium but after a much more testing transition period for the total fertility rate. Here, all fertility rates under age 40 years fall rapidly to zero, and rates among those more than 40 years start from zero but still remain low (Table 78–2 and Fig. 78–5). As a result, the total rate falls to 0.3 in 2065 before returning to 2.06 in 2100 (Vallin and Caselli, 1997). In fact, the paradox could easily have been taken further to make total period fertility zero for a period of several years.

So, the most salient outcome of such a change is to cause wide swings in the trend of different demographic parameters, starting with the growth rate (Fig. 78–6) and considerably extending the time frame to

achieve a stationary population once stationarity conditions are fulfilled. Although the transition to the one-child world or even bimodal fertility scenario required only a hundred years for the growth rate to become constant, this scenario will take several centuries: not until over 5 centuries later, after 2570, would the amplitude of oscillations diminish to less than 1%.

Throughout this entire period of fluctuations, the age structure concertinas wildly. So, for example, the proportion aged 60 years and over would rise from 25% in 2050 to 44% by 2090, dropping to 25% in 2145, rising 36% in 2175, dropping again to 26% in 2200, and so on for over 5 centuries (Vallin and Caselli, 1997). By way of illustration, Fig. 78–7 compares the population pyramids for 2150 for fertility following the UN medium scenario and the postponed childbirth variant considered.

As these wild swings are caused by a short-lived collapse in fertility, they would also start with a sharp fall in total population size, which would never be made up. Of the 7.9 billion in 2050, only 4.3 billion would remain a hundred years later in 2140, rising

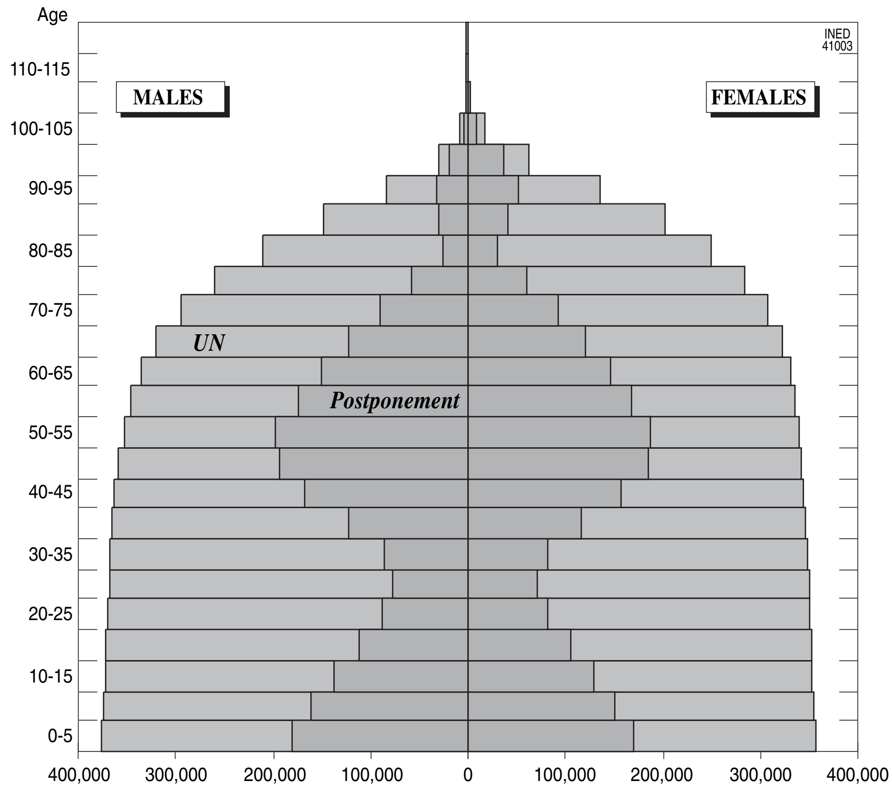

FIGURE 78–7 Age structures in 2150 (population in thousands) for fertility following the United Nations' medium variant and the postponed childbirth model (2.1 children per woman, life expectancy of 85 years, sex ratio at birth of 1.05 males per female).

back up only to 4.8 billion around 2165, at the beginning of a long series of oscillations around its future stabilization level of 4.45 billion inhabitants.

Finally, the least improbable of these three fertility scenarios, the one-child variant (which requires no biological change), would also be the most detrimental. But what about mortality?

III. LIFE EXPECTANCY: 85 OR 150 YEARS?

As mentioned in Chapter 48, the prospects for increasing longevity are a hotly debated issue. There is general agreement, in light of recent steadily rising trends in the most advanced countries, that the mean length of life is likely to increase further in the coming decades. But to what point is where opinions diverge.

In the very early 1950s, Jean Bourgeois-Pichat (1952) calculated a *biological limit life table*, giving the life expectancy that might be attained by removing all the *exogenous* causes of death that, being owing to clearly identified pathogens or external causes, could be avoided if the benefits of medical progress were extended to the world population. He calculated maximum life expectancies of 76 years for men and 78 years for women. The UN world population projections (UN, 1982), indeed, long assumed an age close to this maximum (75 years) as the level toward which all populations would tend.

It is clear that reality has now overtaken fiction, at least as far as women are concerned, because female life expectancy is already above 80 years in a score of industrialized countries, topping 83 years in France and 85 years in Japan. The question is whether that is owing to the discovery of hitherto unknown or ill-identified pathogens and ways of defeating them, or whether recent advances in life expectancy are actually owing to a retreat in *endogenous* mortality itself, which, for Jean Bourgeois-Pichat, was owing to the biological makeup of the human organism and would be much more difficult to influence.

Revisiting the distinction between endogenous and exogenous mortality 30 years later, but in the light of the most recent knowledge about the nature of disease factors, Bernard Benjamin (1982) calculated significantly higher life expectancy limits of around 85 years of age for both sexes together. This is very close to the result obtained if *degenerative diseases* are taken as the only cause of death (Vallin and Meslé, 1988). More recently, Jay Olshanski (1990), drawing on the work of the biologist James Fries (1980, 1989), finds it unlikely that life expectancy can ever exceed 85 years: it will continue to rise for a time through conventional rectangularization of the survival curve but will necessarily reach a maximum that, because of the inviolable longevity of humankind, cannot be above the age of 85 years. This maximum of 85 years (82.5 for men and 87.5 for women) is what the UN projections have been using since the early 1980s.

But there is another take to be had on recent developments. Have we not now developed the means of effectively slowing down people's biological aging and increasing their longevity? In other words, where we have so far only allowed a growing number of individuals to near the biological limit, are we now not raising the bar? First, the main reason why life expectancy has been lengthening in the northern world since the 1970s is the reduction in cardiovascular diseases, which (along with cancers, in Jean Bourgeois-Pichat's time) were the main age-dependent diseases. And what has mainly prevented a sharp drop in cancer deaths is smoking, although this has been declining (among men) for some time now, especially in the United Kingdom, the United States, and now France and Italy. Also, recent decades have seen a rapid increase in the rate of mortality decline among the oldest old (Kannisto, 1996). In France, for example, the female probability of dying between ages 80 and 89 years was still 72% in the early 1970s, but had fallen to 54% by the mid-1990s (Meslé, 1995; Vallin and Meslé, 2001). Declining mortality is also occurring among 90- to 99-year-olds, but life expectancy among centenarians has risen among women from 1.5 years in the 1950s to 2.2 years in the 1990s (Allard *et al*., 1996; Meslé *et al*., 2001; Meslé and Vallin, 2002). That does not necessarily mean that the upper limit of life is rising, but it seems increasingly obvious that, even were it to be otherwise, life expectancy at birth would be very likely to considerably exceed the 85 years that some have taken as an all-but absolute limit. For example, by simply extrapolating recent age-specific mortality trends by reference to a constant life expectancy of 101.5 years, it has been possible to show that French men could have a life expectancy of 84.2 years by the turn of the century; French women, 91.3 years (Vallin and Meslé, 1989).[5] But what if longevity itself is already increasing? For a start, the oldest age at death is rising steadily year over year in the most advanced countries (Wilmoth and Lundström, 1996). Jeanne Calment is probably the first woman ever to have lived to over 120 (Allard *et al*., 1994; Meslé *et al*., 2000). Also, the clearer research into mortality at extreme ages becomes, the more it appears that exponential growth in age-specific mortality rates, generally interpreted as the direct result of the process of biological aging which leads to death, slows down beyond a certain age. This slowdown can be construed as the product of extreme selection operated by the high death rate at these ages on an initially very heterogeneous population growing more homogeneous around the hardiest individuals (Vaupel *et al*., 1979, 1998; Barbi *et al*., 2003). How long will it be before we can identify why some individuals are so long-lived, so as to extend the benefits to the greatest number? In other words, are we on the threshold or even at the start of an effective revolution in the sphere of human longevity? It was that belief that prompted Roy Walford (1984a,b) to announce a life expectancy of close to 150 years during the next century as quite within the bounds of possibility. The fact that there is little likelihood of that happening during this century should not stop us exploring some of the ramifications.

But simply setting the new limit of life expectancy at 150 years does not tell us the new bounds of human life. We must still know what survival curve will take us to that figure, which, as yet, is beyond comprehension. There are two extreme possibilities. Either a life expectancy of 150 years is achieved through a technological quantum leap that could immediately benefit the greatest number—in other words, one that is consistent with the rectangularization of the survival curve within which we have evolved for 2 centuries —or the same result is achieved by an accelerated mortality decline at the oldest ages, entailing a rapid expansion in ages at death and a derectangularization of the survival curve. Let us consider both.

To illustrate the first hypothesis, we simply step-shifted the survival curve corresponding to the UN upper limit table toward increasingly higher ages. So, survival at 15 in the UN table becomes, 10 years later, survival at 20; 10 years after that, survival at 25; and so on. However, the share of survival under 15 years had to be considered differently: so we gradually increased this to completely eliminate child mortality. Above the age of 100 years, which is where the UN table stops, we have expanded it by extrapolating the quinquennial death probabilities so as to achieve one at 135 years before making changes in the corresponding proportions of survivors. This takes us from a UN life expectancy of 85 years to a life expectancy of 150

[5] According to recently updated calculations, based on more recent data that take into account the decline of mortality owing to road accidents and the increase of life expectancy at very old ages, life expectancy could reach 91.1 years for males and 94.9 years for females in 2100 (Vallin and Meslé, 2001).

years for both sexes in 140 years' time. In other words, taking the UN projection for 2050 as the baseline, the new upper limit sanctioned by technological advance will not be achieved until 2190. It is a revolution, certainly, but a very gradual one. We favor this conservative projection to a more rapid evolution. In fact, for population projections, we must work on a sex-specific basis. This leads us to raise the male life expectancy of 82.5 (UN upper limit) to 147.4 years and the female one from 87.5 to 152.5 years (Fig. 78–8; Table 78–3).

The alternative scenario, a derectangularization of the survival curve, is portrayed here no less simply: all the quinquennial death probabilities are reduced by 10% every 5 years so that the age at which the probability is equal to one is lowered by 5 years each time. Clearly, this proportional reduction more greatly benefits ages in which mortality is highest, which is more

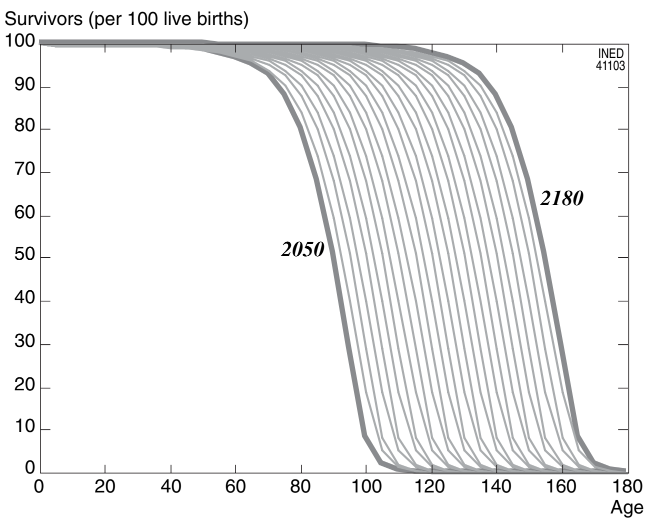

FIGURE 78–8 Female survival curve in the transition from the United Nations' maximum life expectancy (87.5 years) to a life expectancy of 153 years, with rectangularization.

than enough to amply derectangularize the survival curve (Fig. 78–9; Table 78–3). This brings us to a life expectancy of 150 years within the same time as before (150.5 years for men and 153.0 years for women after 140 years), but with a very different extreme age: the final deaths occurring between ages 270 and 275 years instead of 190 and 195 years in the preceding case. Figure 78–10 illustrates this approach for women.

The first result of the shift to a life expectancy of 150 is to upset the conditions of population growth for a century, regardless of the fertility scenario (Fig. 78–11). In the UN generation replacement scenario, a life expectancy of 150 years irrespective of the shape of the survival curve would almost double the world population in 2320 to nearly 25 billion rather than 13.5 billion. The only difference between the maintained survival curve rectangularization and the expansion of age at death scenarios is that this doubling of the final result comes earlier in the former case than in the latter case.

In the case of postponed childbirth, the lengthening of life expectancy to 150 years compensates, either immediately (rectangularization) or in the longer term, the population fall attributable to the low fertility period.

Last, in the scenario of a transition to the one-child world, lengthening life expectancy, although it clearly cannot stave off the threat of ultimate extinction, can at least defer the drop by several decades (in the event of rectangularization, there is even a short-lived increase) such that by around 2225, the world population is still above 2 billion, whereas with a limit of 85 years, it has already fallen below 400 million.

Figure 78–12 shows in more detail how, throughout the century in which life expectancy increases, the growth rate, although quickly turning negative, does not collapse as it would with a maximum limit of 85 years. It is also clear how the maintenance of survival

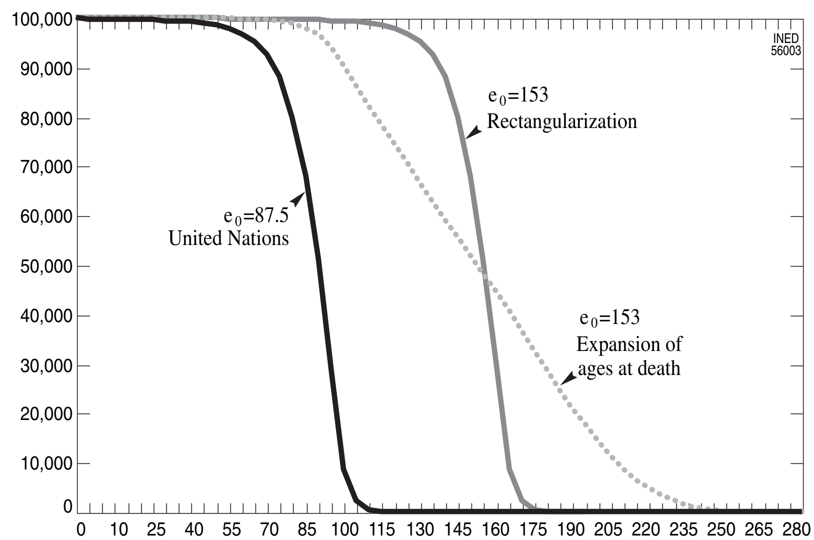

FIGURE 78–10 Comparison of two female survival curves for a life expectancy of 153 years with that for the United Nations' limit of 87.5 years.

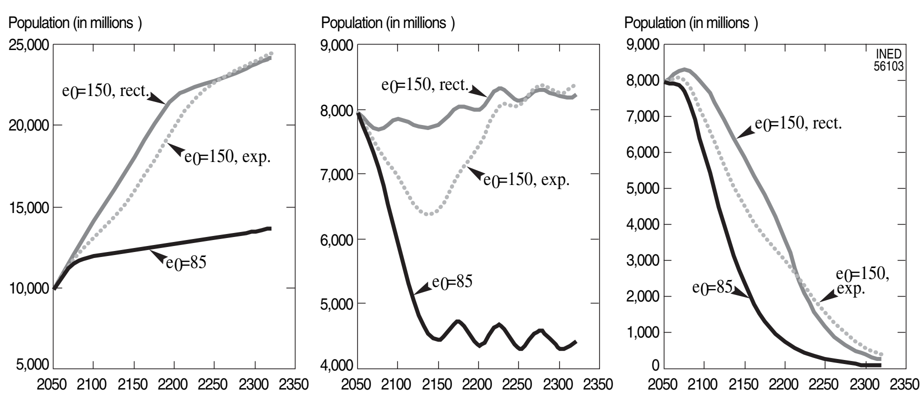

FIGURE 78–11 Comparative world population trends (2050–2320) in three mortality scenarios with fertility following the United Nations' medium variant **(left)**, returning to 2.1 in a postponed childbirth scenario **(center)** or shifting to the one-child world **(right)**.

curve rectangularization initially staves off that collapse. But going to the other extreme, this scenario is one in which the growth rate collapses abruptly once the period of lengthening life expectancy has ended.

The second major consequence of a rise in life expectancy to 150 years is to radically transform the age distribution of the population; the shape of the survival curve is clearly crucial. Consider just two cases of fertility: the UN model with 2.1 children per woman and the transition to the one-child world. In the former (Fig. 78–13), there is a clear trend toward a stationary population, and the pyramid shape corresponds exactly to the survival curve. If life expectancy rises to 150 years and the survival curve remains rectangular, the age structure increases by 70 increments but the shape remains essentially unchanged. By contrast, with an expansion of age at death, the pyramid top reverts to a tapered profile that has long since disappeared from the landscape of the northern world.

The question then arises which of the two pyramids so obtained is the "oldest." Ostensibly, it could be the second (the third in Fig. 78–13), which rises much higher in age. But what if greater longevity can only be achieved if there is an age-for-age improvement in health and if old age-related problems are clustered in the final third of the maximum human life span (currently, between 80 years and Jeanne Calment's 120 years, i.e., 9% of the population). With a life expectancy of 150 years in the first case (rectangularization), our calculations give survivors up to 190 years, so the same age bracket would rise from 130 to 190 years, i.e., 13% of the population. In the second (expansion of ages at death), the final survivors reach 270 years of age, widening this age bracket from 180 to 270 years but compressing it to just 4% of the total population. In this definition of the truly "old" population, the transition to a life expectancy of 150 clearly ages the population if the survival curve remains rectangular but would have the reverse effect of "rejuvenating" the population in the event of an expansion of age at death, to some extent turning centenarians into the "youngsters" of the age force.

The situation would be worse in the one-child world variant; with a life expectancy of 150 years, aging would assume such a magnitude that the population would contain little more than centenarians and supercentenarians (Fig. 78–14).

The effect of the one-child world variant on a population with a maximum life span of 85 was seen earlier: ultimately, 56% of the population would be more than 60 years of age and 24% over 80 years. But only 1% would be over 100 years. With a life expectancy of 150, more than 90% of the population would be over 60 years (91% or even 95% with an expansion of age at death), and centenarians alone would make up 74% of

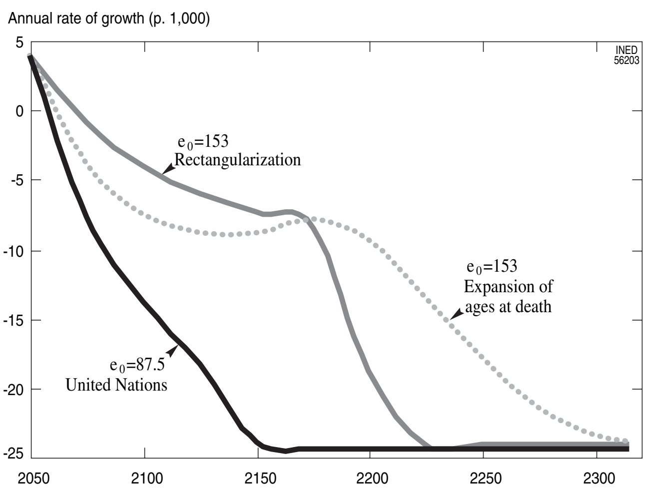

FIGURE 78–12 Comparative trends in the annual rate of growth (2050–2315) according to the three life expectancy hypotheses in the transition to the one-child world scenario.

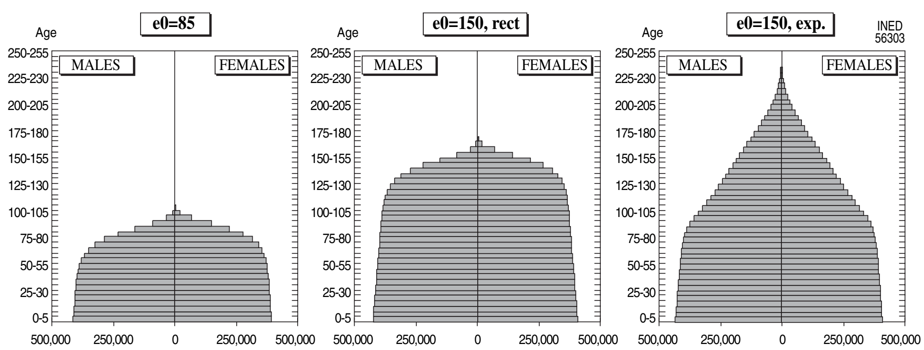

FIGURE 78–13 Age structures in 2300: effect of the transition to a life expectancy of 150 by type of survival curve, in the case of the United Nations' fertility variant of 2.1 children per woman (population in millions).

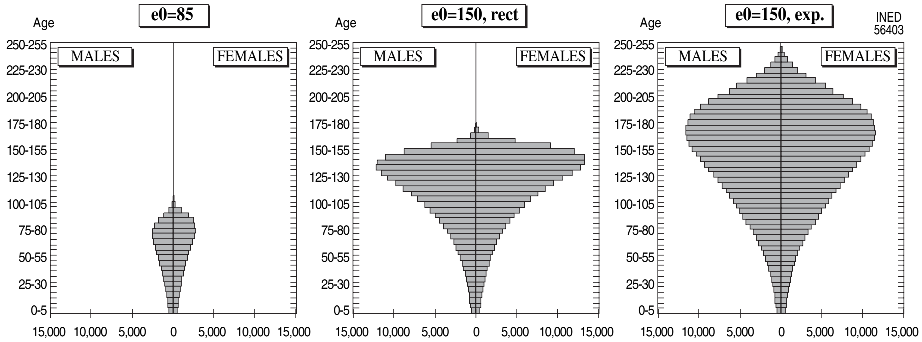

FIGURE 78–14 Age structures in 2300: effect of a rise in life expectancy to 150 years by type of survival curve, combined with a transition to the one-child world (population in millions).

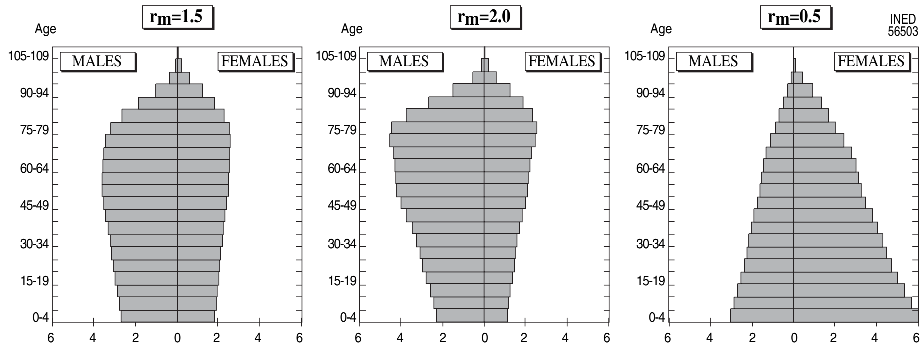

FIGURE 78–15 Population pyramids in 2150: effect of the change in the sex ratio at birth (r_m) with United Nations' scenario fertility of 2.1 children per woman and a maximum life expectancy of 85 years (proportions %).

the total population in the event of rectangularization and even 84% in the event of an expansion of ages at death! In either case, young people under the age of 20 would account for less than 2%.

IV. THE EFFECTS OF A RADICAL CHANGE IN SEX RATIO AT BIRTH

Returning to the classic scenario of 2.1 children per woman and a life expectancy of 85, what would be the result of a long-term change in the sex ratio at birth? To gain some insights into this, we explored three assumptions that deviate to differing extents from the 1.05 males per female norm:

At 1.5, the level is barely above that extractable from the current situation in a handful of Chinese and Indian provinces (Zhang *et al.*, 1983; Calot and Caselli, 1988; Miller, 1996).[6]

At 2.0 the level merely extends slightly the consequences of a strong son preference.

At 0.5, the level finally portrays the consequences of a female birth resurgence.

In all three scenarios, even when unceremoniously applying the new norm as of the projection baseline year of 2050, stabilization is almost entirely achieved within a bare century, by 2150. However, each of these three assumptions radically changes not just the sex structure but also the age structure of the population (Fig. 15). Were the sex ratio (r_m) to rise to 1.5 at birth, then in the stabilized population the share of women would fall from just over 50% (with $r_m = 1.05$) to under 42% and the population would have aged considerably: the proportion of young people under 20 would fall from 24% to 19%, whereas the proportion aged 60 and over would rise from 30% to 36%. Obviously, with a sex ratio of two males per female, this twofold development is accentuated: the proportion of women falls to 35% and that of young people to 15%, and the share of 60 years or more rises to 42%.

In both variants, the baseline replacement-level population declines at varying rates according to the ratio chosen. From a baseline of 9.8 billion in 2050, the

[6] The increase in the sex ratio at birth is a phenomenon that has very recently affected three countries of the Caucasus, with the sudden and perfectly simultaneous rise observed since 1995 in: Armenia, Azerbaidzhan, and Georgia (Badurashvili *et al.*, 2003).

world population would be no more than 3.6 billion by 2300 ($r_m = 1.5$) or even 1.2 billion ($r_m = 2$) instead of the 13.4 billion projected by the benchmark scenario. After 100 years, the growth rate levels off at a markedly negative level: –0.6% with $r_m = 1.5$ and even –1.2% with $r_m = 2$. That is because as the proportion of women declines at equal fertility rates, the birth rate stabilizes at a level below that of the benchmark scenario: instead of 12 per 1000, it rises to no more than 9 in the first case and even to less than 7 in the second (Appendix 2). At the same time, as the population ages, the death rate stabilizes conversely at the higher level of 15 or even 18 per 1000 instead of 11, according to the sex ratio used (Appendix 3).

Conversely, if the sex ratio at birth favors females, then not only does the proportion of women in the total population increase but the population also rejuvenates. With a ratio of 0.5, after stabilizing (from 2150), women's share of the total population rises to 68%, and the proportion of young people increases from 24% to 33% and that of the 60 and older falls from 30% to 21%. So, although in the benchmark scenario women's life expectancy gain makes them more contributory than men to the aging of the population, the excess of females to males at birth would produce an unhoped-for rejuvenation.

Obviously, that would come at the price of very rapid population growth. With women far outnumbering men, at constant fertility, the birth rate stabilizes at a much higher level than in the benchmark scenario (just over 18 per 1000 against 12). However, with a rejuvenated population, the crude death rate stabilizes at 7 per 1000 instead of 11. With a clearly positive rate of increase of 1.1%, the 9.8 billion population of 2050 would be 113 billion by 2300.

Would this high growth and rejuvenation potential be enough to offset the reverse effects of the transition to the one-child world? As Fig. 78–16 clearly shows, from this point of view, the result obtained with a sex ratio at birth of two females per males, is much better than those stemming from a rise in the sex ratio at birth, which actually worsens the baseline situation. Even so, a sex ratio at birth of two females per males remains manifestly too low to restore balance.

After stabilization in 2150, there would be 13.5% young people under 20 years of age (instead of 8.5% with $r_m = 1.05$) and 46% aged 60 and over (instead of 56%). Population loss would be substantially delayed, with the world population still at 400 million instead of 60 million in 2300 (Appendices 1 and 5).

What sex ratio at birth, then, would fully offset the effects of the transition to the one-child world? There could not be one, because it would entail women bearing only girls and reproducing without men. Only parthenogenesis or cloning could achieve that, bar establishing a huge sperm bank before allowing the last man to be extinguished.

The same sex ratios were combined with a rise in life expectancy to 150 years (in the sole case of a rectangularized survival curve). The results (see chapter appendix) are illustrated in Figs. 78–17 and 78–18, which speak for themselves: unsurprisingly, the effects specific to greater longevity (longer stabilization time, rise in the age structure) intersect with those of the sex ratio variation, whether 2.1 children per woman or the one-child scenario.

To add one final wild imagining, suppose that the sex life expectancy gap were to widen such that only women lived to 150 years (more precisely here 152.5 years) and the men's maximum longevity was 85 years (more precisely, 82.5 years). To cap it all, let us suppose that happens in a one-child world.

Figure 78–19 shows two final pyramid variants: one with a sex ratio at birth of two males per female, the other with two females per male. Both cases clearly end with an overwhelmingly female population and, perhaps less immediately evident, identical proportions in both cases: 87.1% when the population

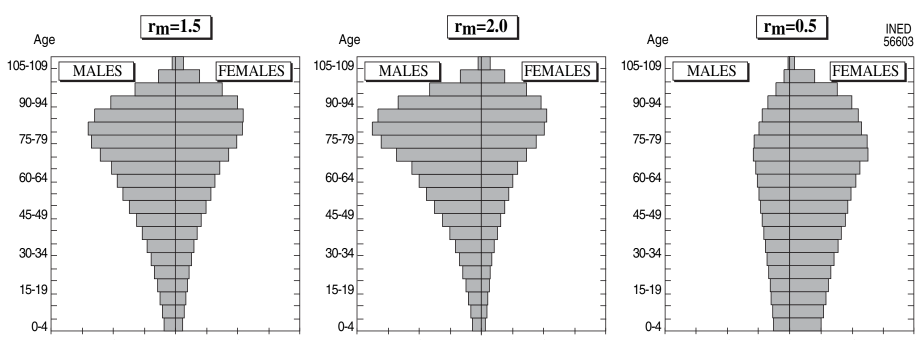

FIGURE 78–16 Population pyramids in 2150: effect of change in the sex ratio at birth (r_m) under a one-child fertility regime with a maximum life expectancy of 85 years (proportions %).

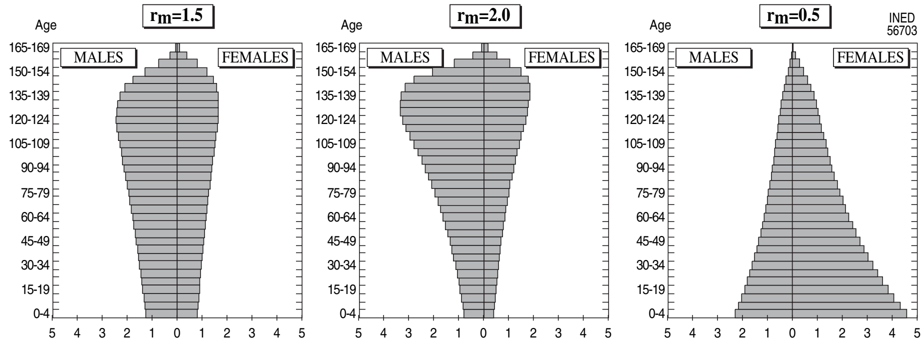

FIGURE 78–17 Population pyramids in 2250: effect of the change in sex ratio at birth (r_m) with United Nations' variant fertility of 2.1 children per woman and life expectancy of 150 years (rectangularized survival) (proportions %).

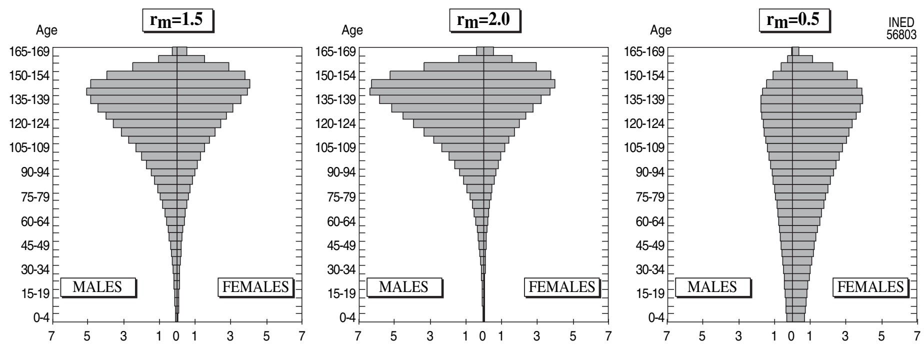

FIGURE 78–18 Population pyramids in 2250: effect of the change in sex ratio at birth (r_m) under the one-child fertility variant and life expectancy of 150 years (rectangularized survival) (proportions %).

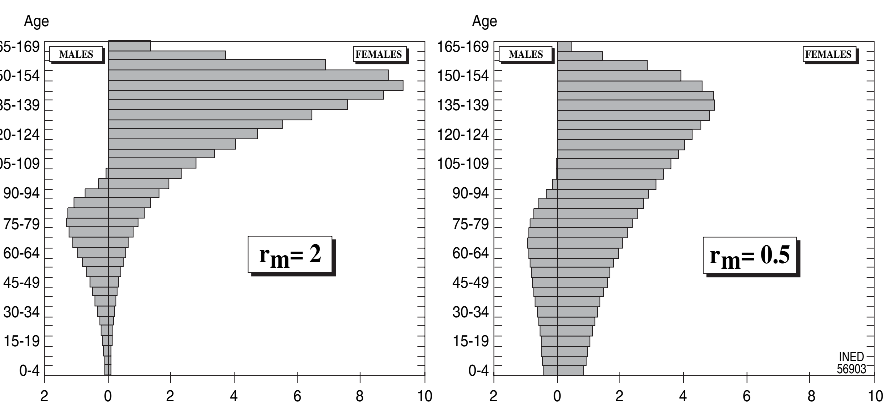

FIGURE 78–19 Population pyramids in 2250: effect of the change in sex ratio at birth (r_m) under the one-child fertility variant and female life expectancy of 152.5 years (rectangularized survival) and maximum male longevity of 82.5 years (proportions %).

stabilizes. However, a male dominance at birth again produces a much more marked aging of the population than does a female dominance. A sex ratio of two males per female gives 93% aged 60 years and over, and even 76% aged over 100 years, whereas two females per male gives proportions of just 77% and 52%.

In the first case, it is clear that a very large number of women aged between 130 and 150 years would have to live with a very small number of comparatively youthful 75-year-old men. However, working on the earlier male health assumptions, these men would not be younger than them. Such a situation would not endure, however, because, just to complicate matters, we have kept the current tempo of fertility for this scenario, so that the left-hand pyramid in Fig. 78–19 clearly shows that the population is likely to be extinguished very quickly for want of women of reproductive age: on stabilization, the annual rate of population increase is –3.7%, such that by 2300, the world population would be just 33 million (instead of 60 million with $r_m = 1.05$ and a life expectancy of 85 years for both sexes, or even 331 million at 150 years for both sexes). The right-hand pyramid leads a little less quickly but no less inexorably to disaster (the final rate of growth would be –1.4%, and the world population would be still 1 billion by 2300).

CONCLUSION

Life expectancy is clearly set to continue rising in many countries over the coming decades. The UN projects are likely to converge around a maximum world limit of 85 years. Should world fertility itself converge toward the absolute minimum replacement level of just under 2.1 children per woman with a life expectancy of 85, all the world's populations would stabilize not just in size but also age structure, at 24% under 20 years of age, 46% aged 20 to 59 years, and 30% aged 60 years and older. But although this life expectancy of 85 years is an absolute limit for some authors, for others it is a downbeat prognosis on two counts. First, even if longevity increases no further, there is a sufficiently wide gap between this putative limit and Jeanne Calment's age of 122 years to give the average person hope of passing it. But not only is there no proof that human longevity is an intractable constant, but there is good evidence that its boundaries are not fixed. As a result, there are no limits to what is possible. We have taken a conservative tack, hypothesizing a rise in life expectancy to around 150 years. All other things being equal, that would double the final prestabilization population size, but obviously at the cost of an unprecedented population aging: at 2.1 children per woman, there would be only 14% of young people aged under 20 years, and 27% of adults aged 20 to 59 years , but 59% aged 60 years and older (and even 30% aged 100 years or more). But there is no evidence that fertility is set to level off permanently at 2.1 children per woman. Were the sporadically observable one-child trend to spread, then the world population would be doomed to die out within a matter of centuries but not before its age structure had altered even more spectacularly: with a life expectancy of 150, the under-20s would account for less than 2%, the 20- to 59-year-olds under 7%, and the 60-year-olds or older more than 91%. Even more acutely, 74% would be centenarians.

However, this brief incursion into an imaginary future clearly lifts only a very tiny corner of the veil on the infinity of scenarios that could be hypothesized. Taking the world population as a whole as the baseline for speculation, we painlessly sidestepped the need for projections on migration, even though that is a phenomenon that is likely to loom large in coming decades. We nevertheless thought the exercise would be more productive if confined to a few basic parameters with a clearly identified role in population dynamics. Migration is a much more complex case that brings into play the population's relations with its exterior. That not only raises the problem of defining that exterior but the nature of the relations between the population and its exterior: in the case of immigration, for example, does the host population attract migrants, or are they imposed on it by exogenous factors. In other words, what population is the benchmark for devising rates from which to extrapolate trends for population forecasts?

For example, by keeping to the world level, we could have gone as far as projecting interplanetary migrations. But not knowing the supply of migrants, how can we apply to it migration rates to the Earth? Granted, departures could have been allowed for, including toward as-yet uninhabited planets.

But, many other equally far-fetched scenarios could have been devised: for instance, a 22nd century raiding party of extraterrestrials abducting large numbers of young women to regenerate their reproductive potential in a latter-day rape of the Sabine women. What impact would this have on the population of our planet? What if it were repeated at regular intervals like the Norman incursions in 9th and 10th century Europe what would the consequences of a permanent regime that included this type of periodic culling be?

In the same vein, one could clearly also muse on all kinds of events likely to set back life expectancy, such as the AIDS epidemic in Africa or the health crisis in Eastern Europe. And why not consider more drastic occurrences such as thermonuclear war or a meteorite crash?

In a more unassuming vein, however, the fertility and mortality trends sketched out and explored here are just a few of the infinite number of possibilities. The field remains wide open for those who wish to imagine other demographic never-never lands.

Of course, in themselves, none of the hypotheses explored here have much of a chance of ever really occurring, and the same is true for the various combinations that can be derived from them. Nonetheless, the possibility cannot be totally excluded, and our aim in studying their demographic consequences is to show that these scenarios are no more improbable than is perfect stabilization in strict terms of generation replacement.

Acknowledgments

This chapter was written with the collaboration of Rosa-Maria Lipsi and Alessandra Reale, Dipartmento di Scienze Demografiche, Università degli Studi di Roma, "La Sapienza," Italy. It is based on an initial article that developed more extensively the hypotheses selected for fertility and mortality trends, and provided more results in terms of birth rates, mortality, and population increase. The article was first published among the Proceedings of the international seminar in Siena (Vallin and Caselli *et al*., 1996), and a second time in English by the IPSEN Foundation (Vallin and Caselli, 1997). More recently, for the special issue of the journal *Population* on human longevity, we completed this essay, adding new developments, in particular the hypotheses concerning the sex ratio at birth, and we presented additional findings concerning changes in the age structure (Caselli and Vallin, 2001a,b). This chapter represents a synthesis of these various publications.

This chapter was translated from the French version by Accenta Ltd.

SECTION

II

POPULATION AND SOCIETY

Introduction

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Volume I, Section I focused on the essence of demography as a discipline: the study of the intrinsic mechanisms of population dynamics. Volumes I, Section II, and Volume II each focused on one of the three main forces in population dynamics—fertility, mortality, and migration—to discuss their determinants. This laid the groundwork for Section I in this volume, which gives an overview of the underpinnings of demographic history and geography and considers prospective medium- and long-term trends. With this section we take a further step, placing population dynamics in its biological, socio-economic, and cultural setting. The final volume, following the original plan of the treatise, will cover the history of ideas and policies on population, and the observation methods and analysis tools used in demography.

Section II is in two rather different parts. The nine chapters of Part I discuss the consequences of demographic change, whereas Part II addresses more broadly the interactions between population dynamics, or demography in general, and the main aspects of the life of populations and societies.

The volumes devoted to fertility, mortality, and migration gave in-depth treatment, in connection with each of those three components, to the biological, economic, social, cultural, and political determinants of population change. In Part I of this section, we consider these determinants from a different angle. It will be a more succinct examination, not because they are less important—far from it—but because the demographer's role is more to develop understanding of demographic processes as such than to describe all the effects demographic change may have in fields that are mainly studied by other disciplines. We will systematically address the main areas affected by demographic change (human biology and health, the economy, society, the environment), but others will be left aside, partly because the causal link is less clear-cut and partly because they lend themselves less readily to quantitative approaches. Admittedly, these reasons are not relevant in all cases; for example, we might very well have explored such cultural consequences as the distribution of languages[1] or religions. It would have been more difficult to examine the relationship among population dynamics and political regimes or legal systems, or the psychological consequences of changes in demographic regime.[2] We had to set ourselves reasonable limits, and we hope we have covered the essentials. We have not focused on fertility, mortality, and migration in turn but have considered the combined consequences of changes in these components from the standpoint of the overall demographic changes they produce in terms of population size and composition. In so doing, we will briefly point out what is mainly owing to fertility, mortality, or migration, but rarely in isolation from the rest.

In the previous volumes and in Part I of this section, we have rarely strayed from the basic principle of demographic analysis, which is to consider a population as a set of individuals who, in the course of their life events and experiences, affect the size and structure of the whole. However, although this approach opens the way to a sound understanding of demographic processes and their determinants, it does not give a sufficient grasp of all the interactions between demography and society. For this reason (although making no claim to exhaustive treatment, because here, too, the fields addressed belong primarily to other disciplines), Part II will put a demographic perspective on the biological, economic, social, and cultural aspects of the life of populations, which transcend the reduction of a population to a sum of individual elements. First, we will view the individual and the demographic events of their life in the context of their life cycle as a whole; and then, we will consider families and households, social structures, sex, economic categories, and genetic heritage.

I

CONSEQUENCES OF DEMOGRAPHIC CHANGE

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Demographic change, particularly the spectacular growth populations have undergone or are still undergoing today through the major historical shift demographers call *the demographic transition* (see Chapters 68, 69 of Volume III), has numerous consequences, affecting almost every aspect of human life from biology and health to the economy, the environment, sociology, and culture. We make no claim to cover all these exhaustively here. More modestly, we have tried to illustrate the diversity of these effects by addressing particular aspects in fields in which they are most striking: biology and health, economy and society, and environment.

The first two chapters discuss consequences for biology and health. The principle of natural selection, which gave rise to the human species as to all others, is based on the evolution of a population's genetic heritage. It is therefore crucial for the future of our species to consider the influence demographic behaviors and changes may have on the evolution of human genetic heritage. This is addressed in Robert Cliquet's chapter on population change and genetic diversity (Chapter 79).

Regardless of the long-term evolution of genetic heritage, all else being equal, a population's health may be affected simply by the fact that medicine has become sufficiently effective to enable many men and women to live to an age which in earlier times only a tiny minority attained. Generally speaking, health declines with age, and if more people live on into old age, the average health of the population is likely to deteriorate. The only possible remedy is for health at any given age to improve systematically as life expectancy increases. Whether we really have this remedy is a matter of some debate. To answer the question, one must be able to make realistic observations in a field that arouses strong subjective reactions. Jean-Marie Robine and Carol Jagger discuss the question methodically and precisely in Chapter 80, "Lengthening of Life and the Population Health Status".

Partly because of its effects on the health situation, the aging of the population also has important consequences in the economic, social and cultural fields. The next two chapters address this in different but complementary ways. Chapter 81, by Antonio Golini, covers "Demographic Trends and Relationships between Generations," whereas Chapter 82, by Jacques Légaré, covers "*Economic, Social, and Cultural Consequences of the Aging of the Population*."

Two chapters deal more particularly with the consequences of migration. We saw in Volume III, Section I how closely migration depends on economic factors, but it clearly impacts on the economy in return. In Chapter 83, Manon Domingues-Dos-Santos addresses "The Economic Consequences of Migration" as such. But migration has other consequences, and besides the genetic mixing it encourages, which is discussed in Chapter 79, it also contributes to the mixing of cultures and social strata, be this successful or conflicting. Although it is far beyond the scope of demography to address this subject as a whole, in Chapter 84 Victor Piché discusses the integration of immigrants.

After these chapters on relatively specific consequences of demographic change in particular fields such as health, or particular aspects of demographic change such as aging and migration, Part I is rounded off with three chapters that address changes in population dynamics more broadly. Chapter 85, by Arnaud Dellis and Pierre Pestieau, reviews theories on the relationship between "Economic Growth and Population Growth." Then in Chapter 86, Jean Coussy discusses the relationship between "Population and Development." In the final chapter, Chapter 87, Françoise Bartiaux and Jean-Pascal van Ypersele discuss "The Relationships between Population and Environment."

CHAPTER

79

Population Change and Genetic Diversity

ROBERT CLIQUET

Population and Social Policy Consultants, Brussels, Belgium

INTRODUCTION

This chapter addresses the effects demographic mechanisms and processes may have on the genetic composition and structure of populations. It is an issue that is, in a long term, of fundamental importance, because the basic demographic variables—mating, fertility, migration, and mortality—are the proximate instruments of population genetic changes, eventually leading to biological evolution. In this perspective, demography appears to be of much greater importance than is often thought, even in the demographic community itself. Whereas demographic variables are routinely included in bio-anthropological and population genetic work (see Cavalli-Sforza and Bodmer, 1971; Adams *et al*., 1990; Lasker and Kaplan, 1995), demography only occasionally deals with these interrelationships (see Léridon, 1973; Sheps and Menken, 1973; Bongaarts and Potter, 1983; Keyfitz, 1984). However, in recent years renewed interest in biodemography seems to be emerging (see Wood, 1994; Wachter and Finch, 1997; Rodgers *et al*., 2000, 2002; Wachter and Bulatao, 2003).

All of the basic demographic mechanisms and processes, as well as the population genetic mechanisms and processes, are closely associated and interact in multiple ways (Fig. 79–1). Every basic demographic mechanism corresponds with one or more of the population genetic mechanisms, and most of the demographic end products are largely the result of population genetic processes. In turn, the basic demographic mechanisms are the channels through which the genetic population composition, that is, the gene or allele frequencies, is changed or maintained. Moreover, the population mating structure and the population size can influence the genetic population structure (i.e. the genotype frequencies).

This chapter first provides a brief overview of the effects the basic demographic variables may have on the genetic composition and structure of populations. Then I will discuss the effects the modern demographic transition has or might have on the genetics of populations.

I. DEMOGRAPHIC AND POPULATION GENETIC INTERRELATIONS IN GENERAL

1. The Behavior of Genes in Populations

In sexually reproducing organisms such as the human species, individuals possess a double set of homologous chromosomes—a set from the female parent and a set from the male parent—on which most of the genes are located that determine or influence hereditary features. With the exception of the features determined by the genes located on the different sex chromosomes of the male (X and Y), every hereditary characteristic is genetically determined by at least two genes. In the case of monogenetic inheritance, only one pair of genes influences a particular feature; in the case

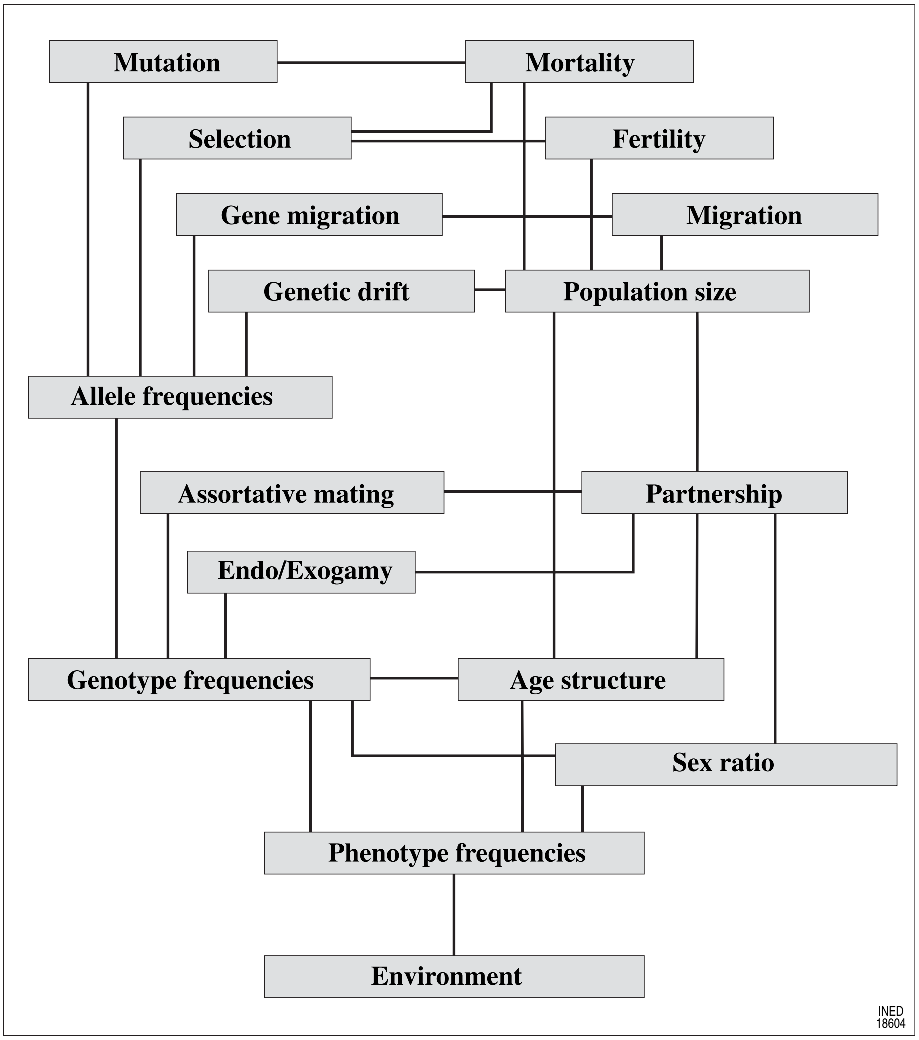

FIGURE 79–1 Demographic and population genetic interrelations. (From Lasker, 1963; Cliquet, 1987.)

of polygenetic inheritance, several pairs of genes influence a particular feature. The corresponding genes on the homologous chromosomes are called alleles. During the process of gamete production, which occurs through a special form of cell division called meiosis, the homologous chromosomes of the germ line cells are distributed over two daughter cells, so that the alleles segregate and the gametes include only one single set of genes. At fertilization, male and female gametes unite, resulting in the reestablishment of a double set of chromosomes with their corresponding alleles for each genetically determined or influenced characteristic. Because a gene for a particular characteristic can take slightly different forms, several allele combinations, named genotypes, can be formed. For a monogenetic feature, determined by two alleles (A and a), three genotypes—AA, Aa, and aa—can be formed. The genotypes with two identical alleles (AA and aa) are called homozygotes, whereas the genotypes with different alleles (e.g., Aa) are called heterozygotes.

The exact genetic composition and structure of a population cannot always be directly deduced from the observation of the phenotypic distribution, that is, from the way the biological features manifest themselves. Some alleles may be dominant, masking the phenotypic effect of recessive alleles. In the case of a dominant allele A and a recessive allele a, the genotypes AA and Aa can not be distinguished phenotypically. Moreover, in many cases (particularly for polygenic characteristics), environmental factors also influence the phenotypic expression and hide or reinforce the genetic effects. With a view of describing correctly the population genetic composition (i.e., the relative proportions of the alleles) and the population genetic structure (i.e., the relative proportions of all of the possible combinations of the alleles in genotypes) for a particular variable in a population in which gene exchange takes place (i.e., in a reproductive community or mendelian population), both the allele frequencies and the genotype frequencies for that variable have to be known. These can be calculated by means of the Hardy–Weinberg law (Hardy, 1908; Weinberg, 1908). In case of a monogenetic variable with two alleles (A and a), respectively, with frequencies p and q, three possible allele combinations or genotypes (AA, Aa, and aa) with the following frequencies can be obtained:

$$(p_A + q_a)^2 = p^2{}_{AA} + 2pq_{Aa} + q^2{}_{aa} = 1$$

The allele frequencies in a population are determined by four evolutionary mechanisms and their interactions: mutation, selection, gene drift, and genetic migration. The genotype frequencies depend on the allele frequencies and the mating system in the population (Wright, 1969; Cavalli-Sforza and Bodmer, 1971; Jacquard, 1974).

Mutation is a change in the chemical structure—the DNA—of a gene or a group of genes. Mutations are at the basis of the genetic variability and, consequently, form the basic condition for possible changes in the genetic composition of the population. Most mutations are deleterious and are eliminated from the gene pool quite quickly by means of selection.

Selection, originally proposed by Darwin (1859) as the major explanatory mechanism for biological evolution, is today usually defined in population genetics as the differential reproduction of carriers of different alleles. Positive selection results in genetic adaptation; negative selection leads to a decrease and eventually the elimination of the targeted genes. At the population level, the selection intensity can be measured by the selection coefficient s, which can vary between zero and one. The degree of genetic change of the population by means of selection can be calculated by introducing the selection values in the Hardy–Weinberg equation. Selection against a recessive allele e.g. changes the Hardy–Weinberg equilibrium to

$$p^2{}_{AA} + 2pq_{Aa} + (1 - s)q^2{}_{aa} = 1 - sq^2{}_{aa}$$

Gene drift, also called Sewall-Wright effect (Wright, 1931), can change the allele frequencies as a result of the accumulation of random fluctuations in the intergenerational transmission of the alleles in small populations. The formation of each new generation is, in fact, a sampling process of the gametes available in the gene pool of the population. The smaller the population, the greater the risk that the allele frequencies in the next generation will deviate from the preceding one. In the absence of the other evolutionary mechanisms, gene drift always leads to the fixation of one allele and the loss of the other(s).

Genetic migration occurs when a genetically differential population section leaves or joins a population. Genetic migration can occur on a small scale, at the level of individual (mate) exchange, or on a large scale, as a massive population invasion. It can occur as a single, non-recurring population move, or as a continuous gene flow between two or more populations. It can be of a unidirectional or a bidirectional nature. It can be merely of a deterministic nature, assuming infinite population size, so that no random elements resulting in drift are included, or it can also be subject to stochastic forces that result in complex interactions between migration and drift (see Piazza, 1990). Genetic migration obviously changes the genetic make-up either of the sending or the receiving population. Genetic immigration leads to an increased heterozygosity and an increased genetic variability within the invaded population, and to a decrease of the between-population variance. It lowers the ratio of the variance between populations to the total (between and within) variance (Wright, 1965). Genetic migration decreases endogamy and increases exogamy (mating within and outside, respectively, the mendelian population). Endogamy is to be distinguished from consanguinity, which refers to the practice of marrying within a geographically or culturally defined population. If the population is small, the risk of consanguinity increases because the number of potential partners is more limited and the chance of meeting a close relative increases. Exogamy is the opposite of endogamy, resulting in an increase of heterozygote genotypes at the expense of homozygotes. The crossing of genetically strongly different populations is an extreme example of exogamy.

Mating can occur at random or not. In the latter case, one can get either a positive or a negative assortative mating. In the first case, the homozygote genotypes (AA and aa) will be favored at the expense of the heterozygotes (Aa) and the population variance increases; in the second case, the opposite occurs. A special case of assortative mating concerns the positive or negative choice of blood relatives. A positive assortative mating for blood relatives leads to inbreeding, whereas a negative results in outbreeding. Inbreeding is a genetic consequence of biologically consanguineous matings, resulting in offspring with a higher than an at random risk to carry a double dose of the genes that were present in a single dose in the common ancestor (Wright, 1921, 1922; Malécot, 1948). Inbreeding changes the Hardy–Weinberg equilibrium to Wright's equilibrium:

$$(p^2 + Fpq)_{AA} + [2pq(1 - F)]_{Aa} + [q^2 + Fpq]_{aa} = 1$$

whereby F represents the inbreeding coefficient which can take values from zero to one. The proportion of the homozygous genotypes (AA and aa) increases and the proportion of the heterozygote genotypes (Aa) decreases according to the size of the inbreeding coefficient F. The average consanguinity in a population is usually measured by the average inbreeding coefficient of its members

$$a = \sum p_i F_i$$

whereby p_i is the relative frequency of individuals with inbreeding coefficient F_i (Wright, 1922). Because many genetic diseases are controlled by recessive genes, inbreeding increases the appearance of such diseases through the formation of homozygote recessive genotypes. The major difference between positive assortative mating and inbreeding is that the first is character specific; the second involves all of the genetically determined characteristics.

The increased genetic risks of consanguineous matings not only are based on population genetic theory but also have been extensively confirmed by empirical studies that systematically show inbreeding to be associated by substantially increased levels of pre- and postnatal mortality and morbidity. These results have been reviewed many times (see Cavalli-Sforza and Bodmer, 1971; Freire-Maia and Elisbão, 1984; Khlat and Khoury, 1991; Bittles, 1994). The inbreeding depression has been shown for major, recessively inherited malformations, for intelligence, and for other biometrical characteristics. For the latter, however, socioeconomic factors may partially be involved because inbreeding often prevails more among the less well to do (Bittles, 1994). Data on fecundity and fertility seem to be inconclusive for the moment. Some studies show reduced levels of primary sterility in consanguineous marriages, but others point to lower fecundability. Fertility levels often are higher among consanguineous couples, but this could be owing to demographic factors, such as younger age at marriage related to cultural traditions or as a reproductive compensatory behavior for increased postnatal mortality (Bittles, 1994). Under high levels of inbreeding, unfavorable recessive alleles become visible and may be subject to negative selection, thus lowering the equilibrium allele frequency for lethal genes (see Khoury *et al*., 1987). The lower incidence of some of those diseases might, however, also be owing to the higher mortality rates in isolates and to the depletion of lethal alleles through inbreeding (Neel, 1992).

Notwithstanding the risks of inbreeding depression, many societies favor modest forms of inbreeding, taking advantage of the socioeconomic profits associated to the maintenance or the increase of the family property (Van den Berghe, 1980). At the same time, the salient negative effects of close inbreeding involving relatives of the first degree (father–daughter, brother–sister relations) are avoided, the latter being the result of Darwinian selected inbreeding avoidance behavior and incest taboo (Westermarck, 1922; Wolf, 1995).

2. The Effects of Demographic Behavior on Genetic Diversity

a. Mating Behavior

Whereas in the past demographers limited themselves often to the study of nuptiality, it has become quite evident that this narrow approach is inappropriate if one wants to comprehensively analyze the demographic effects of relational behavior. A broader perspective is, in any case, indispensable for the study of the genetic effects of partnership. Mating behavior is one of the essential components of the reproductive process. Hence, it can influence the genetic outcome of that process. Broadly, mating behavior can influence the genetic diversity of a population in two respects: it can influence the genetic population composition (i.e., the allele frequencies) and the genetic population structure (i.e., the genotype frequencies).

The first issue to be dealt with is mate selection, the question of whether one chooses a mate or not. From a genetic point of view, mate selection obviously is only relevant when the people who do not choose a mate have genetically distinct features from those who do. In that case (sexual) celibacy constitutes one of the mechanisms by which genes are eliminated from the gene pool. It is a selective mechanism that is often lost out of sight. More refined studies on differential reproduction (see Higgins *et al*., 1962; Bajema, 1963; Waller, 1971; Retherford and Sewell, 1988) have amply shown the methodological and empirical importance of considering mating behavior in a comprehensive way and of not limiting it to nuptiality.

In the second place, mate assortment has to be considered. Assortative mating influences the genotype frequencies: positive assortative mating favors the production of homozygotes and increases the population variance; negative assortative mating results in the increase of heterozygotes and lowers the population variance (see Crow and Felsenstein, 1968). Whereas negative assortative mating is only substantially found for sexual orientation, positive assortative mating has been observed for many particularly polygenetic characteristics: intelligence, body height and weight, constitution type, complexion, physiognomic details of the face, and even sociopathological features such as criminal behavior, alcoholism, and psychiatric disorders (see Suzanne, 1967; Spuhler, 1968; Roberts, 1977; Epstein and Guttman, 1984; Rushton and Nicholson, 1988). More importantly, positive assortative mating is associated with higher relational stability, fecundity, and fertility (see Thiessen and Gregg, 1980; Epstein and Guttman, 1984). The latter findings imply that assortative mating not only influences the genotype frequencies but also, indirectly, can influence the genetic composition of the population by facilitating selection through the differential fertility of extreme genotypes. Assortative mating for polygenetically determined features obviously occurs via the phenotypes. The genetic effect of this phenotypic assortment depends on the heritability of the traits, that is, on the degree to which the population variability of these traits is determined by genetic factors (Mather and Jinks, 1982). Positive assortative mating for blood relationship results in inbreeding, which increases the risk of all of the gene loci to be brought into homozygous condition. Consanguinity, however, increases the risk of inbreeding depression, which is characterized by an increased morbidity and mortality.

b. *Fertility*

Fertility behavior includes two major aspects: timing and intensity of reproduction.

The timing of births is not independent of its genetic outcome. The frequency of a number of genetic impairments is positively correlated to the age of the parents, either of the mother or of the father, owing to the increase of the mutation rate with parental age: genetic conditions, such as Down syndrome and other trisomies, and syndromes owing to nondisjunction of the X chromosome increase with mother's age; conditions such as achondroplasia, Apert syndrome, Marfan syndrome, and myositis ossificans increase with father's age (Vogel and Motulsky, 1982). Some impairments, such as rhesus incompatibility, are related to birth order. Whereas the above-mentioned associations have only a generational or ontogenetic effect, the timing of births can also have an intergenerational genetic effect by increasing or decreasing the generation length of the reproductive period. When genetically different sections of the population are characterized by differences in average generation length through a variation in average birth interval, this can speed up or slow down the intergenerational transmission of genes. Genetic differentials in generation length form one of the mechanisms that result in selective processes (see Cole, 1954; Bajema, 1963).

Differences in the number of children related to genetic diversity obviously are of greater importance. The differential fertility of carriers of different alleles, indeed, forms one of the most powerful mechanisms producing selection. It influences, proximately, the reproductive fitness and, ultimately, evolutionary adaptation (Fisher, 1930).

c. *Mortality*

Mortality is the other major demographic tool of selection. In each generation, a broad genetic variation appears. Genetically differential mortality considerably reduces this initial variation by eliminating genotypes that are not able to meet the challenges of the environment. The largest part of this elimination process occurs prenatally, particularly during the very early stages of embryonic life (see Hertig, 1967; Wilcox *et al*., 1988; Macklon *et al*., 2002). Karyotypological research shows that intrauterine mortality largely consists of a genetic elimination process (see Boué *et al*., 1975; Creasey *et al*., 1976; Clark, 2003; Rubio *et al*., 2003).

In preindustrial living circumstances, mortality continued this elimination process virtually during the whole life cycle, resulting in a survivorship curve that approached closely the constant death-rate logarithmic curve (Comfort, 1979). Although it is probably impossible to document the genetic component of this earlier elimination process properly, it is difficult to imagine that the earlier mortality pattern would not have considerably decreased the genetic diversity, leaving the more fit as survivors up to high age. The genetically differential effect of mortality must have shown up in the population age structure, in which the older age groups may be supposed to have been genetically less variable.

Senescence is the time-dependent accumulation of genetic damage that progresses during the life course, resulting in increasing levels of frailty, impaired function, disease, and ultimately death (see Carnes and Olshansky, 1993). According to some scholars, senescence evolved through the accumulation of deleterious mutations that act only in later life, after the reproductive phase of life or the period of life during which the survival of grandchildren can be influenced, that is, when the force of selection decreases or disappears (Medawar, 1952). Others are of the view that senescence is the result of antagonistic pleiotropy; that is, genes with favorable effects during the early years of life would have unfavorable side effects later in life (Williams, 1957). Whatever mechanism may be at the basis of senescence, genes with late deleterious consequences can only accumulate and show up among individuals who live long enough (Kirkwood and Holliday, 1986).

d. Migration

Demographic migration is only of relevance here if it is associated to genetically differential population movements. Obviously, this is often the case. For example, long-distance migrants usually come from populations that are genetically different from the populations in the immigrant regions (Mascie-Taylor and Lasker, 1988). Although the genetic differences between populations constitute only a small fraction of the total genetic variation in humans (see Lewontin, 1972; Rosenberg *et al*., 2002), they remain important biological markers of group identity and continue to play a crucial role in in-group/out-group relations (Reynolds *et al*., 1987; Thienpont and Cliquet, 1999).

Migrants may differ not only from the populations they join but also from the populations they leave. In the latter case, selective emigration is seen (see Shapiro, 1939; Martin, 1949; Illsley *et al*., 1963; Mascie Taylor, 1984; Steegman, 1985). Migrants may differ from the sedentary population in fecundity, morbidity, longevity, intelligence, energetic drive, etc. (Termotte, 1984). Often, selective migration movements appear to be cases of social assortment, effecting the genetic composition of both the population of destination and the population of origin (Bogin, 1988).

In principle, the effects of genetically differential migration are easy to understand: they change the allele frequencies and genotype frequencies of the populations involved in the directions and the degrees of the migration movements. However, the specific biological characteristics of migrants should be carefully assessed: they may, indeed, be the result of a genetic assortment, but they may also be caused by an assortment of features that are the result of environmental influences (e.g., nutrition, education, infection) or even of a phenotypic adaptation to their new environment (Bogin, 1988).

Migration may change the gene frequencies in two different ways. It may lead to the splitting up of a population in several subpopulations that further evolve in isolation, and it may lead to the fusion of several populations, resulting in hybridization. The splitting up of populations leads to genetic isolation by distance, that is the decrease of genetic exchange between populations with increasing geographical (or social) distance, resulting in decreasing (coefficients of) kinship and genetic similarity (see Wright, 1943). Geographic isolation (lack of gene migration) is an important factor that determines the extent of the genetic distance, that is, the degree of genetic differentiation between populations (see Constandse-Westermann, 1972). The less migration there is, the more relatedness will build up within groups. According to Hamilton (1975), the number of migrants, rather than the size of the colonies, determines the degree of intrarelatedness. Fusion of genetically different populations can occur with different intensity: it may occur on a massive scale in a short period of time, but it may also be achieved by a slow but continuous gene flow, spread over a very long period of time. It may involve neighboring, closely related populations or geographically and genetically more distant populations. Most migration, however, occurs over a short range, among neighboring populations who are often genetically similar. Demographic and population genetic research on marriage distance in traditional societies has shown that the reproductive communities on average only slightly transcended the village or parish (see Cavalli-Sforza *et al*., 1964). The effects of emigration may, moreover, be compensated or counterbalanced by return migration (see Relethford and Lees, 1983).

Almost all known experiences of contacts between human populations, even in agonistic situations, lead to bridal exchanges and/or gene flow. This is the reason why isolation by distance explains most of the genetic variation in large populations settled for a long time and on a large scale (see Morton *et al*., 1972). It is also one of the reasons why interpopulation variation is characterized by genetic gradients or genoclines: these are neighboring populations isolated by distance, forming small overlapping mendelian populations and approaching a stepping-stone model with continuous variation of genetic traits between adjacent groups of people (see Reddy, 1984).

Migration movements may involve much more complex population genetic situations. Genetically differential immigration may lead to the establishment of new, hybrid populations in which the immigrants are genetically integrated. However, in many cases, the immigrants remain in endogamous communities, reproductively isolated from the main, autochthonous populations. In such cases, the geographical population may be composed of a series of endogamous reproductive communities, which each one of them sharing a different gene pool. The African-American population is an interesting case in this respect, because it combines features of both migration processes: partial genetic isolation and partial hybridization. Although the social prevalence of formal marriages between blacks and whites in the United States is extremely rare, the European contribution to the gene pool of the African-American population has been estimated to accumulate to 30% on average, with a strong regional variation going from

10% to 50% (see Reed, 1969; Workman, 1973). The gene flow from the European to the hybrid African-American population, over a period of ±12 generations, has been calculated to be on average 2.5% to 3.5% per generation (Glass and Li, 1953; Roberts, 1955). A continuous gene flow, which is not counteracted by other population genetic processes, inevitably results in population genetic replacement and overall homogenization (see Hiorns *et al.*, 1969; Mascie Taylor and Lasker, 1988). The degree of substitution only depends on the rate of gene transfer. If the European gene transfer to the African-American population continues at its past rate, the genetic identity of the African-Americans will disappear in a few millennia (see Benoist, 1986; Cavalli-Sforza *et al.*, 1994). In their mathematical analysis of the effects of migration on the relatedness between populations, Hiorns *et al.* (1969) obtained the surprising result that, even with modest degrees of exogamy, it takes only a limited number of generations to produce genetic homogeneity in a defined geographical space. The present increasing trends in migratory movements and exogamic behavior definitely stopped the earlier fission in favor of an increasing fusion movement.

The genetic effects of migration are not necessarily limited to population genetic fission or fusion. It may also be related to or induce other demographic processes, resulting in genetic changes. For example, migration may be associated to differential fertility. Immigrants with higher fertility levels will speed up the change of the genetic composition of the population. A typical example is Brussels, where Moroccan and Turkish immigrants have a cohort fertility of more than 4 children, and the autochthone inhabitants and Flemish and Walloon immigrants have, on average, 1.5 children (Schoenmaeckers *et al.*, 1997). Migration may also be associated to genetically differential mortality and hence to selection processes. Migrants may arrive in environments to which they are less well adapted or in which they are freed from their former selective pressures, as has been clearly shown for sickle-cell anemia (see Devoucoux *et al.*, 1991). Migrants may increase the mortality of the autochthones, either by introducing diseases to which the natives are not resistant or by genocide (see Vogel, 1992). Both these migration-induced population genetic effects have been observed in the partial, and in some cases even total, population genetic replacements of the Indian-American populations in North America and the Caribbean by populations of European and African origin during the colonization of the Americas.

Immigration may also induce emigration and strengthen local or regional population genetic substitution processes. The residential segregation of genetically distinguishable ethnic minorities in many European and American metropolitans is a well-known phenomenon (see de Lannoy, 1978; Van der Haeghen, 1995). Last but not least, migration may lead to population fragmentation, resulting in small isolates that then become sensitive to phenomena such as the Sewell-Wright-effect, the founder effect, and inbreeding.

e. Population Size

The demographic size of a reproductive community may have different, although partially interrelated, effects on the genetic diversity of the population. All of them, however, manifest themselves when a reproductive community is small and when there is little or no immigration. The combination of endogamy and a small population size results in the production of isolates, that is, relatively homogeneous populations separated from related groups by geographical or social factors (see Wahlund, 1928; Dahlberg, 1929; Jacquard, 1976).

Usually two major types of isolates are distinguished, the genetic effects of which may be different: (1) primary isolates, tribal populations of ancestral origin closely approaching genetic equilibrium and often characterized by the presence of private polymorphisms (i.e., alleles restricted to a single tribe), and (2) secondary isolates, offshoot populations detached from a large, national population itself usually being an amalgamation of earlier smaller groups. Secondary isolates are usually not (yet) in genetic equilibrium (Neel, 1992).

In the first place, a small population size triggers random genetic drift. Population genetics has knowledge of many and different types of small reproductive communities—isolated island or mountain populations, religious, ethnic, or other social isolates—with (monogenic) allele frequencies that fluctuated or diversified owing to the sampling processes linked to the formation of new generations by a small number of individuals (see Cavalli-Sforza and Bodmer, 1971; Roberts *et al.*, 1992). Hence, the demographic size of a population can influence its genetic composition.

A special case emerges when a population goes through a demographic bottleneck, as a result of emigration, high mortality, low fertility, age, or sex imbalance (see Leslie, 1990). It then becomes susceptible to the founder effect: particular genes, carried sometimes by one single individual, get easily spread over the small population. The presence of bottlenecks leads to a rapid increase of the genetic distance and a reduction in heterozygosity. It produces long branches in phylogenetic trees (Livshits and Nei, 1990).

In combination with the absence of immigration, the small size of a reproductive community inevitably also leads to inbreeding. When the number of potential mates decreases, the chance of meeting a (close) relative increases. As was already explained, consanguinity promotes the formation of homozygote genotypes for all genes and consequently leads to inbreeding depression. Population genetics has documented this phenomenon with amazing examples of small isolates in which many and rare genetic diseases showed up with high frequencies (see Pollitzer *et al*., 1964; Witkop *et al*., 1966; Roberts, 1968). Not only do recessive genes show up in homozygous combination, but also unfavorable dominant alleles can spread easily owing to the close web of kinship (Roberts, 1992).

Population size may also affect the genetic population composition when it becomes too large, particularly with respect to its available resources. Population pressures may then increase the within- and between-population competition and induce selective processes, or it may lead to selective outmigration, for example, in the form of brain drain (UNESCO, 1984). However, the immediate cultural effects of this phenomenon may prove to be of more importance than are the population genetic effects, which may appear only on a longer-term basis thanks to the greater genetic stability of polygenetically influenced characteristics.

II. THE EFFECTS OF THE MODERN DEMOGRAPHIC TRANSITION ON GENETIC DIVERSITY

The human species has experienced several demographic transitions (Muhsam, 1979). Here, only the recent transition is considered, associated to industrialization and other aspects of modernization demographically, the transition is mainly characterized by a substantial acquisition of control over mortality and fertility (Landry, 1934; Kirk, 1996). Although mortality and fertility control are undoubtedly the most important characteristics of the modern demographic transition, it must be acknowledged that virtually all demographic variables are involved in this transition. For the issues at stake in this chapter, the discussion has to deal with mating behavior, fertility, migration, mortality, and population size.

1. Mating Behavior

Modernization is characterized by several societal changes that may influence mating behavior: there is, for example, a shift from a socially controlled toward a more personally determined way of life; the population size and the communication and travel opportunities increased; or scientific knowledge became available about the detrimental genetic effects of inbreeding. All of those changes result in the presence of larger pools of possible mates. Notwithstanding the existing tendencies with respect to in-group behavior, it can be expected that the new opportunities for choosing mates will be taken advantage of. This is what is being observed.

In the first place, the traditional small marriage distance or mate pools that were largely limited to the town and to neighboring villages or towns, increased considerably. On average, people in modern society choose their partner(s) from a much larger geographical or social area (see Walter, 1956; Boyce *et al*., 1968). This broadening of the marriage or mate distance has two distinct population genetic effects. First, isolates are broken up, reducing inbreeding and diminishing the inbreeding depression. Second, exogamic matings increase, leading to interpopulation mixtures and, in some cases, to crossing between genetically strongly distinct populations (see Lionetti and Newell-Morris, 1982), thus resulting in a higher population heterogeneity.

In the second place, assortative mating on the basis of preferred mate characteristics may increase. This increase is difficult to document, because no historical data are available that can be compared with more recent data. The latter, however, clearly show that assortative mating is a common behavioral pattern in modern society (Fig. 79–2). Assortative mating results in increased homozygosity and larger population genetic variance, obviously to the extent that the characteristics involved in mate choice are (partly) genetically determined.

A particular question relates to mate selection. In the past, at least in Western societies, celibacy was not an uncommon phenomenon, either for religious or for economic reasons. In modern culture, religious as well as economic celibacy seems to be regressing. However, the recent decrease in nuptiality may not be considered as a new increase in celibacy. Marriage has simply been replaced by other forms of unions (cohabitation; living apart together [LAT] relations; loose relations) (Villeneuve-Gokalp, 1997). It is difficult to evaluate the genetic effects of changes in mate selection. The earlier forms of celibacy probably had very diverse genetic effects (de Lapouge, 1896). The current strong reduction of those who obey the call in Catholic regions, and who were formerly undoubtedly belonging to the more intellectually gifted individuals of the population, might be considered to have a eugenic effect. But what about the other changes in mate selection? On the whole, one would expect that the decrease of celibacy

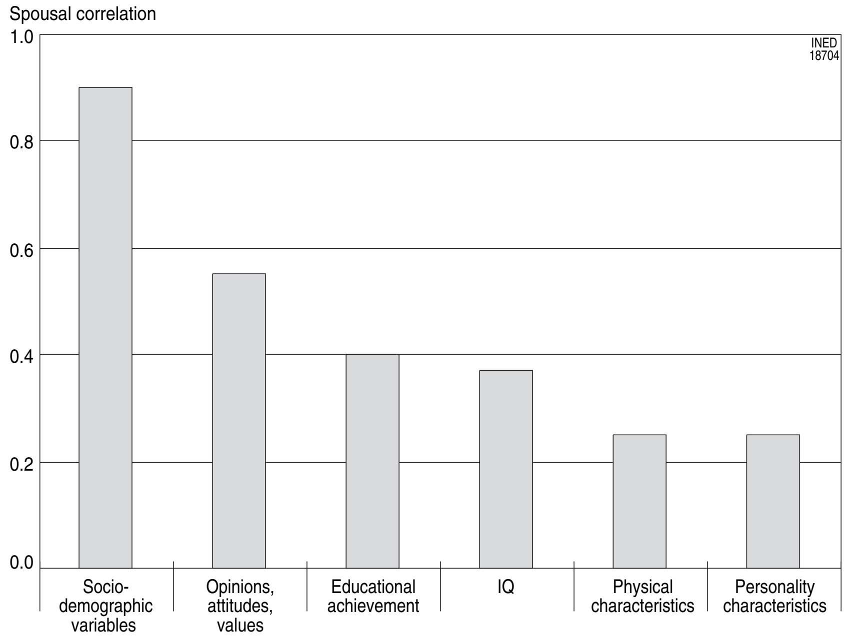

FIGURE 79–2 Spousal resemblance on a variety of characteristics. (From Susanne, 1967; Spuhler, 1968; Roberts, 1977; Thiessen and Gregg, 1980; Mascie-Taylor, 1988; Rushton and Nicholson, 1988.)

might induce a decrease in selection, resulting in an increase in population genetic heterogeneity.

2. Fertility

The modern demographic transition is characterized by profound changes in both the timing and intensity of fertility. As far as the timing is concerned, births are no longer spread over the fecund period of life. With respect to fertility intensity, both the average and the variance decreased. Last but not least, the transition from a high to a low fertility regime has, in many cases, been associated with strong sociobiological differentials in reproductive behavior.

In demographically post-transitional societies, births are avoided at younger ages, in particular during adolescence, and at higher ages, especially after age 35. The latter phenomenon is generally considered to have a eugenic effect, because the prevalence of several genetic impairments increases with parental age and/or birth order and, hence, can be avoided by controlling fertility at higher ages or parity (see Matsunaga, 1966). In recent decades, however, the postponement of births is pushed further up in the life course. In some countries such as The Netherlands, the average age of a woman at her first birth is close to 30 (see Beets *et al.*, 1994), which means that most women will have their children in their 30s instead of their 20s. In addition to increased risks of fecundity problems (primary and secondary sterility start to increase substantially after age 30), relatively older parents also risk higher frequencies of particular genetic disorders. Fortunately, more genetic impairments can be detected prenatally and eliminated by selective abortion, if so desired.

The availability of selective abortion may have two distinct effects on the genetic composition of the population. First, it allows families who have a substantial risk to get genetically impaired children to avoid the birth of seriously handicapped offspring and to replace them with phenotypically normal children. Selective abortion not only avoids genetic impairments but also avoids infertility: it allows couples to build up a normal family with healthy children (see Evers-Kiebooms, 1994). However, the reproductive compensation resulting from the replacement of defective offspring by normal children increases the relative frequency of carriers of the genetic condition in heterozygote individuals, who may transmit the defective allele to future generations and contribute to the increase of the allele frequency in the population. However, it may be expected that more refined future genetic screening techniques will be able to prevent such an increase.

Fertility regulation, resulting in a lower parity combined to an earlier timing, may have other, but perhaps less important, genetic effects. In fact, all genetic phenomena that are differentially related to maternal or paternal age may be supposed to be influenced by fertility regulation. Walter Fuhrmann (1969) has argued that family planning may lead to an initial decrease and a subsequent increase of dizygotic twins. Because the prevalence of dizygotic twins increases with maternal age, the avoidance of births at higher ages must lead to a decrease. However, family planning concerns pregnancies, not births. In the case of twins, a single pregnancy results in two births. In a regime of fertility limitation, the relative share of twin children will become more numerous on the totality of children born, and hence the genes involved will increase and counterbalance the effect of the decreasing maternal age. Fertility limitation at higher ages may also slightly influence the sex ratio because the birth of males decreases with maternal age, but this phenomenon cannot be supposed to have intergenerational effects. Smaller families result in lower numbers and proportions of close relatives and, consequently, may decrease the risk of the formation of consanguineous unions (see Chandrasekar *et al*., 1993).

The modern decreases in fertility average and variance have to be considered together, because the opportunity of selection depends, according to Crow's index of total selection, on the ratio of the variance (V_w) to the square of the mean (w^2) of the number of first generation descendants per individual (Crow, 1958):

$$I = V_w / w^2$$

This index can be separated into two components, I_m and I_f, due to differential mortality and fertility respectively:

$$I = I_m + 1/p_s I_f$$

$$I_m = p_d / p_s$$

$$I_f = V_f / x^2_s$$

where p_d is the proportion of premature deaths, and p_s is the proportion of survivors, with x_s as mean and V_f as variance of the number of births per surviving parent.

Whereas the mortality decline of the modern demographic transition resulted in a decrease of I_m, the fertility decline, contrary to what might intuitively be expected, does not necessarily induce lower opportunities for selection (see Matsunaga, 1966; Spuhler, 1976; Hed, 1987). On the contrary, when the average fertility decreases more strongly than does its variance, the opportunity for selection may even increase. Data from different countries seem to suggest that, at least in the initial stages of the demographic transition, the I_f increased slightly, whereas in later stages it decreased (Fig. 79–3).

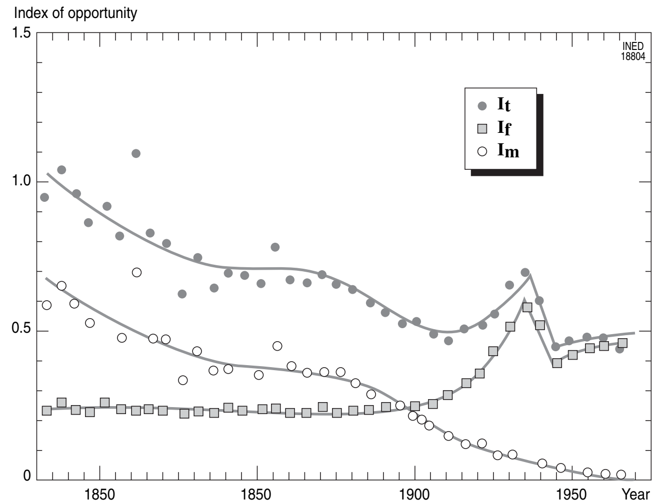

FIGURE 79–3 The changes of the fertility index of opportunity of selection (I_f) in the course of the demographic transition. (From Adams and Smouse, 1985.)

The degree to which selection actually occurs depends on the genetically differential fertility observed. The modern fertility decline in most early transitional societies occurred in a socially differentiated way: birth control first spread among the higher educational and socioeconomic strata, initially resulting in outspoken negative associations between fertility and a variety of indicators of social stratification (see Wrong, 1958; Cochrane, 1979).

Given the substantial positive correlation between educational level or other indicators of socioeconomic status (SES) and intelligence (see Jensen, 1981; White, 1982; Lynn, 1996), the positive correlation between intelligence of parents and children, the abovementioned negative correlation between social status and fertility, as well as direct observations on the negative correlation between intelligence and fertility (see Cattell, 1937, 1950; Vining, 1986) induced the theory of the contraselective effect of modern culture on intelligence, predicting that the intelligence level in industrial societies would start to fall (see Cattell, 1937; Graham, 1970). Contrary to this prediction, however, large-scale surveys on the intelligence level in subsequent generations initially did not show a decrease, but no change, or even an increase (see Cattell, 1950; Flynn, 1984; Lynn and Hampson, 1987). Nevertheless, on the basis of large-scale surveys and data on differential fertility and other demographic mechanisms such as mate selection, differential mortality, and generation length with a view of assessing the net effects of demographic differentials on the intergenerational changes in intelligence levels and interpreting them in the light of findings on the heritability of cognitive

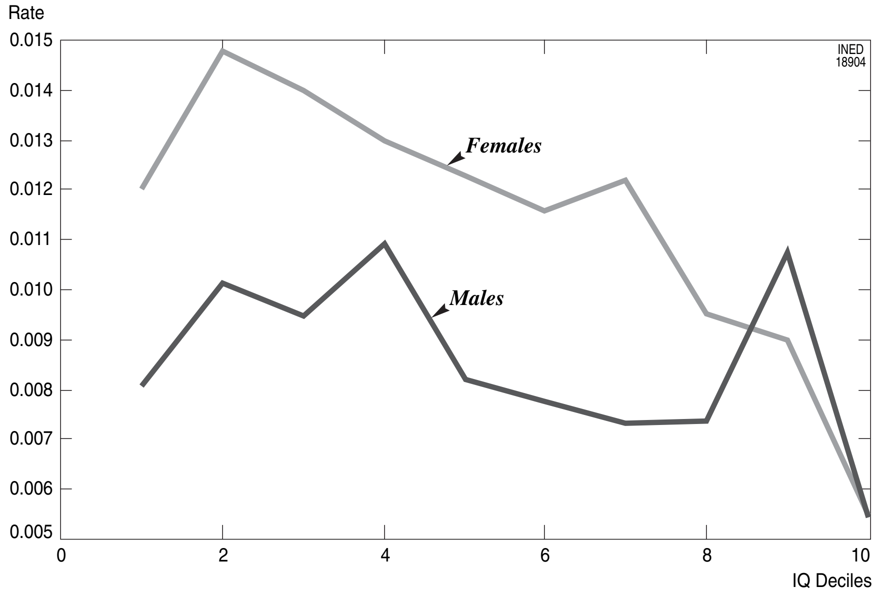

FIGURE 79–4 The intrinsic rate of natural increase *r* by intelligence quotient deciles and sex, derived from the Wisconsin Longitudinal Study. (From Retherford and Sewell, 1988.)

ability,[1] several scholars concluded that the demographic transition had a slight dysgenic effect (see Vining, 1986; Retherford and Sewell, 1988; Loehlin, 1997; Lynn, 1999). For complex features such as cognitive ability that are determined by many monogenetic and polygenetic gene pairs and can, moreover, be influenced by environmental factors, the intergenerational genetic effect of differential reproduction is always smaller than the fertility differentials suggest (see Carter, 1966; Cliquet and Delmotte, 1984). Last, but not least, many industrial societies still experience negative relations between fertility and a variety of SES indicators, but the differentials have decreased substantially because birth control also became a common practice among the lower educational and social-status strata (see Kirk, 1969; Vining, 1986; Perusse, 1993). In some countries the earlier negative association between fertility and SES indicators show the first signs of a possible reversal, confirming Osborn's (1952, 1968) eugenics hypothesis, stating that in a situation of free choice the distribution of births will favor more children being born in the most favorable home environments. This implies that the end of the demographic transition might be characterized by a positive association between reproductive fitness and socially valuable traits.

Although the modern demographic transition is in the field of reproductive behavior mainly characterized by a decrease in fertility, modernization has also increased, in absolute or in relative terms, the fertility of particular population categories. Modern health and welfare care, particularly therapeutic replacement,[2] has not only postponed mortality but also relieved morbidity, in some cases allowing individuals or couples, whose reproductive fitness was strongly reduced in previous times, to get (more) children. In cases in which genetic factors are involved in the etiology of diseases, health care and therapeutic replacement result in selection relaxation. Several mental or physical conditions are known for which medical treatment has a positive effect on reproductive fitness.

[1] Although quantitative genetics (see Mather and Jinks, 1982), and in particular behavior genetics (see Hay, 1985; Plomin *et al.*, 1990), are well-established disciplines, some of their concepts and fields of application such as heritability of cognitive ability continue, partly because of ideological interferences (see Kamin, 1974; Herrnstein and Murray, 1994) and partly because of methodological issues, to raise scientific controversy (see Capron *et al.*, 1999; Hay, 1999; Vogel, 1999; Vetta and Courgeau, 2003). Ronald Fisher (1951) considered the heritability coefficient as one of those unfortunate shortcuts that appear often in biometrics owing to a lack of thorough analysis of the data. Albert Jacquard (1983) has shown that this term covers three different concepts and argued that none of those parameters proposed by geneticists can be used for resolving the questions linked to the transmission of behavioural characteristics such as intelligence quotient. The progress in molecular genetics can be expected to throw more light on the transmission of quantitative trait loci (QTL), just as it is doing for monogenetic traits (see Plomin *et al.*, 1995; Plomin, 1997; Chorney *et al.*, 1998; Mackay, 2001), even if some authors believe that it is really impossible to distinguish the effects of heredity and environment (Gottlieb, 2001).

[2] Medical intervention allowing to supplement a deficient function or to replace a deteriorated organ.

Schizophrenic patients traditionally had and still have a lower reproductive fitness than do other people, owing to lower marriage rates, higher divorce rates, and lower fertility rates (Erlenmeyer-Kimling *et al.*, 1969; Ritsner *et al.*, 1991). In recent decades, however, thanks to medical treatment that allows deinstitutionalization, the fertility rate of schizophrenic patients shows a slight upward trend (Bodmer, 1968; Ödegaard, 1980; Erlenmeyer-Kimling *et al.*, 1969). The same phenomenon has been observed for individuals with diabetes (Aschner and Post, 1956/57). Adams and Smouse (1985) have illustrated the effect of selection relaxation during the demographic transition by calculating the selection coefficients for three hypothetical diseases as examples of traits with different age of onset patterns. The selection intensity decreased, mainly for the trait with an early age of onset, owing to the concomitant effects of mortality decline and a decrease in generation time as a result of a greater proportion of child-bearing being accomplished at earlier ages. Selection relaxation may also act against subfecundity. More and more medical interventions are developed aimed at treating subfecundity conditions (De Jonge and Barratt, 2002; Cetin *et al.*, 2003). Moreover, fertility limitation profoundly changes the parity frequency distribution in favor of the lower parity numbers (Fig. 79–5). The combined effects of replacement therapies and the changed parity distribution might, in the long run, also decrease the fecundity or at least increase the proportion of people facing subfecundity problems (see Graham, 1972; Medawar, 1974).

In recent years an increasing interest can also be observed on the effects of new developments in genetics and evolutionary anthropology on the understanding of human reproductive behavior in modern society with its strong changes in family planning and fertility behavior (Rodgers *et al.*, 2000, 2002; Wachter and Bulatao, 2003).

a. Mortality

One of the major components of the demographic transition is the epidemiologic transition. Mainly because of the control of infectious diseases, the major causes of death in industrial countries have shifted to chronic diseases of late onset (Weiss, 1990). These diseases are much less subject to natural selection, because the force of natural selection decreases with age, more particularly after the reproductive period of life, leading to an accumulation of unfavorable mutations producing senescence and ultimately death (Finch, 1990; Rose, 1990). The control of infectious diseases allows people to reach higher ages, at which the accumulated effects of deleterious mutants can manifest themselves. In addition, the protective nature of modern culture, through improved living circumstances of all sorts and medical replacement therapies, allows more frail individuals to survive and even to reproduce (see Cook, 1956–1957; Vogel, 1992). The modern mortality control is decreasing substantially the mortality component of Crow's (1958) index of opportunity for selection ($I_m = p_d/p_s$) (Fig. 79–3). Modern culture has, in this way, increased the adaptability of persons who would not have lived long and whose reproductive fitness would seriously have been reduced in preindustrial living circumstances. In modern culture, these individuals are better adapted to survive, a nice illustration of the relativity of the normal or abnormal nature of genes and genotypes that changes with medical and social progress. A gene that was, in premodern circumstances, experienced as abnormal, is no longer considered deleterious if the carrier can now have a normal life. However, it also means that such persons depend more on the preservation and further progress of a technologically highly developed culture and society.

The modern mortality transition is rectangularizing the human survival curve and is profoundly changing the quantitative age composition of the population. However, this curve-squaring strategy (Gordon *et al.*, 1979) also influences the quality of life because the gain in years is partially associated to an increase in largely genetically determined chronic diseases (see Verbrugge, 1984; Riley, 1990; Robine *et al.*, 2003) (Fig. 79–6). Future efforts to further rectangularize the survival curve might even worsen this trend. The ideal of a full rectangular survival curve might, however, not be completely reachable owing to the genetic heterogeneity of the human species and its species-specific maximum life span (Weiss, 1990). On the other hand, future progress in molecular genetics might break through the maximum life span and extend the human-specific longevity (Gordon *et al.*, 1979).

Biodemographers have tried to model the age-specific hazard function of frailty (see Manton and Stallard, 1994; Vaupel, 1990; Weiss, 1990). This is, however, extremely difficult, because the life course history of many diseases is not well known. Moreover, both genetic and environmental factors influence many diseases and may be responsible for phenotypic heterogeneity. Last, but not least, the shape of the hazard function is not necessarily uniform for all variables involved, as Weiss (1990) has recently shown for various forms of cancer. A substantial, if not the largest part of the frailty hazard is of a (partial) genetic nature. In modern culture, the genetic component of the frailty hazard is increasing, in relative as well as in absolute

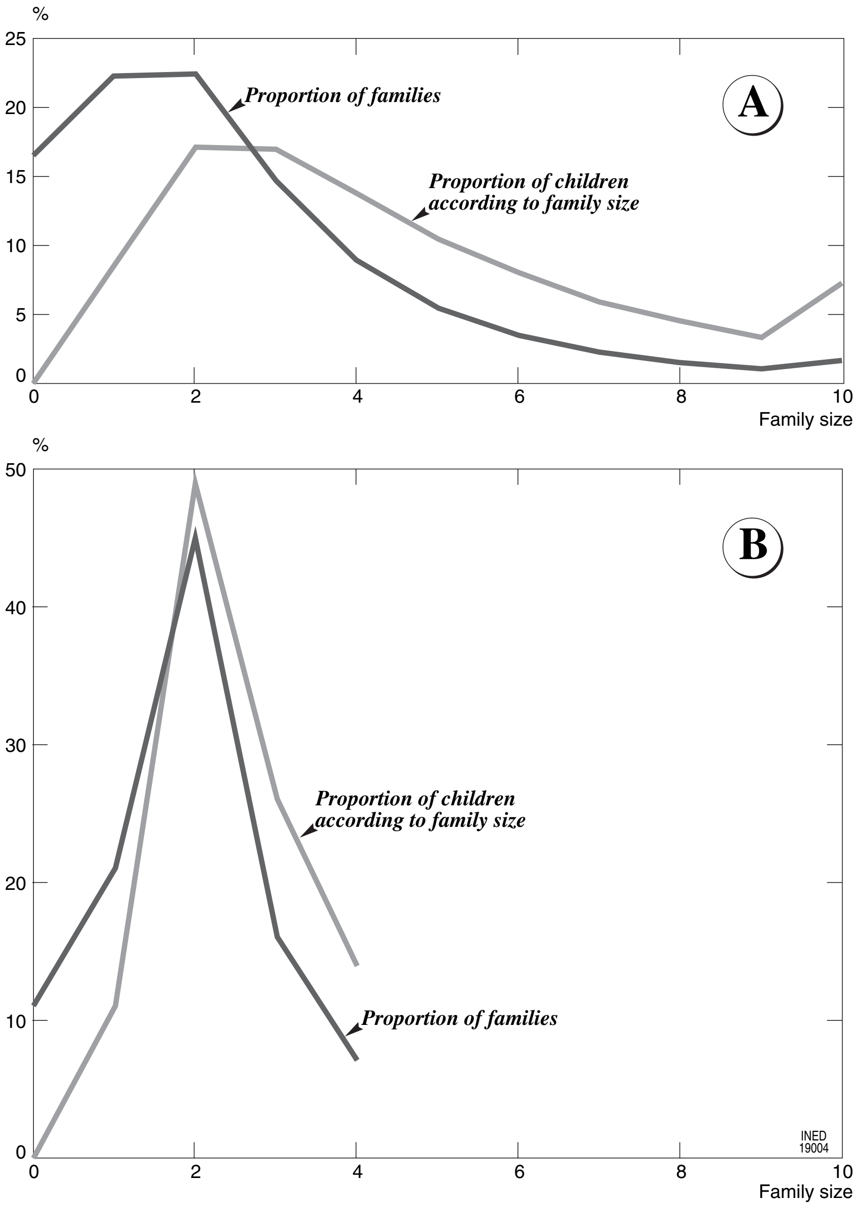

FIGURE 79–5 Family size and offspring number distribution: (A) in a demographically pretransitional regime (France, birth cohort 1881); (B) in a demographically post-transitional regime (Flanders, birth cohorts 1950–1954). (From Vincent, 1946; Callens and Schoenmaeckers, 1993.)

terms. The general protective effect of modern culture and the spreading of replacement therapies results in a selection relaxation (Cavalli-Sforza and Bodmer, 1971; Crow, 1966). The epidemiological shift and the selection relaxation both result in an increase of the genetic heterogeneity of the population. This increasing genetic diversity induces a larger phenotypic vulnerability, which requires a further enhanced medical and welfare care (see Manton *et al*., 1990).

The selection relaxation of mortality control, just as the one of morbidity control, may be reinforced by an increased reproductive fitness. Surviving individuals may find (a) partner(s) and get children. This has already been shown for individuals with several diseases, such as diabetes (Aschner and Post, 1956–1957) and schizophrenia (Erlenmeyer-Kimling and Paradowski, 1966; Ritsner *et al*., 1991), for which replacement therapies or other types of medication have been developed. The reproductive fitness of such patients undoubtedly has been enhanced, so that an increase in the frequency of the alleles responsible for those conditions may be expected to increase.

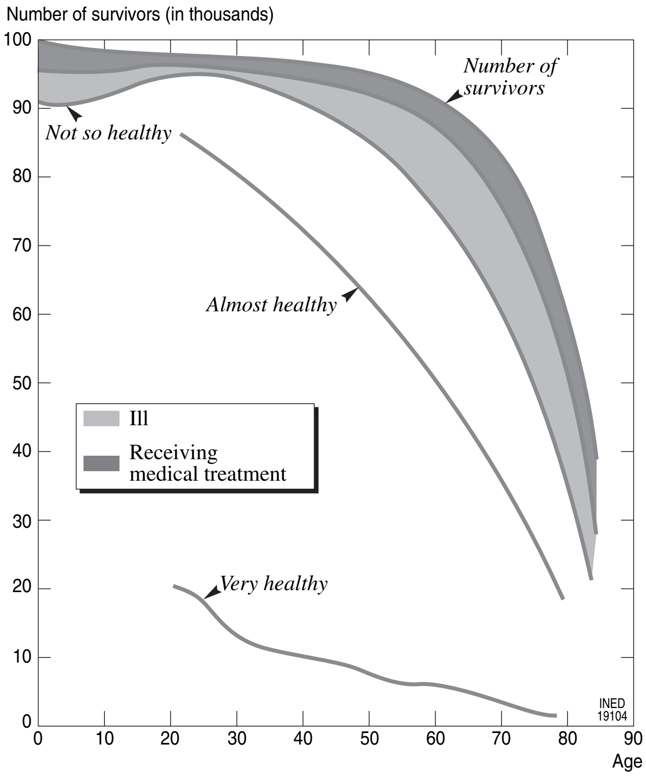

FIGURE 79–6 Survival and frailty curves of females in modern society. (From Koizumi, 1982.)

The quantitative effect of the selection relaxation depends on several factors: the relation between the mutation pressure and the degree of relaxation, the effect of the replacement therapy on the reproductive fitness, and the mode of inheritance (dominant, recessive, polygenetic inheritance) (see Cavalli-Sforza and Bodmer, 1971). Computer simulation shows that in all types of inheritance, the increase of the allele frequency is very slow, especially for recessive alleles or polygenetic conditions, in which most deleterious alleles are hidden in heterozygous combinations.

The possible dysgenic effects of morbidity or mortality control may be counteracted by birth control. In the future, it may be expected that the demographic transition, mainly through the experience of mortality and fertility control, will contribute to shift this control from quantitative to qualitative goals and from phenotypic to genotypic concerns. This way, the human species would control not only its demographic growth and phenotypic development but also its genetic composition, that is, its future evolution (Cliquet, 1996). This proposition may, at the beginning of this century, sound quite daring, if not appalling, just as, in the beginning of the 20th century, quantitative birth control was vigorously opposed. In a longer time perspective, however, it is difficult to image that humans, once they have mastered the necessary technology, will not try to avoid genetically determined diseases and to promote genetic features that are considered socially desirable or advantageous, such as heterosexuality, cognitive ability, sociability, beauty, and mental and physical health in general.

b. Migration

Modernization has increased considerably the opportunities for geographical mobility by enlarging the communication and transportation facilities. This has resulted in a substantial increase in migratory movements, internally as well as internationally.

Modernization not only increased the opportunities for geographical mobility but also influenced the values and norms with respect to in-group behavior. Communication and transportation opportunities and knowledge about and experience with others via a diversity of channels (e.g., scientific discoveries, commercial and industrial activities, mass media, and tourism) have broadened people's minds and made them less averse to strangers, to out-groups. Inevitably, this leads to a further broadening of the mating and reproductive communities and hence to the breaking up of geographical and social isolates, in-groups, etc.

Increasing migration flows make populations genetically more heterogeneous. On the basis of plant and animal experiments, one might expect to witness signs of heterosis or hybrid vigor. Some authors are of the view that the modern secular increase in body height is partly owing to increasing exogamy. However, conclusive proof of the effect of heterosis in the human has not yet been established.

Wherever the increasing migratory movements are of a massive nature and the immigrant populations are not well integrated, new isolates may be formed. Such forms of migration may lead to population genetically stratified societies, in which the immigrant groups often are confined to the lower socioeconomic and occupational strata and are residentially segregated in less attractive quarters (de Lannoy, 1978; Van der Haeghen, 1995). It is a picture that is traditionally well known in the Americas, but which, in recent decades, has also emerged in many Western European metropolitan areas and even in fast-growing economies in the Near East and the Far East.

It is difficult to judge whether the demographic transition has also influenced selective migration processes. There are indications that such forms of migration do occur (Bogin, 1988). Migration policies are, in most cases, selective in one or another way. Guestworkers are usually attracted on a temporary basis in periods of economic boom and are afterward expected to return to their countries of origin. For permanent migrants, on the contrary, selection policies seek to attract highly skilled or economically well-off people. To the extent that such social characteristics are correlated to partially genetically influenced features such as intelligence and physical health, the migration flows may be in part genetically selective. "Brain drain" is an issue that increasingly preoccupies developing countries (UNESCO, 1984). However, because the biological features (intelligence, health) involved in such migratory processes, are largely determined by polygenes, the immediate effects of such migratory processes are largely of a cultural and not of a genetic nature. Such migration flows might have genetic effects only on a long-term basis (Mather and Jinks, 1982).

A fundamentally important effect of the increased opportunities of geographical and social mobility is that it enhances the size of the population, particularly of the breeding unit or effective population size.

c. Population Size

The modern demographic transition is characterized by the broadening of the marriage or mating distances (see Walter, 1956; Lebel, 1983; Walter, 1956; Wijsman and Cavalli-Sforza, 1984), the breaking up of isolates (see Sheets, 1980; Yanase, 1992), the increase of interclass, inter-religious, intertribal, and interethnic matings (see Coleman, 1992; Relethford and Mielke, 1994), and the increase of population genetic exogamy (see Leonetti and Newell, 1982). All of these processes, in fact, involve increases of (effective) population size.

The population genetic effects of increasing population size are obvious: decrease or even disappearance of genetic drift, founder effect, and inbreeding. These changes have been most extensively documented for inbreeding, which is observed not only in developed countries (see Sutter and Tabah, 1955; Imaizumi, 1992) but wherever modernization and industrialization spreads (Fig. 79–7). Studies have documented this phenomenon in developing countries (see Khlat, 1988; Chandrasekar *et al*., 1993). The decreasing inbreeding levels are obviously associated to the decrease, if not the disappearance, of inbreeding depression.

Of course, these changes do not occur everywhere at the same speed; it may, in some cases, even be counteracted by rising fundamentalism, the isolation of immigrant minorities, or the traditional socioeconomic advantages of modest forms of consanguinity (Bittles, 1994). Hence, in some countries the early stages of modernization were characterized by an increase of consanguinity, not because of a lack of available mates but because some population categories wanted to keep their wealth in the family on basis of social status and ethnic identity (Jorde *et al*., 1992). Moreover, the early demographic changes themselves, among others resulting in an increase of surviving children and consequently of available relatives, produced a temporary increase in consanguineous marriages (Sutter, 1969).

CONCLUSIONS

This chapter examined the effects demographic mechanisms and processes may have on the genetic composition and structure of populations and, in particular, the effects the modern demographic transition has or might have on the genetic diversity of populations. These are important issues because the basic demographic variables—mating, fertility, migration, and mortality—are the proximate instruments of population genetic changes, eventually leading to biological evolution. Demography and genetics are closely intertwined: all of the basic demographic mechanisms and processes, on the one hand, and the population genetic mechanisms and processes, on the other hand, interact, often in multiple ways.

The demographic transition influences via all of the major demographic variables—mating, fertility, mortality, migration and population size—the genetic composition and structure of populations.

The broadening of the marriage or mate distance has two distinct population genetic effects: isolates are broken up, reducing inbreeding and hence diminishing the inbreeding depression, and exogamic matings increase, leading to interpopulational mixtures and enhanced genetic heterogeneity. Assortative mating on the basis of preferred mate characteristics increases, leading to a higher population genetic variance. The decreasing levels of celibacy may reduce selection intensity and increase genetic heterogeneity.

Changes in fertility—timing as well as intensity—may have different effects. The avoidance of births at higher ages lowers the frequency of genetic impairments, the appearance of which is correlated to parental age. The practice of selective abortion has the same effect, but may, in the long run, raise the equilibrium level of harmful recessive alleles owing to reproductive compensation. Whereas the mortality decline of the demographic transition resulted in a decrease of I_m, the fertility decline does not necessarily induce lower opportunities for selection. Data from different countries seem to suggest that, at least in the initial stages of the demographic transition, the I_f

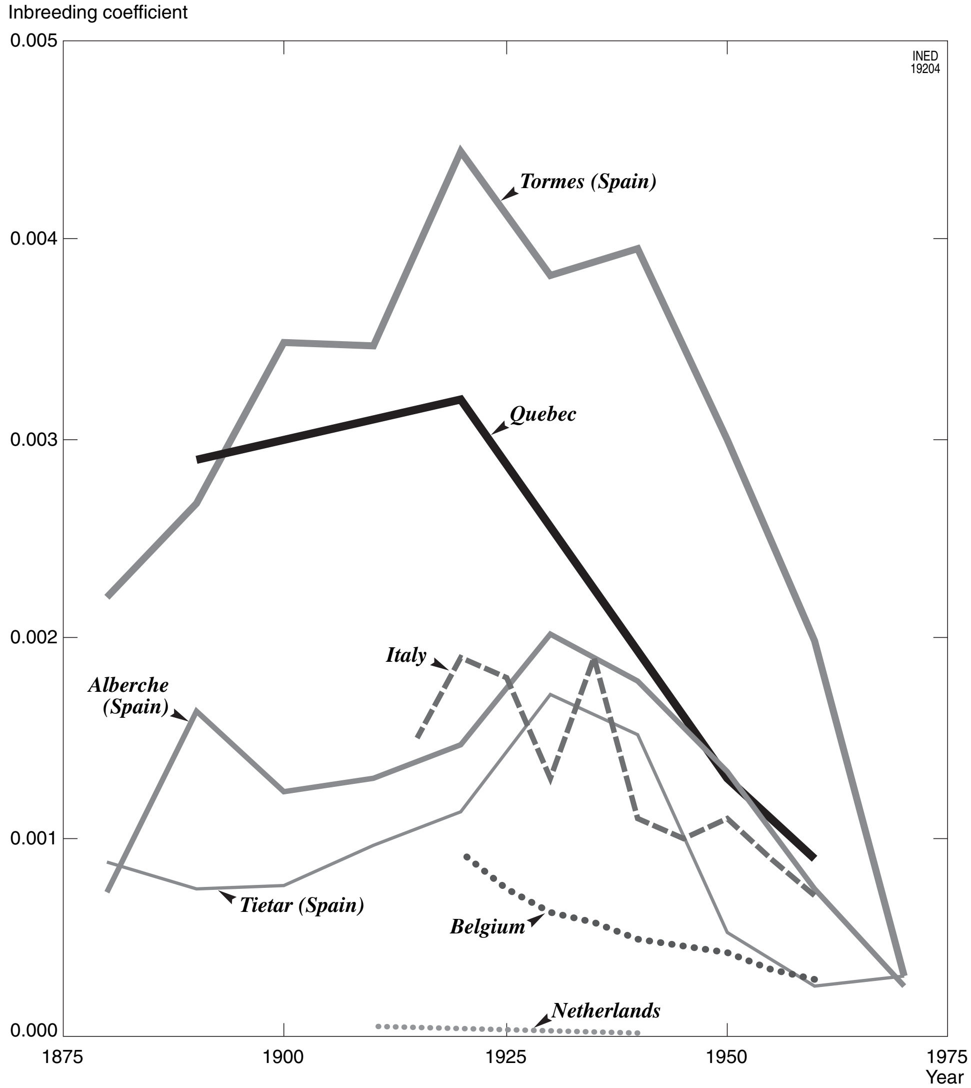

FIGURE 79–7 The change of the coefficient of inbreeding *(F)* in the course of the demographic transition. (From Twisselmann *et al.*, 1962; Moroni, 1969; Cavalli-Sforza and Bodmer, 1971; Fuster *et al.*, 1996.)

increased slightly, whereas in later stages it decreased. Although intelligence-related differential fertility is decreasing, the demographic transition seems so far to have had a slight contraselective effect.

The mortality reduction results in a selection relaxation. Improved living circumstances of all sorts and medical replacement therapies allow more frail individuals to survive and to reproduce. This results in a selection relaxation and in an increased adaptability of persons who would not have lived long. The increased survival rates are associated to an increase of biological frailty and of genetic heterogeneity.

Increasing migration flows also enhance population genetic heterogeneity. In combination with increasing population size, they break up isolates, decrease consanguinity levels, and lower inbreeding depression. The present increasing trends in migratory movements and exogamic behavior stopped the earlier fission in favor of an increasing fusion movement. Modern culture may have strengthened selective migratory processes, for example, by means of brain drain migration.

In the future, it can be expected that the demographic transition, mainly through the experience of mortality and fertility control, will contribute to shifts in life goals from quantitative to qualitative concerns and from phenotypic to genotypic concerns. Some less favorable genetic effects that may have been associated with the demographic transition are probably to be considered as temporary consequences of a major shift in demographic regime. They might be neutralized, if not reversed, by a future progress in genetic knowledge and genetic engineering and by raising expectations about quality of life.

Lengthening of Life and the Population Health Status

JEAN-MARIE ROBINE AND CAROL JAGGER

Démographie et Santé, Institut national de la sante et de la recherché medicale (INSERM), Montpellier, France

Department of Epidemiology and Public Health, University of Leicester, United Kingdom

INTRODUCTION

Over the past 2 decades, in many developed and developing countries, life expectancy has greatly increased owing to the decrease in mortality. However, this positive change has raised new questions concerning the quality of the years of life gained, particularly for older people. Indeed, the individuals who escape death may still accumulate disabilities, after effects of accidents, or consequences of chronic diseases. So is there reason to fear that current and future progress in life expectancy will bring a deterioration in the mean health status of the population? Several theories have been put forward to answer this question. We will begin by presenting the general outlines of these theories.

These theories need to be confirmed with facts, and an accurate appreciation of the direction in which the facts are evolving is essential to adapt public health policies accordingly. This is why the concepts of health state expectancy, a composite measure of morbidity and mortality, and disability-free life expectancy (DFLE; or active life expectancy [ALE]) have been developed to address this question. We will discuss the development and definition of health state expectancies, defining the concepts underpinning the measurement of health states and giving some results of differentials in health state expectancies to demonstrate the relevance and utility of these indicators.

I. EXPANSION OR COMPRESSION OF MORBIDITY?

For a long time, the increase in life expectancy meant an improvement in the health of populations. Today, this is no longer enough because chronic diseases have replaced, or are progressively replacing, infectious diseases and the risk of becoming ill is not solely linked to the risk of dying (Riley, 1990). Thus, with a constant recovery rate, if the risk of dying diminishes more than the risk of becoming ill, the risk of being ill increases. In other words, the prevalence of chronic disease in the population can increase as a result of an increase in the duration of survival if the decrease in fatality is not offset by an equivalent decrease in incidence.

In the absence of pertinent data on the evolution of morbidity, the relationships that can exist between the patterns of evolution of these risks have been debated, gradually focusing on three theories: (1) an improvement in the state of health or a *compression of morbidity* (Fries, 1980, 1989); (2) a decline in the state of health leading to an *expansion of morbidity* (Gruenberg, 1977; Kramer, 1980; Olshansky *et al.*, 1991); and (3) *dynamic equilibrium*, a kind of status quo (Manton, 1982).

The theory of compression of morbidity states that (1) if the morbid period is defined as the period from appearance of the chronic disability until death, and (2) if the moment when such a morbid event appears can be postponed, and (3) if adult life expectancy is relatively constant, then (4) morbidity will be compressed into a shorter time (Fries, 1989).

According to Ernest Gruenberg and Michael Kramer, the decline in mortality is owing to the decrease in the fatality rate of chronic diseases and not to a reduction in their incidence or a slowing down in their rate of progression. Postponement of the moment of death causes more severe states of chronic disease to appear. This is the theory of the *pandemic of mental disorders and disabilities* or, more generally, expansion of morbidity.

Kenneth Manton (1982), who introduced the concept of dynamic equilibrium, proposed that the increase in life expectancy could be explained partly by a slowing down of the rate of progression of chronic diseases. Thus, the prevalence increases as mortality falls, but the prevalent states are, on average, less severe.

These three theories require the development of additional concepts such as the severity of prevalent states or that of disability. Indeed, the consequences of chronic disease are varied, ranging from death to the absence of any discomfort. They have been the object of international classifications (WHO, 1980, 2001), which place disability at their center. Disability is, at the same time, an indicator of the severity of morbid states and an indicator of the quality of years lived. Its introduction led to a considerable improvement in models of health (Fig. 80–1); the risks of disability can

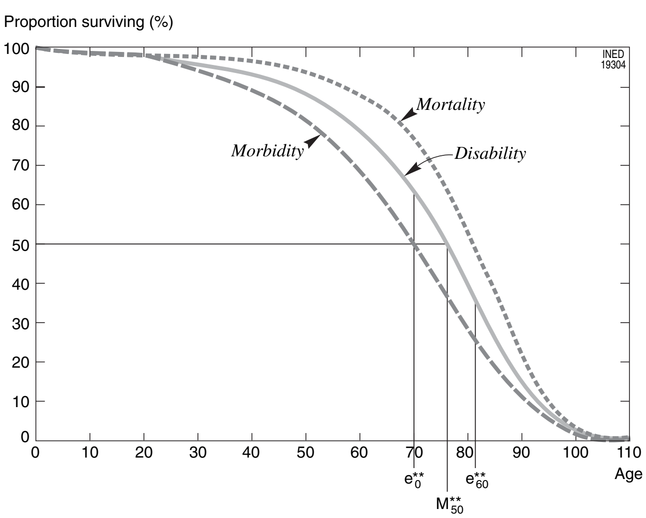

FIGURE 80–1 General model of health transitions according to the World Health Organization. The observed mortality and hypothetical morbidity and disability survival curves for females in the United States of America in 1980. $**e_0$ and $**e_{60}$ are the number of years of autonomous life expected at birth and at age 60, respectively; M_{50} is the age to which 50% of females could expect to survive without loss of autonomy. (From WHO, 1984.)

thus be added to the risks of disease. By distinguishing levels of severity, the risks of decline or improvement in the functional state of an individual can be measured.

First, the concept of disability allows us to rigorously define the progress of different scenarios of a populations' health corresponding to the three theories summarized above. Second, the breakdown of life expectancy into the years lived with or without disability provides the necessary tools to observe empirically which of these scenarios is confirmed. Thus, the theory of expansion of morbidity corresponds to the scenario in which the proportion of years lived with disability increases within life expectancy. The theory of compression of morbidity translates into the scenario in which the proportion of years lived with disability decreases within life expectancy. It thus becomes clear that the theory of compression of morbidity is not inevitably linked to the rectangularization of the survival curve (see Chapter 48). It is simply a verifiable fact that the survival rates without disability increase relatively more than do standard survival rates. Finally, taking into account the severity level of the disability, the theory of dynamic equilibrium corresponds to the scenario in which the proportion of years lived with disability—all levels combined—increases while the proportion of years lived with severe disability remains the same or even decreases within life expectancy. These theories correspond to different displacements of the survival curves of Fig. 80–1 to the right. One can imagine that they correspond to different phases in the health transition (see Chapter 57).

The first indicators of health state expectancy to be proposed were disability-free life expectancy (Sullivan, 1971) and, more particularly for the elderly, ALE (Katz *et al.*, 1983). A first calculation of health state expectancy, mostly DFLE, has been made for 49 countries, and repeated calculations exist for 14 of them (Robine and Romieu, 1998; Robine *et al.*, 1999). These calculations pertain to 20 of the 25 developed market economy countries; 4 of the least developed countries; 22 of 97 other developing countries; and 3 of the 22 economies in transition (Table 80–1). At present, it is impossible to compare these health state expectancies directly as the methods and the data used are very different from one country to another (UN, 1990). Similarly, for lack of comparable data, the World Health Organization (WHO) is currently producing crude estimates of disability-adjusted life expectancy for the 191 countries belonging to the organization (WHO, 2000).

An international research network, REVES (Réseau Espérance de Vie en Santé/Network on

TABLE 80–1 Health State Expectancy in the World According to Level of Economic Development

Level of development	Number of countries	Countries with calculations	
		n	%
DMEC	25	20	80.0%
LDC	47	4	8.5%
ODC	97	22	22.7%
ET	22	3	13.6%
Total	191	49	25.7%

From Robine and Romieu, 1998.

Health Expectancy and the Disability Process) was set up in 1989 to facilitate international comparisons by examining the requirements for harmonization of health state expectancies (Bone, 1992). The network includes nearly 200 researchers from more than 100 research institutes or universities worldwide. The growth in the numbers of calculations shows there are as many possible health state expectancies as there are health concepts.

II. DEFINING AND CALCULATING HEALTH STATE EXPECTANCIES

An important first step toward valid international comparisons of health state expectancies is the harmonization of the conceptual approach to health state measurement. In the following section, we outline the functional approach to health, this being the main category of health state expectancies calculated to date. We also present the calculation methods actually used, because their convergence and harmonization constitute the second step in permitting international comparison of health state expectancies. However, it is important to note that other factors also require harmonization—such as the severity of the states of health taken into account, the protocol of surveys, and the formulation of questionnaires—before the calculations are strictly comparable.

In contrast to mortality, notions such as health or morbidity are complex and thus difficult to define. Health is “a composite of current state and prognosis (i.e., the probability of movement to other states) that occurs throughout an individual’s life” (Fanshel and Bush, 1970). In this way, health is not only “the ability to function now, but the outlook for future functional ability” (Fanshel, 1972). This life-course definition of health is the justification for the use of health state expectancies, as fundamental health indicators for populations, because they measure the lifetime spent in different health states.

During the 20th century, the epidemiological framework changed from communicable and acute diseases to long-term chronic diseases, with a consequent change in the approach to diseases and health. Beyond the presence or absence of disease, the classical biomedical approach, health status may be assessed through perceptual, functional, or adaptive approaches. With the functional approach, good health relates to ideas of effective achievement of roles and tasks, the fulfillment, without difficulty, of different activities. With the perceptual approach, good health relates to ideas such as well-being; a happy attitude to life; or a full, fruitful, and creative life. With the adaptive approach to health, good adaptation testifies to a harmonious relationship with one’s environment. The functional approach and the underlying conceptual framework of the disablement process are key factors in the health assessment of older people, making health state expectancies in combination with this approach and the resulting DFLE, of the utmost importance. Because the majority of health state expectancies calculated can be classified under the functional approach, we will look at this in more detail.

1. The Functional Approach

The functional approach to health is mainly addressed by four models, with some overlap: the model of disablement process (Nagi, 1965, 1976, 1991); the model of the International Classification of Impairments, Disabilities, and Handicaps (ICIDH) (WHO, 1980); the model proposed for the revision of the classification, the International Classification of Functioning, Disability and Health (ICF, WHO, 2001); and the model of handicap creation process (Fougeyrollas *et al.,* 1998). The majority of these models distinguish between a maximum of five states: disease, impairments, functional limitations, activity restriction, and handicap.

Saad Nagi (1991) has the first three states (disease, impairments, functional limitations) followed by disability, which is defined as the inability or limitation in the fulfillment of activities and social roles in relation to work, the family, and an independent life (Nagi, 1991).

The ICIDH combines functional limitations and activity restriction under disability (Fig. 80–2), corresponding to any restriction or lack (resulting from an impairment) of ability to perform an activity in the

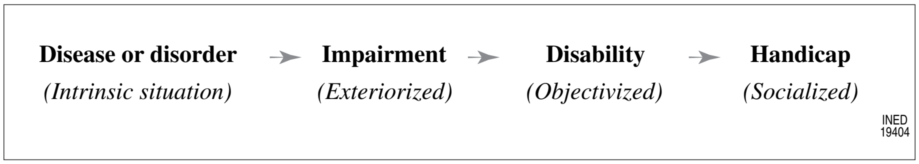

FIGURE 80–2 International Classification of Impairments, Disabilities and Handicaps (ICIDH): integration of concepts. (From WHO, 1980.)

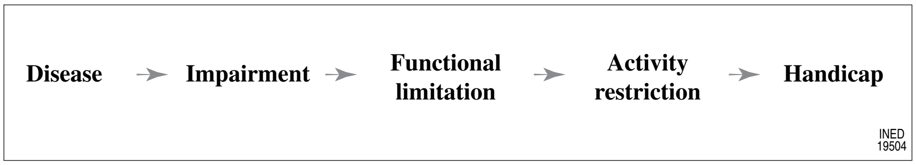

FIGURE 80–3 Disablement process, initial diagram by Philip Wood, 1975. (From Wood, 1975.)

manner or within the range considered normal for a human being. Under this framework, handicap is characterized by discordance between the activity and status of the individual and the expectations of his social environment (WHO, 1980). For fuller definitions see Appendix 80–1.

The boundary difficulties encountered, together with a need to further specify the area of mental health in the framework, made a revision of the ICIDH necessary. This revision, the ICF (WHO 2001), defines "functioning" and "disability" as umbrella terms covering the three new dimensions: (1) body functions and structure; (2) activities at the individual level, from simple to complex activities; and (3) participation in society. Functioning and disability are conceived as dynamic interactions between health conditions and contextual factors, which include both personal and environmental factors.

At the same time as the revision, an alternative model was devised that established the importance of the environment in the creation of handicap (Fougeyrollas *et al.*, 1998). This model of handicap creation puts the interaction between personal factors (organic systems and abilities) and environmental factors (facilitators or obstacles) at the heart of the model, the result of handicap situations (life habits). Risk factors (causes) are associated with personal factors, organic systems range from integrity to impairment, and abilities range from ability to disability.

Several attempts have been made to combine all or a part of the models described above through a disablement process (Verbrugge and Jette, 1994) or a general model (Robine *et al.*, 1997). The distinction between functional limitations and activity restrictions is central to these attempts, and the scheme with five levels (Fig. 80–3) (Wood, 1975) is preferred by those concerned with international comparisons as it clarifies the limits between impairment and disability and between disability and handicap. Thus, a difficulty concerning actions such as bending or reaching an object is a functional limitation, whereas difficulties concerning activities of daily life (dressing or domestic chores) are activity restrictions. The distinction between functional limitations and activity restrictions has been further blurred by existing measurement instruments that often combine these two levels and rely on apparently similar questions. Moreover, it has been suggested that functional limitations may be used as early indicators of activity restriction, thus avoiding potential heavier care burdens (Fried *et al.*, 1996; Lawrence and Jette, 1996). This two-step approach opens the way for research into new methods of measuring the functional health of populations by using functional limitation and activity restriction as two levels at which public health action could intervene.

2. The Health Expectancy Classification System

Initially, the term *disability-free life expectancy* was used without any reference to specific disability concepts. It was sometimes even used as a generic term to designate all health state expectancies. The concepts of the ICIDH (WHO, 1980) makes an initial distinction between life expectancies with or without impairment, life expectancies with or without disability, and life expectancies with or without handicap (social disadvantage). The clarification of concepts and terminology is very important; it facilitates communication between scientists at national and international levels and provides a means to promote these concepts more effectively among those responsible for health policy and the general public. It is the first step toward international harmonization of health state expectancies.

Table 80–2 summarizes the classification system currently used (Mathers, 2002; Robine 2002), which generalizes a first system developed by REVES for the WHO on the occasion of the first World Health Report (Robine *et al.*, 1995; WHO, 1995) and is based on previous work by The Netherlands Organization for Applied Scientific Research (Boshuizen and van de Water, 1994) and REVES (Mathers *et al.*, 1994).

Health expectancy is a generic term for all the health-related indicators expressed in terms of expectancy. It includes two main classes of indicators, the health state expectancies and the health-adjusted life expectancies.

Health state expectancy is a generic term for all the health-related indicators that express a defined state of health in terms of life expectancy. These indicators apply equally to positive and negative states of health. Thus, the sum of a complementary series of health state expectancies must always be equal to total life expectancy (Mathers *et al.*, 1994). The calculations of health state expectancy aim to provide indications on the current conditions of mortality and health. The repetition of calculations would make it possible to assess the progress of these conditions.

According to the concepts of the International Classification of Diseases (WHO, 1992), *life expectancy with or without disease* is the average number of years an individual can expect to live with or without disease if the current conditions of mortality and morbidity persist. A well-known example of this indicator is that of *life expectancy with or without senile dementia* (Ritchie *et al.*, 1993).

The International Classification of Handicaps (WHO, 1980) distinguishes among the concepts of (1) *life expectancy with or without impairment*, the average number of years an individual can expect to live with

TABLE 80–2 Classification System of Health Expectancies

Concepts	Indicators
Expectancy	Health expectancies (generic term for all)
Health state	**Health state expectancies**
Biomedical approach Disease (ICD)	Life expectancy with or without disease e.g., life expectancy with or without dementia
Functional approach	
Current system (REVES, 1994)[a]	
—Impairment	—Life expectancy with or without impairment
—Disability	
—Functional limitation	—Life expectancy with or without functional limitation
—Activity restriction	—Life expectancy with or without activity restriction
—Handicap	—Life expectancy with or without handicap
—Reduction in physical independence	—Life expectancy with or without reduction in physical independence
—ADL measures	—Active (independent) life expectancy[b]
—Mobility	—Life expectancy with or without mobility handicap
—Occupation	—Life expectancy with or without occupational handicap
—Other ICF (2001)	—Life expectancy with or without other handicap
—Impairment	
—Activity limitation	—Life expectancy with or without impairment
—Participation restriction	—Life expectancy with or without activity limitation
	—Life expectancy with or without participation restriction
Perceived health approach	Life expectancy in good perceived health / life expectancy in bad perceived health[c]
Health-adjusted	**Health-adjusted life expectancies**
Functional approach	Disability adjusted life expectancy (DALE)[d] (WHO, 2000)
Disability	

[a] The current REVES system for the functional approach combines the International Classification of Impairments, Disabilities, and Handicaps concepts, (WHO, 1980), the activities of daily living measures (Katz, 1983) and the REVES recommendations (1990).

[b] The use of the term independent life expectancy in place of active life expectancy is recommended to facilitate translation and comparability between countries.

[c] The terms healthy life expectancy or unhealthy life expectancy are often used for life expectancy in good perceived health or life expectancy in bad perceived health respectively. This was previously recommended by REVES, but given the current use of healthy life expectancy as a synonym of health expectancy by the WHO, this terminology should no longer be used.

[d] As proposed by the WHO (2000) to summarize the health of a population.

or without impairment; (2) *life expectancy with or without disability,* the average number of years an individual can expect to live with or without disability; and (3) *life expectancy with or without handicap*, the average number of years an individual can expect to live with or without handicap if the current conditions of mortality and impairment, disability, or handicap persist (cf. definitions in Appendix 80–1). The ICF (WHO, 2001), for its part, distinguishes among (1) *life expectancy with or without impairment,* the average number of years an individual can expect to live with or without impairment (i.e., with functional and structural integrity); (2) *life expectancy with or without activity limitation,* the average number of years an individual can expect to live with or without activity limitation; and (3) *life expectancy with or without participation restriction,* the average number of years an individual can expect to live with or without participation restriction if the current conditions of mortality and impairment, activity, or participation persist (cf. definitions in Appendix 80–1). The correspondence between the two classifications has yet to be defined, but life expectancy with a handicap in the original ICIDH meaning (WHO, 1980) is the nearest indicator to consequences of accidents and chronic diseases in daily life. Fortunately, all deficiencies (impairments) do not lead to a disability (or an activity limitation), and all disabilities do not lead to a handicap in daily life (or a participation restriction). The original ICIDH defines seven major dimensions of handicap (social disadvantage): handicaps of orientation, physical independence, mobility, occupation, social integration, economic self-sufficiency, and the other handicaps. In the same way, definitions are given for *life expectancies with or without handicap of physical independence, of mobility, of occupation, etc.* However, when the handicap is measured in a global manner, the corresponding indicator is a *life expectancy with or without handicap* in a general sense.

According to the recommendations of the committee of REVES on conceptual harmonization (Chamie, 1990) and to the attempts to combine the different conceptual models (Verbrugge and Jette, 1994; Robine *et al.,* 1997), life expectancy without disability sensu original ICIDH, encompasses the following concepts: (1) *life expectancy with or without functional limitation*, the average number of years an individual can expect to live with or without functional limitation; and (2) *life expectancy with or without activity restriction*, the average number of years an individual can expect to live with or without activity restriction if the present conditions of mortality and functional limitation or activity restriction, respectively, persist (cf. definitions in Appendix 80–1).

According to Katz *et al.* (1983), the ALE measures the average number of years an individual can expect to live without needing help to accomplish a whole series of basic activities of daily life or activities of daily living (ADL), if the current conditions of mortality and disability persist (cf. definitions in Appendix 80–1). ALE is, therefore, a life expectancy without handicap of physical independence in the sense of the original ICIDH. For this reason, it has been suggested that the term *active life expectancy* be replaced by *independent life expectancy*. This calculation can be extended to the need for help in realizing a whole series of complementary activities or instrumental activities of daily living.[1]

According to the perceived health approach, it is necessary to distinguish between perceived health expectancies. *Perceived health expectancy* is a generic term for all health state expectancies based on data on the perceived state of health. Thus, *life expectancy in good perceived health* is the average number of years an individual can expect to live in the favorable part of the distribution of perceived states of health (generally according to a scale of the form *very good, good, fair, bad, or very bad*).

Health-adjusted life expectancy is a generic term for all the life expectancies weighted by the social value given to different states of health in which the years are lived. The weighting used generally ranges from zero for death to one for perfect health (Mathers *et al.,* 1994; Mathers, 2002). This class of indicators is much less developed and contains mainly the disability-adjusted life expectancy, the new WHO indicator for the World Health Report (WHO, 2000), partly drawn from a Canadian indicator (Wolfson, 1996).

3. Calculation Methods

There are three calculation methods for health state expectancy: (1) the method of observed prevalence tables (Sullivan, 1971), (2) the method of double extinction tables (Katz *et al.,* 1983), (3) and the method of multistate tables (Rogers *et al.,* 1989). In this section the historic DFLE is taken as an example, but the different methods discussed here apply equally well to any other health state.

The main advantage of the *method of observed prevalence tables* (or Sullivan's method) stems from separate

[1] In French *espérance de vie active* means working life expectancy, with *actif* meaning in the labor force (occupied or unemployed). In English active life expectancy means life expectancy without physical dependence for personal care activities. As demographers have always paid attention to ease of translation, we strongly recommend the common use of independent and dependent life expectancy.

data collection on mortality and disability. The data on mortality come from standard mortality tables, and the data on prevalence of disability come from independent cross-sectional surveys.[2] However, the indicator obtained is not really a period indicator as the *period* prevalence is approximated by the prevalence observed in the survey.

The *method of double extinction tables* is based on the observation of two events during the study corresponding to two possible departures from the state of good health: death and entry into disability. In practice, it is sufficient to observe directly the probabilities of survival without disability. The main advantage of this method is that it provides a true period indicator from data that are not too difficult to collect. However, the method assumes that the disability studied is irreversible, which is the case with dementia, and that the recovery of lost functions is negligible.

The *method of multistate tables* was proposed to take recovery to good health into account. The main advantage of this method, based on transitions between different states of health, is that it provides a period indicator that takes the reversibility of states of disability into account. However, the data necessary for the calculation are scarce as they are difficult and expensive to collect. Finally, note that the multistate methods, as the method of double extinction, imply that the data on mortality and disability are collected in the course of the same study. The precision of mortality data depends, as a consequence, on the sample being of a sufficient size.

Most of the calculations of health state expectancy have been obtained with the method of observed prevalence tables (Sullivan's method, cf. Appendix 80–1). This method provides a very useful indicator as long as its limits are well understood (Robine and Mathers, 1993). The difference between the Sullivan and the multistate methods is not the use of prevalence versus the use of incidence and recovery. In both methods the prevalence is used in the calculation and comes from incidence and duration (recovery and lethality). But in the Sullivan method, the cross-sectionality observed (or current) prevalence comes mainly from past flows of incidence and recovery, whereas in multistate methods, the *equilibrium* prevalence (or table prevalence) comes from current flows only.[3] So the use of observed prevalences is not a suitable method for making instantaneous comparisons of health conditions in two countries or for establishing projections concerning the future health of populations. For all these reasons, it is preferable to observe and to use the period transitions between the different states of health. (For more details on the standard and advanced methods, respectively, see Cambois *et al.*, 1999; Laditka and Wolf, 1998.) EuroREVES, the European REVES committee has produced a first manual on the Sullivan method (Jagger, 1997), and a software application on the multistate approach has been finalized (Lièvre *et al.,* 2003).[4]

The health state expectancies aim to answer practical questions. Is the increase in life expectancy accompanied or not by an increase in the time lived with disability? Is DFLE increasing faster than is life expectancy, leading eventually to a compression of the time lived with disability? With the current concepts of disability, health state expectancies now aim to assess eventual differentials in the evolution of life expectancy without functional limitation and life expectancy without activity restriction. The disablement process—leading from accidents or chronic diseases to activity restrictions and social participation limitations—is complex, and measures to halt the process may be taken at different levels. Thus, an increase in the time lived with functional limitation may not necessarily be followed by an increase in the time lived with activity restriction or social participation limitation. Another question is whether or not an increase in the time lived without disability is accompanied by an increase in the time lived in good perceived health, a closer indication of individual satisfaction.

The goal of health state expectancies is clearly to monitor health transitions at work through the different components of health: mortality/longevity, measured or reported morbidity, functional limitation at the body level, activity restriction in daily life (i.e., in the daily environment), and perceived health. The

[2] In epidemiology, cross-sectional surveys study a population at one point in time: they serve to collect information on stocks (prevalence) or on past events. Longitudinal surveys follow a group of subjects over a period of time and allow the registration of new events (incidence). Demographers would prefer the term *point survey* to cross-sectional survey and the term *prospective survey* to "longitudinal survey", but the terms cross-sectional and longitudinal are standard throughout the literature.

[3] In this regard, the Sullivan method is much more robust than is the multistate approach. The methodology to assess the accuracy and quality of data collected through cross-sectional surveys is well developed, known, and used. It constitutes the topic of several chapters in statistical textbooks about the accuracy of estimations (e.g., confidence interval) and in epidemiology textbooks about the validity of indicators (e.g., sensitivity, specificity). Conversely, the methodology to assess the quality of data on individual transitions through longitudinal surveys is underdeveloped: in particular, how should expected misclassifications be separated from true transitions (according to the sensitivity-specificity of the indicator used) in the successive waves?

[4] Imach Version 0.8 (Lièvre *et al.,* 2003) available via the Internet (http://euroreves.ined.fr/imach).

period life table offers a strong conceptual and statistical framework for this, making it possible to design a complete family of integrated indicators. Health state expectancies, together with life expectancy, thus form a coherent set of health indicators to monitor health transitions at work in different countries. All the indicators are expressed in years so that basic combinations, such as summation or ratios, are easy to calculate and are immediately meaningful. The aim of these indicators is to summarize the health and mortality conditions over a period of time. This period characteristic is the essential precondition for monitoring change over time by repetition of the calculations.

III. TRENDS AND DIFFERENTIALS IN HEALTH STATE EXPECTANCIES

In addition to change over time, the estimates of health state expectancies already reported have brought information on sex, socioeconomic, and geographic differentials. They have also supplied information on the causes of morbidity and disability. The references of the studies summarized here can be found in Robine and Romieu (1998) or Robine *et al.* (1999), otherwise they are given in notes.

1. Sex Differentials

The wide differential between sexes found in life expectancies is not reproduced as strongly with the health state expectancies. Most studies indicate that life expectancy and positive health state expectancy (e.g., handicap-free, disability-free) are longer for women, and that the proportion of positive health state expectancy to total life expectancy is slightly lower for women in developed (Fig. 80–4) and in developing countries (Lamb, 1999).

Results from studies using data from repeated waves of surveys have suggested that the greater proportion of years lived with disability or handicap by women may be explained by the relatively higher survival of women after the development of these disabilities or handicaps (Robine and Ritchie, 1991; Mor *et al.*, 1994).

2. Socioeconomic and Sociodemographic Differentials

To date, socioeconomic variables have been included in studies from nine developed countries: Austria, Belgium, Canada, Finland, France, The Netherlands, Sweden, the United Kingdom (London), and the United States. All studies except one from the United States (Guralnik *et al.*, 1993) have demonstrated that social inequalities in health are much greater than has been shown by differential mortality: not only do the poorest and the least educated not live as long, but they also experience a greater part of their life with disability or handicap.

This was first observed in Canada, according to income levels (Wilkins and Adams, 1983). The gap in life expectancy between the richest and poorest sections of the community increased from 6.3 years for overall life expectancy to 14.3 years for occupational handicap-free life expectancy (Table 80–3).

Finnish and Dutch studies point to socioeconomic inequalities by level of education. The conclusions are

similar: the higher the educational level, the higher the life expectancy and positive health expectancy. The calculations comparing different ethnic groups in the United States (Hayward and Heron, 1999) show dramatic differences to the detriment of the black population and to the benefit of the Asian population.

In France, repetition of the calculations at 10-year intervals shows that social inequalities in health remained constant for men over age 35 over the 1980s: gaps between the managerial staff group and the manual workers group in terms of life expectancy and DFLE, at ages 35 and 60, have not changed. In 1980 and 1991, at age 35, the managers group could expect an additional 5.4 years of life and an additional 7 years of life without disability compared with levels for the manual workers group. At age 60, the gaps reached 3 expected years of life and 4 expected years of life without disability. Nevertheless, this upholding of inequalities over the period is the result of an equivalent increase in life expectancy and DFLE for the socio-occupational groups (Cambois *et al.*, 2001). See Table 80–4.

3. National Geographic Comparisons

Several countries have computed estimates in order to make geographic comparisons across large geographic areas (Australia, Canada, France, Italy, Spain, and United Kingdom) (Robine and Romieu I, 1998) or between rural and urban areas (China and India). As with differences in life expectancy, differences in health expectancy across different geographic areas in the same country vary widely, although no general trends can be inferred.

In India, for example, comparisons in physical DFLE have been made between rural and urban males and females. Both life expectancy and physical DFLE are longer in more developed urban areas than in the less developed rural areas (see Table 80–5).

Figure 80–5 illustrates the area variations by using data for the United Kingdom. British researchers have computed expected years of ill health for numerous local areas, using data from the 1991 census. These calculations show that the local area with the shortest life expectancies also have the largest expected number of years in ill health. Whatever the causes of these area variations, it is more obvious that there may be a strong relationship between short life expectancy and amount of morbidity.

In all the situations studied and presented here based on sex, socioeconomic status, and geographic differentials, life expectancy and DFLE are positively associated with little evidence of the hypothetical trade-off between quantity and quality of life.

4. Causes of Handicap, Disability, and Mortality

Potential gains in DFLE can be calculated after elimination of various pathologies, with a resulting ranking of the causes contributing to mortality and prevalence of morbidity (disability or handicap). Studies of this type have been undertaken to date for five developed countries (Australia, Canada, The Netherlands, United Kingdom, and United States). These studies have demonstrated an important effect produced by the elimination of osteo-articular diseases and accidents; in developed countries, these causes are of major importance after cardiovascular disease.

The results for The Netherlands in 1987–1988 show that although the elimination of fatal diseases leads to an increase in life expectancy and DFLE, it may also lead to an increase in life expectancy with disability, thus increasing the burden of disability to society (Nusselder *et al.*, 1996). However, the elimination of disabling nonfatal diseases results in a decline in life expectancy with disability (Table 80–6). Thus, the suppression of certain cancers would strongly increase life expectancy without increasing DFLE in the same proportion and therefore would strongly increase life expectancy with disability. Conversely, the suppression of nonfatal diseases, such as arthritis, would strongly increase DFLE without changing total life expectancy and therefore would strongly decrease life expectancy with disability. Between these two extremes, the suppression of fatal disabling diseases, such as heart diseases, would increase life expectancy and DFLE in various proportions.

5. Time Trends

Several time series of handicap-free life expectancy or DFLE have now been produced for 15 developed countries. A time series consists of at least two cross-sectional health surveys using the same measure of disability and handicap and comparable samples allowing comparisons over time. When the series are juxtaposed, they cover a period that extends over more than 30 years. Most authors distinguish between life expectancy without severe disability and life expectancy without disability, all levels of severity combined. DFLE most often means all levels of disabilities combined.

Figure 80–6 presents total life expectancy and life expectancy without disability—all disability levels combined—at age 65 in men in eight countries (United States, United Kingdom, Finland, Australia, France, New Zealand, Germany, and Canada) from 1970 to 1995. The analysis of the oldest series demonstrates that life expectancy without disability—all levels combined—is stagnating. However, the series across countries differentiate over time. For instance, the Canadian and Finnish series still suggest that DFLE is leveling off, whereas the American, French, British, and German series show that DFLE is now increasing, and the Australian series is decreasing. Hence, no general conclusion can be firmly drawn for this level of disability even if the general perception—when looking at Figure 80–7—is that although life expectancy is increasing whatever the country, DFLE—all severity levels combined—is apparently leveling.

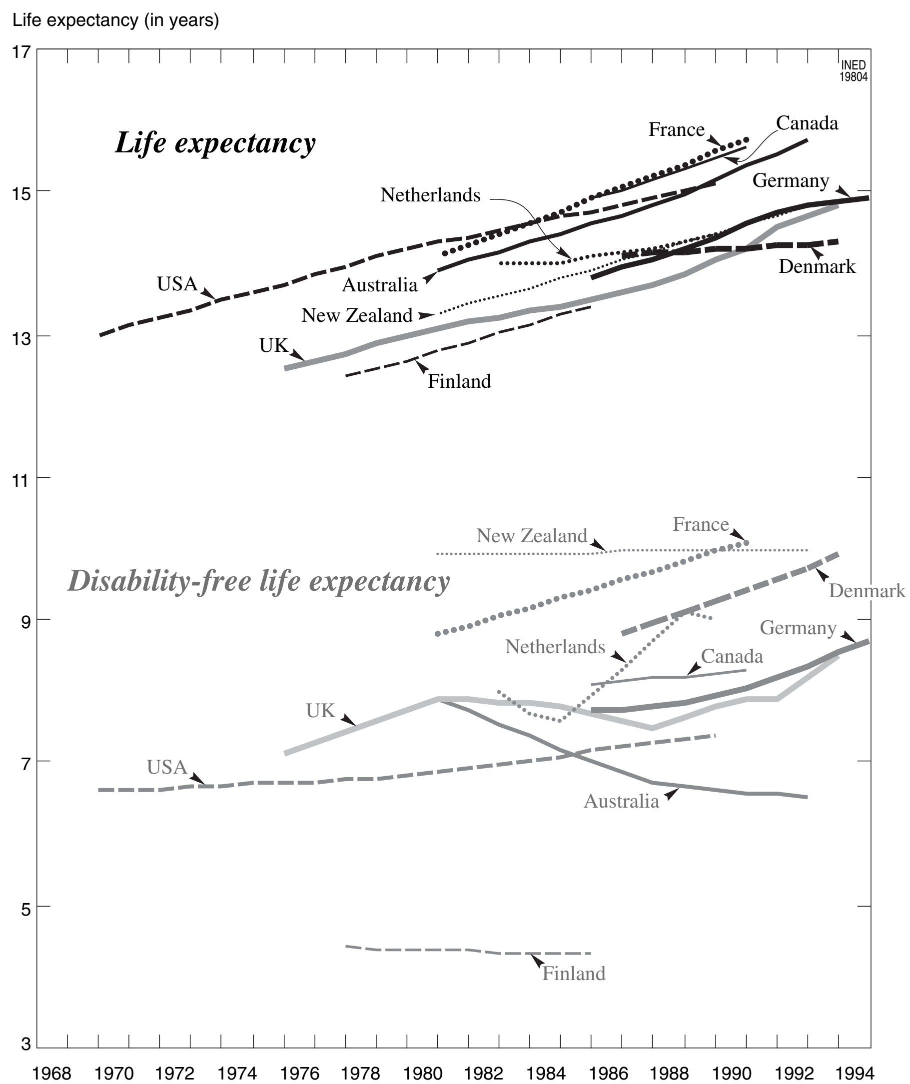

FIGURE 80–6 Evolution of life expectancy and disability-free life expectancy—all disability levels combined—in various countries at age 65. (From Robine and Romieu, 1998.)

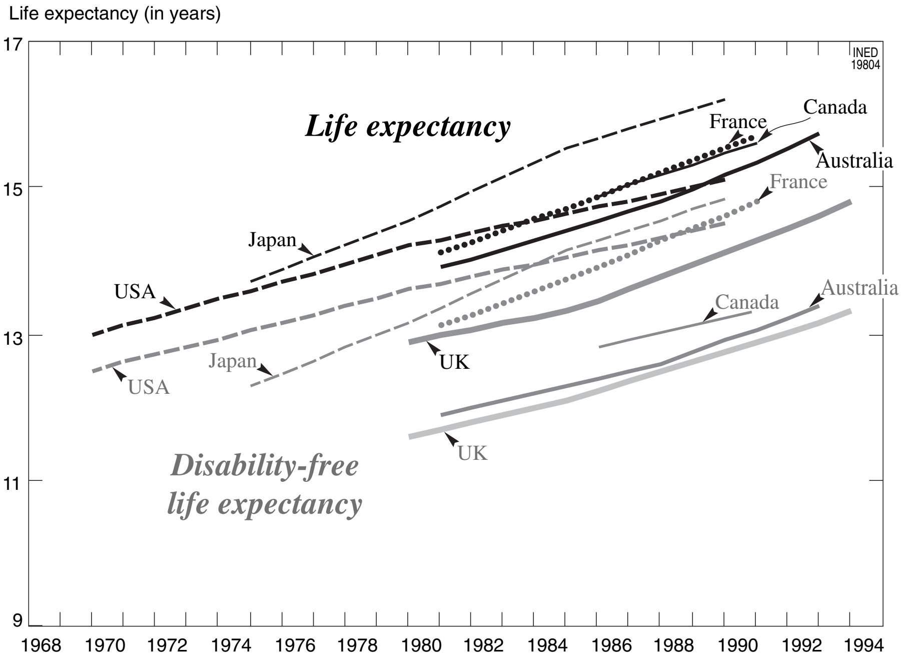

FIGURE 80–7 Evolution of life expectancy and life expectancy without *severe* disability in various countries, at age 65. (From Robine and Romieu, 1998.)

Total life expectancy and life expectancy without severe disability at age 65 is shown for men in six countries (United States, Japan, United Kingdom, Australia, France, and Canada) from 1970 to 1994 (Fig. 80–7). Life expectancy without severe disability roughly parallels total life expectancy, meaning that the number of years lived with severe disability is leveling off. This result can be verified whatever the developed country or the period of time studied or the indicator of severe disability considered (e.g., institutionalization in the United States; institutionalization or confinement to house for France; personal help or supervision required or impossibility to perform basic tasks in relation with self care, mobility, and verbal communication in Australia).

It is probable that the difference between the results obtained for severe disability and disability (all levels combined) is attributable to the less subjective declaration of severe disability compared with declaration of light disability. As time goes on, health requirements are increasing, and what was once considered normal for an age, sex, or social position is now considered disabling. This may well explain an apparent decrease in DFLE as well as incoherent trends between countries, with cultural differences explaining different perceptions of health. Nevertheless, this type of subjective trend has a greater effect on light disabilities than on severe disabilities, as the latter have always been perceived as disabling. The trends in severe DFLE are probably much more representative of the health status of the population.

In summary, it is apparent from the data available, that the increase in life expectancy is not accompanied by an increase in the time spent with severe disability. The results indicate at worst a pandemic of light and moderate, but not severe, disabilities. These results therefore tend to confirm the theory of *dynamic equilibrium,* which partly explains the increase in life expectancy by a slowing down in the rate of progression of chronic diseases (Manton, 1982). Thus, although the decline in mortality can lead to an increase in the prevalence of disabilities, these disabilities are less severe.

In France the general model of health transitions (WHO, 1984) has been used to compare the evolutions of life expectancy, DFLE, and life expectancy without chronic disease. The results show that the increase in life expectancy between 1981 and 1991 has been accompanied by a parallel increase in DFLE, and life expectancy without chronic disease has remained constant (Fig. 80–8). This apparent contradiction in the evolutions of morbidity and disability again illustrates the theory of dynamic equilibrium proposed by Manton in 1982: with the decline in mortality, the prevalence of chronic diseases increases but the diseases are less severe (Robine *et al.*, 1996).

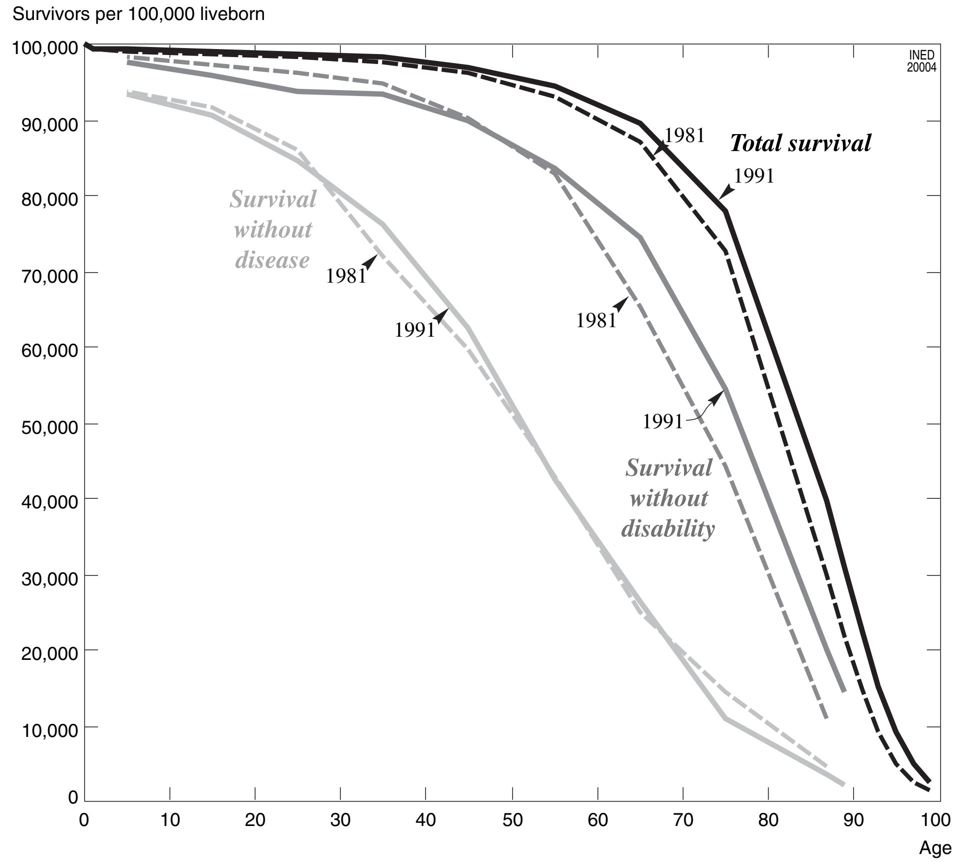

FIGURE 80–8 Survival without disease and survival without disability (World Health Organization model, 1984) France, 1981–1991, females. (From Robine *et al.*, 1996.)

IV. WHAT CONDITIONS CONSTITUTE THE YEARS LIVED IN BAD HEALTH OR WITH DISABILITY?

Finally, Tables 80–7 and 80–8 are given to illustrate the nature of years lived in bad health or in disability by people over 65 years.

In France, the health survey of 1991–1992 showed that a problem of disability or of handicap affected 39.8% of years lived outside institutions by men over 65 in France and 51.2% of years in women (Table 80–7). In men, 28.7% of years lived were with functional limitations of mobility and agility (unable to walk 200 m without stopping and without severe discomfort, great difficulty in going up and down stairs, or picking up an object from the floor), whereas 14.7% of years were with difficulties of communication (great difficulty in reading or following a conversation on the telephone), 12.1% of years were confined to the home, and 9.0% of years were lived with handicaps of physical independence (confined to a bed or an armchair or great difficulty getting dressed, washing, going to the toilet,

TABLE 80–8 Different Health State Expectancies at Age 65, United Kingdom, Nottingham, 1985

Quality of life	Male		Female	
	Years	%	Years	%
Life expectancy	13.4	100	17.4	100
With mental impairment	1.1	8.3	2.0	11.3
Institutionalized, or with a				
Visual impairment	2.8	20.9	5.1	29.4
Hearing impairment	5.2	38.5	5.8	33.2
Poor or fair perceived health	5.0	37.3	9.0	52.0
With urinary incontinence	2.0	14.6	4.1	23.8
With mobility impairment	0.6	4.5	1.4	8.1
With depression	1.2	8.9	2.9	16.6
At least one of these problems	9.5	70.6	13.7	78.7

From Jagger *et al*., 1994; Bone *et al*., 1995.

or feeding oneself). For 2.9% of the time lived, men had great difficulty in feeding. It can also be seen that each of the most severe levels (time lived with great difficulty in feeding, in institutions, or with a dementia or time confined to a bed or an armchair) concerns only a small part of the years lived. The table also shows that although women declare many more functional limitations of mobility and agility, there are no great differences in the handicaps of physical independence. On the contrary, with regard to the proportion of years lived, not only without disability but also with good performance in the instrumental activities of daily life such as preparing a meal or filling in care expenditure claim forms, the proportion is higher for women (43.8%) than for men (37.8%).

Table 80–8 shows similar information from longitudinal surveys in Nottingham and Leicestershire, England, in 1985: 37.3% of years lived by men over 65 years are not perceived as years of good health (52.0% for women), 14.6% of years are lived with urinary incontinence, 8.9% with depression, 8.3% with mental impairments, and 4.5% with impairments of mobility (idea close to confinement to bed or an armchair).

The development of dementia-free life expectancies initiated by Ritchie (1991) has been conducted in 10 countries (Australia, Belgium, Denmark, France, Japan, The Netherlands, Spain [Catalonia], Switzerland, United Kingdom, and United States), although only 4 of the calculations are presented at a national level. In parallel with dementia-free life expectancies, other types of mental health expectancies are now being developed such as depression-free life expectancy and life expectancy in good mental health (Jagger *et al*., 1998).

CONCLUSION: POLICY RELEVANCE OF HEALTH STATE EXPECTANCY INDICATORS

Health state expectancies can be considered as a family of indicators in which each can be analyzed independently or according to each other. They can be added to each other: for example, the sum of DFLE plus life expectancy with disability is equal to total life expectancy. They can also be presented as a ratio of DFLE to total life expectancy—generally expressed as a percentage—indicating the proportion of life expectancy lived without disability. Health state expectancies offer a positive assessment of the time spent in different health states, similar to the way that life expectancy provides a positive indication of human longevity. They provide positive indications on the health of populations, on their vitality, or on their quality of life.

Health state expectancies can also assist in establishing public health priorities when potential gains are calculated. Gains in health state expectancies make it possible to classify priorities according to the survival or health criteria used in the calculation. This leaves a degree of choice to public health authorities by providing them with all the elements necessary to decide between longevity and, for example, duration of life with or without disability.

Health state expectancies can be used for direct comparison of the different groups that make up the population, whatever the distribution criterion used—e.g., sex, socio-occupational category, region—because, for their calculation, the years lived are divided by the number of survivors, which make them independent of the size and age structure of the populations from which the data are obtained.

As a rule, the calculations of health state expectancies are based on observed data: period life tables, results of population censuses, and results of various surveys (e.g., living conditions, health, disability, labour force).[5] This explains why estimations of health state expectancies are currently available for only about 50 countries, and why these estimations are not directly comparable from one country to another. In fact, the national characteristics of the different surveys, in terms of protocol, questionnaire, or question formulation, make international comparisons difficult. This is the major weakness of the present calculations of health state expectancy.

[5] However, when the data necessary to the methodological works devoted to health expectancies and its calculation methods were not available, they have been simulated (Mathers and Robine, 1997).

The profusion of possible indicators, as illustrated by Tables 80–7 and 8, makes it necessary to make a choice, consistent with the basic conceptual framework, because too many indicators may divert attention and too few indicators may hide the possible trade-off between the different facets of health as well as the effects.

Standardization of disability data should become a priority. A first objective could be the harmonization of the underlying concepts followed by the measurement of disability according to severity levels in the general population. For the most severe states, a consensus should not be too difficult to find, as almost all the countries use measures of personal care activities limitations to calculate severe disability (e.g., eating, dressing, washing). Moreover, these elementary activities are universal. The extension of this approach to other types of activity is worth exploring to standardize the measurement of less severe disability levels (e.g., mobility, household care activities, professional or school activities).

In conclusion, health state expectancy indicators are relevant and meaningful indicators for policymaking. Health state expectancies are not summary measures of population health aimed at replacing life expectancy or the most basic indicators, such as the prevalence or the raw figures. However, they do make it possible to assess whether the increase in life expectancy is accompanied by a compression of morbidity or by an expansion of disability. Very recent studies show that people with the lower risks (defined on the basis of smoking, body mass index, and exercise patterns) not only live longer but experience fewer years of disability before death (Vita *et al.*, 1998; Ferrucci *et al.*, 1999; Nusselder *et al.*, 2000). None of these three studies suggest that there is a trade-off between quantity and quality of life but rather, at least for two of them, that there is a possible compression of disability, with quantity and quality going hand in hand. Thus, if future increases in life expectancy are owing to better behaviors, they could be accompanied by a larger increase in DFLE, leading to a compression of morbidity. In fact, in the United States, certain forecasts of disability in elderly populations are very optimistic (Manton *et al.*, 1997).

Nevertheless, health state expectancies have not become a routine indicator of the health status of the population as they are not currently comparable across countries. Standardization of the concept and of the disability questionnaire used to calculate health state expectancies would resolve this problem. Direct comparisons across countries would then be as easy as the comparisons of life expectancies are today, and this task has already begun in the European Union (Robine *et al.*, 2001).

APPENDIX 80–1

1. International Classification of Impairments, Disabilities, and Handicaps

In the International Classification of Impairments, Disabilities, and Handicaps (ICIDH), the World Health Organization distinguishes among *impairments, disabilities and handicaps* (WHO, 1980). Basically, one finds an organic or functional anomaly corresponding to the intrinsic situation, which can be exteriorized by the *impairment*, objectivized by the *disability,* and socialized by the *handicap.*

Impairments

In the field of health, impairment corresponds to all loss of substance or alteration in a physiological or anatomical structure or function (WHO, 1980). Impairments are linked to pathologies that can be organic as well as functional.

Note that impairment is wrongly interpreted as an organic or functional lessening as it also means all forms of organic or functional surplus (having six fingers on one hand is a impairment) likely to hinder the normal function of an individual's faculties.

Disabilities

In the field of health, a disability corresponds to any partial or total reduction (resulting from a impairment) in the capacity to carry out an activity in the manner or in the limits considered normal for a human being (WHO, 1980).

Within the subject of disability, a distinction can be made between *functional limitations* and *activity restrictions* if one chooses to distinguish between the realization of *actions* and the realization of *activities*, which the WHO does not do.

Note that disability is wrongly interpreted only as an "impossibility or a difficulty in realizing an *activity*," whereas all forms of inappropriate, exaggerated, or untimely realization of an *activity* outside the normal must be considered.

Handicaps

"In the field of health, the handicap (social disadvantage) for a given individual results from an impairment or a disability which limits or prevents the accomplishment of a normal role (consistent with age, sex, social and cultural factors)" (WHO, 1980). Such a *handicap* is assessed on the basis of a judgment, which depends on the *performance* of *activities* making up the role studied.

2. Functional Limitation and Activity Restriction, REVES Classification System

Functional Limitation

Depending on the *degree of severity,* functional limitation is impossibility or difficulty in performing an *action.* The measurement of functional limitation is complicated, as individuals generally have daily *activities* in common (eating, personal hygiene, housework, etc.), but they are not always challenged by the same *actions* in the course of these *activities* (e.g., housework does not necessarily mean climbing stairs, reaching up, bending down, etc., for everyone). It thus becomes difficult to obtain information on the *performances* of the subject; to reveal a specific functional limitation, it is preferable to obtain information either on the *aptitude* in performing a defined *action* or the cause of the difficulty encountered when faced with a particular *activity,* generally including the realization of the *action* being studied.

Activity Restriction

This represents impossibility or difficulty, depending on the *degree of severity* in performing an *activity.* It is measured in terms of *performances* when the *activity* is considered to be an unavoidable component of a *role* studied. For example, all subjects whose *social role* is housekeeping will be questioned on their ability to wash the dishes, do the housework, and do the laundry.

Finally, a distinction can be made between the difficulty or impossibility, depending on the *degree of severity,* of carrying out a gesture, an action, an activity, or a role. When limited to the field of locomotion, which is more illustrative, a correspondence table grading these different types of difficulty can be drawn up. A difficulty in performing a *gesture* is an *impairment.* A difficulty in performing an *action* a *functional limitation.* A difficulty in performing an *activity* corresponds to an *activity restriction.* A difficulty in performing a *role* corresponds to a *handicap.*

3. Activities of Daily Living, Basic or Instrumental, Proposed by Katz *et al.* (1963) or Lawton and Brody (1969)

Personal Care Activities

These are a set of *activities* considered to be indispensable for ensuring *minimal independency* such as washing and eating. They correspond to *activities* that the subject must do for himself, with or without *help*, and that nobody else can do for him. From this definition, Sydney Katz *et al.* (1963) elaborated a model bringing together six activities of daily living considered to be common to all with the aim of *minimal independency*: feeding, bathing, going to toilet, dressing, transfer (moving in and out of bed or chair), continence. This forms the model of reference for many studies.

Household Care Activities

These are all the *activities* representing the *ability to live alone in a private home.* They include *household care activities* known as instrumental activities of daily living such as filling in forms, shopping, or cooking. They correspond to *activities* normally carried out by the subject in daily life, with or without help, but that may possibly be carried out by someone else. The model of reference was proposed by Powell Lawton and Eliane Brody (1969).

4. International Classification of Functioning, Disability, and Health (ICF, WHO, 2001)

In the context of a health condition:

Body functions are the physiological functions of body systems (including psychological functions).
Body structures are anatomic parts of the body such as organs, limbs, and their components.
Impairments are problems in body function or structure such as a significant deviation or loss.
Activity is the execution of a task or action by an individual.
Activity limitations are difficulties an individual may have in the performance of activities.
Participation is involvement in a life situation.
Participation restrictions are problems an individual may experience in involvement in life situations.
Environmental factors make up the physical, social, and attitudinal environment in which people live and conduct their lives

Sullivan's Method

Principle

The years lived by the population in a life table are separated into years lived with or without disability. The rates of institutionalization (which generally come from population censuses) and the short-term or long-term disability prevalence rates (which generally come from health or disability surveys) can be used for this purpose. Once the table is modified, life expectancies with or without disability are calculated in the usual way. Thus, by including only the years lived without disability, a life expectancy without disability is obtained, or conversely, by including only the years lived with disability, a life expectancy with disability is obtained.

Calculation

Using the survivors (b) from a life table (cf. table below), the number of years lived between each age (c) is calculated. The prevalence rates of disability (d) can then be used to calculate the number of years lived with disability. By simple subtraction, the number of years lived without disability (e) is obtained. These years are then added together (f) from any age x and divided by the total number of survivors at this age (b) to obtain the life expectancy without disability (g).

Example

The total number of years lived without disability from 65 years of age is 1,153,013.2 in the table. This total is divided by the number of survivors at 65 years old to estimate life expectancy without disability at this age: 1,153,013.2 (f) divided by 89,347 (b), i.e., 12.9 years (g).

For more information, see Jagger (1997).

TABLE 80–A Disability-Free Life Expectancy According to Sullivan's Method, France, 1991, Female (Simplified Estimation Calculated from Long-Term Disability)

CHAPTER

81

Demographic Trends and Relationships between Generations

ANTONIO GOLINI AND RAFFAELLA IACOUCCI

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

INTRODUCTION: A FEW DEFINITIONS

Almost every discipline has its own definition of the word "generation." Jurists, economists, sociologists, historians, teachers, politicians, and even technocrats have their own understanding of the word, which depends on each discipline's interpretation of how individuals, events, or objects succeed each other in time. Thus, in political science, a group of persons who went through major experiences together are referred to as a generation, such as postwar generations or the 1968 generation. In the field of computer science, a recent discipline, the word generation refers to each of the successive stages of technological development corresponding to the creation of ever more sophisticated products; computer scientists speak of second-generation or third-generation computers.

Demographers use two different words, depending on whether a person's birth is considered in the context of the general population (cohort) or in the family context (generation). The two notions, however, are closely linked both structurally and conceptually, and for this reason, they cannot be dissociated.

Indeed, on one hand, when dealing with all the individuals that make up a population, demographers consider that all persons born in the same year represent a birth cohort (sometimes the group includes persons belonging to several cohorts, for instance over a 5-year span) and study their demographic behavior; in this case, for example, they speak of the fertility and mortality of the cohort born in the year t. The notion of cohort is very frequently referred to in demographic analyses (see Chapters 6 to 13).

On the other hand, when population specialists deal with individuals within a family and study how each person is related to the rest of the family at the time of his or her birth, they use the word generation, which comes from the Latin *generare*, to give birth to, to describe all the members of a family who are equally related to a common ancestor. Thus, from generation to generation, a newborn baby can be linked to its most distant ancestor, and conversely, the chain can be linked going back the other way, from the ancestor down to the most recent generation: upward from the children to the parents, grandparents, great-great-grandparents, great-great-great-grandparents and downward to the grandchildren great-grandchildren, etc.

In this sense, it is interesting to determine how many generations coexist at a given moment. The number of coexisting generations obviously depends on (1) biological or voluntary infertility (the more childless women there are, the more cases in which the generation chain is broken); (2) the distance between generations at the time of birth (the older the average age of the mother and the father at the time of childbirth, the lower the probability, all other things being equal, of observing a large number of coexisting generations); and (3) mortality conditions (the higher the life expectancy, the higher, all things being equal, the probability of having a large number of coexisting generations).

In most European countries today, we observe a situation of low fertility, an increase in the distance between generations and low mortality. Developing countries may soon follow, even though such a prospect seems quite remote for most. European countries, however, may be considered as precursors in dealing with problems tied to the aging of the population, in particular those that will be discussed in this chapter. Even though our description of these problems is limited to Europe, it can be used as reference by "young" countries when their turn comes to face the same type of demographic trends and determine the number of coexisting generations.

However, from a social, familial, and individual point of view, the important point is not only the *number* of coexisting generations but also, and especially, the *percentage* of the population that finds itself in a situation of coexistence with several generations and the *duration* of the period of coexistence; we may also consider the number of *years of life* spent by each individual in the position[1] of child, grandchild, parent, grandparent, or other positions. In the past, families in which four generations coexisted for a short period of time were rare, and cases of five coexisting generations were extremely rare, limited to families in which people had children young and lived very long. Today, cases of five coexisting generations remain quite rare, but cases of four coexisting generations have become relatively common. However, the proportion of persons coexisting at a given age with living relatives going back one, two, and three generations and the duration of this coexistence have radically changed and will continue to change because elderly persons, especially women, are living longer. Indeed, at the age of 65 or 70 years, some women are still the child of a living parent, something that recently was hardly conceivable.

This chapter deals essentially with the notion of generation. We will describe mainly the dramatic changes in the quantitative balance (within a population or a family) among living children, parents, grandparents and great-grandparents, as well as between adult children and elderly parents. We will then describe a few typical traits pertaining to psychological, cultural, social, or economic relationships between the different generations. Last, we will address the question of transmission, as well as the various aspects linked to changes in the distance between generations: these changes have had an impact well beyond simple material inheritance and age difference. In each case, our angle of analysis will be essentially demographic.

I. SEEING THE GENERATIONS

Figure 81–1 shows the situation of four successive generations: their life courses, the system of relations linking them within the general population (in relationship to their cohorts) or within the family and linking them to periods when demographic events are likely to occur (first union, marriage, childbirth, divorce, migration, chronic degenerative diseases or disabilities, death). The four diagonal stripes correspond to both cohorts and generations, according to the definitions given in the Introduction, whereas the number of diagonal stripes crossing the vertical columns corresponds to the number of generations coexisting during a given calendar year or a given period of time.

This diachronic and synchronic study shows the complexity of the links among generations, age, and period, in all respects: economic (both micro- and macroeconomic), educational, professional (aspects tied to social advancement), or even those concerning legislation, norms, etc.

Indeed, the number of events in each parallelogram of the Lexis diagram (i.e., the number of marriages, births, divorces, migrations, and deaths occurring within a given cohort during a calendar year and thus at a given age) depends not only on the conditions under which a given cohort was born and grew up—on the social, economic, political, and health context of that year or brief period (and especially, as concerns migrations and divorces, on changes in the current legislation)—but also on the person's age at the time and the type of support (family or social) she or he received. One example of the link between context and age, in Italy, is that of the generation of women born in 1950, whose formative years (18 to 20) took place in 1968 to 1970 in a very specific political and ideological climate; this combination occurred once again in 1974, when they turned 24, at the time of the first large-scale referendum on divorce. The events of 1968 and 1974 obviously had a different impact on women born in 1964, who were only 4 in 1968 and 10 in 1974.

These examples show the complexity—highlighted several times in this treatise[2] and widely researched in the literature—not only of the links among age, generation, and period but also of interrelations between generations; it seems that the instruments developed

[1] This position exists when both persons concerned in the family relationship (parent and child, grandparent and grandchild) are alive.

[2] In addition to Chapters 6 to 13 of Volume I, which have already been referred to, see also Chapters 17 and 18 (also in Volume I).

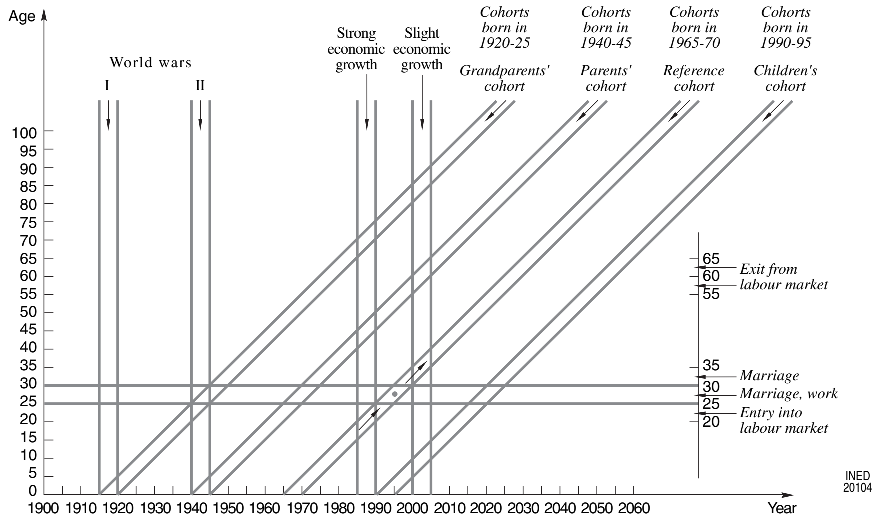

FIGURE 81–1 Relationships between age, cohort, and period in terms of population or family. (Adapted from Golini, 1992:779.)

through the APC (age/period/cohort) method of analysis are not sufficient to fully describe and explain this complexity. For example, the point drawn in Fig. 81–1 represents a woman belonging to the group of cohorts born in 1965–1970, and who reached the age of 25 to 30 years around 1995. The demographic behavior of this woman depends of course on her age but also on the period when she was 25 to 30 years old and on her own past as well as that of her cohort. These factors will all influence her future life in the next 10 to 20 years. But there are other factors as well, such as the coexistence of her parents or grandparents, along with the intense influence of the *generation of remembrance*.[3] This underscores the importance of how this woman experienced her formative years in her family of origin, how she perceived and internalized her remembrances of her parents' relationship as a fertile couple, and how she as an adult perceives her parents' marital life. A kind of parental or grandparental legacy thus emerges, a nonmaterial, emotional legacy taht carries its own specific risks, such as divorce or illness.

II. THE COEXISTENCE OF GENERATIONS IN THE FAMILY

It is not easy to determine the number of persons who, at different ages, still have at least one living grandparent, and how many grandparents, on average, are still alive. The same is true for the number of adults or elderly people who have grandchildren. Different studies have yielded estimates on these situations, which are the basis of significant (and widely researched) relationships between grandparents and grandchildren. Our main, though not exclusive reference is an Italian survey conducted by National Institute of Statistics (ISTAT).

1. Grandparents and Grandchildren

Figure 81–2 shows that the number of living grandparents varies considerably according to the age of the person and very little according to the respondent's sex. It can be seen that 97.8% of Italian children under 15 years have at least 1 living grandparent, and on average, they have 3 living grandparents; in other words, for 100 children, there are 293 grandparents; compared with the maximum allowed of 400 grandparents, this figure is very high. For children aged 15 to 25 years, the proportion and the average number remain high, respectively 82.8% and 2.2, representing a total of 182 grandparents for 100 children. For those aged 25 to 34 years, the number drops to 68 grandparents for 100 persons, and only 6 grandparents for 100 persons aged 35 to 69 years.[4]

If we change our perspective, we can see in Fig. 81–3, for Italy, how many adults or elderly persons

[3] I would like to thank Chiara Saraceno for having suggested this evocative phrase.

[4] It is difficult to understand why, in order to analyze a phenomenon such as relationships between grandparents and grandchildren, the National Institute of Statistics constructed its tables on the basis of such a large and inadequate age group (35 to 69 years).

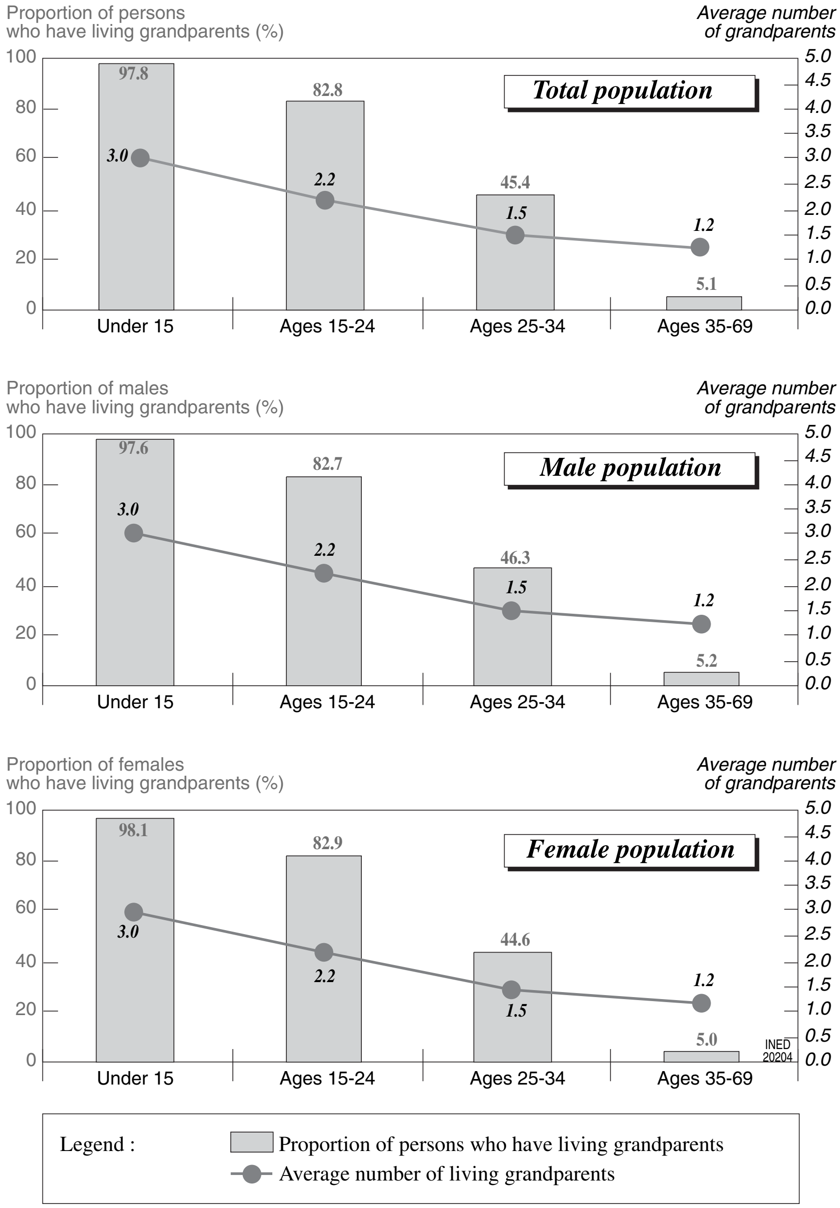

FIGURE 81–2 Proportions (%) of persons who have living grandparents and average number of grandparents, according to sex and age group up to 69 years in Italy, 1998. The average number is calculated on the basis of persons who have at least one living grandparent. (Data from ISTAT, 2001.)

have grandchildren and how many they have on average. One hundred years ago, the shortness of life spans made it quite unlikely that a person would live long enough to see all his/her grandchildren and especially long enough to see them grow up, whereas today it has become quite frequent. However, in the past, grandparents who were fortunate enough to survive long enough to see their grandchildren had a large number of them, whereas today grandparents are numerous but the number of grandchildren has diminished, with many already teenagers or adults. As a result, the grandchild/grandparent relationship is often more intense, and grandparents often find themselves playing an important role in the daily lives of not only their grandchildren when they are young children but their grown-up grandchildren as well.

Among persons aged 65 years and over, only 70.8% have at least one grandchild, and those who do have grandchildren have an average number of four grand-

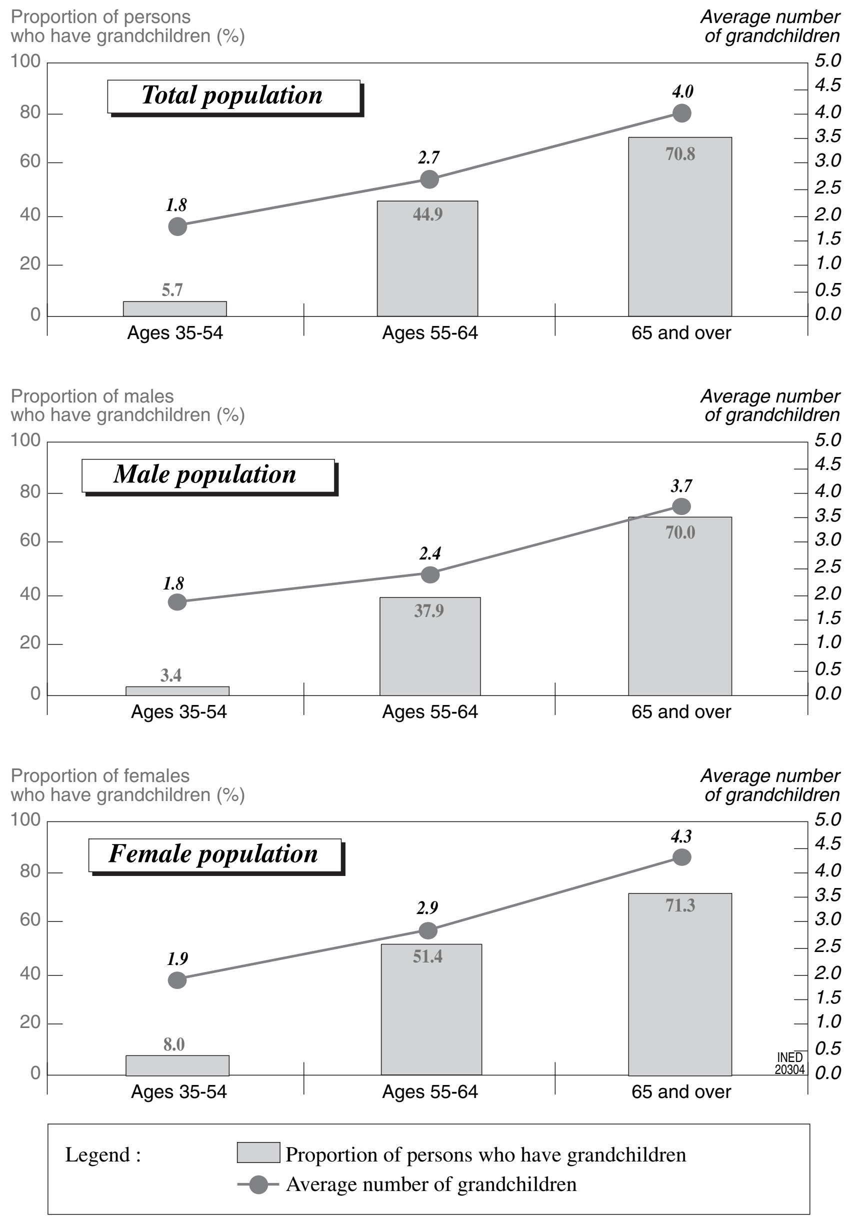

FIGURE 81–3 Proportions (%) of persons aged 35 years and over who have grandchildren and average number of grandchildren according to sex and age group: Italy, 1998. The average number is calculated on the basis of persons who have at least one living grandparent. (Data from ISTAT, 2001.)

children. This number varies considerably according to sex.[5] For 100 men aged over 65 years, there are 259 grandchildren (70.0% of the men of that age group are grandfathers, and each has on average 3.7 grandchildren), whereas for 100 women there are 307 grandchildren, an additional 19% (71.3% of the women of that age group are grandmothers, and they have on average 4.3 grandchildren). The fact that the average age of women over 69 years is much higher than that of men of the same age group increases the probabil-

[5] It is hardly necessary to mention that there is no perfect symmetry between the relationships linking grandchildren to grandparents, or young children to elderly adults, and those linking grandparents to grandchildren or elderly adults to young children. Indeed, although a child necessarily has two parents and four grandparents (not necessarily living), an elderly adult does not necessarily have children, and if she or he does, these in turn do not necessarily have children either. This explains the difference between the very high proportion of children under 15 years who have a living grandparent (97.8%) and the lower proportion of persons over 65 years who have grandchildren (70.8%). Of course, this reasoning only concerns biological relationships between generations.

ity that the average number of grandchildren will be higher than that observed for grandfathers. But one must also underscore the fact that about 30% of persons over 65 years do not have living grandchildren.[6] In these persons' families, the generational chain has been broken off and the elderly have been deprived of an entire category of descendents (grandchildren) to whom they could have transmitted an inheritance and on whom they could have relied for support.[7] The proportion of persons who do not have grandchildren is naturally much higher among persons aged 55 to 64 years, an age at which nearly 50% of the women do not yet have any grandchildren: this high proportion is owing in part to the age of the person concerned and to the increase in the average distance between generations or in the average number of children who decide not to have children themselves, an increasingly frequent phenomenon.[8]

According to a French survey conducted in 1999, the number of grandparents has reached 12.6 million, of whom 2 million are great-grandparents (Cassan *et al.*, 2001). At the age of 56 years, one out of two persons has at least one grandchild; at 66 years, three out of four. Among persons aged 70 years, 20% have no grandchildren, a lower proportion than that observed in Italy: in France, intergenerational relationships with descendants, down to grandchildren, are more frequent, because fertility is much higher in France than in Italy. In France, the age at which people become grandparents has increased over the years: the proportion of grandparents aged 50 years is about 35% for the cohorts born in 1930–1935 and 25% for those born in 1940–1945. At the time of the survey, grandparents had on average a little over four grandchildren, but the number of grandchildren depends on the number of children: persons who have one child have barely two grandchildren on average, whereas those who have three children have on average seven grandchildren. In addition, 85% of the women aged 85 years who have more than three children have great-grandchildren.

Most often grandparents and grandchildren enjoy close contacts and relationships. Today, grandparents usually do not live in the same house as their grandchildren; nonetheless, about 10% of grandparents share the home of at least one of their grandchildren, and the frequency increases with the age of the grandparents, especially grandmothers (ISTAT, 1999). According to a 1999 American survey, 5.5% of grandchildren were living with their grandparents; this proportion has been increasing constantly. Indeed, in 1970 the proportion was only 3.2% (Bryson and Camper, 1999). From 1992 to 1997, the most sizeable increase has been that of grandchildren living with their grandparents without either of their parents: this increase has been attributed to growing drug abuse among parents, to the increase in teenage pregnancies, to the increase in divorce rates and in the number of single-parent families, and to mental and physical diseases, AIDS, delinquency, and incarcerated parents, sexual abuse of minors, etc. (Fuller-Thomson *et al.*, 1997)

In any case, in Italy, physical proximity is quite common. Over 44% of grandparents have at least one of their grandchildren and his/her parents living within a radius of less than 1 km. This nearness encourages close relationships: 84.2% of grandparents take care of their grandchildren (81.2 of grandfathers and 87.0 of grandmothers) in one way or another, and in 29.8 of cases, they do so when the parents are at work (ISTAT, 1999). The educational potential of grandparents who can positively contribute to the development of their grandchildren's personal identity should also be mentioned. In addition, grandparents participate financially: in Italy, in 1999, their contribution to the small and larger expenses of their adult children, sons and daughters-in law, reached the equivalent of the impressive amount of 82.6 billion euros, or 15% of the total annual expenses of Italian families (Più and Fenacom, 2001).

2. The Increasing Probability of Having Living Parents and Grandparents

Of course, the probability of having living parents and grandparents varies according to the age of the person of reference and changes over time and depends on the degree of relationship (parents, grandparents, great-grandparents). In the absence of direct observations yielding information on the subject, we may try to evaluate variations through life tables per-

[6] It is difficult to assess how many grandparents have lost all their grandchildren and thus on a given survey date have ceased to be grandparents. The probability is likely to be quite low, unless they were grandparents of an only grandchild. The observations made in this article nevertheless remain valid, even in these cases.

[7] One must take into account the fact that in the 35- to 69-year age group, the proportion of persons who do not yet have grandchildren can be quite high, and all the more so if there is among them a high proportion of women who had a child after the age of 35. An National Institute of Statistics publication (1999) provides additional details, in particular the fact that the proportion of persons aged at least 75 years who do not have grandchildren is about 25%, a proportion that is not likely to decrease as the respondents grow older.

[8] If, from one generation to the next, the average age at first childbirth for women were constant (27 years old) and if the proportion of women without children also were constant (at about 15%), it is obvious that by the age of 55 years, one would expect the proportion of women who have grandchildren to reach 70% instead of the 51% resulting from the data provided in Fig. 81–3.

TABLE 81–1 Proportions (%) of Females Who Still Have a Living Mother, Grandmother, or Great-Grandmother, According to Italian Life Tables of 1911, 1951, 1990, and 1998

Age of (in years)		Life table			
The female	The relative	1911	1951	1990	1998
Mother					
0	27	100.0	100.0	100.0	100.0
5	32	96.6	99.2	99.8	99.8
10	37	93.2	98.3	99.5	99.6
20	47	86.1	95.5	98.4	98.6
30	57	76.8	89.7	95.7	96.3
40	67	59.1	76.6	89.2	90.9
50	77	27.4	46.5	72.2	76.6
60	87	3.3	10.7	33.5	41.2
70	97	0.0	0.0	3.1	5.6
Grandmother					
0	54	80.1	91.1	96.8	97.2
5	59	74.1	87.9	94.8	95.6
10	64	65.8	81.8	91.8	93.1
20	74	37.6	57.6	79.1	82.5
30	84	7.6	19.4	46.9	54.1
40	94	0.0	1.3	8.3	13.0
Great-grandmother					
0	81	14.7	30.4	59.4	66.0
5	86	4.5	13.1	38.0	45.5
10	91	0.0	3.7	17.2	23.8

Data from the following: until 1990, Golini and Silvestrini, 1995; for 1998–1999: ISTAT, 2001.

taining to different periods for a given average age at childbirth. The results of this computation are provided in Table 81–1 and illustrated in Fig. 81–4.[9]

Even though the evaluations of Table 81–1 are based on approximations, they are very similar in terms of quantities to those of the graphs of Fig. 81–2, which are based on real data. Indeed, these show that in 1998, 98.1% of children aged 0 to 15 years had at least one living grandparent, whereas the proportion for children aged 5 to 10 years calculated on the basis of the life tables of 1998, is of 93 to 96%.

The results of Table 81–1, which are thus relatively reliable, may be commented as follows.

1. *A phenomenal increase in the duration of the period spent in the position of child.* According to the 1911 life table, at the age of 50 years, only one in four persons still had a living mother, whereas in the 1998 life table, three out of four were in that situation. The proportions are even more spectacular if one considers women aged 60 years: only one out of 30 women still had her mother in 1911, whereas according to the most recent life table, one out of two at that age still have their mother. This means that in 50% of the cases, the person caring for a very elderly person (the mother of a 60-year-old is about 87 years) is him/herself elderly.[10] Last, in 1998, one in five Italian women died at over 90 years old, and it is most likely that they were taken care of by daughters over 65 years.

2. *A very high increase in the number of living great-grandmothers and, as a result, frequent coexistence of four generations.* Whereas in 1911, one in 20 little girls aged 5 years had a living great-grandmother, in 1998 the proportion was about one in two. Regardless of emotional and relational considerations, the coexistence of four generations, with the simultaneous presence in the family of a child of 5 years and great-grandmother aged 86 years, can clearly pose problems of organization: if the child's mother, age 32, is working and needs the grandmother's help, the latter will have to take care not only for her own mother but also for her daughter's daughter. Thus, women aged 55 to 59 years are often described as the "sandwich generation" because they are torn between the need to care for their mothers and to help their daughters by caring for their grandchildren. This situation probably partly explains the low fertility of Italians, because it is difficult for daughters to ask their mothers for extra help with a second child.

3. *The disappearance of orphanages.* In 1911, about 3.5% of girls aged 5 years had lost their mothers; in 1998, the proportion was only 0.2%. For girls aged 10 years, the proportions were, respectively, 6.8% (one out of 15 girls) and 0.4% (one out of 250). Biological orphans practically disappeared during the last century. It is true that they have been replaced by "social" orphans, that is, children of divorced or separated parents, but these children are often brought up by their grandparents, as shown in the above-mentioned American survey. Thus, because of the decline in the number of orphans and the simultaneous increase in the number of living grandparents, orphanages have practically disappeared from today's social landscape.

In countries where fertility and mortality are low, the age structure of multigenerational families, in which four generations often coexist, looks like a column with a swelling in the middle: very few young

[9] The results given in Table 81–1 and Fig. 81–4 were obtained by applying a method suggested in 1986 by Noreen Goldman, which has already been used in previous research (Golini and Silvestrini, 1995) and has been updated. The exercise consists in applying period life tables with a constant interval between generations.

[10] Indeed, one must take into account the fact that a 60-year-old woman has a husband aged 63 years on average. If we look at the health situation of a couple of that age, we find, according to the last National Institute of Statistics health survey, that 66% of the women and 62% of the men report suffering from at least one chronic disease.

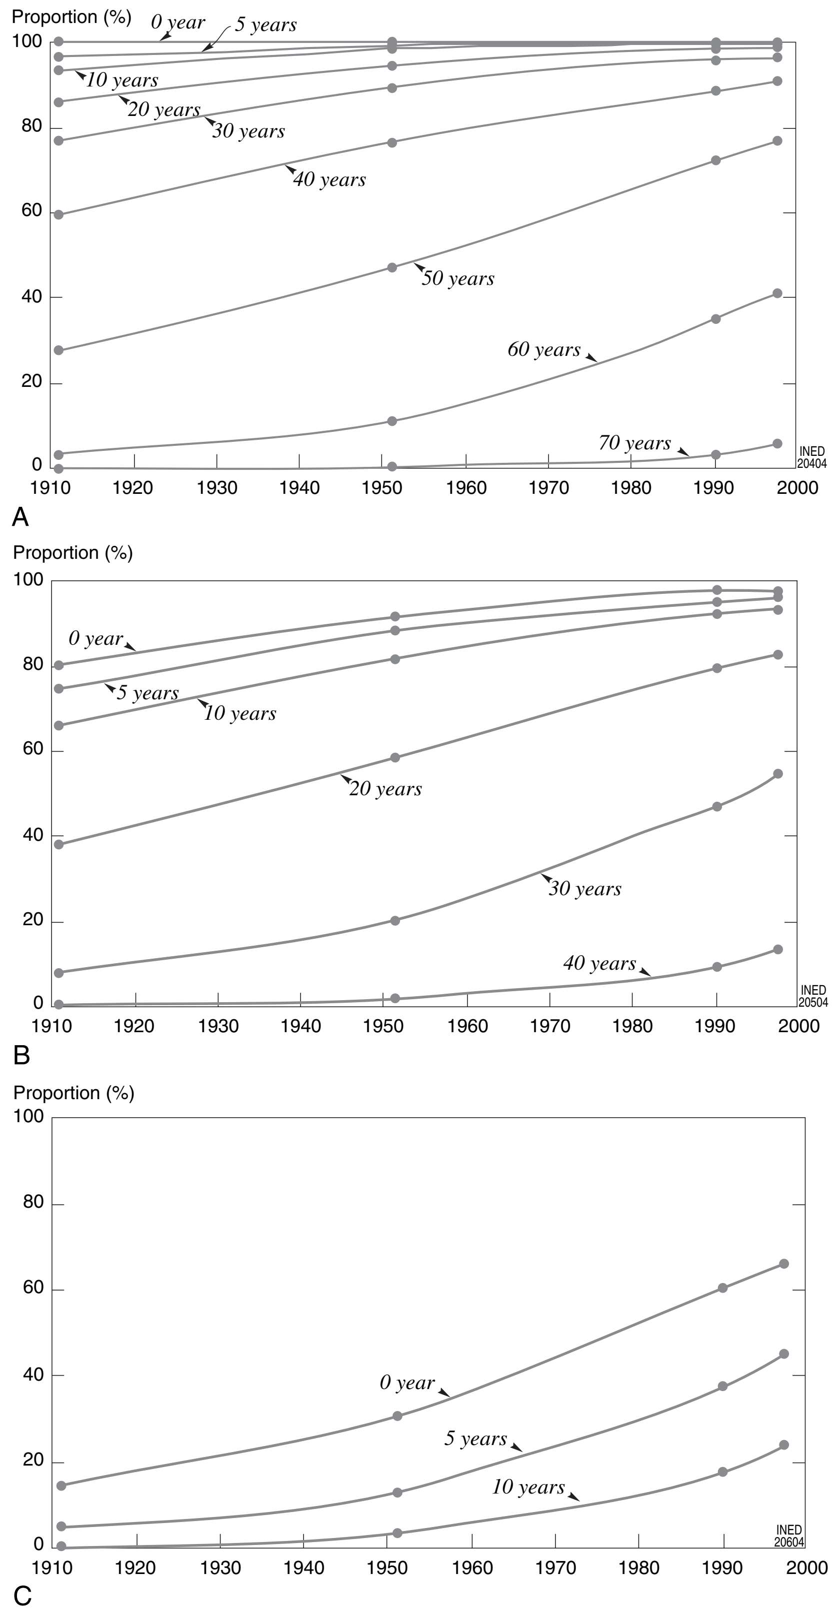

FIGURE 81–4 **(A)** Proportions (%) of females aged 0 to 70 years whose mother, who is 27 years older, is still alive, based on Italian life tables of 1911, 1951, 1990, and 1998–1999. **(B)** Proportions (%) of females aged 0 to 40 years whose grandmother, who is 54 years older, is still alive, based on Italian life tables of 1911, 1951, 1990, and 1998–1999. **(C)** Proportions (%) of children aged 0 to 5 years whose great-grandmother, who is 81 years older, is still alive, based on Italian life tables of 1911, 1951, 1990, and 1998–1999. (Data from the following: until 1990, Golini and Silvestrini, 1995; for 1998–1999 ISTAT, 2001.)

TABLE 81–2A Estimate of the Average Number of Living Relatives of an Italian Woman Aged 80 Years Old Who Has Been Married, According to Date of Birth

Year of birth (year of observation)	Husband, brothers, and brothers or sisters-in-law	Children and sons and daughters-in law	Nephews and their partners	Grandchildren
1900 (1980)	2.3	5.4	25.8	6.5
1930 (2010)	3.4	4.4	16.8	3.9
1960 (2040)	3.7	3.4	9.1	3.1

TABLE 81–2B Estimate of the Average Number of Living Relatives of a Yound Italian Aged 20 Years, According to Date of Birth

Year of birth (year of observation)	Brothers	Cousins	Parents	Uncles and aunts (including those by marriage)	Grandparents
1930 (1950)	1.8	7.1	1.7	9.8	0.8
1960 (1980)	1.4	5.8	1.8	8.5	1.2
1990 (2010)	0.8	3.7	1.9	7.2	1.9

Data from Barbagli *et al.*, 2003:201.

children at the bottom, very few great-grandparents at the top, and a large number of adults, parents, and grandparents (biological or adoptive) in the middle. The result are *family networks* that are smaller and more complex, both because of the increase in the number of coexisting generations and because of the increasing frequency of divorces, separations, cohabitations, and second marriages. This has led to an increase in the number and diversity of family relationships, within networks that have become more extended and less direct.

3. Transformations in Kinship Systems

More generally speaking, the entire kinship system has been deeply transformed by the increase in life expectancy and the fertility decline. Within the space of only 15 years, from 1983 to 1998, the proportion of families with at least one child dropped from 39% to 25%, whereas the proportion of families with at least one very elderly relative rose from 28% to 35% (Barbagli *et al*., 2003). The data provided in Table 81–2 reflect the profound changes that have occurred in the size and structure of kinship systems.

The ratio of elderly parents to adult children has drastically changed in the past 60 years. In 1980, for 100 elderly persons, there were 163 adult children; in 2010, the ratio may drop to 100 for 100; in 2040, for 100 elderly persons, there may be only 72 adult relatives (Barbagli *et al*., 2003). Over the medium and long term, a very difficult phase seems to be in the making, because there will be many elderly persons without adult children or without enough adult children they can rely on for support (Golini, 1999).

Economically advanced countries will thus soon have to deal with the fact that because of this disproportionate ratio between young people and adults, families will no longer be able to function as a support system for their elderly members and will not be able to care for them consistently. It is true that technology may be able to offset part of this problem, because new systems are being developed, for example, the use of microscopic cordless sensors to watch over elderly persons and young children. These systems also have applications in the field of the environment and traffic regulation, and these new developments are opening new avenues for exploration that may have many social repercussions.[11]

Aging and the vertical extension of the family are an object of concern for not only the elderly, and the issue of who will care for them, but also young children and young people. In countries with very low fertility, because of the couple's wishes, as in Italy, or because of authoritarian policies, as in China, the number of only children will rise and each child, or nearly, will be surrounded by numerous adults or elderly persons full of concern for him/her and eager to satisfy every one of

[11] This view was provided by Alberto Sangiovanni-Vicentelli, technologist and professor at the University of California at Berkeley, in an interview published in the June 13, 2003, issue of *Il Sole-24 ore* (p. 11).

her or his physical and psychological needs. One may wonder about the personality structure of these "little emperors" growing up in such an emotional and psychological environment. Only children often receive more attention from their parents, but this can sometimes have a negative impact: when this special attention is measured, it can help the child develop self-confidence, a sense of security, and wide-ranging interests, thus resulting in deep bonds between parents and child. If this attention is excessive and not well directed, the child may feel oppressed, become too dependent and incapable of facing individual responsibilities and difficulties later on in life, and end up rejecting his or her parents (Golini, 2003:141).

4. The Pattern of the Succession of Generations Has Changed

The growing imbalance between generations can be seen in an analysis that compares persons aged 20 to 24 years, 45 to 49 years, and 70 to 74 years (Figs. 81–5—81–8), over the span of a century (1950–2050), in Italy and France.[12] The aim of this research was to study how combined trends of births, deaths, and migrations have modified and will modify the relationship between three generations separated by an average of 25 years, as well as relationships between grandchildren and grandparents in a country with long-standing very low fertility, such as Italy, and in a country with low fertility, such as France. Naturally, the total population of a certain age group, separated from the previous and the next age groups by 25 years each way, cannot be considered as a generation in the strict sense of term as we have used it so far (in the sense of grandparents in relation to children and grandchildren). As concerns family categories, however, the historical series illustrated in Figs. 81–5 and 81–6 may be considered as approximations; to make things simpler, we will refer in the following comments to children, parents, and grandparents.

1. The long-term trend shows the successive birth peaks separated each time by 25 years. For example, in Italy, in 1990 we observe a population peak at ages 20 to 24 years, which shifts to 45 to 49 years in 2015 and 70 to 74 years in 2040. Naturally, this succession changes the relationship between the three age groups under consideration, not only from a numerical point of view but also from an economic and social point of view. The 45- to 49-year age group, which in 1950 represented 2.9 million persons, should revert to 2.6 million in 2050 after peaking at 4.7 million in 2015 (15 years later, this peak will cause a crisis in the pension system). In France, where births follow a more regular pattern, no such peaks are observed.

2. The ratio of adult children to elderly parents (45 to 49 years/70 to 74 years) dropped from 2.6 in 1950–1955 to 1.4 in 2000–2005 and will fall to 0.7 in 2040–2045. At that time, the present system of aid and care based on family support will be completely ruined (also because the life span of elderly persons is expected to increase considerably). In France these three ratios are, respectively, 2.2, 1.7, and 1.0; the system will be under much less pressure than that in Italy.

3. The children/parent ratio is even less favorable if one looks at the following generations (persons aged 20 to 24 years and 45 to 49 years). For the three periods under consideration in comment 2 above, the three values are, respectively, for Italy: 1.4, 0.8, and 0.7; for France, the values are 1.0, 0.9, and 1.0.

4. Looking at the information given in comments 2 and 3 above, we observe that certain generations are presently or potentially in a position of disadvantage: in 2005, in Italy, for example, the ratio of the 45- to 49-year age group to its parents will be 1.4 to 1, whereas that of their children will be 0.8 to 1.

5. If the ratio of children aged 0 to 4 years to elderly persons aged 70 to 74 years is taken as a proxy of the ratio of grandchildren to grandparents, the number, in Italy, of grandchildren per grandparents would shift from 3.9 to 0.9 and 0.5. In France, the number of children and grandchildren has declined less sharply, and the ratio is expected to drop from 2.9 to 1.5 and 0.9.

III. FAMILY INHERITANCE AND RELATIONSHIPS BETWEEN GENERATIONS

When speaking of inheritance and hereditary patrimony, we usually think in terms of either property, personal or real estate, accumulated by parents and grandparents during their life, or of physical or biological, genetically transmitted heredity. These subjects, which play an extremely important role in the relationship between generations, have already been extensively written about, and for this reason, we will only briefly mention them in this chapter. Moreover, in the field of genetic transmission, new evidence is being brought to light every day (see Chapters 79 and 96).

In addition to these types of heritage, there is another kind that is less direct and less obvious and is

linked to emotional relationships between generations, to these generations of remembrance mentioned above. These relationships (studied here from a bidirectional point of view, i.e., from parents to children and from children to parents) are often neglected despite their significance in the lives of individuals and in relationships between generations. Indeed, individuals cannot be separated from their pasts and from their relationships with persons of reference. We will discuss here three types of transmission: intergenerational transmission of disease risk, children who support widowed parents, and the intergenerational transmission of the divorce risk.

1. The Long-Term Consequences of Parental Conflicts

In 1992, an interesting and innovative French study was conducted on the health problems of adults seen in the light of family difficulties experienced during childhood (Menahem, 1992). The performances in school and in the professional world of children with divorced or separated parents have been extensively studied, especially in the United States, but there have been very few wide-ranging and statistically significant studies on the consequences of childhood traumas in terms of health. Table 81–3 and Fig. 81–9 clearly

TABLE 81–3 Average Number of Reported Illnesses, According to Several Variables Concerning the Adult Respondent's Youth

Variables and variants	No. of cases	Average no. of reported illnesses	Index
Serious conflict or separation or divorce of parents (before youth becomes 18)			
Neither separation nor conflict	4,199	2.99	98
Only separation or divorce	187	3.26	106
Separation or divorce and serious conflict	114	3.62	118
Serious conflict without separation	151	4.44	145
Death or serious illness of the respondent's mother			
Neither death nor serious illness	4,127	3.01	98
Death without illness, disability or serious accident	300	3.29	107
Illness, disability or serious accident	224	3.82	125
Serious financial problems (before youths becomes 18)			
Never or rarely	2,108	2.77	90
Occasionally	1,222	3.01	98
Often	1,321	3.59	117
Total	4,651	3.06	100

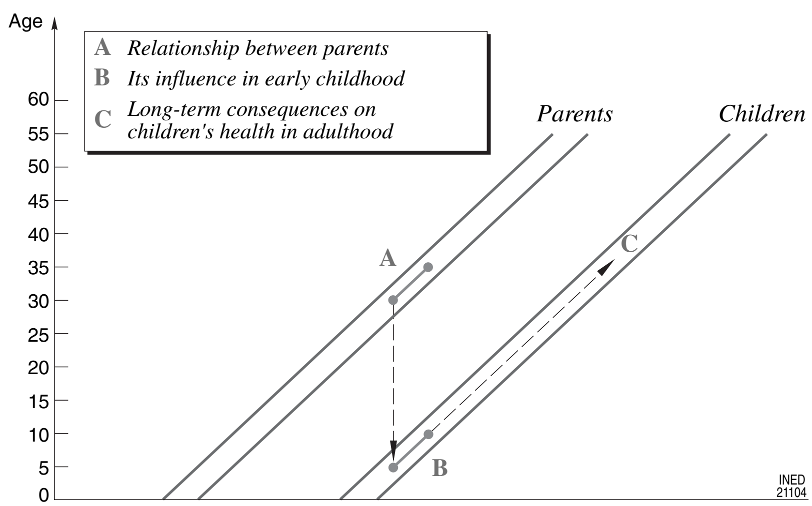

FIGURE 81–9 Pattern of the influence of the parents' relationship on the health of their children once they have become adults.

show the negative impact of childhood traumas; in particular, they reveal that even when the parents do not separate or divorce, serious conflicts between parents can have negative repercussions on their children once they have become adults.

The findings of George Menahem could be interpreted as a statistical confirmation of the Freudian hypothesis as to the significant impact of childhood traumas on the later life of a person. However, regardless of one's theoretical references, the survey clearly shows that there are some individuals whose physiological vulnerability is heightened in certain critical situations, causing them to fall ill, sometimes very seriously.

2. Children and their Parents' Health

Unlike what might have been expected, persons who have children do not have a lower mortality than persons who do not. An interesting Belgian survey covering 149,000 widows and widowers aged 30 to 84 years, interviewed in 1991 with a 5-year follow-up period, showed that—age, sex, duration of widowhood, and level of education being equal—neither having children nor their number seems to have any influence on how long a person survives after the death of his/her partner (Lusyne *et al*., 2002). A possible explanation can be the fact that childless widowers or widows can find alternative networks of support among their relatives, friends, and neighbors, which play the same supporting role as a child would for his or her widowed parent. One could also surmise that on the contrary, from an emotional point of view, the loss of a partner is so painful that neither the presence of children nor that of friends can help. However, these findings do not in any way contradict the large body of research showing the importance of children and relatives in the task of caring for the elderly, especially if they are widowed, ill, or disabled.

3. Transmission of the Divorce Risk

Children of divorced parents divorce much more often than do children of parents who stay together. The intergenerational transmission of the divorce risk has been observed in several industrialized countries: in the United States (Wolfinger, 1999), Australia (Dronkers and Hox, 1998), Germany (Engelhardt *et al*., 2003), and The Netherlands (Fisher and De Graaf, 2002). Overall, five main causal mechanisms have been identified: (1) the stress generated by the parents' divorce leads children to leave home early, get married, and have their first child quite soon, thus increasing the risk of divorce; (2) persons who, during childhood, experienced conflictual relationships at home may have difficulty creating and enjoying decent interpersonal relationships later on in life; (3) the loss of economic status after divorce has a negative influence on the children's lives (especially in terms of education and professional career), and this in turn increases their own risk of divorcing; (4) the stigma of the parents' divorce has a negative impact on the children's later opportunities in life; and (5) parents and children have in common a few hereditary character traits that can favor (or on the contrary prevent) divorce. All these mechanisms are not mutually exclusive may interact with one another (Engelhardt *et al*., 2003).

Less is known about the influence of family policies and family law on divorce risks. A recent survey, based on the *German Life History Study* and using a multivariate analysis of biographies shows that the interaction of family policies and laws on divorce with the transmission of divorce risk is complex but does exist (Engelhardt *et al*., 2003).

IV. TRANSFERS WITHIN THE POPULATION

Intergenerational transfers within a population and their potential inequity, especially when one observes or foresees strong, lasting, and significant numerical imbalances between generations (as described in the preceding chapter), are the subjects of increasingly wide-ranging and multidisciplinary debate. Not only does it raise the issue of the aging of the population (the increasing number of elderly persons, on one hand, and the decreasing number of children and young people, on the other), but also that of the changes in economic life cycles that will modify the duration of periods of economic dependence (e.g., the increase in the duration of studies and professional training); another issue is the modification of the legal context surrounding the transfers necessary to finance these dependent stages (the lengthening of the period of compulsory education, or changes in the legal retirement age, etc.). Thus, there are at least three spheres in which demographic changes interact with the system of social security and intergenerational transfers (Lee, 2020). Of course, aspects of collective psychology, or social or cultural aspects can contribute to bring about changes both in the economic cycle of life and in the legal framework.

These three spheres interact in turn with relationships between the generations of a given family, whose situation, good or bad, has a strong impact on periods of economic dependence, because this factor either shortens or lengthens the period during which a person will be receiving an education or working. Figure 81–10 shows quite clearly that the consequences of demographic changes for public finances depend not only on the age structure of the population (which as we know is the result of the history of successive cohorts) but also on the numerical size of the population.[13]

The redistribution of income between generations is a very complex problem. To quantify the phenomenon, several economists have elaborated a framework of analysis called "generational accounts." These accounts determine how much a typical member of the present generation and of future generations will pay in taxes during his or her life, and will deduct from that what the member has received in the

[13] Nicola Sartor (2003:33) underscores that "a fertility increase, and thus the demographic size of a population has a positive impact on public finance, at least on the long term, and this impact can be perceived when assessing the per capita tax reductions necessary to maintain public services at a constant level and ensure the long-term sustainability of the public debt. [*gli effetti che un aumento della fecondità, e quindi della dimensione demografica di una popolazione, sortirebbe sulla finanza pubblica sono positivi, sebbene nel lungo periodo, e possono essere espressi attraverso la stima delle minori imposte pro capite necessarie per mantenere invariati i servizi pubblici a tutti i cittadini e per assicurare la sostenibilità di lungo periodo del debito pubblico*]."

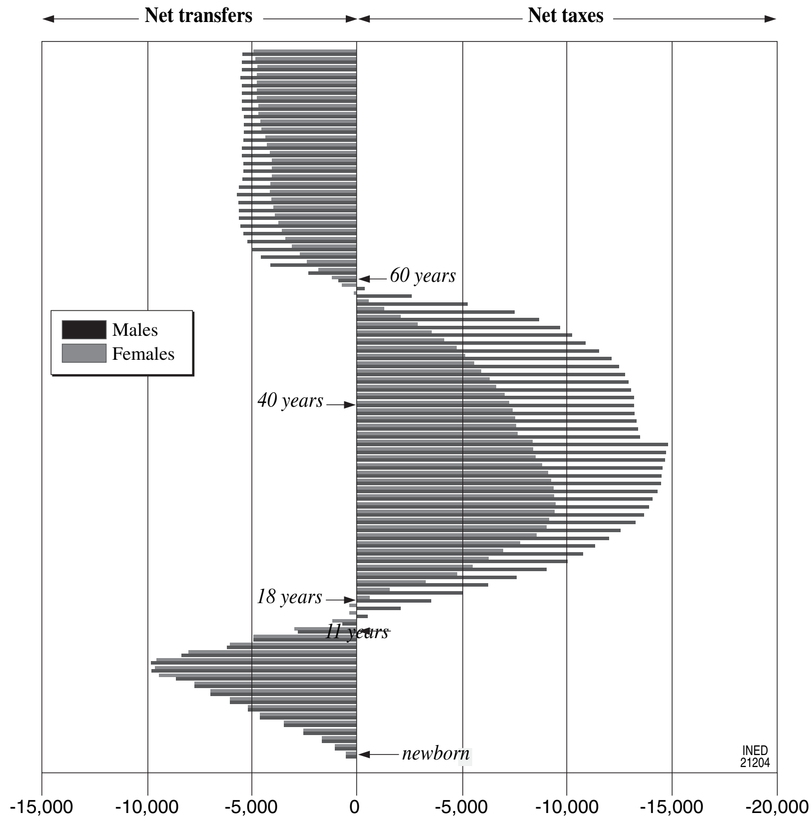

FIGURE 81–10 Net financial position of the different age groups/cohorts in public administration accounts, Italy. (Data from Sartor, 2003:32.)

form of transfers and services (an example is shown in Figure 81–11). The Organization for Security and Cooperation in Europe asked several experts (including Professor Nicola Sartor of Italy) to elaborate generational accounts according to a constant method. The results for Italy are shown in Table 81–4.

This theme is particularly sensitive, because the limited nature of resources means that one must take from one age group (that is a group of cohorts) or one social group to give to another. This entails serious technical and political difficulties, for many reasons; we will only mention the most important among them.

In a democracy, a political decision aimed at withdrawing resources or privileges from one age group or social group in favor of another in order to offset an imbalance must be based on a consensus. This consensus is often long and difficult to obtain, and in some cases, it is totally impossible owing to the opposition of the concerned group or lobby. When that happens, the problem is tied to the institutional system, with the risk that "given the way representative democracies function today, collective decisions may correspond only to the preferred options of a part of the group, those which have won over the short term, and not to those of the entire group of citizens." (Petroni, 2003:6).[14]

The population dynamics observed almost everywhere but especially in countries with very low fertility over a long period of time, such as Italy, Spain, or China—where one observes a strong decline in the number of children and a strong increase, both in absolute numbers and in proportion, of elderly persons—should necessarily result in a transfer of physical, human, and financial resources from the former to the latter. The best solution—which is very difficult to determine and implement, as this is a completely new phenomenon for which there is no precedent—would be to establish a horizontal transfer of resources to ensure that the per capita resources

[14] *"La forma assunta dalla democrazia rappresentativa ai giorni nostri, fa sì che le decisioni collettive non riescono a corrispondere all'intero insieme delle preferenze dei cittadini, ma soltanto a una parte di esse, quelle maggiormente legate al breve periodo."*

Values are in billions of dollars as constant prices, adjusted according to the development of real incomes, converted according to 1993 average rates of development. The present generations correspond to cohorts born in 1993.

[a] Case A, World Bank population projections based on the hypothesis that fertility rates will return to replacement level in 2030; case B, a more rapid increase in fertility rates that reaches replacement level in 2010.

[b] The imbalance between generations is obtained through the difference between the discounted current value of the taxes paid by a typical member of present and future generations, expressed in percentages of the net payment of taxes by the present generation.

(which in many cases should be themselves increased) to be received by the children do not decrease.[15]

For the first time in the history of mankind, and especially in the West, we are in a situation in which human resources have become either stationary or are declining and in which there is an employment crisis. Such a situation requires great flexibility on the part of the work force and an extensive and significant system of mutual social support to organize this flexibility and weather the crisis. One of the most difficult problems is that social welfare measures for adults and the pension system for retirees are based on the prevailing structure, which means that the entire burden is borne by the working population; in times of demographic or economic crisis, this burden can become too heavy to bear.

For the pension system, the distribution pay-as-you-go model (which divides population and society horizontally between those who work and contribute and those who receive pensions) weakens the capacity to accumulate capital within the family and reduces the time span during which individuals can make their own decision. As a result, the responsibility of single persons over the long term is reduced, as is the responsibility of public decision makers, and their strategies and choices are increasingly considered over the short-term (Petroni, 2003). However, the capitalization advanced-funded model does not represent a fully convincing alternative, especially given the enormous long-term financial risk and the high management costs. Thus, over the middle term, the pension system seems to be in a dead-end situation; the way out seems to be a new efficient and applicable system based on two (or three) basic elements (distribution + capitalization + possibly private savings).

The close link between work and chances of survival, which has always existed in the history of mankind and was still very strong three or four generations ago, has to a large extent disappeared from collective, individual, and family psychology. Social welfare now often tends to be taken for granted and is no longer considered as something that must be gained through long and hard work, remunerated by the market or by public funds. Thus, aging genera-

[15] Concerning this issue, Nicola Rossi (1997) takes into account demographic trends, economic development and social solidarity measures and examines them also from a long-term point of view. Less support should be given to the fathers and more to the sons (*meno ai padri, più ai figli*).

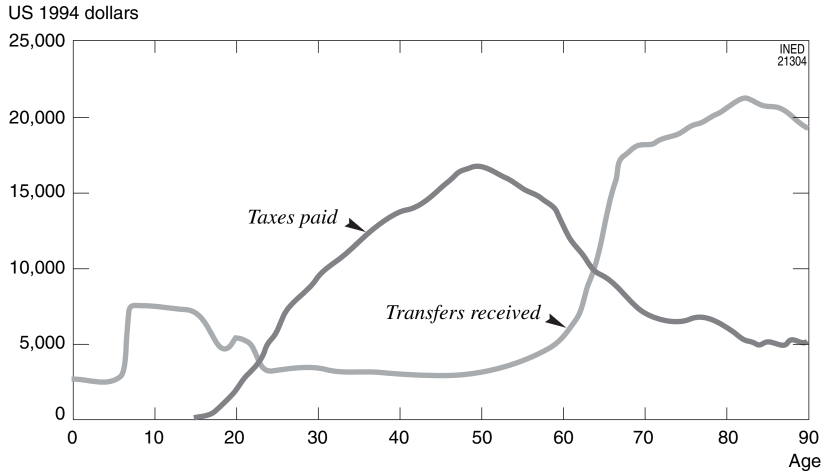

FIGURE 81–11 Age profile of the transfers received from the public sector and taxes paid, United States, 1994. (Data from Lee, 2002.)

tions tend to aspire more and more to the status of a paid *nonworker* rather than to that of pensioner, according to more varied forms of professional or social *occupation*.

V. SOCIAL, PROFESSIONAL, AND PSYCHOLOGICAL DISTANCE BETWEEN GENERATIONS

Demographic change cannot be separated from the modernization process as a whole. Thus, both within the family and among the general population, educational levels and all forms of mobility (professional, social, matrimonial, and territorial) have increased from one generation to the next.

In the realm of education, the differences among grandparents, children, and grandchildren is considerable, not only from a quantitative point of view (the number of years spent in school is much higher than it was in the past) but also from a qualitative point of view (in general, in the past, education had a cultural purpose, whereas today it is market-oriented). As concerns the professional realm, today's grandfathers and grandmothers generally had the same occupation all their lives, whereas their children and grandchildren often have many different occupations, either successively or simultaneously. As regards travel, if one compares today's generation of children with that of their parents (not to mention their grandparents), the number, frequency, and length of trips made by individuals aged 20 to 40 years has considerably increased. In addition, one must also take into account the fact that a rising proportion of young people will live with brothers and sisters, parents, and grandparents belonging to their father's or mother's second family. In contrast, many children of divorced couples only seldom see or will get to see their father.

All this increases the distance between generations. Situations and family networks today do not have much in common with those of the past and even less with those of the future. And at the level of the population itself, things have changed a great deal, because relationships between cohorts can be seen as the complex and collective consequences of the relationships between generations within the family.

Modernization comes along with new technologies; these are highly innovative and invasive and have also widened the gap between generations. The ability to react and adapt to modernization varies a great deal with age. The older generations rely on their past experience, and their ability to develop new competences is more limited. In addition, new technologies have a heavy impact on the quantity and quality of available employment as well as on the quality of life of the different generations and of society as a whole. Rapid modernization and the spread of Internet may widen the gap still further. The ability to adapt to new technologies and take advantage of their potential, as well as the ability to learn and master the language of technology and the possibilities they offer, vary with age. The paradox is that the older generations are providing the younger generations with the very technologies that contribute to the widening of the generation gap.

Present generations have much more time at their disposal than did their elders to accumulate property (because of economic and professional reasons and because the duration of life has increased). But the age at which their heirs inherit this patrimony keeps increasing. In Italy, the real mean age of a husband at the time of his death is 71 years; the children then inherit 50% of the inheritance and the widow the other half. On average, the widow is 68, and her remaining mean duration of life is 17 or 18 years. The children thus receive the first half of their inheritance at 42 years and the second half around 60 years, at the death of their mother. A few decades ago, people inherited at a much younger age.

Thus, the contributing factors to the increase in the social, professional, and psychological distance among generations are extremely varied; today this distance is probably the largest it has ever been. In addition, the increase goes along with a reversal in values, because there are few children and many elderly persons. In the past, old-timers were valued and not children, but today the opposite is true.

VI. A NEW SOCIAL CONTRACT BETWEEN GENERATIONS

From a global point of view, it must be pointed out that the conjunction of the demographic crisis with an economic crisis is mostly a European phenomenon. It is difficult to imagine what type of economic development will take place in Europe, especially in countries that are not very competitive, such as Italy. Will they be able to remain competitive compared with China or India, which have many young people and good educational systems? Will it be possible in Europe to maintain a social, cultural, psychological, and political balance among an aging population, traditional ethnic minorities (those linked to European history), and the young immigrant population that is absolutely necessary to these countries? It is difficult to imagine the consequences of new technologies, in particular robots, on the labor demand and more generally on the economy and society (e.g., one could imagine a system of provisional taxes on computers and robots). If the labor demand decreases, will it not be necessary to redesign (on schedule, on a regular basis, and as efficiently as possible) the social solidarity system and redefine the social contract between generations?

Indeed, strong measures aimed at redefining a social contract must be developed. One could, for example, imagine a pension system based on the three "foundations" (public pensions financed by contribution, pension funds financed by compulsory savings, and pensions financed through private insurance) with a complete revision of the system of retirement ages, and, in particular, the creation of a transitional period between full-time work and full-time retirement.

At the microeconomic level—still referring to the European experience—one observes a strong rise in individualism. This phenomenon is for the most part rooted in the rising level of education, which is based on personal investment and consequently on the necessity of taking advantage of one's "human capital" and taking good care of one's physical health. Individualism is also reinforced by the fact that during his or her life, a person may have an increasing number of families (in the past, people had only two families, that of their parents and their own, whereas today they can have three, four, or more families). The family is no longer experienced as a basic social structure in whose context a person will satisfactorily spend his or her adult life, but rather as a transitional stage experienced by an isolated adult moving from one family to another. If intergenerational links have weakened within families, one may expect them to weaken in society as well.

Is it possible to imagine a new social contract that would be increasingly intragenerational, without forbearing the traditional relationships and obligations that exist between generations? Such a project could be based on three main principles:

1. The creation of a *compulsory general civil service* devoted mainly to caring for the elderly and to the environment. This service could have several advantages: reducing individualism and promoting a spirit of self-sacrifice and team work, reinforcing or creating intergenerational spirit outside the family context in a social context, and reducing the cost of the social mutual support system.
2. Encouraging the development of the nonprofit sector, in particular volunteer work for elderly people in good health, who could help care for older persons with physical, psychological, or cognitive disabilities.[16] The senior citizens who participate in this volunteer work could earn credit, enabling them to receive aid if and when they need it at a later stage.
3. Measures to reduce the numerical imbalance between generations, whenever necessary. To achieve this, given that a mortality increase would not be desirable and that none has been foreseen (even if one cannot exclude the possibility), something must be done about the other two components of population dynamics: fertility and migration. As concerns fertility, an increase must be stimulated in those areas where it has been excessively low for a long time. This is a dif-

[16] This type of activity is already quite widespread in small Italian mountain towns or villages, where the population is very old and where there are absolutely no young people at all: efficient systems of mutual support have been set up enabling senior citizens to care for each other.

ficult task for many reasons; one of them is that it is difficult to imagine the goals and demographic behavior of today's youth, just as it is difficult to imagine what kind of parents they will be once they have decided to have children (as concerns industrialized countries, Chapters 103 and 104 deal with the question of fertility policies and their efficiency). As regards migration, the solution would be to favor immigration, but in that case, the difficulty remains of ensuring the peaceful and productive coexistence of native and immigrant populations.

As demographic changes accelerate and intensify (beyond the modernization and globalization processes that go along with these changes), the gap between generations grows wider and more conflict-filled. In many ways, this gap may become a potentially explosive issue for societies, if the latter are unable to establish a dynamic process of adjustment.

Economic, Social, and Cultural Consequences of the Aging of the Population

JACQUES LÉGARÉ

Department of Demography, University of Montreal, Montreal, Canada

INTRODUCTION

The 21st century will increasingly be characterized by the proliferation of elderly people. Not only are the raw figures for older people increasing in all the national populations, but the proportion of the old in these populations is growing considerably. Such results were easily foreseeable as soon as the demographic transition reached its conclusion; that is, the control of mortality and fertility enabled these two phenomena to reach equilibrium. In 1956, Jean Bourgeois-Pichat revealed by means of population models the economic and social implications of aging (UN, 1956), but unfortunately, this famous document—according to the rules for United Nations (UN) publications—did not mention his name.

Such changes in the age structure of populations are not without consequences for the societies that undergo them. They have already aroused interest in the major international organizations: the UN (1988, UN-EEC 1992, 1994), the Organization for Economic Cooperation and Development (OECD, 1996, 1998, 2000), and the World Bank (1994). But, as with all theories, the theory of demographic transition has its limits when confronted with reality (Chapter 69), and the economic and social consequences of aging for actual populations differ from the forecasts for theoretical populations, sometimes to a marked extent. And it is this point that I shall endeavor to explain in this chapter.

The demographic history of the 20th century has shown that, for both fertility and mortality, the passage from a relatively high to a low level does not occur in a regular way. There have been variations both in an upward and downward direction during the secular decline in fertility, principally allied to civil wars and genocides in certain countries and to the world wars and baby boom in the West. The baby boom, frequently succeeded by a baby bust, has caused important variations in the size of the successive generations, and these changes have effects throughout the life cycle of these generations (Golini, 2003). However, the recent increases observed in certain countries in the former communist empire and those related to AIDS in Africa were unpredictable.

Another dimension completely unenvisaged by the demographic transition theory is that the replacement of the generations has no longer been attained in a good number of national populations, and the life expectancy of many children born in the early 21st century will probably reach 100 years. Among the major effects on the life of individuals and populations can be mentioned the reduction in the sizes of the total population of influential countries on the world stage and the dazzling increase of the very aged, including a large number of 100-year-olds.

I. DEMOGRAPHIC CONTEXT OF AGING SOCIETIES

Up to the present, the amazing decline in mortality and its implications for the survival of children and the growth of populations have been studied more fully than have its relations to demographic aging.

The elderly have always existed in human societies, but there were considerably fewer when mortality (excluding epidemics) was high. If indeed a model life table is interpreted correctly, it will be found that when life expectancy at birth is around 25 years, there will nevertheless be 15% of the initial cohort that survives until 60, and these survivors can hope on average to live a further 10 years. With the impressive progress in preventing premature death and with life expectancies at birth approaching 80 years over a large part of the planet, more than 90% of the initial cohort will reach advanced ages and experience an increasingly long old age. We are therefore witnessing what I have called a democratization of old age (Légaré, 1991), in the sense that it is no longer reserved to a few but is available to a very large majority of the population. One of the principal outcomes of all democratization is to destroy (for better or for worse) the homogeneity of the elite, formerly fawned upon but now part of a more heterogeneous group in which individuals are less fawned upon. That certainly applies to aging societies in which the subpopulation of retired persons increasingly resembles that of the whole population in socioeconomic and cultural terms.

Although demographic projections are quite often hazardous, especially in the long term, the same cannot be said for the projections concerning the numbers of older persons. Effectively, all elderly persons of 50 years or over in 2050 are already born, and updating these projections at national level depends on the precise evaluation of their behavior in terms of mortality and migration. Predicting the sizes of yet unborn generations is much more uncertain.

The past development of fertility and mortality that mechanically provokes the aging of populations not only disturbs the population pyramid at its summit but also affects the whole pyramid. Throughout the whole aging process, it is not only the median age of the whole population that increases but the median age of both the subpopulation of retired persons and the subpopulation of those of working age—those effectively to be found on the labor market. It follows that the population of 85-year-olds and over will grow more quickly than will that of the 65-year-olds and over (Suzman *et al.*, 1992) and, in most Western countries, an important decline in both the raw and relative numbers of persons of working age can be anticipated (Légaré, 2001a). In light moreover of past (and also future) differential life expectancy according to sex, there are, and will continue to be, more elderly (and especially very old) women than men, as is clearly characteristic of contemporary aging societies (de Jong Gierveld *et al.*, 2003).

Even though the aging of populations is regarded less as a negative phenomenon but just a logical consequence of one of the great advances in human progress—the increasingly effective control of mortality and fertility—it still gives rise to considerable apprehension. Future societies will certainly be older, but will they be more aged and engender a pandemic of sick or disabled persons? Are we capable of evaluating the implications of administering an aging society according to whether the total population is increasing or decreasing demographically? In this era of increasing globalization, such demographic mutations affecting all populations on the planet—although occurring at different times and to different degrees—will certainly have geopolitical repercussions.

To affirm that future societies will clearly be more aged than those of today is to assume that the threshold of old age is unalterable in time and space. Such an affirmation is being increasingly questioned, at least by certain demographers and historians (Desjardins and Légaré, 1984; Bourdelais, 1993). Will the physical and economic dependence that characterize aging be transferred to much more advanced ages, so that future societies will certainly be more elderly but without necessarily being more aged?

In fact, can aging be defined? According to Furetière (1690), "Old refers to a certain age at which, upon attainment, one is decrepit: men are old at 60, horses at 20." The qualifier "decrepit" refers to dependence, as evoked earlier. The difference between human beings and horses refers here to the important difference in their average lifespan. *Ceteris Paribus*, when we observe in human societies an important difference in life expectancy at birth, the threshold of aging must logically increase. To take account of this development, Norman Ryder (1975) suggested that the threshold of aging should not be defined as a certain time passed since birth, such as 50 or 60 years, but rather a certain number of years remaining to be lived. Employing the terminology of the life table, this would be the age x for which the life expectancy e_x equals, for example, 10 years. That is admittedly as arbitrary in one case as in another, but Norman Ryder's proposal admits the possibility of taking better account of reality. In addition, this period before death can be made to vary according to the assumed compression of morbidity (Fries, 1980, 1989; Myers and Manton, 1984). With the help of model life tables (Table 82–1), it can be seen that when

TABLE 82–1 Aging Threshold Defined as 10 Years Remaining To Be Lived, According to the Indices of Model Life Tables

Aging indicators	Life expectancy at birth e_0 (in years)				
	25	40	60	80	91
Old age threshold (x) for $e_x = 10$ years	60	65	70	75	84
Surviving ‰ to the age (x) (S_x)	150	300	500	750	840

Data from Coale *et al.*, 1983 (West model, feminine sex), except for $e_0 = 91$: Duchêne and Wunsch, 1990.

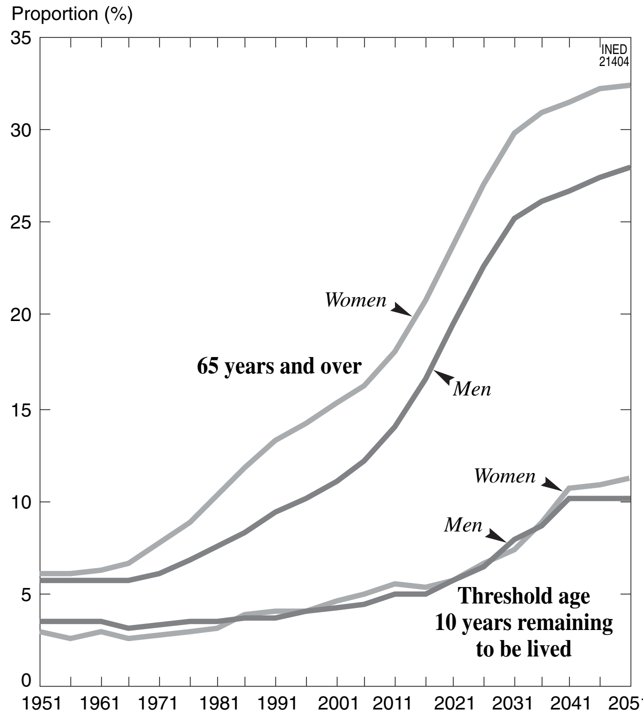

FIGURE 82–1 Evolution of the proportion of persons aged 65 years and over and proportion of persons surviving beyond the age threshold "10 years remaining to be lived," Quebec, 1951–2051. (Data from Statistics Canada, Canadian censuses of 1951–1996, and the Quebec Statistical Institute, *Perspectives démographiques du Québec de 2001–2051*.)

the life expectancy at birth varies between 25 and more than 90 years, the threshold age for 10 years remaining to be lived could itself vary from 60 to nearly 85 years. With such a definition, the proportion of the *aged* in an actual population (in this case that of Quebec) (Fig. 82–1) scarcely triples over a period of 100 years, whereas the proportion of 65-year-olds and over is multiplied by nearly 6. Such a development doubtlessly applies to all human populations and dismisses theories of hardened pessimists and smug optimists concerning the coming aging of our civilizations (Henripin and Loriaux, 1995; Gee and Gutman, 2000).

Considerable confusion has arisen in this area through assimilating the threshold of old age to that of retirement (Légaré and Desjardins, 1987). Although in the past, especially in farming societies, working only ceased when precluded by declining strength, it is completely different in industrial and postindustrial societies (Guillemard *et al*., 1995). The right to retirement has become a welfare entitlement that permits a period within the life cycle when living is sustained more from benefits than from earnings, but without incurring poverty or ill health. This is the new "third age" of Peter Laslett (1989), which extends from retirement to old age and consigns to a "fourth age" the period in the life cycle when an individual becomes dependent on other members of the population, especially for reasons of declining health. Because this new step in the life cycle has never previously existed in any civilization, our societies have to invent everything in order to ensure that this stage in the life of individuals shall be as beneficial as possible both for themselves and for the societies in which they have evolved. This reality is so new that it is not yet known how to designate those who form part of it. Because the term "old people" is no longer appropriate, one should perhaps use the Latin word *seniores*, or *aînés*' in French and "seniors" in English. These denominations correspond to the roles of mentors that these persons now play, or at least should play, in our industrialized societies. These roles fit well into the context of "active aging," an expression, when applied to young retired people, that is often understood as an extension of the opportunities that they may use for improving their social and functional independence through the enrichment of various aspects of their social life (as full- or part-time work), as well as their physical and mental health.

The demographic perspective illuminates in an original way the phenomenon of aging populations and has given birth to a well-defined niche in our discipline: the demography of aging (Loriaux *et al*., 1990; Martin and Preston, 1994; NRC, 2001). This is a field of study that clearly differs, for example, from the disciplines of gerontology and geriatrics, despite being limited to the study of the subpopulation of elderly persons (Myers and Légaré, 2000). Such developments will obviously have a repercussion in the area of transmitting knowledge about the aging of populations (Golini, 2002).

After these clarifications that shed light on certain little known demographic aspects concerning aging societies, it is now appropriate to verify the extent to which the aging of populations is really an economic weight and a delicate social problem for countries (Légaré, 2001b). Must the social contract be reviewed (Véron *et al.*, 2004)?

II. SOME ECONOMIC CONSEQUENCES OF DEMOGRAPHIC AGING

A consideration of the economic consequences of demographic aging leads us to enquire about the costs of the social programs allied to aging and to their financing of them (Gillion *et al.*, 2000; Queisser, 2000).

1. Estimated Costs of Dependence

It is customary in demography to estimate the burden represented by the dependence of the young and retired people relative to the economically active persons by calculating the dependency ratios. The sum of those from 0 to 19 years of age and from 65 and over, for example, is related to the total number of those of 20 to 64 years of age. Strictly speaking, this is only an indicator of the structure by age of a population and is consequently frequently now designated in English by the expression "demographic dependency ratio." For a better grasp of the development of the dependency costs of older people, it is preferable to follow the course of more significant indicators, such as those that relate the inactive persons of 55 years and over to all those who are active (Légaré *et al.*, 1991).

This dichotomy between dependants and non-dependants becomes completely understandable within a family or household when responsibility for dependency is entirely assumed by the active members among them, as is habitually the case in traditional societies. The situation becomes complicated in the case in which this responsibility falls to the community. Greater reference is then made to social legislation in which the aid given is allied to obligations based on acquired entitlements, rather than assistance on a voluntary basis. The main areas of expense involved by this legislation are education, health, and retirement, the social costs of the community. As these costs vary enormously according to age, educational expenses are important in a young society, whereas for an aging society, it is those allied to health and retirement (Fig. 82–2).

Although children in industrial societies generally depend on and are supported by the economically active population, especially for their professional training, the same does not apply to elderly people in relation to retirement and health costs.

The first subject of preoccupation is therefore the health expenses for elderly persons. It would be better, in fact, to refer to the cost of illnesses and disablement, because the costs relating to prevention in the area of

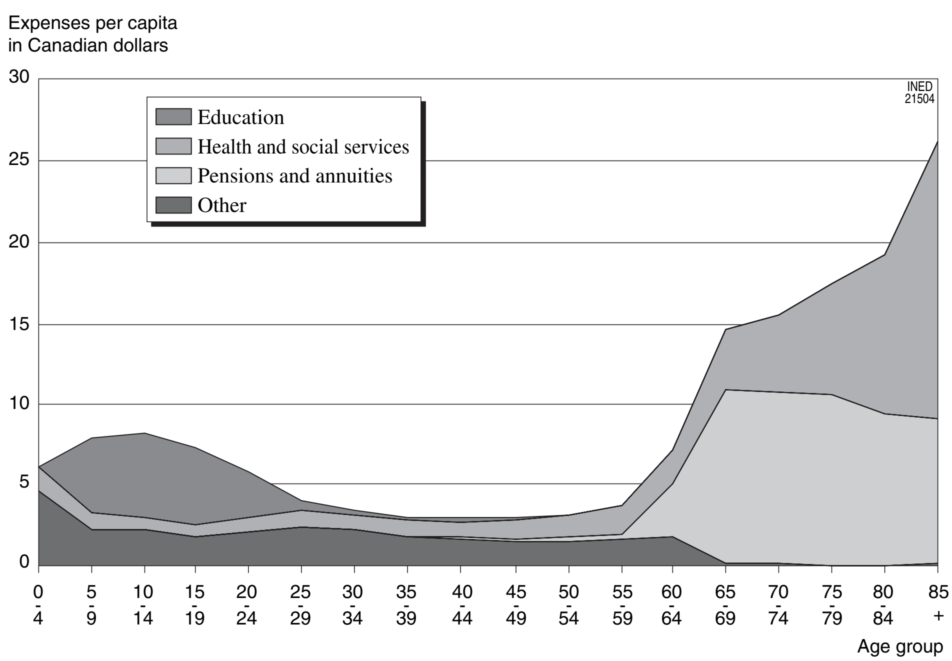

FIGURE 82–2 Public expenditures per capita according to sector and age, Quebec, 1998. (Data from the Quebec Statistical Institute.)

health apply especially to the younger ages. The past has clearly shown that the aging of populations correlated little with the astronomical increases in health expenses (Barer *et al*., 1995). These were first and foremost related to the employment of new technologies and to a greater supply than the demand for elderly persons. In future, it will be the expenses for social services allied to *caring* that will have precedence in relation to medico-hospital expenditures—budgetary appropriations will have to take account of the powerful medical and pharmaceutical lobbies allied to *curing*. An encouraging point for the future is that medico-hospital costs will not increase at the same rate as the growth in the elderly population, but according to the number of deaths of aged persons, which will be less when the baby boomers enter into the third or fourth ages. This will be the case because these expenses for elderly persons are concentrated around the time of their death, irrespective of their age (Zweifel *et al*., 1999).

Concerning the cost of retired persons, it must not be forgotten that in general they pay taxes on their incomes as well as the consumption taxes. The real costs for them should be net and not gross. In fact, as was stressed some 20 years ago by Henri Mendras and his colleagues of the *Observatoire français des conjonctures économiques* (Dirn and Mendras, 1984), the members of the new third age are frequently not only holders of the national heritage and ensured of their revenues but also good clients, especially for food, accommodations, and services. We may ask ourselves whether we are not experiencing a certain aristocratization of the new third age, as within many societies the elderly people possess a large part of the wealth and power of their nation and greatly influence its social and economic policies.

2. Financing of the Social Costs of Aging

According to the principle of solidarity, dependent persons are taken cared for by those who are not dependent. In more traditional societies, it is family solidarity that has precedence. In social solidarity systems (welfare societies), the state assumes a large part of the costs allied to dependence. To ensure the young people receive suitable training for professional life and the elderly have a time of well-deserved rest after the labors of an active life, an appeal is made to intergenerational solidarity. The adult generations support those in retirement in the hope that when they themselves reach retirement age, they will be supported by the succeeding generations.

Before the democratization of aging as previously defined, the impact of old people within society was not at all dramatic. There were very few old people and a large reservoir of adults of active age—a situation well illustrated by the population pyramid. The aging societies of tomorrow will, however, be better illustrated by spinning tops or age cylinders rather than by pyramids. The size relationships will be very different, and certain thresholds of tolerance relating to the burden of social charges in the incomes of an individual or household will have to be reasonably determined and respected.

It follows that the development of the present aging societies will generally be accompanied by structural changes that call into question certain operational methods in the functioning of social security within a society (Légaré, 2001a). Among the most important will be the development of education (especially by way of compulsory schooling) among the young. This is why the age of 15 years can no longer be considered the lowest limit of the economically active age group, because it does not accord with reality. In addition, the life expectancy of retired people never ceases to grow. Such changes create problems for the financing of the social expenses and induce governments to review certain methods of financing.

For retired persons, because there must be a certain equilibrium between payments and benefits and because the global amounts depend on the numbers of contributors and beneficiaries, certain parameters of the equation have to be changed (OECD, 2001). There is therefore a choice among increasing the contributions, reducing the benefits or raising the age of retirement, or employing a combination of these three elements. To maintain a reasonable living standard on retirement and to avoid possible poverty arising from the demographic structural changes, retired people will have to diversify their sources of income (Smeeding, 2003). As suggested by the "Four Pillars" model (AIEEA, 1996), these diversified sources could be the following:

State retirement benefits, via social security;
Retirement benefits coming from public or private systems, allied to employment;
Individual income from savings; and
Secondary employment incomes, for the younger.

This fourth source of income is directly allied to the calling into question of the low rates of employment for persons of 55 years and over (Guillemard, 2003). At the individual level, it is not imperative that the age at which the principal employment ceases should necessarily coincide with that of the access to social retirement benefits, because there may be several sources of income on retirement. Clearly, however, independent of age, social assistance should always be concerned with the most vulnerable and the most impoverished.

The baby boom generations decided to have fewer children; they had to accept their responsibilities regarding their retirement and avoid encumbering the less numerous cohorts that they had created with too heavy social charges. Even in a system of financing by distribution (pay as you go), certain reserve funds have to be set up to provide for important variations between the sizes of the younger and older generations. There are many ways of paying for these reserves, one of them being that of the user-payer. The same reasoning applies to the financing of health costs (Légaré *et al*., 2005). Inaction in this area risks the disastrous consequences in terms of intergenerational iniquity. With the help of demographers, economists have devoted themselves to measuring methods for limiting the damage, known as "generational accounting" (Auerbach *et al*., 1994, 1999; Gauthier, 1995). While continuing to improve the long projections needed for this approach, the use of these methods, despite their precariousness, should not be avoided.

III. SOME SOCIAL CONSEQUENCES OF DEMOGRAPHIC AGING

As the social consequences of aging are numerous, we shall limit ourselves here to addressing only those that are directly linked to demography.

1. Succession of Very Different Cohorts: Toward an Increasing Greater Autonomy for Old People

As was said in the preceding chapter, the accelerated demographic aging experienced by our societies is usually accompanied by important social mutations. The cohorts of old people follow but do not resemble one another (Stone, 1999). Not only are they different in terms of size (Golini, 2003; preceding chapter), but also they differ especially according to their socioeconomic characteristics (Marcil-Gratton and Légaré, 1987). The more important role of education among the young has already been mentioned, without losing sight of its repercussions throughout the various stages of life. In particular, a better level of education for women has the effect of increasing their participation in the remunerated labor market, of enabling them to acquire a certain degree of both economic and social independence, and of ensuring them an old age very different from that of their mothers and grandmothers. It follows, that when we wish to project the future by observing old people of today, we must always clearly distinguish between the effect of age and that of the birth cohort. The best example is the observation that relatively few old women drive a car, and those who do so have taken driving lessons at an advanced age. Most of tomorrow's old women, however, will have learned to drive in their youth and will be able to continue driving in their old age without any particular stress. Similar conclusions would be reached (though doubtlessly more negative) by studying the effects of smoking.

2. Ways of Living: Living Alone No Longer Necessarily Implies Isolation

Among adults, the most usual way of living is as a couple. In light of the important effect of mortality in producing widows and widowers, the diversity is sometimes greater among old people (Légaré and Martel, 2003). Even more so, the fact of having lost a spouse through divorce, a comparatively rare situation nowadays but one that can be envisaged as being more frequent in the future, places the individual entering old age in a quite different context from that of having lost a spouse by death (Martel and Carrière, 2003). Living without a spouse among other people generally reflects a certain physical, affective, or economic dependence (UN, 2001). In Third World countries, however, it is more often the case that elderly people with or without a spouse go to live in an extended family (Légaré *et al*., 2002), even though, with populations becoming increasingly urbanized and living spaces frequently more limited, accommodating a dependant relative at home is not easy.

The proliferation of single-person households in the Western world is doubtlessly allied to the high degree of economic independence enjoyed by adults without spouses. It must be stressed, however, that this applies equally to the young and old people. Among old people, it is principally women who live alone, particularly if they are in good health. Whereas, in the past people lived alone out of necessity, it is nowadays, a reasoned choice that does not necessarily imply isolation for the old person (Marcil-Gratton and Légaré, 1992). In Europe, if these people living alone are very old, this may mean that there is an extreme precarious state of accommodation (Gaymu, 2003). This is another good example of a cohort effect rather than one of age.

Everything, of course, is brought into question when the old person becomes disabled. Living in an institution often then becomes a necessity, even though this arrangement frequently entails being among very old people with social rather than health problems (Trottier *et al*., 2000). One must, however, be very careful when analyzing the way of life in an institution. The fact of there being more old people in institutions does not necessarily imply an increase in the population of old people suffering from bad health. This way of life is first and foremost much more a function of supply and demand. Nevertheless, the weaker the supply, the more the persons accommodated will be old and disabled.

3. Quality of Life Versus Quantity of Life: A Choice for the Aging Society

Although it is observable that old people live increasingly longer, can it be assumed that they are healthier (Légaré and Carrière, 1999)? It has already been observed that more members of a cohort are reaching retirement and old age, and that once this threshold is attained, they have an increased life expectancy. Effectively, in modern and therefore aging societies, premature deaths from disease have to a large extent been eliminated—most of the deaths among young people are allied to our ways of living, such as death by suicide or road accidents.

But even though establishing a death is simple, determining the health of an elderly person is much more complex (see Chapter 41). There are grounds, moreover, for clearly distinguishing the observed state of health from that as discerned by the person concerned. Among old people, the latter aspect often varies considerably from country to country, especially for cultural reasons (Egidi, 2003). Nevertheless, thanks to data arising from health surveys, demographers and epidemiologists have created indicators, such as life expectancy in good health, that enable a better understanding of the real situation (see Chapter 80). By comparing the evolution of life expectancy in all states of health with life expectancy in good health, it can be seen whether the years gained are those in the latter state. In short, has there been an increase in the years of life or of life in good health? It is easier to ask this question than it is to answer it. It can be affirmed, however, with considerable reserve, that although disability-free life expectancy (at all levels) has scarcely improved over the past 30 years, life expectancy without severe disability has tended to follow the improvement in life expectancy for all states of health (Robine and Romieu, 1998). Such an assertion does not automatically imply a future increase in disability among old persons (Jacobzone *et al*., 1998).

There is increasing insistence, moreover, that individuals deliberately lead a healthy life throughout their life cycle to preserve their physical and mental health better in old age. Campaigns against bad eating habits and nicotine addiction are concrete examples that are attaining a certain success. When asked, moreover, the large majority of *healthy* old people declare their preference for living less long but in good health, rather than much longer but disabled and ill (Somers, 1988). Respecting such a choice on the quality of life that transcends the apprehended increase in health costs (Bonneux *et al*., 1998) implies the abandonment of prolonging life by medical means and reorienting the current priorities of biomedical research on mortal diseases, such as cancer, toward such chronic diseases as Alzheimer's (van de Water *et al*., 1995; van de Water, 1997). Even more, it implies that in aging societies, priorities for the health of old people should move farther toward *caring* than toward *curing*, and that health personnel should learn to listen as much as to cure.

For some people, living for 120 years (which biogenetic engineering, having already proved itself in the veterinary domain, appears to make possible) may seem an objective. Yet there is still so much left to do in order to make all individuals equal in relation to the risk of death, even in our advanced societies but especially in the Third World countries, where the differences in mortality and morbidity are enormous compared with those that are industrialized.

4. Aid to Old People Who Are Losing their Autonomy: The Role of Informal Support Networks

Loss of autonomy is an evolving process for old people. Most people of 65 or over are not impaired—something that is too frequently forgotten. Subsequently, the need for assistance is gradually felt both for activities of daily living as defined by Sidney Katz *et al*. (1963):

Attending to personal care (feeding, washing, dressing, and going to the toilet unaided);
Getting into and out of bed;
Moving about the house.

Also important are the activities of domestic life, called instrumental activities of daily living as defined by Lawton and Brody (1969), such as,

Preparing meals;
Doing the shopping;
Carrying out domestic chores;
Managing personal finances;
Moving about outside the home.

Also included are activities of everyday life (Carrière *et al*., 1996), a mixture of certain activities from the two preceding categories.

Because, in light of the implied costs, institutionalization has increasingly become a solution of last resort, the leaders of aging societies wish to reinsert aid services for old people into the community and, in particular, to develop home care. They hope, moreover, that the informal networks (inferring principally families) will make up for the formal networks whether private or public, and ideally readopt the role that was allotted to them in former or more traditional societies. Now, in the course of the aging process, populations and families have themselves undergone considerable mutations; conjugal and parental life have been transformed in a radical way. The old people of tomorrow will have seen their married life more frequently ended by divorce. As for the parental dimension, even though in the succession of cohorts the decline in fertility was less brutal than in the period perspective, the size of the families fell by at least 50% (Carrière *et al.*, 2003). Lastly, given the extreme mobility of modern populations, children frequently do not live in the same region as that of their old disabled parents. In consequence, health service managers will have to apply themselves to developing the organization of formal aid networks for old people.

IV. SOME CULTURAL CONSEQUENCES OF DEMOGRAPHIC AGING

Two principles among the social characteristics that distinguish societies across the world and within multicultural countries are ethnic groups and religions. Given their demographic behavior during the second demographic transition (van de Kaa, 1987), several industrialized countries have had, are having and will have to resort to important international immigration—especially from southern countries—in order to mitigate partly their accelerated aging and apprehended negative growth. Societies, often monolithic from the point of view of ethnic groups and religions, will have to adapt to a new status of multicultural societies.

For rulers, the management of an aging society has not the same implications in Pakistan as in Canada or in China, both in the management of the aging phenomenon itself and for the services offered to old people. The role of the state in relation to the demographic problem is often ambiguous, especially for cultural reasons. In many Third World regions, an aging society will have to be administered even though the young population is still exploding, which is obviously not the case with industrial countries. The same will apply to the questions of the rights and duties of old people (UN, 2002).

It is first necessary to distinguish old people who are healthy from those who are not. The social role of the first will vary tremendously from one culture to another, in particular according to the sex and the matrimonial status of the individual. The independence observed for aged women in most industrialized countries, whether economic or social, has still a long way to go before being currently accepted in societies in which the emancipation of women is still in question. The role of the close or extended family will vary considerably from one culture to another.

This latter point becomes fully significant at the moment when an old person becomes disabled or ill, especially in multicultural societies. Contacts among old people, their family, and the medico-hospital system will vary enormously according to the ethnic group and religion. In addition, the services offered by immigrants in industrialized countries will often be more sympathetic than are those sometimes by the nationals. In contrast, the probable incompatibility between the cultural baggage of the person treated and that of the person treating greatly endangers the effectiveness of such a measure. Lastly, the decision to place a person in an institution will raise many problems according to the cultural environment of the old person.

As to death and the circumstances surrounding it, this then touches the foundation of the cultures, whether it concerns a premature decease such as with a child or the death of an elderly person. Religion and destiny are clearly opposed to the more individualistic positions of modern societies. Over time, it is individuals and not the collective households and their standards that have chosen the partner to the union, the number of children they will have, and the divorce in case of a failed marriage. It is difficult to see how society will be able to stop individuals in the near future from choosing the moment of their death, if they so desire (Légaré and Marcil-Gratton, 1990). The medical means and palliative care (its counterpart) appeal to values that differ enormously according to the cultures, so that those concerned with the health and social services must be very aware of these problems in multicultural societies.

CONCLUSION

The aging of populations is a great step forward and a benefit for humanity. And aging societies are here to stay. One of the main effects of this development is that several generations are now present at the same time and quite often for a fairly long period, whereas, in the past, two generations at most rubbed shoulders for a good part of their life cycle. This is not without a major implication at the level of intergenerational relationships. Can intergenerational conflicts be avoided (Kessler, 1996)? The best way to achieve this is to manage these aging societies in a climate of intergenerational ethics, which will only be achieved by a reasonable equilibrium between intergenerational solidarity and equity.

CHAPTER

83

The Economic Consequences of Migration

MANON DOMINGUES DOS SANTOS

Centre de recherché en economie et statistique (CREST), Université de Paris, Paris, France

INTRODUCTION

In 2002, 175 million people were living outside of their country of birth or citizenship, representing only 3% of world population (United Nations, 2002). Should we conclude from the relative weakness of recorded migration that international migration does not constitute (or no longer constitutes) an important economic phenomenon? Certainly not.

As a first objection, it is useful to note that this global evaluation conceals quite pronounced regional differences: although foreign-born persons represent only 1.5% of the population of southeast Asia or Latin America, they constitute 5% of the European population, 8.6% of population of North America and 18% of the population of Oceania. International migration thus constitutes a major contemporary phenomenon for a good number of countries.

Moreover, observed migration very likely represents only a part of potential migration. Over the past quarter century, numerous traditional receiving and sending countries have established restrictive and selective migration policies that strongly limit migration. Indeed, as in he past, migration generates tensions that push legislators to want to regulate these flows. Natives in the receiving countries often fear the impact of immigration on their well-being and most especially on pay and employment opportunities. In contrast, in the sending countries emigration is often perceived by those who do not move as a loss of their most capable compatriots, which is able to compromise or slow their development.

Thus, the question of international migration constitutes a major political issue. To what degree can economic analysis allow us to understand the consequences of migration, in order to evaluate the pertinence of the migration policies that have been put in place? This chapter seeks to respond to this question.

The economic literature devoted to migration has experienced remarkable growth over the past 25 years.[1] There is, nonetheless, a marked dichotomy between, on the one hand, contributions focused on the determinants of the migration choice and the individual characteristics that may influence that choice and, on the other hand, more macroeconomic approaches analyzing the consequences of the observed migration flows for incomes, employment, or growth, without reference to an explicit microeconomic choice. The first set of contributions generally considers migration to be a rational economic choice, the individual *freely* choosing to locate in the region where his well-being is highest, taking into account possible migration costs. These works provide us with information on the qualitative and quantitative characteristics of unconstrained migration flows, that is, flows freed from the effects of all government inter-

[1] See *Handbook of Population and Family Economics* (1997), Volume 1B, Editions North-Holland.

ventions that could shut off or modify them. Substantial differences can be observed between this hypothetical migration, which would result directly from the implementation of individual choices, and actual migration, most notably when international migration is concerned. In fact, international migration is subject to migration policies seeking to facilitate entry of some people and to prevent the arrival of other people, depending on criteria that are sometimes economic but also political (right to exile) or social (family reunification). Migration policies thus constitute a selection prism between hypothetical migration and actual migration between nations.

It is useful to evaluate the pertinence and efficacy of this prism. More specifically, confronted with a relative deterioration of employment opportunities for unskilled workers, but also facing ongoing population aging, numerous developed countries, such as Australia, Canada, and the United States, have already adopted selective migration policies favoring immigration of skilled workers. Thus, the traditional welcoming countries are looking to limit immigration of less-skilled workers but stimulate that of elites, which the sending countries disapprove of. It therefore should be noted that, at present, the skills of migrants constitute the central focus of migration policies. A question thus emerges: to what degree do the relative skills of migrants *effectively* influence the economic performances of the countries involved? The objective of this contribution is precisely to spell out the responses to this question, theoretical and empirical, that economics can provide.

To understand the impact of migrant skills, a two-step procedure can be adopted. This procedure consists first in analyzing the determinants of salaries, of unemployment rates, and of national growth rates in order to be able to evaluate the degree to which the skills of migrants influenced these determinants. But worker skills are an established essential determinant of employment and growth. Training constitutes an effective bulwark against unemployment and a means to earn a higher salary. The accumulation of knowledge is likewise perceived as one of the principal engines of economic development. Thus, observing that worker skills are indeed a major determinant of economic prosperity is tantamount to acknowledging that the impact of migration very much depends in an essential way on the skills of migrants. Understanding the consequences of migration therefore requires that we study how skill level interacts with the migration choice in order to be able to define the relative skill level of migrants, with regard to their country of origin and of destination. It will then be possible to understand and evaluate the economic consequences of the migration flows on the countries involved.

The first part will thus deal with the lessons from theoretical and empirical work analyzing the skill level of migrants, and the second part will address the consequences of migration in the labor market. Finally, in the last part, the links between migration and economic growth will be made explicit.

I. IS MIGRATION SELECTIVE?

Worker skills being one of the keys to prosperity, it is necessary to know and evaluate the extent to which migration can be determined to be selective. That is, do the skill levels of emigrants and immigrants differ from those of their counterparts who remain or of the people in the country of destination? To illuminate this question, we begin by reviewing the lessons from work looking at the determinants of the migration choice before examining results of empirical studies.

1. Skills and Migration Choice

Most work bases the decision to migrate on a simple axiom: a worker will choose to locate in the region that assures him the highest well-being, taking into account possible migration costs. Thus, as Larry Sjaastad showed as early as 1962, migration may be considered as an investment, resulting from a weighing of the expected benefits and the costs that it entails. It is thus useful to analyze the impact of level of skill on the propensity to migrate by first analyzing the impact of skill on returns and then on the costs incurred by the move.

a. Skills and Expected Returns

Conforming to human capital theory, initiated by Gary Becker, individuals can choose to improve themselves in order to acquire the abilities that will enhance their productivity. Education facilitates their entry to the labor market and allows them to seek higher-paying jobs. The best-trained workers thus have an incentive to locate in an area where their skills are well remunerated. Consequently, the impact of skill level on the propensity to migrate is ambiguous, a priori: it depends on the relative earnings of human capital in the potential regions of residence (see Roy, 1951; Katz and Stark, 1987; Heckman and Honoré, 1990; Borjas *et al.*, 1992). In short, when the most prosperous regions provide a higher return to skill, it is the most skilled workers who have an incentive to migrate there, whereas in the opposite case, it is the least trained workers who are motivated to migrate.

b. Skills and the Costs of Migration

Emigration may also turn out to be costly. Migration engenders financial costs that one must be able to finance, such as transportation costs, liquidation of real estate, or the search for new housing or new employment. Migration also entails psychological costs attributable to being far from friends and family, to the necessary adaptation time, and to the difficulties inherent in integration to a new environment. But there are a number of arguments that suggest that migration costs diminish as the individual's skill level rises. First of all, if the migration entails substantial financial costs, the potential migrant may be subject to a liquidity constraint that prevents him from financing his move. Thus, as emphasized by John Vanderkamp (1971) or Gary Fields (1979), if current income, highly correlated with the initial skill level, is too low, this may prevent a worker from realizing a move that otherwise is optimal. Moreover, skilled workers generally have access to a more-developed network of acquaintances that, among other things, allows them to reduce their costs of job search or housing (Schwartz, 1973; Inoki and Suriban, 1981; Da Vanzo, 1983). Finally, knowledge of a foreign language can reduce migration costs and promote integration.

Theoretical work devoted to migration choices thus tells us that the selectivity of migration with regard to skill depends a priori on the relative returns to human capital in the regions of potential location. And this is so even if the costs of migration may be larger for less-skilled workers.

2. An Empirically Established Selectivity

To analyze the consequences of migration for the economies of sending and receiving countries, it is essential to estimate if the average skills of emigrants and immigrants differ from those of their counterparts who remain or those of natives living in the destination regions.

a. Relatively Skilled Emigrants

A considerable consensus emerges from the empirical work examining the impact of individual characteristics on the propensity to emigrate. The majority of studies show, in effect, a positive influence of the skill level of workers on their propensity to migrate (for the United States, see Nakosteen and Zimmer, 1980; for the United Kingdom, see Gordon and McCormick, 1981; for Japan, see Inoki and Surugan, 1981; for Cote d'Ivoire, see Vijverberg, 1993; for Kenya, see Hoddinott, 1994). William Carrington and Enrica Detragiache (1998, 1999), in a study of 61 developing countries, show that for some of these countries, the emigration rate of the most skilled workers is especially high, a phenomenon commonly referred to as a brain drain. A good number of countries, especially the small countries of Africa, the Caribbean, or South America, have lost more than 30% of their natives who have attained tertiary-level education. In Guyana, the country statistically most affected by this phenomenon, close to 70% of workers with a tertiary education have emigrated to the United States.

In total, emigrants appear to be relatively skilled compared with their those compatriots who remain. This selectivity of migration with regard to skill level can thus be explained by the importance of the phenomenon of diminishing migration costs as the level of skill rises.

b. Relatively Unskilled Immigrants

Evaluation of the relative capabilities of immigrants raises numerous methodological problems, as reflected by the numerous contributions on this theme.

A first approach consists of simply comparing the skill levels (diploma obtained or number of years of school completed) reported by immigrant workers and natives in specific surveys. Such a procedure usually shows that the natives are more skilled than are the immigrants (Table 83–1). The pertinence of this procedure is, however, limited. Indeed, one must think about the question to which an immigrant worker is responding, a worker who has done all or a part of his schooling in another country, when asking him about his level of schooling. Does he reply using a conversion scale that adequately compares diplomas given in his country of birth to those given in his present country? Can he evaluate the diploma that he would have been able to have given his capabilities? Moreover, can one compare the accumulated abilities from a year of study when the school systems are different? Are these abilities really transferable?

Mitigating the limits of this first approach, numerous authors, beginning with the original contribution of Barry Chiswick (1978), seek to estimate the initial relative skill level of immigrants and the evolution of their capabilities during their residence by evaluating the evolution of their performance in the labor market.

A number of these authors base their results on *cross-sectional analysis* (for Germany, see Dustmann, 1993; for Canada, see Baker and Benjamin, 1994). In simplifying, this approach consists, at a date t, of classifying immigrants according to the duration of their

TABLE 83–1 Percentage of Individuals Having Less than a Secondary-Level Diploma

United States	35	15.7
Germany	48.5	13.2
France	63.3	33.4
Canada	22.2	23.1

Data from OECD, 2000.

stay, D. It rests on the central hypothesis that the earnings received after x years by an immigrant who arrived at date t are equivalent to the earnings received at date t by a worker having immigrated x years previously. The procedure consists, in short, of estimating the following equation:

$$\ln (w_i) = \alpha_1 X_i + \alpha_2 I_i + \alpha_3 D_i + \varepsilon_i,$$

where w_i represents the wage received by individual i, X_i is the vector of his socioeconomic characteristics such as education (in addition to age and sex), I_i is a dummy variable equal to one if the individual is an immigrant and zero otherwise, and D_i is the number of years since immigration if the individual is an immigrant and otherwise equal to zero.

Generally, α_2 is estimated to be negative and α_3 is estimated to be positive. In his study using American data for 1970, Barry Chiswick found that at their arrival, immigrants earned 17% less than did natives, but this gap diminished by 1% per year. Chiswick concluded that at their arrival immigrants experienced a loss of productivity, largely owing to the nontransferable nature of a part of their knowledge. Then, in the course of their stay, they accumulate human capital, which allows them to become assimilated with the native work force (Lalonde and Topel, 1991).

The interpretation of these results is, however, subject to caution. As George Borjas (1995) has emphasized, the sign of the coefficient α_3 may be owing to a cohort effect. That is, it may reveal a reduction in the relative skill level of cohorts, with the most recent immigrants being less qualified than the earlier ones. Longitudinal studies allow one to circumvent this constraint. They follow the same cohort of immigrants and natives over time, allowing one to observe individuals for a long period. For the United States, George Borjas (1999) shows that in 1960, immigrants earned, on average, 4% more than natives, whereas in 1990, they earned 16.3% less. According to the author, close to half of this reduction in the relative earnings of immigrants can be explained by changes in their observable characteristics, and especially their level of education. Further, George Borjas shows that in 1960 immigrants who had emigrated less than 6 years earlier earned 13.9% less than did natives compared with 38% less for immigrants who had arrived less than 6 years earlier in 1990. These results appear to confirm the lowering of the relative skill level of new cohorts of immigrants and the existence of a process of assimilation contingent on the duration of the immigrant's stay.

At the end of this first part, an observation is evident: although emigrants are more skilled than those compatriots who remain, immigrants are in general less qualified than are the native workers, even if they have a tendency to assimilate with the nonimmigrant population. Until recently, effective migration represented a departure of relatively skilled workers from the countries of emigration and arrival of comparatively less skilled workers in the receiving counties. Clearly, then, emigration had a tendency to reduce the size of the working population and the share of skilled workers, whereas immigration will have contributed to a larger labor force and growth in the share of less-skilled workers.

II. DOES MIGRATION INFLUENCE SALARIES AND EMPLOYMENT?

Evaluation of the influence of immigration on the well-being of native workers provokes much debate, often polemic, and made concrete by an abundant literature. Two hypotheses may, however, be envisaged. Certain authors advance the hypothesis of *replacement*, according to which immigrant workers substitute for natives. Immigration thus contributes to reducing earnings of natives and to increasing their likelihood of unemployment. Other authors favor instead the hypothesis of *segmentation*, according to which immigrants have jobs that natives do not want, or they would generate, in the long run, a demand for labor equivalent to the number of jobs they hold. To evaluate the pertinence of these two hypotheses, it is useful to review the lessons from economic theory in order to interpret the principal results of empirical work.

1. Lessons from Theory

The impact of migration on the conditions of remuneration and employment depend, of course, on the horizon that one is considering. Salaries and company hiring policies take time to adapt to a change in their environment. Taking account of these adjustment delays, it is useful to distinguish the short-term influence of migration from the long-term effects.

a. Short-Term Impact of Migration

The Lessons from Neo-Keynesian Models

With regard to the conditions prevailing in the labor market, an inflow or substantial departure of workers is like a shock that affects the size and the structure of the supply of labor. But whatever the manner in which the labor market being considered is regulated, earnings always take a certain time to react to a change in the economic environment. In the same manner, enterprises observe a certain delay before changing their production methods. Most traditional macroeconomic models, seeking to represent the short-run functioning of an economy, thus assume that prices, salaries, and productive capital are fixed. Their functioning may be summarized as such. In the short term, with prices being assumed fixed, it is the demand for goods and services coming from households, firms, and the government that determines output and employment. Unemployment thus results from the imbalance between the demand for labor needed to satisfy the demand for goods and services, given the state of technology, and the supply of labor, largely determined outside of the model. From a longer-term perspective, the *wage-price spiral* plays an important role. The unemployment rate affects the rate of growth of earnings, by virtue of the Phillips curve[2], and the evolution of wages and salaries has implications for prices. Inflation then feeds back on the demand for goods and services.

In the context of these neo-Keynesian–inspired models, immigration is analogous to an exogenous increase in the supply of labor and emigration is a decrease in supply. Thus, immigration[3] immediately increases the number of workers without affecting the level of employment, because prices and wages are fixed. The inflow of workers translates to an increase in unemployment, because the same number of jobs must be divided among a greater number of workers. However, this increase is only transitory. The increase in the unemployment rate moderates salary demands: wages fall and prices follow. This then stimulates demand for goods and services and hence for labor, this latter effect thereby contributing anew to reduce the unemployment rate. In the end, the reduction in prices is such that the initial effect on the unemployment rate is entirely offset. Immigration thus has only a transitory impact on the unemployment rate, and this effect persists less when prices and wages adjust rapidly.

By way of illustration, for the case of France, in relying on the estimates by Pierre Cahuc and André Zylberberg (2001) of the Phillips curve for the period 1970–1998, one can calculate that immigration resulting in an increase in the growth of the labor force by 1% would lead to a short-term increase in the unemployment rate by 2.4%. However, estimation of an average delay of adjustment of wages to prices of less than a semester (Artus and Muet, 1995) leads one to anticipate weak persistence of this effect.

The Lessons of Matching Models

Matching models (Pissarides, 1990) postulate that some time is required for a worker to find a job suited to his capabilities and for a firm to find a worker suited to the job vacancy that it seeks to fill. These delays imply that at any moment in time in the labor market there exist both unemployed workers searching for jobs and vacant positions. In this context, if one considers an inflow of immigrants, those who are newly arrived will devote some time to finding a job conforming to their expectations. Immigration[4] thus translates instantly into an equivalent increase in the number of unemployed, which raises the unemployment rate. Nonetheless, this increase from the recruitment pool increases the probability for an enterprise of rapidly filling a vacant position, which will diminish the cost of doing so. Thus, by increasing the profit associated with the creation of a job, immigration stimulates job creation. This process remains operative as long as the gain associated with listing a newly vacant employment remains positive, that is, until the unemployment rate returns to its initial level.

Hence, when wages and prices show a certain delay in adapting to changes in the economic environment and workers take some time to find a job suited to their skills, immigration can temporarily increase the unemployment rate and emigration can temporarily reduce it.

b. On the Long-Term Impact of Migration

The long-term impact of migration on wages and working conditions depends on how the labor market in question is regulated. There is a certain dichotomy between the lessons of Anglo-Saxon work, which is done in the context of a flexible labor market, and the lessons of European-inspired work, which favor the

[2] The Phillips curve shows an inverse relationship between the evolution of nominal earnings and the unemployment rate. More specifically, an increase in unemployment induces a decline in the rate of growth of earnings. One of the usual explanations for this causality is grounded in the process of salary negotiations. Basically, when the unemployment rate rises, employed workers are led to moderate their salary demands.

[3] For emigration, the direction of the effects is opposite.

[4] For emigration, the direction of the effects is opposite.

hypothesis of a rigid labor market characterized by the persistence of substantial unemployment. The former concentrate on the impact of migration on salaries, whereas the latter focus on the consequences of immigration for unemployment.

Flexible Labor Market, Migration, and Wages

To analyze qualitatively the impact of migration on wages, it is useful to consider an elementary model of the supply and demand for labor. This approach assumes that wages adjust to equilibrate supply and demand for each type of labor. The supply of a factor is constituted by the sum of the quantities of the factor held by natives and immigrants. Thus, immigration directly increases the supply of the kind of labor similar in productive characteristics to immigrant labor. The demand for labor coming from firms depends on the cost of labor, technological possibilities for substitution, and their situation in the market for goods and services. These are the properties of factor demands that condition the impact of immigration on the remuneration of all factors of production: the effect of an increase in the supply of a certain factor of production on the payments to all factors will depend principally on the elasticity of substitution between the different types of factors and their share in the total factor costs. Basically, labor immigration contributes to reducing the remuneration of factors of production that are perfectly substitutable for the labor of the immigrants, and it increases remuneration of factors of production that are complementary to it. Thus, in supposing that capital and skilled labor are complementary factors, and that unskilled labor is substitutable (Hamermesh, 1993), immigration of unskilled workers tends to reduce the wages of unskilled workers but increase remuneration of capital and of skilled labor. Furthermore, the emigration of skilled workers tends to increase remuneration of skilled workers and of capital, but it reduces compensation of unskilled natives.

Rigid Labor Market, Migration, and Unemployment

Numerous countries confront substantial unemployment. Wage rigidity and the structure of the working population are largely evoked to explain the persistence of a situation of underemployment. Basically, a country's unemployment rate may be considered as a weighted average of the unemployment rates of different categories of workers. Thus, migration can influence the national rate of unemployment via two mechanisms. Migration can influence category-specific unemployment rates: immigration of unskilled workers can affect the unemployment rate of unskilled native workers, whereas emigration of skilled labor can affect the unemployment of skilled labor who remain. Migration can also modify the respective shares of the different categories of labor in the total labor force. If migration increases or decreases the share of workers having structurally a higher rate of unemployment, this effect, called a *structural effect* or *compositional effect*, can likewise modify the average unemployment rate. Consider successively the mechanisms dealing with these two effects.

Migration, Equilibrium Category-Specific Unemployment Rates, and Unemployment

As previously noted, immigration (emigration) increases (reduces) the size of the labor force with productive characteristics similar to those of the immigrants (emigrants). From this perspective, evaluating whether migration influences the unemployment rate of the category of labor to which the immigrants belong entails examining the long-term links between the unemployment rate and the size of the labor force.

Recent findings in labor economics shed light on the sources of long-term category-specific unemployment. Endogenous mechanisms of salary determination are largely invoked. Thus, salary negotiations between employees and employers or salary policies adopted by firms, confronted with the turnover costs of labor or information asymmetries with regard to the characteristics of workers and the intensity of effort they put forth (for a review, see Cahuc and Zylberberg, 2001), can bring about a salary rigidity that gives rise to unemployment. In a general way, specifying the determinants of wages tends to limit the impact of migration on long-term unemployment rates by category (see Stiglitz, 1974; Calvo, 1978; Schmidt *et al.*, 1984; Bulow and Summers, 1986; Domingues Dos Santos, 1999b). Indeed, in equilibrium unemployment models, equilibrium category-specific unemployment rates turn out to be independent of the size of the labor force being considered. One result thus emerges: immigration (emigration) of a certain type of worker increases (reduces) the number of this type in the labor force, but this increase (reduction) will not have any impact on the long-term unemployment rate of the labor category being considered. Hence, immigration of unskilled workers will increase the number of unskilled workers, but this increase will not, in the long run, have any impact on the unemployment rate of unskilled workers. Correspondingly, emigration of skilled workers reduces the number of skilled workers but will have no long-term impact on the unemployment rate of skilled workers who do not migrate.

Migration, Compositional Effect, and Unemployment

Immigration and emigration can influence average unemployment rates if the migrants have, on average, a tendency to be unemployed that is different from the unemployment of natives or those who do not migrate.

Empirical work shows that immigrants have, on average, a higher unemployment rate than that of natives. For the case of France, the average unemployment rate of immigrants in 2000 was around 20.9%, compared to 9.9% for the entire labor force. This greater vulnerability to unemployment primarily can be explained by their lower skill level, with skill level clearly being one of the most effective bulwarks against the risk of unemployment.

Moreover, the propensity to emigrate seems to be greater when the individual is unemployed. Numerous arguments explain this selectivity of migration with regard to labor force status. Employed workers have, in effect, a higher opportunity cost of emigrating. With regard to speculative migration,[5] they are confronted with a risk of unemployment. They may also lose some of the advantages they had acquired, especially those linked to seniority.

Compositional effects would thus contribute to increasing the average unemployment rate in receiving nations and to reducing it in sending nations, because the tendency of migrants to be unemployed is greater than that of natives or of those who do not migrate.

The lessons from theoretical work lead us to think that migration has a negligible long-term effect on long-term category-specific unemployment rates. However, immigration could produce a transitory increase in unemployment in the receiving region, and emigration could result in a transitory decrease in unemployment in the sending region. It is useful now to evaluate the empirical relevance of these assertions.

2. Empirical Results

Empirical work on the impact of migration on wages and employment has two peculiarities. First, until recently, the majority of these studies looked at immigration to the United States. The specific features of American immigration and the functioning of the American labor market have thus limited the ability to generalize results to other countries. In addition, different econometric methods have been used, with approaches in terms of factor proportions, spatial correlations, and natural experiments being the most widely utilized.

[5] We refer to speculative migration when describing migration that takes place prior to securing employment in the destination.

a. Factor Proportions

The factor proportions approach, initiated by Jean-Baldwin Grossman (1982), entails three steps. The first step consists of determining, given the assumed technology of production, the theoretical labor demand functions. Then plausible values are determined for the elasticities of substitution among the different factors and the share of their remuneration in income as well as the relative skills of immigrant labor, in order to evaluate with which type of labor it is substitutable and the degree to which immigration modified the relative factor endowments. Finally, one can simulate the impact of immigration on the earnings of natives. George Borjas, Richard Freeman and Lawrence Katz (1997) estimated that between 27% and 55% of the reduction in relative earnings of unskilled workers in the United States between 1979 and 1995 could be attributed to immigration, which apparently increased by 15% to 20% the share of these workers in the labor force. In his own work George Borjas (1999) considers a technology with three factors of production: capital, unskilled labor, and skilled labor, with workers having less than a completed high school education being considered as unskilled. Using U.S. data, he estimates that in 1995, skilled workers represented 91% of the total labor force but only 68% of the immigrant population. He estimates that in the short run, that is, with the stock of capital fixed, a 10% increase in the labor force induced by immigration would reduce by 2.29% the earnings of skilled workers, and the earnings of unskilled workers would decline by 3.72%. In the long run, once the capital stock is adjusted by firms, earnings of skilled workers would rise by 0.46%, whereas earnings of unskilled workers would fall by 4.27%. However, the relative weakness of this effect has recently been called into question by George Borjas (2002). In refining the categorization of the work force by level of education and most notably in integrating work experience, he estimates that between 1960 and 2000, an increase in immigration that would have increased the supply of certain types of labor by 10% would have reduced by 2% to 3% the earnings of natives and by 2 weeks the number of weeks worked.

The approach in terms of factor proportions thus concludes that there is an important influence of immigration on the relative earnings of unskilled natives. However, this approach may prove to be unsatisfactory. The applications are all on the

American case, in which the labor market is presumed to be flexible. Further, this approach does not consist of *estimating* the actual influence of immigration but rather of *simulating* that influence by using a counter-factual method that should be viewed with caution.

b. Spatial Correlations

The approach in terms of spatial correlations consists of identifying the correlations that exist at a given moment between observed earnings or employment opportunities in a sample of regions and the density of their respective immigrant populations. In short, if, for example, it turns out that the regions having a high density of unskilled immigrant workers or substantial immigration of this type of worker are those in which earnings of unskilled native workers are the lowest or increase the least, this approach tends to conclude that there is a causal relationship. Work based on this approach typically finds a not very significant or insignificant effect of migration on local employment conditions, as well as a strong dependence on the period being considered (for United States: Lalonde and Topel, 1991; Altonji and Card, 1991; Borjas *et al.*, 1997; Card, 2001; for Germany: De New and Zimmerman, 1994; Pischke and Velling, 1997).

However, the spatial correlation approach presents two drawbacks that limit the significance of certain of the results.

The first is linked to the problem of simultaneity resulting from self-selection of migrants. In brief, if migrants are attracted by the regions where employment opportunities are favorable, observation of a positive correlation between immigration rate and employment opportunities may simply reflect the causes of the migration choice and not the consequences. Utilization of the *method of instrumental variables* permits one to relax this constraint somewhat (Altonji and Card, 1991; Pischke and Velling, 1997). This procedure consists of identifying certain variables that influence the location choice of immigrants but do not affect conditions in the labor market being considered. However, it appears that introduction of instrumental variables has little effect on empirical results: immigration does not seem to influence in any substantial way earnings and employment opportunities of natives.

The second drawback of this approach is to obscure the mobility of native populations that can vote with their feet. Clearly, if immigration pushes natives to emigrate, this will limit the impact of immigration on conditions of employment. However, David Card (2001), for the United States, and Jörn-Steffen Pischke and Johannes Velling (1997), for Germany, estimate that this phenomenon is not very consequential.

Evaluations using the method of spatial correlations thus show generally that the impact of migration on remuneration and employment opportunities of natives is relatively modest or even insignificant.

c. Natural Experiments

The authors of some empirical work base their estimates on what are called natural experiments. These studies exploit the consequences of policies that generated intense migration flows for a specific period in certain regions.

Thus, David Card (1990) evaluated the consequences of the "Mariel boatlift." In 1980, after a disagreement between the Cuban and Peruvian governments, Fidel Castro announced the opening of the port of Mariel for any Cuban desiring to leave Cuba. This announcement provoked an exodus of more than 125,000 Cubans to the United States between April and September 1980, with half of these migrants settling in Miami, where the labor force grew by nearly 7%. To evaluate the consequences of this massive immigration, David Card compared changes in unemployment rates and earnings in Miami with the changes observed between 1979 and 1985 in other cities having similar characteristics, such as Los Angeles, Houston, Atlanta, and Tampa/St. Petersburg. During the 1970s these cities had experienced changes in employment similar to those in Miami, and similar to Miami, they also had important black and Hispanic communities. The similarity of the labor markets of Miami, the experiment city, and the control cities, allows one to attribute to the Cuban immigration the differences in performance of the labor market subsequently observed. David Card concluded from his analysis that changes in unemployment rates and earnings in Miami were very close to those observed in the other cities. In the long term, then, the impact on unemployment and earnings of this immigration, even though it was massive, was apparently negligible.

Another study, done by Jennifer Hunt (1992), looked at the consequences of the flow of French repatriated from Algeria during 1962. After the signing of the Evian agreement granting independence to Algeria, 900,000 French returned to the mother country in 1962, principally in the southern regions. To evaluate the impact of this migration flow on employment opportunities of natives, Jennifer Hunt compared changes in unemployment rates and earnings in the 90 metropolitan departments, controlling for a set of external variables that could also influence the variables studied. She estimated that an increase of 1% in the labor force induced by this immigration would have increased the unemployment rate of nonmigrant natives by 0.2%. Moreover, their average salary in 1967 would have been at most 1.3% lower than what it otherwise would have been. The comparison of the results of David Card and Janet Hunt suggests that the American labor market has a greater absorption capacity than does the French labor market. The rigidities of the European labor market, characterized notably by a more marked protection of employment and higher replacement rates, can be evoked to explain the greater impact of immigration on unemployment rates.

In this regard, work by Joshua Angrist and Adriana Kugler (2003) seems to confirm the role of labor market rigidities on the capacity of concerned regions to absorb a flow of immigrant labor. These authors evaluate the impact of consecutive exoduses from the Bosnia and Kosovo wars on each of the receiving countries, using a database covering the period from 1983–1999. Their results suggest that an increase of 10% in the proportion of immigrants induces a reduction in the rate of employment of natives of between 0.2% and 0.7%. In addition, the authors show that this reduction is more pronounced if the country in question is characterized by a rigid labor market.

The work based on the analysis of natural experiments seems to confirm a moderate impact on the conditions of employment of natives. However, this apparent capacity of receiving economies to absorb the newly arrived appears to be weaker in the presence of institutions limiting the flexibility of the labor market.

At the end of this section, an observation is pertinent: empirical work seems to validate the lessons of theoretical work concerning the impact of migration on earnings and unemployment. The effect of migration on salaries and the propensity of natives to be unemployed appears to be relatively weak. In total, the replacement hypothesis seems to be invalidated: economies are not characterized by a given number of jobs that must be divided among the individuals present. Rather, they have a tendency to create jobs in proportion to the number of individuals who work and consume there.

III. MIGRATION AND GROWTH

Up until now, we have ignored any possible impact of migration on the prospects for growth of the countries involved. But the international mobility of workers, bringing with them their knowledge and a part of their belongings, can influence growth and technical progress in both the sending and receiving regions. Let us be explicit about the pertinent mechanisms here, so as to highlight the results of empirical work.

1. The Lessons of Empirical Work

The impact of migration on growth depends, of course, on its influence on the two principal engines of expansion: capital accumulation (physical and human) and technological progress.

Although the authors who base their analyses on the *Solow growth model*[6] exclude, a priori, any impact of migration on technological progress, because this variable is considered exogenous to the model, they nonetheless make explicit the effects of migration on the dynamics of overall capital accumulation. These works conclude that there is a positive influence of migration on the convergence of standards of living of sending and receiving regions (Barro and Sala-I-Martin, 1995). Two arguments support this conclusion. In the first place, workers have an incentive to migrate to the region where income per capita is highest. But because income per capita will be determined by the per capita stock of capital, migration flows will be from the region where the per capita stock of capital is lowest to the region where it is highest. In the second place, migrants bring with them relatively little capital. In total, then, emigration increases the capital stock per capita and hence income per capita, whereas immigration reduces these two variables.

However, these assertions are worth discussing in view of the selectivity of migration with regard to skill level. Indeed, it is assumed that migrants bring relatively little capital with them. Hence, evaluating the relative capital, physical and human, brought by migrants turns out to be essential.

We know in reality that on average, immigrants are less qualified than are natives. Moreover, if we consider the costs of mobility of physical capital held by individuals before their migration (costs of sale and purchase of personal property and real estate), it is reasonable to think that, on average, immigrants will have an overall stock of capital that is less than that of natives.

Nonetheless, we saw that emigrants on average are more skilled than are their compatriots who remain. Hence, the proposed assertion is only pertinent if emigrants experience substantial losses of physical capital or if they leave to their next of kin a large part of their

[6] The Solow growth model spells out links between growth of per capita income, accumulation of physical and human capital, and population growth. However, this approach considers technological progress as exogenous. By its nature, then, the Solow model excludes any possible influence of capital accumulation or population structure on technological progress.

goods. However, consideration of the financial transfers that emigrants send to their countries of origin can relax this condition. Numerous studies document the importance of the share of their income that emigrants remit to their country of origin (Blitz, 1977; Chandavarkar, 1980; Lebon, 1994; Cashin and Loayza, 1995). Thus, these substantial capital transfers, conditioned by prior emigration, can have a favorable impact on income of the sending region, a priori the less developed region.

However, work on migration in the context of *endogenous growth models* is primarily oriented toward the problem of brain drain. The principal objective is to explain the consequences of emigration of the most skilled workers from developing countries. According to endogenous growth theories, the average skill level of the labor force constitutes one of the principal engines of economic development. Thus, emigration of skilled workers would have a negative effect on both the income of workers who do not emigrate (Miyagawa, 1991) and the rate of growth of the sending region (Haque and Kim, 1995). Andrew Mountford (1997) shows, however, that this effect may be attenuated if the choice of training is taken into account. In brief, because remuneration of a skilled worker is greater in developed countries, a nonzero probability of being able to emigrate toward these regions increases the return to education and thus provides greater motivation for workers to acquire training. If some of these workers cannot emigrate, the effect of greater motivation to acquire training can compensate for the direct adverse effect of the brain drain. Moreover, I have shown (Domingues Dos Santos, 1999a) that it may be optimal for the region where innovation activity is less efficient to allow a part of its skilled manpower to emigrate if the region can benefit from technological advances realized in the receiving region, via a process of imitation. Finally, migration may favor the growth of developing countries if workers return home and diffuse some of the knowledge they acquired during their stay abroad (Domingues Dos Santos and Postel-Vinay, 2003).

Thus, when one excludes a priori any impact of migration on technological progress, migration will tend to favor the convergence of standards of living between the sending and receiving countries. Nevertheless, the brain drain may compromise the growth prospects of developing countries, which limits the generality of this assertion.

2. Results of Empirical Work

It is necessary to acknowledge that up until now, there is little work that tries to evaluate the impact of migration on the convergence and the growth prospects of the regions involved. The lack of homogeneous international data that would allow estimation of these phenomena is certainly one of the essential explanations for this deficiency. Let us nonetheless consider the principal results that have been found.

a. Migration and Convergence

Robert Barro and Xavier Sala-I-Martin (1995) studied the process of convergence for regions of the United States (for the period 1920–1990), for Japan (for the period 1955–1990), and for Europe (for the period 1950–1980), both with and without migration. They show that the differences in estimated convergence speeds are small. The work of Alan Taylor and Jeffrey Williamson (1994), however, suggests that these results are not robust with respect to modification of the period being considered. In carrying out a counterfactual analysis of 17 countries of the old and new world for the period 1870–1910, the authors conclude that 73% of the reduction in the dispersion of output per worker, and 50% of the dispersion of output per capita can be attributed to migration. Work by Moses Abramovitz (1986), Angus Maddison (1991), and Jeffrey Williamson (1995) tends to confirm this assertion. They decompose the period from the mid-19th century to the present into four subperiods based on the criterion of dispersion of per capita income: the initial period, when the dispersion is substantial; the period from 1870–1913, characterized by a convergence of per capita incomes; the interwar period, during which there was substantial divergence; and the period from 1950 to the present, one of strong convergence. But according to Jeffrey Williamson, it is precisely migration that differed across these periods: the reduction in transportation costs resulted in massive migration after 1870, whereas migration flows substantially declined owing to introduction of migration quotas and the increase in transportation costs and the uncertainty linked to the war.

Although work on migration in developed countries for recent periods suggests that the influence of migration flows on convergence is limited, it does seem that there was a considerable influence in earlier periods.

b. Brain Drain

The absence of work seeking to evaluate the consequences of brain drain is especially obvious. Michel Beine, Frédéric Docquier, and Hillel Rapoport (2001) nonetheless shed some interesting light on this question. Exploiting data constituted by William Carrington and Enrica Detragiache (1998), these authors seek to explain investment in human capital and the rate of growth for a sample of 50 developing countries. They confirm the assertion of a motivating effect on training. However, ex post the effect becomes negative once the migration rate exceeds 20% or when the percentage of educated workers is greater than 5%. The consequences with respect to growth remain generally limited, when the brain drain is not too intense.

Work on the links between migration and growth thus teaches us that international mobility of workers should tend to favor convergence when it occurs between relatively developed countries. At the same time, emigration of skilled workers from developing countries tends to limit the prospects for growth of these countries and thus their chance of reaching a level of prosperity comparable to that of better-off countries. The selective migration policies that have recently been implemented by these latter countries can only strengthen this observation.

Immigration and Integration in the Developed Countries: A Conceptual Framework

VICTOR PICHÉ

Inter-university Centre for Demographic Studies, Ethnicity and Society Research Group, University of Montreal, Montreal, Canada

INTRODUCTION

The pattern of international migration to and from developed countries has changed radically since the early 1970s. Immigration to North America and Europe has gradually originated mainly from the developing countries, producing significant shifts to ethnic and racial compositions (Kuijsten, 1994; Massey *et al*., 1998). Over time, Western countries have awoken to their multiethnicity, mostly through heated public debates on the need (or not) to shut the door on immigration. But at the same time, multiethnicity was not just pervasively present but an inescapable reality, requiring political and social responses to the many challenges posed by the new immigration. In countries such as the United States, Canada, and Australia, whose histories are inextricably bound to large-scale immigration, multiculturalism has long been a focus of debate and policy. Western European immigration countries, in contrast, have only recently been compelled to consider the relationships among ethnic diversity, national identity, and citizenship, and to consider multiculturalism-oriented policies (Castles, 1993:28; Bauböck and Rundell, 1998).

It is against this changing background that integration of immigrants has become a key policy and research issue. Demography has not stood aside from this resurgence of interest in integration research because "there is a political demand which demographers and statisticians cannot ignore" (Magaud, 1997:2). Over and above the purely descriptive studies of migration and indicators of integration that have long typified demography's contribution, a growing body of demographic research focuses on the process of integration and especially on factors of inclusion and/or exclusion of immigrants and minorities.[1]

Research into the determinants of integration is still lacking in many respects. First, the indicators of integration are too often one-dimensional. Studies on the measures of economic integration are a case in point: comparative studies that find immigrant incomes to be lower than native-born incomes are often held to be evidence of immigrants' disadvantage on the labor market. But, the validity of this type of exercise depends on factoring other variables into the equation, such as period of arrival, age, educational level, sex, and previous work experience. In short, integration is a multidimensional process that involves a great many factors that are linked to immigrants' social and economic status in a given society.

Second, the wide variations in the number and types of factors included in empirical studies

[1] Demography's contribution is undeniably quite recent and as yet still tentative. Two recent illustrations of how demographers have stepped into the ethnic demography arena are Rallu *et al.* (1997) and Halli and Dreidger (1999).

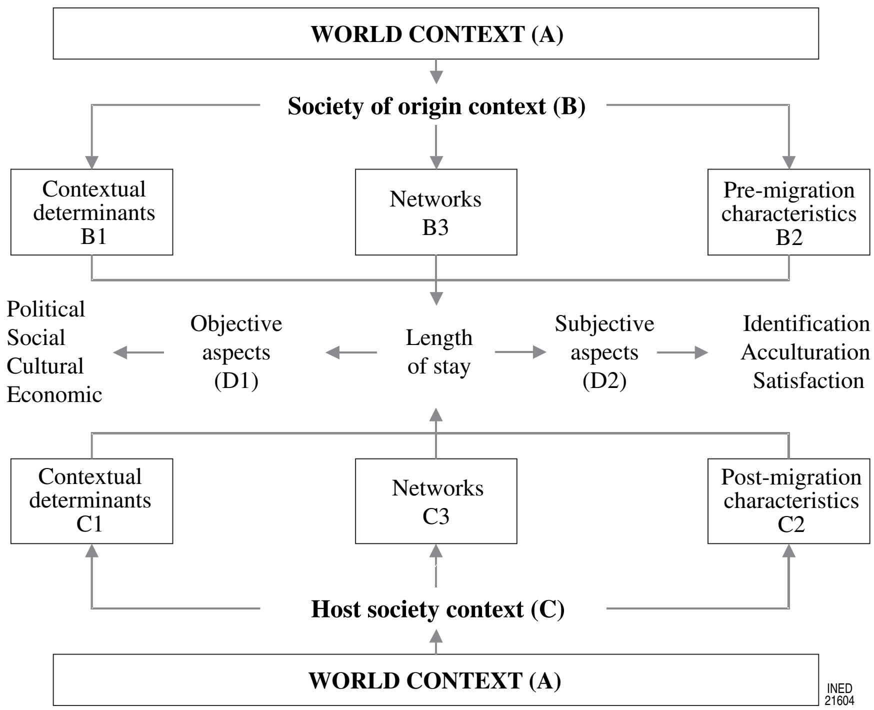

FIGURE 84–1 The integration of migrants: a conceptual framework.

constitute a serious obstacle to a comparative perspective. Factors of integration vary along theoretical and conceptual lines: hence, two schools of thought have developed in a parallel fashion. One approach insists that integration is mainly predicated by individual, human capital-related factors (e.g., educational level, age), whereas another perspective gives more importance to macrostructural and political factors. It is worth pointing out that the micro approach, heavily influenced by human capital theory (Borjas, 1994) and culturalism (D'Souza, 1995), has largely dominated North American research, whereas European (especially Western European) research on immigration has centered almost exclusively on historical and structural factors (Castles and Kosack, 1985; Simon, 1999) with a particular focus on racism and discrimination (Wrench and Solomos, 1993; Wieviorka, 1994). Arguably, this compartmentalization can yield partial or distorted results, because integration is a process that results from the complex interplay between immigrants' characteristics and the specific historical (economic and political) contexts of the host societies (Portes and Rumbaut, 1990).

What is proposed here in order to account for the complexity of the integration process, and especially its multidimensional character, is a conceptual framework that pinpoints what current research considers to be the key factors of integration. It aims to incorporate multiple types of factors and levels of analysis (Fig. 84–1).

I. DEFINING AND MEASURING INTEGRATION

There is no clear consensus on what is meant by the concept of "integration," which tends to be used in the literature to cover a wide range of situations. In some cases it is equated with assimilation and involves "the filtering out of migrants' cultural differences and migration characteristics" and "the convergence of behaviors in key areas" (Tribalat, 1996:254). Areas of convergence include indicators such as labor market performance, family and marriage practices, language, religion, education, housing, and citizenship. In this approach, immigrants' behaviors must converge, that is, resemble those of the native-born population. In most cases, however, integration refers to the multicultural model and involves both convergence in very narrow areas (e.g., relating to human and civic rights) and retention of certain cultural and other differences of migrant communities (Kymlicka, 1998). Inherent in this latter concept, therefore, is that immigrants should not entirely forsake their identity (Breton, 1994:240). In fact, there is an interplay of influence between immigrants and members of the host society in the process of integration, leading both groups to change over time.

Over and above theoretical concepts, what concerns us here are the operational and empirical definitions of integration. Broadly speaking, most authors conceptualize integration as a process that is measurable on a continuum ranging from nonintegration (e.g., leaving the country) to "successful" integration (e.g., exhibiting the same performance as the nonimmigrant or native-born populations). For many aspects of integration (e.g., economic, linguistic, residential), the indicators seem readily measurable and, as such, are the subject of consensus in so far as they are widely used and not routinely criticized. For example, the criterion of linguistic integration is knowledge of the language of the dominant group (or community). Whether in the home, at work, and during socializing and/or choosing media or a residential neighborhood, the basic questions are "which of the two languages (language of origin or language of the host country) is preferred?" and "what factors facilitate or hinder the adoption of the official language(s)?" As to economic (essentially the labor market) and educational integration, success is often measured against the average of the native-born population. The factors of economic and educational integration are therefore those that facilitate or hinder performance in these areas. Hence, successful economic, linguistic, and residential integration is achieved when differences in indicators between immigrant and native-born communities become nonsignificant.

By contrast, the indicators of social and cultural integration are much more problematic (Rallu, 1997). There is no ready consensus on a norm in these areas (Breton, 1994:243), and thus, the issue of successful integration poses huge problems of definition and remains normative and ideological. What are the criteria of success, and to whom do they apply: to immigrant groups or the host society? It is legitimate to suppose, for example, that indicators of success in the labor market are as valid for the economic integration of members of the host society as for immigrants. But the modes by which economic performance is achieved may be a critical issue. Ethnic enclaves are a case in point. Although some would argue that enclaves provide readily-available jobs and on-the-job training for immigrants (positive aspect), others considers enclaves as reflecting a measure of refusal to integrate into the supposedly nonethnic dominant economy (negative aspect).

Residential integration raises more problems still. However apparently neutral residential segregation measures may be, ethnic concentration, for instance, is seen as both positive and negative: positive because it is an expression of solidarities and the pooling of community resources enabling access to housing, and negative because the host society often perceives ethnic concentration as barriers to interaction between the immigrant and nonimmigrant populations. The same can be argued for educational integration. There seems to be a consensus on the measures of educational achievement (e.g., marks, drop-out rates, educational difficulties and low rates of education). However, where the values transmitted by the school and those of immigrant children and parents diverge, it is harder to define measures of integration or nonintegration. That, indeed, holds true for all indicators of social and cultural integration. The difficulty here, to quote Breton (1994:240–241), is "to identify the assemblage of attitudes and behaviors from which to conclude that an individual or category of individuals has become completely integrated." How are we to determine the cultural norm that should be the benchmark against which to measure the degree of integration? In a pluralistic society with such a diverse mix of values, defining that norm can be a highly controversial undertaking.

Ultimately, the definition of integration used here is very close to that of David Coleman (1994:43): integration involves the opportunity for immigrant populations and minority groups to participate fully in all aspects of society (social, economic, and political). And although equality of opportunity in society and the absence of discrimination on the grounds of national origin are certainly key factors in successful integration, so, too, are the characteristics of immigrants themselves, and the circumstances of their migration. That is what is conveyed by the conceptual framework presented below.

II. CONCEPTUAL FRAMEWORK FOR STUDYING THE FACTORS OF INTEGRATION

Figure 84–1 shows a simplified version of the conceptual framework proposed here to study the factors of integration.[2] Three broad groups of factors are identified. First are factors linked to the world context (A-type factors), which affect both societies of origin and host societies: generally, these are mainly but not exclusively macrostructural-type factors impinging on the economic and political spheres. This group of factors refers to such things as international relations, north–south relations, external/foreign policies, and globalization. They shape the conditions at origin,

[2] Adapted from the Goldlust and Richmond model, 1974.

which act as push factors, and the host country policies on selection and integration: in Fig. 84–1, this is called the society of origin context (B-type factors) and the host society context (C-type factors).

Figure 84–1 shows that the B- and C-type context variables are symmetrical. Three sets of factors are identified for origin (sending country) and destination (receiving country): (1) contextual determinants or structural factors (B1 and C1); (2) the pre- or postmigration micro-individual characteristics (B2 and C2); and (3) networks (B3 and C3). In the first case (B1), examples for the society of origin include factors such as economic and social development, industrialization, new urban development, and educational levels; political systems; state policies affecting migration; wars; and natural disasters. For the host society, (C1) factors would include economic and demographic conditions, the degree of pluralism, levels of discrimination, new urban development and stratification, and government policies, especially immigration policies.

Premigration characteristics (B2) refer to individuals: these may include education or vocational qualifications, demographic characteristics, previous experience, and motives. Likewise postmigration characteristics (C2) include immigration status, age, sex, occupational mobility, and social class. One characteristic—length of residence—is singled out in this model as a key factor in the integration process.

Implicit in the network variables are the circumstances in which the migration proper (B3) and the process of integration in the host society (C3) unfold. In both cases, these refer essentially to the role of the family, formal networks (e.g., churches, ethnic voluntary organizations, trade unions, employers' associations), and informal networks (e.g., intermediaries, friends) in facilitating emigration (origin) and integration (destination).

Finally, the conceptual framework identifies two types of dependent variables by which integration can be measured: the objective (D1) and subjective (D2) aspects of integration. The objective measures of integration tend to comprise behavioral or performance indicators such as type of participation in political and social life, type of media consumption, and economic activities (e.g., employment, unemployment, income). The subjective aspects are more perceptual and attitudinal and concern ethnic or linguistic identity and satisfaction with postmigration living conditions. The remaining part of this chapter will focus on the objective aspects of integration only.[3]

[3] For an application of this model to economic integration, see Piché *et al.* (2002a,b).

III. INFLUENCE OF THE WORLD CONTEXT

Contemporary international migration cannot be examined in a purely national, or even regional, setting. The formation of a world system (Wallerstein, 1979) requires international migration trends to be conceptualized within their global context, and a body of recent research has sought to demonstrate the relevance of such an analytical framework (Gungwu, 1997; Applebaum, 1999; Dieckhoff, 2000; Simmons, 2002). Stephen Castles (1993:17), for example, argues that the world is entering into a new phase of mass population shifts in which Europe-bound migration and the situation of ethnic minorities in Europe can only be approached in the global context. Likewise, Alan Simmons (1995:343) argues that the history of international migration cannot be separated from the history of the growth of world capitalism. He also hypothesizes three possible explanations for the changing directions and forms in the *global system of international migration* since the mid-1960s: they have acquired a more global scope (involving a growing number of hitherto comparatively remote countries), more flexible time-scales (a rise in short-term migration), and more decentralized control mechanisms (growing importance of families and networks in migration strategies increasingly outside state control).

Although it may appear obvious that the world economic context shapes not only the volume and direction of world migration patterns but also integration processes, research in this area is still mostly speculative and conjectural. Also, the effects of the world context are still unclear as to their positive or negative role in integration. As an illustration, five hypotheses can be suggested as ways in which the world context may be linked to integration.

1. The world economic situation—with its numerous crises and responses in the form of structural adjustment programs—has led to labor market tightening that more specifically affects the economic living conditions of recent immigrant groups (for the United States: Borjas, 1994; for Canada: Bloom *et al.*, 1994; for Europe: Coleman, 1994), which may block economic integration and fuel anti-immigration sentiments.

2. Trade globalization, reflected among other things in the formation of large-scale regional blocs, shifts discussions of immigration to the international level and makes immigration a strategic issue in treaty negotiations, be it North American Free Trade Agreement[4] in

[4] North American Free Trade Agreement (NAFTA) concluded in 1992 by the United States, Canada, and Mexico, applied from January 1994.

North America (Simmons, 1996) or the Maastricht Treaty in Europe[5] (Miles, 1992). These reorganizations may either favor integration through such things as freedom of movement for nationals in the new regional spaces and the adoption of universal antidiscriminatory measures, or impede it through the development of restrictive immigration and integration policies (e.g., exclusion of nonmember countries, tightening up of admissible categories, especially relating to families and refugees, restriction in welfare programs).

3. One frequently cited consequence of globalization is a trend toward the strengthening of local identities (Gungwu, 1997:8), which may reflect new solidarities or degenerate into ethnic conflicts (Weiner, 1997:101).

4. Globalization also affects ideologies and norms, thereby encouraging the emergence of a world public opinion (Badie, 1997). This arguably creates leverage in favor of human rights[6] (Withol de Winden, 1994) and antiracist, antidiscriminatory, and nonassimilationist policies (Gungwu, 1997:15–16). But at the same time, it can be responsible for the rise in anti-immigration sentiments (Wrench and Solomos, 1993:7) and an upsurge in nativism[7] (Weiner, 1997:100).

5. Finally, migration-driven transnationalization brings international relations into the forefront (Badie, 1993), often allowing immigrant populations to live in networks that may represent a threat to national sovereignty (Hollifield, 1994; Schnapper, 2001). New forms of international migration, the demands for recognition of minority identities, and the growing importance of transnational networks make national borders more permeable and lead to a radical rethinking of national identities and the very concept of citizenship (Castles, 1998; Soysal, 1998). For some, the forces of globalization are undermining the very foundations of the nation-state (Dieckoff, 2000; Seymour, 2002).

In short, the current context of globalization is producing radical changes to the way we approach integration. As was said earlier, research in this area is still conjectural and insufficiently comparative. Also, the effects of such global (and sometimes very abstract) phenomena are not readily measured by current methods. In any event, there is no denying the real and often opposing effects exerted by current world forces. Immigrant groups and their allies may be comforted by the portion of world public opinion that favors more tolerance and multicultural pluralistic systems that aim to facilitate the integration of immigrant populations. But at the same time, opposing forces are calling for more restrictive measures to stem the new migration flows that, they argue, pose a threat to national identities and political stability. Be that as it may, the study of the factors of integration can no longer afford to brush this kind of issue aside.

[5] The treaty signed in 1991 by the 15 European Union Member States (Germany, Austria, Belgium, Denmark, Spain, Finland, France, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, United Kingdom, Sweden).

[6] Myron Weiner (1997:114) goes so far as to talk of "global human rights."

[7] Nativism is a school of thought that aims to preserve the cultural character of a country as it has been shaped by the native-born population.

IV. CONTEXTUAL FACTORS IN THE COUNTRIES OF ORIGIN AND DESTINATION

However necessary the world system may be to the equation, it is not enough to address the practical modes of integration. In a sense, the world setting is often remote of the real life of immigrant populations, which unfolds in specific countries and societies in which the pressures of the world system are mediated through national histories (Tarrius, 2002). Integration research, therefore, must consider the contexts characterizing societies from which immigrant populations leave and into which they enter. There is a growing consensus among analysts of migration on the necessity to take into account factors related to the country of origin: international migration is therefore defined as a system comprising a set of countries interchanging a relatively large number of migrants (Kritz and Zlotnik, 1992:2). In this context, the countries are linked to one another by migration and other flows (e.g., capital, goods).

With respect to integration research, little consideration has been given to the macrostructural aspects of the country of origin. It is reasonable to think, however, that integration of immigrant groups will vary with the greater or lesser social, cultural, and economic distance between the country of origin and the country of immigration. Local social and economic indicators include, among other things, language, religion, types of family organization, and the level of economic development of the country of origin. In a recent study, for instance, it was demonstrated that the economic level of the country of origin of immigrant populations had a significant influence on their degree of economic integration measured by income and socioeconomic status: other factors being equal, immigrants from poor countries have more problems than do others integrating into the labor market (Renaud *et al.*, 1997).[8]

[8] The question of national origins will be considered further in the section on micro-individual factors.

Host country contextual factors have received far more extensive attention. Three factors are particularly relevant for immigrant populations: government policies regarding selection and integration, labor market conditions, and the characteristics of their ethnic community (Portes and Rumbaut, 1990:85). Political factors relate to how open or closed the country is to certain groups. To that extent, integration policies may become a key factor in the success or failure of integration. With growing pluralism, some countries are striving to develop integration policies either by encouraging assimilation and discouraging the perpetuation of minority groups, or by adopting a policy of multiculturalism designed to help immigrant minority groups to preserve their language, culture, and traditions (Coleman, 1994:41). Unfortunately, the present state of research in this field does not allow any conclusion to the effect that one model of integration is better than any other; that conclusion would require a comparative approach that does not currently exist. However, selection and integration policies may arguably have tangible effects within a country (Portes and Zhou, 1995), with the success of integration varying between groups of immigrants as a function of differential access to integration measures.

The second contextualizing factor for integration is the labor market situation. Labor market integration theories distinguish two levels of factors: macro and micro. Micro-individual factors will be dealt with in the following section. The macrostructural approach focuses on organizational aspects of the labor market that determine the rules of entry according to specific internal market rationales. Strictly speaking, what we are dealing with are multiple, differentiated markets rather than a single market. Hence, in a segmented labor market, the methods of integration will vary by segment, and some groups, regardless of their individual characteristics, will end up concentrated in specific segments (Portes, 1981). Arguably, therefore, there are institutional barriers to employment, at least in certain particular sectors, which in a way act as factors of exclusion of certain categories of workers, including immigrant groups. As a result, various groups of immigrants will either end up concentrated in insecure jobs (Coleman, 1994:55) or will develop strategies for integration based on the ethnic economy and form niches (Light, 1984) or even enclaves (Portes and Manning, 1986). In short, in this approach, some groups of immigrants, especially the lesser-skilled ones, are consigned to the bottom rung of the socio-occupational ladder (Castles and Kosack, 1985), mainly because of their vulnerable position on the market or institutional barriers that often involve discrimination against them.[9] This body of literature focuses on discrimination and racism that some categories of immigrants suffer, and that occur more or less across the developed world (for the United States: Poston, 1994; for Canada: Richmond, 1992; for France: Tribalat, 1996; for Western Europe: Castles, 1993). Authors such as John Wrench and John Solomos (1993:4) are in no doubt that immigration and racism are becoming critical issues for many European countries.

The third and final contextual factor affecting integration is linked with community and ethnic support structures (Musterd and Murie, 2001). Most immigrants move to societies in which there is already an established community, prompting a number of authors to argue for a strong family and ethnic network influence on integration. In many countries, massive immigration has resulted in the formation of strong ethnic identities (Featherstone, 1990; Gungwu, 1997:15). Networks operate at all levels: they are involved in the search for jobs and housing, as well as the organization of cultural and religious activities. Two types of integration have been particularly studied in connection with community networks: ethnic enclave labor markets and residential concentration. Although the ethnic factor is important in both cases, its impact remains moot. Does it facilitate integration, or does it rather contribute to the formation of ethnic ghettos? The same question has been asked about the influence of Islam in Europe (Coleman, 1994:67–69). In the case of North America, the ethnic diversity that has resulted from immigration is seen as an asset for society and plays a major role in the redefinition of national identities (Piché, 2002).

V. MICRO-INDIVIDUAL FACTORS

Contextual factors may be important in accounting for differential modes of integration between various groups of immigrants, but they do not explain all the inter- and intragroup differences. Intergroup differences may also be connected with the characteristics of the individuals that make up the different migration flows. A number of individual factors have been identified as potentially influencing the process of integration: length of residence, period of arrival, age at entry, language skills, education, sex, and immigration status (admission class and type of migration). If integration is seen as a long-term process (Bastenier and Dassetto, 1995), time variables such as length of residence and

[9] In this approach, immigrant populations are often seen as cheap labor (Burawoy, 1976).

period of arrival are key factors (Goldlust and Richmond, 1974; Tribalat, 1996). As economic integration is also the key to social integration, human capital variables will also be central factors: immigrants who are young and educated and who know the official language(s) find integration easier. Finally, migrant status plays a major part in the integration process: (1) illegal (undocumented) immigrants have many more problems integrating than do migrants entering through official categories; (2) among selected immigrants, refugees have more difficulties than do other categories of immigrants; and (3) among the refugee groups, refugee claimants are the most disadvantaged.

Research into the individual factors of integration is mostly based on cross-sectional data, mainly from censuses and, more occasionally, immigrant surveys. These studies usually establish comparisons between immigrant and native-born populations, with a strong emphasis on economic aspects. Income gaps between the two groups show generally that immigrants are on arrival disadvantaged in comparison to the native-born population. There is however a time-related rising trend in immigrant incomes after a period of adjustment to the new environment, which enables them to optimize their skills. American and Canadian research suggests that immigrants quite quickly rise up to the average income levels of the native-born population, except for recently arrived cohorts (Chiswick, 1986; Lalonde and Topel, 1992; Bloom *et al.*, 1994; Beaujot, 1997). Furthermore, between-group variations can be observed in immigrants' probability of economic success. In the United States, a social and economic hierarchy of immigrant groups by region of origin can be observed, with immigrants of European origin at the top of the hierarchy and non-Europeans—especially Latin Americans (Poston, 1994), recent Third World immigrants (Lalonde and Topel, 1991, 1992), and more specifically Mexicans (Chiswick, 1978) at the bottom. The same trend is found in Canada (Bloom *et al.*, 1994). In continental Europe, the use of ethnic categories is more problematic than in America or England, especially so in France (Simon, 1998). Nevertheless, recent surveys in France also show the existence of ethnic stratification (Tribalat, 1996).

These studies on the process of differential integration by national or ethnic origin have been considerably enriched by recently conducted longitudinal surveys. Three such surveys merit particular mention. The first is the establishment of new immigrants (ENI) survey carried out in Montreal, Quebec (Canada). This is a longitudinal 10-year follow-up survey of a sample cohort of newly arrived immigrants in Montreal in 1989. The study confirmed that the individual characteristics mentioned above were important for economic integration (measured by access to first job and income): age at entry, sex, migrant status, and language skills are all discriminant factors. But more importantly, even after all these factors are taken into account in multivariate analyses, national origin remains a significant factor in integration, suggesting that some form of discrimination is operating (Piché *et al.*, 2002a,b).

After 10 years, however, between-group income and employment status differentials have disappeared (Renaud, Piché and Godin, 2003). Three possible explanations may be advanced for this finding. First, the only way these groups of immigrants can counteract stigma and job mismatching entailed by initial discrimination is by developing "reskilling" strategies. What this amounts to is a strategy of overcompensation (these groups must do more to achieve the same results as the native-born population): this may account for the disappearance of differentials after 10 years. A second alternative explanation is that recruitment practices in Quebec may be very different from those found in some immigrants' countries of origin. The organizational culture, which includes interview practices, comes readily to mind. Over time, immigrant groups learn the host country's specific labor market culture, thereby experiencing a labor market socialization process. Hence, the idea of differentiated social capital on entry may offer insights into differential processes of economic integration. The third and final hypothesis is that host societies, especially employers, have changed in the past 10 years, becoming as it were more receptive and less exclusionary or discriminatory. The implementation of charters of rights, the demands and lobbying of immigrant groups, and the setting up of equal opportunity programs may have had a significant effect on discriminatory practices. Taken to the extreme, this third hypothesis would mean that job segregation would to all intents and purposes have vanished, which appears unlikely. Obviously, these are not either/or conjectures, and the three mechanisms may have operated simultaneously and in conjunction with one another.

A second example is provided by the National Institute for Statistics and Economic Studies (INSEE)'s Permanent Demographic Sample, from which a subsample of respondents, aged between 4 and 18 years in 1975, were followed-up in France from 1975–1990 (Héran, 1998). The multivariate analyses of unemployment-related factors for men and women aged 25 to 33 years in this population also show the importance of national origin for certain groups, especially young people from the Maghreb, who are significantly disadvantaged on the job market (Richard, 2000). The study concluded that "the likelihood is that some firms practice discriminatory policies towards young people of foreign origin, especially Muslims and those from the Maghreb" (Richard, 2000:72–73).

A third and final example is the joint INED/INSEE "geographical mobility and social integration survey"[10] carried out in France in 1992. This was another longitudinal survey, this time on three samples: immigrants, children of immigrants born in France, and a control population representative of the French population (Dayan *et al*., 1997:115). The findings on the role of national origin concur with those of the Quebec study: (1) human capital factors—especially age at entry, year of entry, educational level, and French language skills—have significant effects on economic integration; (2) sex is also significant, with female immigrants having more difficulties on the labor market than do males, particularly because of domestic responsibilities; and (3) the net effect of national origin (i.e., after control of other factors) is still significant, with a negative effect for immigrants of both sexes from Algeria, Turkey, Asia, and sub-saharan Africa, whereas no discernible disadvantage was found compared with the control population for male immigrants from Portugal and Spain (Dayan *et al*., 1997:123–131).

What explanations can be advanced for ethnic stratification found in all developed countries? First, recent research has discarded the idea of race or ethnic group as essential categories that brand certain groups as having innate characteristics that make them less fitted to the labor market (Zuberi, 2001). Also, differential integration cannot be attributed to human capital factors only, because even after controlling for these factors, some groups of immigrants still have greater difficulty than do the native-born population or other groups of immigrants in finding and keeping a job. Three possible explanations may be suggested. First, some immigrant groups may have more difficulty negotiating and securing the recognition of skills acquired in their country of origin (Borjas, 1994). Indirect discrimination would arguably be at play here, with training undergone in some countries being wrongly and unjustifiably undervalued. Second, access to ethnic networks may vary widely by immigrant group, which may explain the greater difficulty experienced by certain groups (Poston, 1994). Finally, differential labor market access by national origin may result from direct discrimination. This seems to be the most popular conclusion given countless references to discrimination in the literature on immigration (Richmond, 1992; Coleman, 1994; Wrench and Solomos, 1993; Richard, 2000).

[10] *"Mobilité géographique et insertion sociale."*

CONCLUSION

What is clear from this review of factors is that integration is a multidimensional process, and it is pointless to oppose macrostructural and micro-individual factors or economic and ethnic factors. Recent research shows that a multiplicity of factors are involved in the integration process and that they vary over time. Furthermore, this research also tends to suggest that integration processes in developed countries are sufficiently similar to warrant more comparative studies (Lloyd, 1993). The typically individualist tradition (United States, Canada, Australia) would benefit from being more greatly informed by the more historical and macrostructural European perspectives, and vice versa.

Various shortcomings in the research on integration need to be addressed in the planning of future research. First, the concept of integration itself raises problems of definition and measurement that are too infrequently ignored. Yet it is very difficult to lay down benchmark criteria of *successful* integration by which to measure the degree of integration, so that what is considered as an indicator of integration by some is not by others. Arguably, the measure of integration is always normative: the benchmark is usually set by reference to the control group, which is either the native-born population or the whole population (national norm). But, as was stated at the beginning, there is no consensus on the norm that should hold for cultural and social dimensions. In the economic sphere, by contrast, there is a consensus on the need for immigrant groups to have the same employment opportunities as those of the general population.

The second conclusion relates to methodology. The research data are drawn from censuses and mainly quantitative surveys. These are basically cross-sectional data and, as such, are unsuited to the study of an essentially longitudinal phenomenon. Simply put, the problem stems from the fact that integration is a process whereas the indicators are derived from cross-sectional data. Longitudinal studies such as those carried out in Canada and France are really the path of the future. Event history-type retrospective surveys and methodologies make this type of survey very useful if not essential.

Third, data collection methods remain highly divided. In particular, there is a sharp division between the quantitative and qualitative approaches. Arguably, this separation is futile, and what is required is more multimethod research. Also, there is too little multidimensional research on the factors of integration. The focus is too often on a very limited set of factors taken in isolation. Where multiple factors are considered, the net effects, or the relative weights of the factors, are rarely assessed.

Finally, the selectivity bias inherent in any study of integration cannot be underrated. The immigrant samples studied are affected by two types of selectivity. The first—selective immigration—stems from the selection criteria used. Here, the categories of immigration are in effect *synthetic* variables that are closely related to the modes of integration, more specifically on the labor market. Any comparative study must therefore always take into account (factor out) the sample composition by admission categories. The second type of selectivity—selective emigration—is more significant. It is a known fact that a significant percentage of immigrants—with wide intergroup variations—leave the host country sometime after entry. What is being studied, therefore, are immigrants who have *stayed*, or are still there at the time of census or survey. The fact that several factors of emigration are directly linked to the factors of integration may seriously contaminate the results based purely on immigrants who have stayed. If those that have most difficulties integrating have left, then studying those who remain will skew the results upward (overestimating success). The opposite may also happen (the most highly skilled leave, skewing the results downward). Furthermore, the direction of the biases may vary between periods. Only a longitudinal approach would, in theory at least, check this bias. But there is a risk of attrition and, hence a risk of bias, even there. Future research should make more allowance for these biases in interpreting the results.

CHAPTER

85

Economic Growth and Population Growth

ARNAUD DELLIS AND PIERRE PESTIEAU

University of Hawaii, Manoa, Hawaii, United States

Université de Liège, Liège, Belgium, and CORE, Université catholique de Louvain, Louvain-la-Neuve, Belgium

INTRODUCTION

The purpose of this chapter is to explore the hypothesis of an influence of population on productivity and technological progress. The recent past has seen the various indicators of productivity and technological progress follow an uncertain evolution. Most recently, a convergent trend to a decline in productivity has been detected in many industrial countries. What does this evolution owe to demographic factors? Ready-made answers to these questions exist. For some, there is an unavoidable connection between falling productivity and an aging population; for others, a smaller work force necessarily implies higher productivity.

We attempt to provide an economist's answer to these questions, based on rigorous reasoning and confirmed by factual evidence. Anticipating on what follows, it will appear that the empirical relationships among population, productivity, and technology—however those three terms are defined—are both tenuous and ambiguous in the present period. Consequently, it would be misplaced, supposing it were possible, to adopt an active population policy with the aim of modifying the current evolution of productivity and technological progress. It would be more efficient to use other instruments that are more certain in their effect.

The theoretical relationship between population and production has been the subject of extensive discussion ever since Malthus and has recently received fresh attention in certain formulations of the theory of endogenous growth. The strength of this theory lies in incorporating the dynamic and interactive dimension of this relationship; its weakness in being too often at variance with empirical evidence and in producing disparate conclusions that depend closely on the initial assumptions.

Our purpose in this chapter is not to present a comprehensive synthesis of the theoretical and empirical works devoted to the influence of population on economic growth but to give a selective presentation of a small number of works and new estimates.

I. POPULAR WISDOM AND SCIENTIFIC UNCERTAINTY

Economics is often compared to medicine. Both can be understood at several levels, most specifically those of the man in the street and of the specialist. Imagine your child comes home from school with a cold. Even before you do anything about treating it, you start looking for the cause, hesitating little between considering a draft and the classmate with a cold. If you ask your family doctor (and *a fortiori* a specialist), he or she will be more concerned about treating the young patient than explaining the origin of the problem. And any answer that is given will be hedged with qualifications.

The same duality, the same contrast between the assurance of the man in the street and the hesitancy of the specialist, is found in economics. Ask an economist for his view about the influence of population growth on productivity, and the answer will be anything but simple and precise. The economist will explain that the question is badly formulated or that it is meaningless. Or the economist will suggest that the terms be reversed, acknowledging that variations in productivity perhaps have an influence on fertility and family structure. The economist may ask if you are interested in the levels of population and production or in their rates of growth. And when your question does receive an answer, chances are that it will take the form of some 20 pages of qualified and careful arguments. It is in this spirit that the present chapter is written.

Popular wisdom, however, does not trouble with these intellectual precautions. It opts without hesitation for a clear and unequivocal answer. Yet at this level there is no single answer. Two in particular are encountered, which we will refer to as Ricardo-Malthusian and Boserupian. It can be noted that both are usually presented in a dramatic context, that of an aging and declining population or, conversely, that of an uncontrolled population explosion.

The Ricardo-Malthusian thesis (see Malthus, 1803; Dupâquier, 1980; Fauve-Chamoux, 1984), for which precursors can be found in the work of Giovanni Botero and of David Hume, is based on two fundamental principles: diminishing returns and the pressure of population on the means of subsistence. It leads to one recommendation: zero growth. We can summarize this thesis by using a diagram (Fig. 85–1). If the means of subsistence in a country are sufficient, the population will tend to grow faster than these means. According to Malthus, the means of subsistence increase at an arithmetic rate, and population increases at a geometric rate. The results are (1) a reduction in the subsistence goods available for each person, causing prices to rise; and (2) an expansion of the active population with a decrease in wages. This takes us to the threshold of subsistence. This is the Malthusian trap.

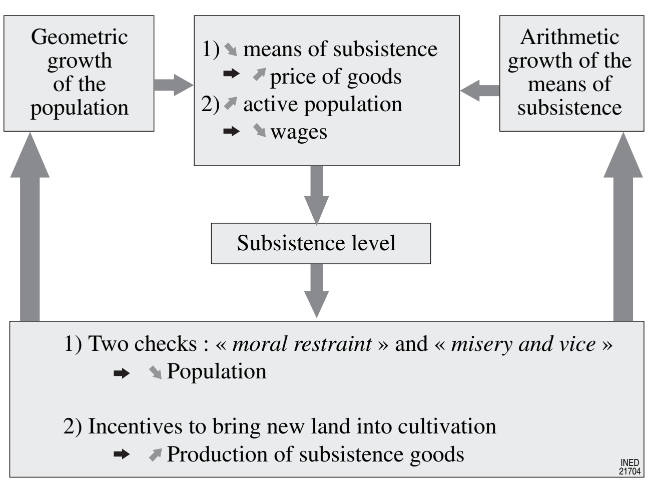

FIGURE 85–1 Illustration of the Ricardo-Malthusian thesis.

At this stage of the process, two types of check to population growth come into operation:

Moral restraint (or the preventive check)—in the form of delayed marriage, which causes fertility to fall;
Misery and vice (or the positive check)—in the form of wars, epidemics, etc., which cause mortality to rise.

The combined effect of these two phenomena is a reduction in population.

In contrast, the higher price of subsistence goods plus the fall in wages is an incentive for farmers to bring new land into cultivation. The resulting rise in the output of the means of subsistence, combined with the decline in population, means that we cross back over the threshold of subsistence, and the Malthusian cycle begins again.

The main criticism of the Malthusian theory formulated by the Boserupian theory concerns the assumption that technological progress is exogenous. More fundamentally, these two theories differ in their approach to the causality of the relationship. For Malthus, the means of subsistence is the key variable in the process of population regulation. For Boserup, population, by exerting a pressure on the economy, is the engine of growth.

The Boserupian thesis—which is also sometimes described as populationist—argues forcefully that a population that is declining, and hence aging, creates a mentality, a value system, and a social balance that are unfavorable to growth and technological progress. Conversely, a population that is growing and young is a guarantee of social and economic dynamism. The symbolism of this thesis is obvious. The idea is simple and powerful and has been incorporated into the programs of politicians sympathetic to this view. It has also found many supporters among the most famous names of economics: Stein Hansen, John Maynard Keynes, Colin Clark, and Simon Kuznets, for example.

The theory rests on several arguments that, although intuitively attractive, often turn out to be unsatisfactory when applied to the developed countries.

Simon Kuznets (1960) and Julian Simon (1981) have developed an argument that holds that the larger the population the greater the likelihood of it containing a genius who will make a major discovery.[1] The difficulty comes from the fact that this argument is not empirically verified. How could we explain that levels of economic growth and innovation are far higher in countries such as Luxembourg or Germany compared with very populated countries of Asia or Africa? Correlating large numbers of major discoveries,[2] as recorded by historians of science, with population size in ancient Greece and Rome is not really a convincing method of proof (Simon, 1981).

Creative pressure: the pressure exerted by population growth is a stimulus to improve production techniques and innovation. This thesis was keenly defended by Eugène Dupreel (1928). A few decades later, Alfred Sauvy (1966, 1979) noted that "*La pression démographique fait jaillir le progrès*" ("Population pressure brings forth progress").

A third type of argument, presented notably by Esther Boserup (1981, 1992), who drew her inspiration from the history of agriculture and urbanization, rests on the hypothesis that certain technological innovations require a critical mass.[3]

Finally, there is an argument whereby a rise in the relative price of capital, after an increase in the active population, could induce capital-augmenting technical changes. But it can equally be observed that in the case of a fall in population, wages will increase, and as a consequence, we would expect to see labor-augmenting technical changes (Arthur, 1989).[4]

II. SOME DEFINITIONS

The debate over the relations among population, productivity, and technology often suffers from ambiguities and misunderstandings that are easily avoided if care is taken over definition of the terms. Let us begin with the demographic component. The expression "population trends" can denote a variety of phenomena. First and foremost, it includes the population's size and rate of growth, two different concepts. There are also the variations of demographic structure, including the ratio between the economically active and nonactive populations and, within the active population, the age structure of the labor force for we know that the population size varies much more slowly and less extensively than does its structure (Coale, 1986). Many countries have thus experienced a net growth in their active population although their total population was stagnating.

The expression "demographic variable" is often applied to phenomena that are more cultural and sociological in nature: the growing labor force participation of women, urbanization, new modes of family life. In general, these phenomena—sometimes incorrectly described as sociodemographic—have a much greater incidence than do population growth and structure on economic growth and technology. We will not discuss this here (see Volumes I and II devoted to the determinants of fertility, mortality, and migration). In addition, through the next section we will consider only variations in the size of the population.

Similar ambiguities are found in the economic component. How many times, for example, is technological progress confused with productivity? In the terms proposed by André Vincent (1968:1), "productivity is the ratio between an output and the factors of production with which it was obtained, or indeed between an output and some of the factors with which it was obtained."

If only one factor is considered, this is partial productivity. A common approach is to divide the volume of output by the amount of labor used; this gives the partial (or average) productivity of labor, a concept widely employed in the works discussed here. There are several problems associated with this concept. First, if population is taken as an indicator of labor, labor productivity and average income are one and the same although their economic significance is completely distinct. Average income is an aim of economic policy, a measurement of its performance; labor productivity, in contrast, is held to represent the state of technology. Furthermore, any variation in the partial productivity of labor may well reflect interaction effects with the other factors as much as the specific action of the labor factor.

In any analysis of productivity, therefore, we need to consider simultaneously all the factors employed to establish a diagnosis of the behavior of the national economy. By proceeding thus, we obtain an indicator of total factor productivity. In a sense this indicator could be taken to reflect the state of technology and its variation, the rate of technical change. Technological progress is usually associated with the introduction and application of new production procedures that

[1] For example, Simon Kuznets (1960:328) writes: "Population growth . . . would, therefore, produce an absolutely larger number of geniuses."

[2] On this point, it can be noted that it is not so much discoveries as their technological applications which interest us here.

[3] See also John Maynard Keynes (1937) and William Reddaway (1939), who stress the importance of demand and investment in technological innovation and see a direct relationship between population and demand.

[4] On the Ricardo-Malthusian and Boserupian theses, see also Ahlburg (1987), Blanchet (1990), Cigno(1984), Hansen (1994), Keyfitz (1996), Kuznets (1973), Lee (1986, 1992), and Srinivasan (1988).

enable existing factors of production to produce more. It can be noted that the equivalence of technological progress and variation in total productivity only holds if the technology is always used efficiently. If this is not the case—in other words, if for any given level of technology, it is possible to produce more by making more efficient use of the factors of production—we speak of technical inefficiency. It can then be shown that the variation in total factor productivity can be categorized into two terms: technical progress and gains in technical efficiency.

In many respects, the populationist arguments based on the idea of population pressure have much more to do with technical efficiency than with technical progress. The correlation between discovery and technological advance, on the one hand, and population growth, on the other, appears doubtful as a universal law, even if it has been empirically verified in certain countries and at certain periods. However, it is plausible to think that population growth and its corollary, the relative scarcity of the other factors of production, will cause a society to use its resources more efficiently, to avoid any kind of waste, and, in short, to move closer to the efficiency frontier.

Thus, it appears that the gap between labor productivity and technical progress can be both conceptually and empirically very wide. It follows that the effect of population changes on one or other of these variables could be quite different. As an example, let us accept the idea of a positive correlation between population growth and technical progress. For population growth also to have a positive effect on labor productivity, we need to be certain that the technical efficiency and the amounts of the other factors can be held constant.

At the empirical level, it has to be admitted that it is relatively straightforward to calculate the partial productivity of labor. The difficulty lies in measuring the labor force that diverges from the total population as a function of age structure, male and female participation rates, retirement and schooling, and the length of the working week—multiple variables that vary greatly across time and space. In contrast, measuring technical progress is an impossible undertaking. The closest approximation that can be achieved is the total factor productivity, estimation of which requires many assumptions. It may be added that measuring technical progress by the amount of investment in research and development or by an enumeration of major inventions or patents is even more questionable. Clear, then, is that the concept of technical progress, at least at the macroeconomic level, remains a black box into which economists hesitate, more than others, before plunging.

III. EMPIRICAL STUDY

In the most aggregated models, production involves only two commodities: one that is produced and can be used either for consumption or for investment; the other figures only as a factor of production and represents labor. The transformation of the inputs, capital *(K)* and labor *(L)* into output *(Y)* can be represented by a *production function* such as

$$Y_t = F(K_t, L_t, t)$$

where t denotes the period considered. This function reflects the presence of technological constraints and depends on the experience and knowledge prevailing at the time. It varies between periods; hence the inclusion of t in the function. A simple form of production function is the Cobb-Douglas function, which is written

$$Y_t = K_t^{\alpha} L_t^{1-\alpha} e^{\gamma t}$$

where α stands for the share of national product going to capital and γ denotes the rate of technical progress.[5] We can also write $y_t = k_t^{\alpha} e^{\gamma t}$, where $y = Y/L$ and $k = K/L$. Suppose that the rate of technical progress is a function of n, the rate of growth of labor, which in the present case is equated with the population. We write

$$\hat{y}_t = \alpha(\hat{K}_t - n_t) + \gamma \qquad (1)$$

where $\hat{y}_t$ is the rate of growth of average labor productivity and $\hat{K}_t$ is the rate of growth of the capital stock. What impact does the rate of population growth have on the growth of productivity? Deriving $\hat{y}_t$ relative to n_t, we obtain

$$\frac{d\hat{y}_t}{dn_t} = -\alpha + \frac{\partial \gamma}{\partial n_t}$$

Put differently, for population growth not to depress the growth of productivity, an effect generated by diminishing returns, it will have to influence significantly technical progress.

Empirical studies of the relationship between population growth and economic growth are numerous. For a long time, no conclusion could be reached one

[5] We can illustrate the distinction between technical progress and efficiency gains by rewriting this function:

$$Y_t = K_t^{\alpha} L_t^{1-\alpha} e^{\gamma t} E_t$$

where E denotes the rate of efficiency (between zero and one). Differentiating, we obtain

$$\hat{y}_t = \alpha \hat{k}_t + \gamma + \hat{E}_t$$

In other words, the growth in income per head depends on growth in capital per head, technical progress and the variation in technical efficiency ($\hat{E}_t$). Naturally, where this efficiency does not vary $\hat{E}_t = 0$.

way or the other. In the past decade, an increasing number of authors seem to obtain a significant negative relationship.

Didier Blanchet (1996), James Brander and Steve Dowrick (1994), and Allen Kelley and Robert Schmidt (1994) represent this new type of research, which has access to more complete retrospective data and more sophisticated statistical techniques compared with earlier studies (see also Kormendi and Meguire, 1985; Barro, 1989; Ehrlich and Lui, 1991; Yip and Zhang, 1996). It should also be noted that recent years have been marked by new attempts to model the interaction between fertility and economic growth in a context of endogenous growth. The majority of these models usually end up with a negative relationship between fertility rate and economic growth rate. Rather than produce a synthesis of these recent works, we preferred to conduct our own verification of this new and relatively recent consensus. We decided to verify the relationship by using two approaches: a cross-sectional approach and a time-series approach.

In the cross-sectional approach, we used the data compiled by Robert Summers and Alan Heston (1991), known as the Penn World Tables (for a description of the different version of the tables, see Summers and Heston, 1991). These authors formed an economic and demographic data set covering the period 1950–1990. We divided these 40 years into seven subperiods of 10 years with 5-year overlaps. The results of estimating the simple model $\hat{y} = a + bn$ (where $\hat{y}$ is the rate of growth of real gross national product per person, n the rate of population growth, and a and b the parameters to be estimated) are given in Table 85–1. They show a negative relationship between these two variables.

Ideally, this relationship would be tested over a long period, not only 40 years. This is what we do in the time-series approach. Here we used the data compiled by Angus Maddison (1995). These cover 56 countries over a period from 1870–1994. This 124-year period has been divided into subperiods of 15 years, with 5-year overlaps. Three cases are studied:

One in which all the data are used as if we were dealing with a single entity.
One in which the constant a is country specific. In this way the national particularities are taken into account.
One in which the constant a is specific to each period, which captures the temporal differences.

The regression results are presented in Table 85–2. As in the cross-sectional approach, we obtain a negative relationship that is significant except when the constant is country specific. In the latter case, the time-series approach produces a weaker association between population growth and economic growth than does the cross-sectional approach; in the latter, parameter b, which measures the relationship, is almost always over one-half in absolute terms, whereas it is always below this value in the time-series approach.

Tables 85–3 and 85–4 present the correlation coefficients by country and by period. A difference is observed depending on the group of countries. For most of the "industrialized" and African countries, the relationship is negative; in contrast the majority of the countries of Asia and eastern Europe present a positive correlation. Regarding the evolution of the relationship over time, a stable negative correlation does not emerge until the second half of the 20th century.

IV. THE GROWTH THEORY PERSPECTIVE

Traditional growth theory (see Barro and Sala-I-Martin, 1995) devotes little attention to the demographic dimension nor *a fortiori* to its links with

TABLE 85–1 Estimation of the Simple Model (Cross-Sectional Approach)

Period	No. of observations	Constant (a)	Population growth (b)	R squared
1950–1960	60	3.78 (0.4785)[a]	–0.6576 (0.2058)[a]	0.1497
1955–1965	74	4.196 (0.4858)[a]	–0.6140 (0.1976)[a]	0.1182
1960–1970	125	4.1687 (0.5102)[a]	–0.5190 (0.2163)[b]	0.0447
1965–1975	126	3.7052 (0.479)[a]	–0.3942 (0.2119)[c]	0.0272
1970–1980	133	3.7928 (0.4581)[a]	–0.6549 (0.1911)[a]	0.0823
1975–1985	134	2.8058 (0.4386)[a]	–0.7987 (0.1784)[a]	0.1318

productivity and technical progress. Both population growth and the rate of technical progress are treated as exogenous. In the long run, growth in labor productivity or in average income depends solely on the rate of technical progress. From Eq. 1 above, in equilibrium, we get

$$\hat{y} = \gamma/(1 - \alpha) \tag{2}$$

where, it will be remembered, $\hat{y} = \hat{Y} - n$ is the difference between the rate of growth of national output and the rate of population growth, γ is the rate of technical progress, and $(1 - \alpha)$ is the share of national income accruing to labor.

A rise in population growth will have no effect on the growth of productivity; however, it depresses the level of productivity. Because increasing returns are excluded from this analysis, the effects of scale that population growth brings about, according to Colin Clark (1978), cannot occur. Julian Simon (1986) and Julian Simon and Gunter Steinmann (1992) have

developed the concept of induced technological progress, a concept first introduced by Kenneth Arrow (1962). Technological progress is viewed here as a cause and as a consequence of growth. Population growth would have a positive feedback effect on scientific knowledge, leading to an acceleration of growth and progress. With this hypothesis, we rewrite Eq. 2:

$$\hat{y}(n) = \gamma(n)/(1 - \alpha) \tag{2'}$$

Most of the works that have attempted to formalize the influence of population on productivity and economic growth consider the situation before long-term equilibrium and often resort to simulation techniques (see Steinmann and Komlos, 1988). It has to be confessed that the conclusions they produce usually follow from the initial assumptions about the relations between population and technology, which need to be checked for empirical validity.

In an empirical perspective, a whole series of works have attempted to quantify the role of particular factors in economic growth. Working with the production function used above, the exercise would start with the following equation:

$$\hat{Y} = \gamma + \alpha\hat{K} + (1 - \alpha)n \tag{3}$$

In this equation the growth of output thus appears as the sum of the contributions of technical progress, capital, and labor. Authors such as Edward Denison (1967) and Jean-Jacques Carré *et al.* (1972) have attempted to disaggregate the contribution of each factor. Thus, for population they distinguish its size, time spent working, educational level, activity rates, and the age–sex structure of the population.

Inclusion of age and sex reflects the hypothesis that productivity varies with these two characteristics and, more specifically, that young and old workers are less productive than are those in their middle years and that female workers have lower productivity than do male workers. In the case of France, the inclusion of age caused the index of labor quality to rise by 2% between 1949 and 1962; at the same time, the inclusion of a sex variable has a negligible effect. Overall, the contribution of the age and sex variables to growth in the various Organization for Economic Cooperation and Development countries is tiny. The contributions of capital and above all of technical progress predominate clearly.

These works are based on the paradigm of what is known today as exogenous growth, the rate of which is determined by the growth—quantitative but also perhaps qualitative—of the population. Two decades ago a new paradigm emerged, that of endogenous growth, under which the rate at which the economy grows can be influenced by the savings ratio, investment in education, or the size of the population.

This paradigm is founded on recognition of increasing returns to scale and of a technological externality. Whether for physical or human capital, economic agents fail to see that not only their own investments but the sum of all investments influence output. Hence they underestimate the real return of their actions, which makes necessary intervention by the public authorities.

In the original version developed by Paul Romer (1986), endogenous growth depends on population size, which can be seen as reflecting the scale of the economy.

Let there be a Cobb-Douglas production function:

$$Y_t = A_t K_t^{\alpha} L_t^{1-\alpha}$$

where A_t is a technology function that depends on the capital stock $K_t = \sum K_t^i$, where K_t^i is the stock accumulated by agent i at period t. Each agent thinks that the return on his investment is $\dfrac{\partial Y}{\partial K_t^i} = \alpha A_t K_t^{\alpha-1} L_t^{1-\alpha}$ whereas in reality if $A_t = K_t^{1-\alpha}$, its real return is $\alpha L_t^{1-\alpha}$. If the rate of savings, s, is fixed in this economy, we write the following:

$$\hat{K}_t = s(1 - \alpha)L_t^{1-\alpha}$$

Thus, we see that both the rate of growth of the economy and the social return to capital depend on population size. Naturally this is an elementary version of an endogenous growth model. Yet it illustrates well the main message of this new paradigm: the rate of economic growth does not depend on population growth alone.

The problem with endogenous growth is that its message depends on assumptions made about technology and externalities. Depending on these assumptions, the relationship between the rate of economic growth and the size of the population, its rate of growth, and even the population structure can vary in opposite directions.

An interesting line of research is the one that combines the endogeneity of fertility specific to the new home economics inspired by the work of Becker, with the technological externality of the endogenous growth models. Two articles provided the initial impetus for this research (Barro and Becker, 1989; Becker *et al.*, 1990; see also Challier and Michel, 1996; Ehrlich and Lui, 1997); it has been validated by several empirical studies (Rosenzweig, 1990; Barro, 1991). These authors work from the idea that agents choose both the number of their children and the level of skills—known as the level of human capital—they wish to give them. Based on the choice—one might even say the trade-off—between these two variables that the authors describe as the quantity and quality of children, we can identify two stable equilibria for the economy: one has high fertility but low levels of human capital and economic growth, the other has low fertility but high levels of human capital and economic growth.

This theory of endogenous fertility sheds fresh light on the negative relationship that we obtained in the previous section.

V. DEMOGRAPHIC STRUCTURE AND PRODUCTIVITY

So far, emphasis has been placed on population increase or decrease without considering the question of age structure. Yet as the most pessimistic projections indicate, it is going to take time for the populations of the industrialized countries to fall significantly, whereas soon we will be witnessing radical changes in their age distributions. Changes in age structure can influence productivity in two ways. First, it is observed that profiles of activity and of productivity vary with age and that, in addition to the age effect, there is a double cohort effect: a size effect (the productivity of a cohort is a function of its size) and a technical change effect (the training of young people incorporates technical progress). Second, at any given date the contents of the basket of goods and services differ sharply when different age groups are considered. This difference influences the productivity of the economy considered in the aggregate.

1. Age and Productivity

Are the efficiency and productivity of labor differentiated by age? An affirmative answer would mean that as regards productivity, for an active population constant over time, some demographic structures are more favorable than are others. We immediately come against the question of how to measure individual productivity. Because the productivity of labor cannot be observed directly, the usual solution is to approach it through its earnings, that is, its cost. This convention amounts to accepting that wages are determined by the marginal productivity of workers. This is a questionable assumption, at least in some respects, although rejecting it is hard in the absence of an effective alternative (for a discussion of this question, see Chesnais, 1978).

Age-earning profiles have an asymmetric hump shape that varies with sex, type of employment, educational level, sector of activity, size, and nature of the firm. Incomes rise up to a certain age more or less close to retirement and then level off and fall back slowly.

It should be noted that what we usually observe are cross-sectional profiles and not the evolution of wages over the life cycle of a cohort. Thus, there is an age effect and a cohort effect, with the latter being a function of technical progress and of cohort size. A younger cohort will tend to have a higher productivity and hence a higher wage at a given age. But in addition to this technological factor, it would seem that both the level and the form of the age-earnings profile are a function of cohort size. A large cohort, such as that of the baby boom, would have a lower wage level and a less steeply rising profile than would a small cohort placed in the same circumstances. This hypothesis has been shown to be correct for many countries. In some European countries, the arrival in the labor force of large cohorts has also had the effect of raising relative unemployment levels (Lee *et al.*, 1988; Bloom *et al.*, 1987).

Thus, a change in the age structure of the economically active population, in the sense of aging, for example, will have contrasting effects on the average productivity of labor. We make the assumption of a constant active population whose membership is subject to aging. The age effect should lead to a productivity increase owing to the relative decline in the number of young workers and the concomitant increase in the proportion of older workers. The size effect mentioned above should also have an incidence of this kind, the young workers present in smaller numbers having a higher productivity. However, the "technical progress" effect should imply a decrease in productivity. There will be relatively fewer young people with technical skills that are more advanced than those of their elders.

Paul Levine and Olivia Mitchell (1988) have attempted to evaluate the influence that the American baby boom can be expected to have in 2020, when old workers will belong to this cohort and when young workers will be relatively few in number. Their conclusion is of a generalized increase in wages, particularly for the young workers. In a long-term simulation on the Netherlands, Evert van Imhoff (1988) highlights the crucial importance of the relative number of young workers whose skills encompass the most advanced technology. He assumes that it is more expensive and harder for the older workers to acquire equivalent skills. For this reason, the growth and productivity of the Dutch economy are extremely sensitive to population variations.

2. Age and Consumption

A distinction must be made between the level and structure of consumption. The theory of the life cycle assumes that individuals save while they are economically active to fund their consumption in old age. Two phases can be identified—that of saving, which concerns the period of activity; and that of dis-saving, which covers the period of retirement—of varying intensity depending on whether or not the individual in question leaves accumulated assets at death. This produces a typical age-specific assets profile that rises and then falls. At the macroeconomic level, the older the population, the lower the savings ratio. In the short-term, a strong consumption demand may be favorable to productivity, but in the medium-term, a low level of savings implies a reduction in the capital stock, which will contribute to depressing labor productivity.

An age effect also emerges clearly in the structure of consumption. The basket of goods and services at a given date is very different according to whether we consider young or retired couples. This is clear in the case of expenditure on the home and consumer durables, which is more concentrated at the beginning of the active period and is influenced by family behavior (Ermisch, 1988). The age effect is also observed in expenditure on food, leisure, and clothing, but the effect is most marked in health expenditure, which rises sharply over the life cycle.

If the emphasis is shifted from losses of expenditure to commodities in particular, we can speak of "old" commodities (e.g., televisions) and "young" commodities (e.g., motorcycles). For the present discussion, we need to know whether the basket of goods and services for elderly people incorporates a more advanced technology, a greater use of capital, than that of young households. Not much empirical work has been done on this question (see Luptacik and Schmoranz, 1980, 1986, 1989; Serow, 1984; Ekert-Jaffé, 1989). One widely held view is that elderly people have greater recourse to services than do younger people, and consequently, their basket of goods and services would imply a lower productivity. Technical progress, as measured by the growth in the total productivity of the factors of production, is known to be much lower in the service sector (zero for 1979–1983) than in manufacturing industry as a whole (1.8% per year for 1979–1983) (Englander and Mittelstädt, 1988).

Even if this idea was empirically correct for the present, it could be invalidated in the future. One of the consequences of population aging and longer life spans is the need for a gradual substitution of the traditional care services for elderly people by techniques based on smaller labor inputs.

VI. BACK TO SOCIOLOGY

The preceding sections sum up quite well the position of the majority of economists. Overall, demographic variations have no predictable influence on technical progress. They influence the partial productivity of labor to the extent that they are not accompanied by parallel changes in the other factors of production. Can nothing more be said? Are there not grounds for going beyond the economic standpoint? As is known, the strength—but also the weakness—of economic methodology lies in its scientific ambition. It aspires to rigor and universality and shuns particular and transitory considerations of a psychosociological origin.

Now if it is true that we cannot say that population growth necessarily has a positive influence on the state of technology and skills in a society, nor can we deny that such an influence has operated in some cases. Thus, to explain the rapid and sustained growth experienced by France in the period 1950–1970, some authors have invoked the recovery in the birth rate and the behavioral changes it is thought to have produced. According to Carré *et al.* (1972:252), "An attitude of narrow pessimism and economic conservatism ('malthusianism') may have given way to the desire to prepare a better future for the young people coming along; then, with the arrival of the new generations, the dynamism characteristic of the young would have spread to the rest of society. The changes on which growth depends thus came to be accepted where they had hitherto been rejected."

In their study of French economic growth published in 1972, Jean-Jacques Carré *et al.* challenge this explanation but do not actually reject it. The authors even admit that it could be of some importance. In his critique of the populationist thesis, which he judges unverifiable, Joseph Stassart (1965) acknowledges that there may be links between demographic change and a psychosociological structure of a nation, and that this linkage could provide some basis for the idea of creative pressure.

In other words, because there is no definitive theory of technical progress and because empirical studies on growth factors often conclude that for some explanations a historical and sociological analysis extending further into the past is needed, we cannot say that demographic variables never have an effect on growth and technology.

As Ron Lesthaeghe and Johan Surkyn (1988) have shown for fertility, economic factors do not explain everything; cohort effects also play an important role. Some birth cohorts are more motivated, more inventive, and more dynamic than are others. Why should this be? A desire for vengeance, an armed conflict, a political challenge, a recovery in fertility? To address these questions, we must proceed case by case, and even then, many areas of uncertainty remain. There is no better illustration of the present limitations of the social sciences, including economics.

There is another angle from which sociology can shed light on the relationship between population growth and economic growth. An aging population will tend to have a more static organization; levels of occupational mobility will be lower (Keyfitz, 1982). However, it will contain more small families, and members of smaller sibling groups are known to achieve greater educational and labor market success (Blau and Duncan, 1967). Lastly, the way in which fertility is reduced across income groups is important. An extreme case can be imagined: families experiencing chronic economic insecurity continue to have many children, whereas the middle class adopts a lower fertility. The consequences of such a change are obvious. Few studies have been conducted on this specific point (McNicoll, 1986).

Empirical works dealing with these social changes are not only rare but should be treated with caution. They are based on a period of higher population growth, and there is a possibility that social behavior, modes of family life, and the rules of social and spatial mobility become modified in an aging society.

CONCLUSION

The purpose of this chapter was to review the works dealing with the influence of population variations on economic growth. We have attempted to provide a synthesis and a critical analysis. Three lessons can be drawn.

First, there are no theoretical arguments or empirical studies that enable us to conclude unequivocally in favor of any kind of relationship between population growth and technical progress. It may be added that at present we possess no good explanatory theory of technical progress. Historians and economists are reduced to supplying interpretations and explanations on an ad hoc basis.

Next, the influence of population on productivity and, in particular, the partial productivity of labor is obvious. This is consistent with the law of diminishing returns. An aging population should experience rising productivity. This influence can, however, be countered by four factors: the variable gap between population and active population, the constraint of scarce resources, capital accumulation, and technical progress.

Lastly, the aging of a population has multiple consequences, both economic and noneconomic. These consequences can ultimately affect the culture and values of our societies. In what way and how? No one can say. By contrast, what is likely is that these mutations can have an effect on technical progress and efficiency in production. This effect is as unpredictable as the effect of aging on culture and social values.

Acknowledgments

We would like to thank Serge Feld and Sergio Perelman for their valuable suggestions. We also thank Francois Héran, Graziella Caselli, Jacques Vallin, and Guillaume Wunsch, as well as the members of the San Miniato seminar for their comments.

This chapter was translated from the French version by Godfrey I. Rogers.

Population and Development

JEAN COUSSY

Ecole des hautes etudes en sciences sociales (EHESS), Paris, France

INTRODUCTION

"Population and development" is a dated concept. Its introduction in the 1950s was inspired by the conjunction of the "discovery"[1] of underdevelopment and fears aroused by the first phase of the demographic transition. The formulation was intended to respond to the needs of emerging states and aid donors, and posed its questions in macroeconomic terms: what was the role of population growth in underdevelopment and its reproduction? Was there an optimal population for a given area of land (problem of density)? Was there an optimal rate of population growth? Did large countries have an advantage in the process of development (problem of dimension)? How does population growth increase the costs of development by requiring demographic investments and the accumulation of capital? What demoeconomic strategy should emerging nations adopt? Were international inequalities a function of differences in demographic regulation? Was economic growth a necessary condition for improvement in demographic indicators (reduction of mortality and morbidity)? Would increases in the standard of living lead to increased fertility (and a Malthusian trap) or fertility decline (and the second phase of the demographic transition)? Could international action (financial aid and information) help resolve the effects of underdevelopment and population growth?

In sum, traditional macroeconomic and macrodemographic questions were reformulated and quantified at the world level. Ideological debates and traditional politics exercised a strong influence on early research and the first statements of position.

There was a rapid re-emergence of Ricardo's classical ideas: a limited supply of land, decreasing returns to agriculture, and the increasing price of food products (wage goods) would lead to a decrease in both profits and the rate of accumulation, and eventually the halt of economic growth. The conclusions can be refined slightly by hypothesizing a phase of increasing returns preceding the phase of decreasing returns. This modification leads to a rediscovery of the concept of optimum population, the level of population that maximizes per capita production.

Ideas based on decreasing returns to agriculture were counterbalanced by a vision that was more optimistic and more favorable to agriculture. This school of thought borrowed several themes from the physiocrats: the capacity of agriculture to create a surplus, making reproduction possible; the complementarity of productive activities (illustrated by the zig-zag of François Quesnay[2]); the necessity of a boost in agricultural activity preceding the takeoff of an industrial economy (Bairoch, 1967); and the possibility that technical progress in agriculture would make it possible to avoid any obstacles imposed by food supply,

[1] In the sense used by Ignacy Sachs in *La découverte du Tiers Monde* ("The discovery of the Third World"), 1971.

[2] In the *Tableau économique* (Quesnay, 1758), a reprint of which can be found in *Quesnay et la physiocratie* (Sauvy and Hecht, 1958), among other sources.

even with a spectacular growth in world population (Klatzman, 1983).

Contemporary thinkers retained little of Malthus' highly elaborate analysis of development; his analysis of demand was notably neglected in the analyses of development of the 1950s. Instead, attention was focused on his analysis of the positive effects of increases in standard of living on birth rates and the negative effects of population growth on standards of living. The succession of these two relationships produces the Malthusian trap. The term "Malthusian" continued to denote a pessimistic vision of the effects of population growth, and it will be used in that sense in the following analysis.

In opposition to the Malthusian vision, both in scientific analysis and at the major world population conferences (notably the one in Bucharest), Marxist positions refuse to attribute poverty and underdevelopment to population growth. Instead, they argue that capitalist dynamics are at the root of these negative outcomes, as well as excesses or deficits of population themselves.[3] Countries disconnected from capitalism could use population as an instrument of development until rising standards of living led to a voluntary reduction in birth rates.

Mercantilist populationism, the quest for population growth as a means toward economic growth and power, resurfaced in numerous poor states. Though less explicitly cited than are Marxist views, this ideology was incontestably present in the outlook of many leaders. According to this perspective, all population growth was desirable, even when it lowered average revenue, because leaders hoped that it would result in an increase in the number of people available to join military forces, an opportunity for revenue from taxation, or an increase in rates of accumulation.[4]

I. THE GLOBAL ANALYSES OF THE PERIOD 1950–1960

During the years 1950–1960, the growing availability of statistics and the introduction of the first models transformed the traditional debates. The available statistics stimulated comparative studies on the growth of per capita gross domestic product (GDP).

A surprising number of tests simply demonstrated that subtracting the population growth rate from the rate of growth of the GDP led to a sharply reduced per capita GDP rate, and even occasionally a negative rate, and suggested that population growth was thus responsible for the slow pace of development. This conclusion confounded arithmetic operations with causal explanations and relied on the strong unstated hypothesis that population growth had not produced any increase in GDP.

Serious studies of the relationship between the growth rate of per capita income and the population growth rate repeatedly showed that there was no observable correlation (Chesnais and Sauvy, 1993). These findings led to doubt over the Malthusian interpretation of underdevelopment and criticism of the results of the macro models then under construction.

The authors of the first macro models worried about the influence of population growth on needs and the possibilities of accumulation. Prasanta Chandra Mahalanobis (1953–1954) using the model constructed by G. Feldman (1964) for soviet planning, Ansley Coale and Edgar Hoover (1958), Léon Tabah (1968, 1969), Hollis Chenery and Alan Strout (1966) using Roy Harrod (1939), and Elsey Domar (1957) assumed exogenous population growth, a macroeconomic production function (with complementary factors, returns on a constant scale, and no technological progress), and a Keynesian savings function.[5]

Under these hypotheses, population growth requires a proportional increase in investment if per capita capital, average income, and employment rates are to be maintained. The absence of this investment sets the stage for decreased per capita income, decreased savings rates, further decreases in investment, etc. In response to population growth, there

[3] These excesses and deficits evolve along with the different eras of capitalism. Capitalism, for instance, caused forced migrations (overpopulating the Antilles and underpopulating Africa), created Indian unemployment with the growth of the textile industry in Manchester, shifted the accumulation of capital at the world scale (Amin, 1976), and lowered the cost of reproduction of the workforce of poor countries by promoting the importation of food goods to the detriment of national producers.

[4] However, these leaders do not seem to have incorporated Alfred Sauvy's theory of the optimal demography of power. The power optimum is defined as the point at which decreasing returns lead to marginal productivity below the minimum wage rate that can be imposed on the producer. The politics of power seem to have been more complex. States probably surpassed not only the economic optimum, but also the power optimum (if only for the purpose of building military forces), even when they had the coercive means necessary to lower the wage rate (in turn occasionally reducing productivity).

[5] In postulating savings as a function of *average* per capita income, the models implicitly broke with the whole tradition of studies on accumulation, which had always been linked to inequality of income. They neglected the possibility that population growth could increase accumulation by increasing inequality (or could reduce both), that it might reduce accumulation by lowering profits (Ricardo, 1817), or that accumulation might, in a capitalist regime, require a certain level of unemployment in order to reduce salaries and increase the profits that generate accumulation (Marx, 1850–1859).

must be an increase in national savings (the solution of Feldman [1964] and Mahalanobis [1953]), a recourse to foreign aid (Chenery and Strout, 1966), a reduction of population growth (Enke, 1974), or the simultaneous application of these three methods (Tabah [1868, 1969] showed that demographic inertia rendered simple solutions implausible).

These models were first applied in simulations for national planners to measure the effects of policies to slow population growth. They were used to measure the aid needs created by population growth (which increases the gap between internal savings and investment needs). Everyone who requested aid used the models, and all of the international organizations made calculations inspired by them, which gave the models diplomatic importance and scientific credibility. They are constantly cited by partisans of population regulation and had, at one point, an ideological influence. Their structure was later integrated into more complex models, notably those of the Club of Rome (Meadows *et al.*, 1977). These latter added other Malthusian hypotheses: exhaustion of nonrenewable resources, decreasing returns to agriculture, and degradation of the environment by population.

But these models were quickly criticized for their Malthusian biases. They argued for a negative effect of population growth on per capita income at a time when, as stated earlier, no negative correlation had been demonstrated, and this conclusion was based on a very simplistic hypothesis (zero productivity of labor in case of a shortage of capital). There were attempts to improve the model by borrowing from Robert Solow's (1972) neoclassical model of growth, a macroeconomic production function with substitutable factors. With a substitutability of labor for capital, population growth no longer automatically produces unemployment and does not reduce the marginal productivity of labor to zero in case of a shortage of capital. In a market economy, development can take place via a reduction of capital intensity resulting from the reduction of salaries, international specialization, or development of the informal sector. In the case of public intervention, investments in human capital can play this role.

For seemingly minor reasons that nevertheless retain their importance today, the original version of the neoclassic model maintained its Malthusian biases: the marginal productivity of labor was assumed to be decreasing, the Keynesian savings function had been kept by Robert Solow (for circumstantial pedagogical reasons), and the neoclassic production function was used most often in its "Cobb-Douglas" form in which the sum of elasticities of production in relation to all factors is equal to one, thus implying that the elasticity of production with respect to population is less than one.

It would be hasty to conclude that no macro model has escaped Malthusian biases. Some models introduced production functions with a sum of elasticities greater than one, increasing returns to scale, and Boserup (1970) effects of stimulation of savings, investment, and productivity by demoeconomic tensions.[6] Because both positive and negative effects of population growth are added together, the results of macro models are no longer determined before the parameters are set. An interesting econometric calculation (Thirlwall, 1972) has even shown that it is possible to produce a period of equilibrium by balancing positive and negative effects. This is consistent with the period of apparent insensitivity of the rate of growth of the per capita GDP to population growth.

Despite this progress, macro models have been eclipsed owing to their narrow fit to the issues of the years 1950–1960. The media success of their Malthusian conclusions and their utilization by the Club of Rome has made them scientifically suspect (Cole *et al.*, 1974). The idea of assistance needs has been devalued by descriptions of the perverse effects of donor aid. The strategic role that development theory once assigned to accumulation has ceded its place to analyses of the progress of productivity, the importance of which appeared in the macro models, which themselves emphasized, following the theory of Edward Denison (1967), that the growth of production factors had less weight than the "third factor." Finally, as Peter Tamas Bauer (1976) has pointed out, the national scale of these models privileged collective norms, devaluing the preferences of families, and seemed superficial compared with disaggregate studies and the progress of micro analyses.

II. DISAGGREGATE ANALYSES AND STRUCTURAL STUDIES

Disaggregate studies of the demoeconomic evolution of poor countries[7] have revealed the great variation in economic and demographic parameters within countries, and the range of possible demoeconomic

[6] The Keynesian function is not Malthusian when growth is under way because the increase in revenues leads to a boost in savings. This virtuous circle is observed in Asia.

[7] This expression might be more appropriate than the expression "population and development," which has been accused of exaggerating the specificity of the problems of poor countries, ignoring periods of regression, and having political (unity of the Third World) and normative (the number of definitions of development introduced moral conditions) connotations.

dynamics. These studies divided national units into subunits that exchanged flows (of people, goods, revenue, capital, information, etc.) and carried out relationships (e.g., equalities and inequalities, complementarities, and conflicts) that sometimes had as much influence on the national demoeconomic dynamic as do national averages and aggregates.

1. Vertical Stratification by Income

Vertical stratification by income creates population dynamics that can differ from the expected effects of global variation in GDP. The persistence of high birth rates in Africa has often been attributed to the fact that only a high-income minority has changed its way of life, and that the majority of the population still lives in a setting in which increases in income have no effect or a positive effect on the number of children. However, incontestable inequalities in access to health services (public and private) have made less difference to life expectancy than some would have believed.[8] We have also seen that income distribution, rather than average income, best explains accumulation rates and the capacity to respond to the need for investment created by population growth. Family solidarities have changed with the level of inequality. The initial hostility of political leaders toward antinatalist campaigns has decreased with their growing fear of classes that are considered dangerous.

2. Regional Disparities

Regional disparities within underdeveloped countries are such that averages and national totals are often not informative. This does not necessarily mean that the strategic parameters identified by macro models are meaningless, as certain regional monographs have argued, but it does suggest that only geographic decomposition into relatively homogenous zones can produce numeric estimates that are realistic and verifiable.[9] Once these relatively homogenous regions have been identified, measures of usable land, demographic load capacity, available production factors, elasticity of food supply, growth or reduction in agricultural returns, opportunities for investment and capacities for accumulation, threats to the environment and conditions for sustainable development, the existence of an informal sector, and the proximity of family planning services and their audience, take meaning. The macro demoeconomic models described earlier may also be best tested at the regional level.

Defining homogenous regions makes it possible to identify both complementarities (comparative advantages) and conflicts (competition and fights over sharing profits). The outcome of national demoeconomic problems is primarily a function of these relationships, including internal migration, the geographic distribution of family members by age, flows of food toward populated zones, intrafamilial interregional financial transfers, and movements of capital toward previously disadvantaged zones or high-potential zones. The geographic redistribution of population and of production is an essential element in reducing demoeconomic tensions (in the case of cooperation) or reinforcing these tensions (in the case of interregional conflict). Economic policy as a function of population is thus often a policy of territory management.

3. Decomposition into Sectors

The process of decomposition into sectors (e.g., traditional and modern, with growing returns and with declining returns, rural and urban, formal and informal) was developed as part of the extension of Arthur Lewis' (1954) dual economy model. The dualist model early emphasized that the overpopulation of rural areas (defined by a marginal productivity of zero) made it possible, by internal migration, to develop a nontraditional sector toward labor with non-null productivity. The principal problem was financing, obtained either by internal taxation or from international capital (of which Arthur Lewis was one of the first to underline the abundance to come). Relations between sectors thus made it possible to loosen the constraints imposed both by Ricardian decrease in agricultural productivity and by the lack of capital described by the macro models of the 1950s. The model was enriched by the migratory models that followed, notably Todaro's (1969) model, and by increasingly detailed definitions of nonagricultural sectors as in the three-part models distinguishing urban sectors with high and low intensity of capital (Hugon, 1983).

[8] The Bariloche model even proposed life expectancy as a synthetic indicator of economic development (Herrera, 1977), but medical progress and the diffusion of information have extended life expectancy even in the absence of economic growth (Preston, 1975; Vallin, 1989, 1992).

[9] This observation is valid for both economic parameters (e.g., production factors, saving and investment rates, growth and shrinkage of returns, scarcity of the land factor, elasticity of food supply, vulnerability of the environment, presence of nonrenewable resources, pollution, level and distribution of income) and demographic parameters (fertility rates, forms of morbidity, life expectancy, mortality rates, propensity to migrate or to receive migrants). For each of these variables, regional statistics are too dispersed for their average to explain the internal dynamics of the nation.

4. Urban–Rural Relations

The conflicts and complementarities of urban–rural relations continue to inspire lively debate on their capacity to resolve the demoeconomic problems of poor countries. In abstract theories, this controversy is often expressed through an opposition between studies of flows, which emphasize complementarities, and studies of prices, which emphasize conflicts. In empirical analysis, urbanization and its consequences have been the object of urbo-pessimist descriptions: overpopulation of megalopolises; increased population growth owing to better conditions of sanitation (in contrast to the effects of urbanization in preceding centuries); degradation of the environment; exhaustion of resources in rural areas; rapid depopulation of rural areas unjustified by the ratio of urban to rural productivity; use of political power to obtain terms of exchange unfavorable to rural areas, discouraging them from food production; recourse to imports and food aid, competition with local agriculture; and the (disputed) existence of an urban bias in social policy (Lipton, 1976). Urbo-optimist descriptions, in contrast, have underlined the stimulating effects of the growth of effective demand for food products, the provision of services and of goods that stimulate agriculture, financial transfers, the growth of informal activities, the value added by urban services, etc. Analysis can only move forward if there are efforts to measure flows, prices, income levels and security, productivity, taxation, donor support, instabilities, etc., and, simultaneously, to take into account the capacity of economic fluctuations, interventions by the state, and exterior actions on incomes and internal politics (e.g., structural adjustment programs) to modify complementarities and conflicts.

5. Horizontal Stratification

Differences between families, between cultures, between religions, or between ethnic groups—sometimes called horizontal stratification—lead to differences in demoeconomic behavior. Behaviors can differ in the domains of marriage transfers, long-term investments, household structure, stability of unions, division of labor within the family, modes and rhythms of accumulation, etc. Horizontal stratification produces transfer zones, areas where financial engagements are respected, and collective procedures of accumulation that in turn create specific economic dynamics. But a nuanced comparative understanding of these dynamics and the interactions between them is often blocked by political and ideological resistance to research and to the production of differentiated statistics.

III. MICRO ANALYSES

Micro analyses of the demography of development have replaced development planners' macro investigations with observations of individual and family demoeconomic behavior in poor countries. They are oriented in two complementary but often conflicting directions: the microeconomic interpretation of demographic behavior and the social analysis of demoeconomic strategies.

The microeconomic interpretation of demographic behavior considers behavior in terms of economic rationality. These analyses examine both substantive rationality (utilitarian and materialist) and formal rationality (optimization strategies in accordance with microeconomic theory). In this interpretation, borrowed from Gary Becker (1964), population change in developing countries is a function of the costs and benefits of demographic decisions as assessed by the population and, in particular, is a function of the changes that development induces in these costs and benefits. For example, the number of births depends on parental predictions of the economic costs and returns of the marginal child; this number changes if development increases the costs of children (education, mode of living), lowers the immediate contributions to production (agricultural), or raises expected adult earnings and reduces the investment risk by increasing the life expectancy of infants and children. Analogous calculations are made for age at marriage, marriage choices, the duration of unions, the size of polygamous households, marriage payments, the amount of intergenerational transfers, the roles and status of women, the extent of networks in which gifts and counter-gifts take place, migrations to urban areas or abroad, etc. Each decision is influenced by long-standing microeconomic calculations, by changes produced by development-induced variation in economic parameters, and by the resulting feedback effects on the shape and pace of development.

This microeconomic interpretation is not only a theoretical construct. The framework is designed to be used in an applied context and to show that change has resulted from this type of calculation. Individual actors' resistance to macrolevel decisions to slow the pace of population growth was rational; conversely, couples have sometimes regulated births in countries where the state was still officially hostile to such practices.

The microeconomic framework also seeks to be predictive, arguing that the world is moving toward globalization of economic behavior and that methodological focus on the individual will be better suited to the study of poor countries as development succeeds in imposing economic rationalization of behavior.

Finally, microeconomic interpretation of behavior is normative, aiming to rehabilitate the behavior of individual actors. It is normative in its judgments on the past: unlike macro voluntarism, it claims to respect household preferences (Bauer, 1984). It is normative for the future, to the extent that it instructs planners to trust in families rather than leaders at the macrolevel to understand change. Finally, it is normative in arguing that if authorities let market signals work (leading to a rise in prices when population growth creates scarcity), households will adapt to new opportunities and new scarcities: in demography, as in economics, the market will promote the convergence of the micro optimum and the macro optimum.

Of course, these optima are Pareto optimal and do not take a position on the existing distribution or the demographic implications of this distribution. In addition, liberal conclusions must be nuanced to take into account the behavior of the "lone rider," for instance, if a household wants to increase its progeny in a country that is already overpopulated. Furthermore, the market only functions if there is perfect information with no delay, but experience shows that, for example, environmental degradation can be well under way, and already irreversible, before prices reflect an increase and households take it into account in their decisions. Even national authorities have very long delays in information and decisions (Meadows *et al.*, 1977). Finally it is possible that, contrary to the basic hypotheses of the theory, behaviors are not modified according to the costs and benefits of demoeconomic strategies because motivations are not uniquely economic.

Social analyses of demoeconomic microstrategies show that demographic decisions, and even microeconomic decisions, are shaped by social norms and by economic calculations. Development may expand the role of calculations, but households adapt to new opportunities in light of both the information available to them and pre-existing social norms.

Increased resources and diversified opportunities are sometimes put to traditional usages: modes of consumption are conserved while the volume of consumption grows; family size increases; the accumulation of social capital continues to be more important than the accumulation of economic capital, so social capital is maintained to the detriment of economic capital (ostentatious consumption, confusion of business stocks with family property); transfers increase; the number of wives increases; marriage payments rise; migration takes place in a family framework; and economic investments are made in the context of social investments. Whatever their origin (microeconomic calculation, rational convention, religious or symbolic group membership), social norms are not, at least in the short term, reassessed with each change in economic opportunities and constraints.

Reciprocally, social norms are used for economic ends and give birth to strategies largely unpredicted by outside analysts: the accumulation of economic capital, as much as the accumulation of social capital, relies on social controls. Social controls facilitate the use of tontines, the fosterage of children enrolled in school, and the collective financing of migration. The security provided by the exchange of transfers and counter-transfers makes it possible to take advantage of even fleeting economic opportunities, and strong social sanctions against those who forget their traditional obligations ensure economic "trickle down"[10] from urban residents to peasant families.

The economic application of social norms progressively transforms their content. Systems of gifts and counter-gifts become monetary, family relations are turned into economic relations, transfers are used for exploitative ends (notably of young people by older people), marriages become financial transactions, and economic benefits are extracted from political power (both traditional and new). This "economicization" provokes tensions over the level of transfers and recriminations against family structures.

These changes usher in a period of demographic and economic innovations that simultaneously modify both economic and social relationships. The family is particularly affected by these innovations, which influence the extent of the family, the division of labor, age at marriage, the roles and statuses of men and women, the position of younger family members, intergenerational relationships, attachment to age grades, the evaluation of rights and obligations, the rules of cohabitation, the location of the morning meal, the modes of preparation of family meals, etc. These innovations could all be described both as economic acts effecting a rise in a globalizing economic rationality and as adaptations to change by family structures (specific to different regions and different cultures). The result is variation in the levels of success in development and variation in the modes of successful development, such as the diversity of family adaptations to adjustment programs (Coussy and Vallin, 1996).

[10] The trickle down hypothesis argues that any increase in income in a country, even if it initially affects only the highest incomes, eventually reaches low incomes.

IV. THE INTERNATIONALIZATION OF RELATIONS BETWEEN POPULATION AND DEVELOPMENT

Since the origins of economic demography, it has been recognized that international economic relations affect the interactions between population and development. International migrations usually result from demographic disequilibrium (although there are forced migrations that are nonequilibrating). The importation of grain, according to David Ricardo (1817), was a means of preventing population growth from slowing development. The neoclassic economic school described international exchanges in conformity with comparative advantages as an imperfect substitute for migration. Alfred Sauvy (1966) argued that exports made it possible for populated countries to specialize in sectors with increasing returns. In the Hecksher-Ohlin-Samuelson model, external trade allowed countries that were poor in capital but rich in labor to specialize in sectors that were labor intensive. According to Arthur Lewis, we have seen, foreign investments made the growth of dualist economies possible. Finally, in the first macro demoeconomic models, outside aid takes on the task of meeting the needs created by population growth.

The capacity of external economic relations to reduce the tensions created by rapid population growth is balanced by their tendency to reduce the effect of growth in stimulating internal supply: decrease in food self-sufficiency, discouragement of saving and displacement of local investors, reduction of Boserup effects, abandonment of projects to develop equipment materials[11], etc.

Along with these possible detrimental effects, external economic relations can have negative effects on the international and internal distribution of income. Dependency theorists, including Marxists, conceive of these negative effects as part of a dynamic in which demoeconomic problems come not from population growth but rather from dependence on foreign countries. Dependency can reduce production and can slow the second phase of the demographic transition by maintaining poverty levels. Dependency-based analyses have not incorporated the possibility that demoeconomic tensions can be regulated at the international level, as in the cases of global improvements in health, the international origins of the green revolution, the use of agricultural exchanges to reduce food insecurity related to climactic instability, the jump-starting of certain national economies by migration, elevated growth rates in countries that specialize in exports, and the growth of employment at the global level. However, some of the relationships revealed by dependency analysis have become even more marked, notably dependency on foreign capital, the power of donors over internal policy, international competition that lowers the remuneration of labor, and barriers to immigration imposed by rich countries.

Currently, however, dependency-based analyses are overshadowed by the general acceptance of the new dynamic of the international economy: inequalities of development among under-developed countries, liberal globalization, erosion of borders, and financial globalization.

The inequality of rates of economic growth has displaced the image of a homogenous Third World. Instead, there are contrasts between, on the one hand, the Asian miracle and renewed growth in South America and, on the other hand, the specter of marginalization in sub-Saharan Africa and South Asia and economic regression in poor countries in transition.

Asian growth has changed views on the optimal size of nations. The "Little Dragons" were able to benefit from growing returns by turning to world markets, whereas large countries such as India and China, contrary to expectations, were braked in the short term by their continental expanse. Open small countries have used population density to their advantage; this situation was not unexpected but served as a counterexample to the textbook view of overpopulated islands. It has often been said, notably in the context of the theory of endogenous development, that productivity and demographic investments in health and education played a larger role in development than production factors. Today, however, the debate is being reopened.[12]

Asian countries have entered the second phase of the demographic transition, which has weakened belief in the inevitability of the Malthusian trap and led to a resurgence in the expectation that development will reduce birth rates. This expectation is con-

[11] In contrast, supply is stimulated when foreign relations increase exports (the case of balanced exchange), when they introduce factors complementary to labor (bringing capital to populated countries), when they make high-cost activities competitive (agricultural productivity), or when exterior aid creates an internal demand in countries where there is a lack of effective demand. Agriculture in west Africa, for example, experienced negative effects of food aid but benefited from urban demand financed in part by financial aid (and taxation on exports).

[12] On the one hand, backers of liberal reform in India cite works blaming Indian delay on the weakness of growth in global productivity (Ahluyallah, 1991; Bhagwati, 1993–1995). On the other hand, using the works of Alwyn Young (1995), Paul Krugman (1994) attributes the success of southeast Asia to the abundance of production factors, which announced the end of the Asian miracle, rather than growth in productivity.

firmed by the example of Africa, where the relatively rich countries of southern Africa have been the first to experience fertility decline. But other examples from Latin America (Cosio-Zavala, 1994) and Africa show that fertility decline can also be a result of poverty (the Malthusianism of poverty).

The contrast between rapid economic growth and declining fertility in Asia and countries (especially in Africa) with low economic growth where the demographic transition has not yet advanced significantly has led to a resurgence of 1950s-era hypotheses on the negative effects of population growth. The world econometric model of the "Asian miracle" (Banque mondiale, 1993; World Bank, 1993a,b) uses a Cobb-Douglas function that, for the reasons discussed above, shows an inverse relationship between population growth rates and growth of per capita income. It is likely not a coincidence that an earlier direct study of the correlation between the two rates (Blanchet, 1996) now seems to indicate a negative correlation rather than independence.

Liberal globalization has created new opportunities for development, first recognized by Arthur Lewis, through exports resting on foreign investments. It has also reinforced the preference for microlevel analyses, which are better suited for analysis of liberalized economies and more in line with current ideology. But globalization has liberalized international movements of capital more than movements of people, and there is a tendency to try to regulate population problems by relocation rather than immigration in developed countries, which is not the original classical optimum. This tendency has also reactivated the idea of development aid as a means of fighting migration, despite limited results obtained by this method.

The erosion of borders has accelerated the international diffusion of modes of consumption, health-related knowledge, changes in family structures, intergenerational relations, and ways of regulating fertility—so much so, that this diffusion sometimes precedes diffusion of income levels. It has increased transborder exchanges, both official and unofficial; family relations and ethnic group memberships have played an important role in these exchanges and have sometimes been reinforced by them in return. But the erosion has also reached more distant borders, allowing the globalization of family activities: migratory networks, financial networks, commercial activities, and the mastery of networks of production and exchange. Liberal globalization has often been cited as a reason to move beyond family-based capitalism in Europe. However, the economic efficacy of families, notably of Chinese families, has popularized the reliance on families in national strategies of development and raised hopes in countries benefiting from a diaspora, as evidenced by the Indian policy toward nonresident Indians. The role of networks based on identity, religious, or ethnic affiliations, which sometimes speak in terms of rupture with the global economy, is more ambiguous.

Financial globalization has modified the conception of capital movements driven by the disparity of population structures. The period 1950–1960 was dominated by models that established a relationship between the population growth of poor countries and their needs for external financing. These models were useful for projections and for justifying international aid, but the models proved to be less apt for describing and explaining the evolution of flows of capital over time. It quickly became clear that the movements of capital to poor countries were less a response to the needs of these countries than a component of the financial logic of the formation of savings and the allocation of capital. In the 1970s, the abundance of world liquidities increased the flow of capital toward poor countries above their capacity of productive absorption (notably in Africa). In the 1980s, the debt crisis reduced flows toward the south, sometimes to the extent that transfer balances became negative. Currently, capital movements are being renewed as an aspect of financial globalization: as a means of matching excess savings in developed countries, where there are numerous workers that have savings, and as a means of savings deficits in emerging countries. This process can be seen as an international extension of life-cycle trends in savings, as, for example, pension funds in Anglo-Saxon countries have a significant effect on loans to emerging countries. The reason for these loans is again demographic, but with a financial justification substituted for a justification based on needs. Capital flows are directed toward rapidly developing Asian countries, not toward African countries headed toward marginalization. And the volatility of these flows has had negative effects in Mexico and, more recently, the countries of the Association of Southeast Asian Nations.

CONCLUSION

The relationships between population and development in poor countries are now studied in the context of economic dynamics that can range from rapid growth to crisis or adjustment. International inequalities in growth have created new relationships between population and economics. These relations can only be studied, even at the national level, by dealing with subunits in which complementarities and conflicts have decisive effects on demoeconomic dynamics. In a period of liberalization, it is logical to orient analysis toward microanalyses (in addition to the simultaneous study of micro- and macrolevels in calculable models of general equilibrium). But microstrategies cannot be reduced to traditional microeconomics; they must be integrated with microsocial and familial relationships that lead actors to make innovations, including international innovations, that are simultaneously both economic and demographic.

The Relationships between Population and Environment

FRANÇOISE BARTIAUX AND JEAN-PASCAL VAN YPERSELE

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Institut d'astronomie et de géophysique Georges Lemaître, Université catholique de Louvain, Louvain-la-Neuve, Belgium

INTRODUCTION

The relationships between population and environment are complex and numerous, and this area of research has been little frequented by demographers. In consequence, our contribution has a double objective: to take account of this complexity and diversity, and to suggest some lines of reflection in an attempt to understand why demographers have been so little interested in this branch of inquiry. For this reason we shall attempt to throw some light on the paradigms that underlie the studies carried out in demography and the natural sciences of the environment. By proceeding in this way, we hope to establish some guidelines for demographers who may wish to investigate the relationships between population and environment. For although some choices have been made (often implicitly), others remain to be determined and ambiguities must be removed, above all those concerning the relationship of man to nature. This problem appears with the formulation of definitions of environment and population that marks our entry into the debate.

The field of population environment is very vast and cannot be completely covered within the confines of this chapter. We would have liked to limit ourselves to the works published in the journals most frequently consulted by demographers, but it is not always apparent whether or not to label authors as demographers, and in any case, the problem would remain for those working in collaboration with scientists from other disciplines, especially because of the multidisciplinary character of the subject and the high specificity of demography.

What Definitions of Environment?

For Yvette Veyret and Pierre Pech (1993:2), it was in 1942 that the term *environnement* appeared for the first time in French geographical literature as a synonym for *milieu géographique*,[1] following the method of the Anglo-Saxon authors.

Nowadays, various surveys among the general public have shown that the word "environment" has various meanings, depending on the social coordinates of the respondents[2] (Guérin-Pace and Collomb,

[1] According to France Guérin-Pace and Philippe Collomb (1997:1), who trace the history of the word *environnement* and its presence in French dictionaries, it was in 1964 that this word appeared in the Robert dictionary for the first time, and was defined there "as the entire natural conditions (physical, chemical and biological) and cultural (sociological) in which living organisms develop."

[2] The *Populations, Espaces de vie, Environnements* (*Populations, Living Spaces, Environments*) survey carried out in 1992 by INED with a sample of 5000 persons representative of the French population, showed that "the less educated populations describe their environment in terms of its immediate proximity, the more favoured social classes speak of the quality of life and natural equilibrium, urban populations make reference to architecture, shops and noise, and country people invoke their rural surroundings, fresh air and nature on their very doorstep. For the oldest populations it is the social environment and quality of human relationships that predominates, and for the youngest the preservation of the natural heritage and accessibility of unspoiled nature, the bearer of freedom and doubtless of hope" (Guérin-Pace and Collomb, 1997:12).

1997:12) and the activities relating to the environment that the person concerned may be carrying out[3] (Dalla Valle *et al*., 2001:165).

According to the survey conducted by France Guérin-Pace and Philippe Collomb (1997:11), "problems allied to pollution are seldom mentioned in the responses." Yet it is this very aspect that has been favored by (the few) demographers who have investigated the question of links between environment and population, as will soon become apparent. We therefore refer here to the definition adopted by Pascal Baud *et al*. (1995:226), for whom environment is now the environment of living beings, which is both fragile and precious and which must be preserved. But the latter normative part of the definition (the environment must be preserved) already contains an action program that demographers are not inclined to follow and constitutes the ambiguity of the connections to nature and action that we shall discuss later.

And What Definitions of Population?

To tell the truth, the definition of population is hardly clearer than that of environment. In the words of Pierre Lannoy and Lionel Panafit (undated), it was in the 18th century that population was born as a concept that enabled the idea of a new link between individuals and the first structures of the nation states that (to employ the expression of Michel Foucault, 1976) controlled individuals through their "biopower." Demography was thus born, as were other sciences pursuing the same aim of public control, such as criminology and epidemiology.

Population is therefore a way of thinking that has become so natural for demographers that we sometimes forget its abstract character. The same surely applies to environment; we have already noted its varied significance among the general public.

The Field of Research within Population-Environment

As stressed by Nathan Keyfitz (1996, p. 335), demographers have shown little interest in the emergence of this new field, which for want of a better term we shall call *population and environment*, and have contributed little to its development.

This opinion is not shared by Wolfgang Lutz, Alexia Prskawetz, and Warren Sanderson (2002b:1) for whom "this literature [hundreds of scientific articles and reports] forms the groundwork for a new interdisciplinary field of studies that we call P-E [population environment] analysis". This field is constituted by a relatively simple study question: "What are the effects of changes in the human population on the natural environment (P-E)? This question has a complement [. . .]: What are the effects of changes in the natural environment on the human population (E-P)?" (Lutz *et al*., 2002b:225). The only recommended approach is therefore dynamic, and any study in the field should, in their opinion, include some demographic forecasts of the population under review (Lutz *et al*., 2002b:242).

According to these authors, the studies in this field are either positive, "the discussion of the way things are or will be, under certain circumstances"; or normative, "how things should be" (Lutz *et al*., 2002b:11).

The concept of the ecological footprint, introduced by Mathis Wackernagel and William Rees in 1996, aims at linking a population and environment in a synchronic and nondynamic way. For a given population living at a certain level, it involves calculating the equivalent surface for producing the resources and absorbing the waste required for this number of people at this standard of living. This concept, nevertheless, does not appear to have greatly interested demographers.

Since the United Nations Conference on Environment and Development held in Rio in 1922, environmental questions are more frequently treated in conjunction with economic and social aspects by integrating them within the framework of sustainable development.[4] To avoid overextending the field of our review, we shall limit our study to the relations between population and environment.

[3] According to an enquiry carried out in Belgium, where 6800 persons over the age of 16 years were questioned in 1998 within the seventh wave of the Panel Study on Belgian Households. The sample was representative at first of the population living in Belgium, but the more disadvantaged households and persons were more difficult to follow on a year-to-year basis, and the representivity tends, as a consequence, to suffer.

[4] The definition given to this concept in the Brundtland report (WCED, 1987; CNUED, 1988) is worth quoting in its entirety:

> Sustainable development is a development that meets the needs of the present without compromising the ability of future generation to meet their own needs. It contains within it two key concepts:
>
> The concept of "needs," in particular the essential needs of the world's poor, to which overriding priority should be given, and
>
> The idea of limitations imposed by the state of technology and social organization on the environment's ability to meet present and future needs.
>
> Even in the narrowest sense of the term, sustainable development presupposes a regard for social equity between the generations, a regard that must extend, quite logically, within a same generation.

I. A REVIEW OF THE WORKS ON POPULATION AND ENVIRONMENT

In this review of the literature, we shall try to limit ourselves to works by (or related to) demographers that concern the interactions between population and environment, despite there having been fewer of them engaged in this topic than biologists, geographers, agronomists, climatologists, and even anthropologists and public health doctors.

As Aïcha Ouharon (1997) stresses, with some exaggeration,

> "the study of the population-environment relationship is marked by two views of the world derived from two disciplines: Economics and Biology. Dominant economic thinking presumes that all individuals are endowed with creativity and perfect reasoning. Confronted by choices under the constraints imposed by the environment, they are presumed to take the correct decision—they follow coherent objectives and employ adequate means for attaining them. Progress enables them to be masters of their destiny and to shape the environment as it pleases them. The other view, offered by biology, recalls that men live in close interdependence with their natural surroundings. Man does not exist for himself, but participates in the equilibrium of a whole system. His survival, as with that of other animal and vegetable species, depends on an equilibrium between his actions and the responses of the natural surroundings. Having succeeded in removing the obstacles imposed by the environment on its reproduction, the human species endangers the survival of other living species, and finally perhaps its own."

Is it because demography feels itself torn between these two paradigms—not easily reconcilable and divergent in the manner in which the (not perfectly rational) individual is represented—that demographic studies on population and environment are not numerous? We shall return to this discussion in the following section, after reviewing the demographic studies of population and environment by successively approaching the population doctrines, analytical methods, case studies, and quantitative global studies.

1. Population Doctrines

A non-negligible part of demographic work on the subject lies within the scope of population doctrines synthesized by Éric Vilquin in this treatise (see Chapter 97). We shall not therefore reopen these researches here, except to stress the proximity of "population and resource" problems and those concerning "population and environment," even though the second is (or could be) much wider.

The vast discussion opened by Nathan Keyfitz (1996) is in line with the history of population doctrines and concerns the past 50 years of demographic, development, and environmental growth. The subject is very wide, and the Keyfitz also includes some reflections on racism and, especially, on the rights of future generations.

Let us stress that it is not always easy to apportion the studies and classify them among the population doctrines or among the global quantitative studies. Many of them are simultaneously in both groups. John Bongaarts (1996), for example, in a quantitative work containing details of the demographic pressure on the supply and consumption of foodstuffs in developing countries, concluded that demand should also be studied, and he estimated that the best way of reducing the demand would be to reduce population growth in the Third World.

2. Syntheses

An issue of *Population Report* presents the state of research and offers numerous figures on the relation between population and environment (Green, 1992).

Other syntheses have been compiled on this topic for countries from the south by Évelyne Thiltgès and Dominique Tabutin (1992); Paloma Agrasot, Dominique Tabutin, and Évelyne Thiltgès (1994); and Dominique Tabutin (1995). According to the latter: "Knowledge about the relations between population and environment is still incomplete. There is a terrible lack of reliable data (especially on the environment) and detailed research integrating both phenomena. Work is based solely on the fragile and uncertain." (Tabutin, 1995:194–195).

Francis Gendreau, Patrick Gubry, and Jacques Véron (1996) have also devoted work to the relations between population and environment in developing countries by approaching the subject from four main angles: problems; production systems and environment; health and environment; and town, living space, and environment.

A brief synthesis of population and environmental problems is to be found in the article by Aïcha Ouharon (1997). Rajendra Pachauri and Lubina Qureshi (1997) report on a conference held on the theme of "Population, Environment and Development." The United Nations Fund for Population Activities (UNFPA) centered its 2001 annual report on the relationships between population and environmental changes (UNFPA, 2001). Mention should also be made of the *Atlas of Population and Environment* published by the American Association for the Advancement of Science (Harrison and Pearce, 2000), which contains numerous statistics on population and environment.

In preparation for the World Summit on Sustainable Development in Johannesburg (2002), the United

Nations Environment Program (UNEP) published the *Global Environment Outlook-3*, or *GEO-3*, in order to take stock of the recent development in the environment, its state, and prospects from now until 2030 (UNEP, 2002). The secretary general of the United Nations, moreover, ordered a series of reports on the five key areas: water, health, energy, agriculture, and biodiversity (WSSD, 2002a–e). Except where otherwise indicated, the data found in the Appendix were taken from the *GEO-3* report.

3. Analytical Methods

As regards methodology, we would especially mention the already cited work by Wolfgang Lutz *et al*. (2002a) on analytical methods in population and environment. The aim of the work is to "consolidate" the field of research from a methodological point of view while presenting a "multiplicity of methods" (Lutz *et al*., 2002b:2) ranging "from highly quantitative dynamic models to decomposition methods and various qualitative approaches" (Lutz *et al*., 2002b:1). The simulation studies presented are derived from the PEDA (*population, environment, development and agriculture*) model applied to various southern countries (see the case studies under the next section), whereas the decomposition methods are based on the equation $I = PAT$, which will be examined in a following section.

4. Case Studies

A number of studies on the interactions between population and environment are presented in the form of case studies. We shall cite some of these, but we acknowledge that our selection is both partial and unilateral.

Mary Tiffen *et al*. (1994), has studied the effect of population density on soil erosion in Kenya and concludes, contrary to widely held opinion, that high population density was helping to protect soils.

Erza Markos (1997) has described the demographic responses to the data on the degrading of the environment and insecurity of the food supply in the northern regions of Ethiopia subject to drought. These data come from a survey involving 2000 married women, and from in-depth interviews with local officials, old people, and development agents. He has also provided a bibliography on the demographic effects of famines.

Véronique Petit (1997) has also combined quantitative and qualitative data in her research into the reasoning behind the migrations of the Dogons of Sangha (Mali), as well as on the consequences for the sedentary populations, in terms especially of the relations between age categories and between men and women.

Wolgang Lutz (1994) has studied the interactions among population, development, and environment in Mauritius. He has mainly used simulation methods, on the basis of the PEDA model. Together with various collaborators, he has also carried out simulation studies that integrate population phenomena (sometimes including the AIDS epidemic), as well as food and environmental safety enquiries for other Third World regions—Cape Verde (Wils, 1996), Yucatan (Lutz *et al*., 2000), Botswana (Sanderson *et al*., 2001), Namibia (Sanderson, Fuller *et al*., 2001), and Mozambique (Wils *et al*., 2001).

Various case studies relating to the Maghreb have been carried out by Slimane Zamoun *et al*. (1995); others, by Francis Gendreau and Claude Meillassoux (1991).

Overall, it appears that the majority[5] of case studies in this area (if not all) are related to countries from the south—a characteristic that seems significant to us and to which we shall return later.

5. Global Quantitative Studies

A review of the works published from 1990–1997 by the *Population and Development Review* indicates that the few articles that come within our sphere of interest are quantitative global studies focusing on two issues: the capacity of the Earth to feed its inhabitants (Smil, 1991; Ehrlich *et al*., 1993; Dyson, 1994; Heilig, 1994; Smil, 1994; Bongaarts, 1996; Naylor *et al*., 1997) and climatic warming (Smil, 1990; Bongaarts, 1992; MacKellar *et al*., 1995; and, on energy: Gilland, 1995).

The first theme is linked to what biologists and certain geographers call *carrying capacity*. Kingsley Davis (1990) has clearly shown that this concept could not be introduced as such in the study of human populations, and Joel Cohen (1995) has also queried the pertinence of applying the concept of carrying capacity used in ecology. Analyzing 26 definitions of human carrying capacity, he observes that the concept is far from having a universal definition and that, despite the veneer of quantification, a good number of published estimates of human carrying capacity should be viewed as political instruments destined to influence public opinion rather than as unprejudiced analyses.

Most of the works published in the *Population and Development Review* are aimed at a more precise

[5] The interdisciplinary study: *The Earth as transformed by human action. Global and regional changes in the biosphere over the past 300 years* (Turner *et al*., 1990) nevertheless includes chapters on the Caucasus, the Russian plain, the great plains of the United States, Sweden, the Hudson basin in the United States, and Switzerland.

measurement of the relationship concerned, and sometimes they introduce concepts and variables that are perhaps unexpected but nevertheless important in the matter. Thus, Gerhard Heilig (1994) denounces the oversimplified underlying model (demographic growth implies an increased demand for food and, consequently, an intensification in agriculture and/or its extension, thus entailing deforestation and transformations of the soil properties) and shows that many changes in the type of soil covering can be attributed to factors other than demographic pressure.

This theme concerning the capacity of the Earth to feed its inhabitants also forms the basis of other studies, and we shall cite three of these, two of which are linked to the concept of density (maximum or not).

In a publication of the UNFPA, Norman Myers defines maximum density as "the number of inhabitants that the planet can accommodate without irreversibly reducing its capacity for accommodating others in the future" (FNUAP, 1991:71; UNFPA, 1991). This definition is usable not only on a planetary scale but also at national level. In the latter case, the UNFPA has remarked that account must be taken of certain reservations that may be made.

One of the areas in which this concept of maximum density has been applied is that of food production. The UNFPA (1991:72) cites the study by the *World Hunger Program* (Chen *et al*., 1990), according to which the planetary ecosystem could, in the present state of agricultural techniques and if the share of foodstuffs were equalized, accommodate 5500 million individuals under good conditions, but only if they were satisfied with a vegetarian diet. If they obtained 15% of their calories from animal products, as is generally the case in South America, the tolerable effective total would fall to 3700 million. If they derived 25% of their calories from animal products (as with the majority of inhabitants in North America), the Earth could only accommodate 2800 million human beings.

For foodstuffs, Hervé Le Bras (1994) concludes that food production is continuing to grow at a slightly faster rate than are populations, but that the abundance and global increase conceal formidable local inequalities and serious ecological problems that are also localized: "soils are deteriorating in many places, some fragile ecosystems are threatened, and poverty is increasing on the surface of the globe. These questions have simply nothing to do with overpopulation. They come from political and social disorders, and unequal distributions of the population at numerous parts of the planet."

Joel Cohen (1995) commented that the capacity of the Earth to feed its inhabitants is determined partly by processes that the natural sciences as well as the human sciences do not satisfactorily explain, and partly by the choices that we and our descendants still have to make. To illustrate this point, he has studied the problem of water. As with other natural constraints, the limitation associated with water interacts strongly with human choices and time limits. Cohen thinks, however, that estimates of human carrying capacity may, despite their limits, serve as useful indicators of the relations between humans and the Earth. He finally considers the suggestions for future action and concludes by offering four recommendations: developing institutions that consider the goals of efficiency and equality in a balanced way; improving the regard for social well-being, material flows and the consequences of each action; integrating our knowledge of populations, economies, environments and cultures; and creating a better understanding of mutual aid, including a quantitative documentation of the benefits derived by the rich from helping the poor live better lives.

With reference to climatic warming and its links with demographic growth, a critical synthesis of some studies carried out on the subject is to be found in our paper presented at the 22nd International Union of the Scientific Study of Population (IUSSP) Conference (Bartiaux and van Ypersele, 1993) and in the book by Brian O'Neill *et al*. (2001), *Population and Climate Change*. The studies reviewed (see Harrison, 1991; Bongaarts, 1992; Lutz, 1992; MacKellar *et al*., 1995) are all based on the celebrated equation ($I = PAT$) of Paul Ehrlich and John Holdren (1971). According to this equation, the influence (I) of the population (P) on the environment (or, in this case, on c1imatic warming) varies according to consumption (A for "affluence") and technology (T). The units of measurement vary according to the problem under consideration.

A presentation of this equation and its variants and a criticism of its bases are to be found in our own chapter, as well as several UNFPA studies that employ the incorrect results produced by an inadequate application of it. Although, indeed, the influence (I) of the population (P) on climatic warming depends not only on consumption (A) and technology (T) but also on the level of aggregation and therefore on the spatial scale employed (cf. the results of Lutz, 1992). This influence also varies according to whether the choice is to study consumption levels per inhabitant (choice more unfavorable for developed countries[6]) or growth,

[6] In particular, we have calculated that between 1950 and 1990, the increase in carbon dioxide emissions per inhabitant in the developed countries has played a more important part in the increase of carbon dioxide emissions worldwide than has the demographic growth of developing countries (Bartiaux and van Ypersele, 1993).

particularly demographic growth (more unfavorable for developing countries); whether it is postindustrial revolution (more unfavorable for developed countries) or post-decolonization (more unfavorable for developing countries; and whether or not to include methane data [rare] (more unfavorable for developing countries). And then, as Landis MacKellar *et al*. (1995) have added, it must be considered whether the analytical unit employed for the population is the individual (more unfavorable for developing countries) or the household (more unfavorable for developed countries, where the size of households is rapidly decreasing[7]), etc. Who still believes that quantified studies are neutral and objective?

Let us finally note the following remark by Hervé Le Bras (1994): "the classification of developed countries according to their participation in the greenhouse effect per inhabitant is in inverse order to the densities." Le Bras attributes this to a negligent use of working and living spaces in empty or new countries, where nature appears to be less restrictive, less congested, and more bountiful. Comparing the effect of the principle causes of wastage and that of demographic growth, he concludes that demographic growth does not play the leading role in the climatic crisis that people wish to attribute to it.

II. WHY ARE DEMOGRAPHERS SO LITTLE INTERESTED IN ENVIRONMENTAL QUESTIONS?

Asking this question also involves enquiring about the specificity of demography and about its paradigms, while comparing them with the paradigms of the sciences for which environment is the object of study.

For these disciplines, we shall examine successively the spatial and temporal scales, the envisioned links between nature and culture, the causal or systematic perspective, the place for research action and value judgments, and finally the customary interdisciplinarity. These aspects to be taken into consideration in comparing demography and the environmental sciences are partly inspired by José Prades (1996).

1. Spatial Scales

Spatial scales in the natural sciences of the environment are varied and range from the local to the global. They can be presented as concentric circles starting with the environmental elements with which human beings are in direct contact.

a. Microenvironment (Radius of about 100 m)

From his immediate environment, the human being takes the elements necessary for his metabolism, and these basic needs have been estimated in the following way, bearing in mind that these are average figures and therefore variable, modifiable and modified according to the societies: oxygen (about 0.5 kg/day), water (2 liters/day) and food (1 kg/day). In addition, every person needs to be surrounded for living by a microclimate defined by a certain range of temperature and humidity, as well as by acceptable levels of radiation (e.g., light, ultraviolet, radioactivity, microwaves). Toxic elements (chemical compounds and microorganisms) can only be present in very limited amounts. Noise must not exceed a certain level. The body must also be able to eliminate the gaseous, liquid, and solid waste from its metabolism without his immediate environment suffering. To guard against diseases, human beings have adopted many chemical elements from the vegetable, animal, and mineral world. The quality of this *microenvironment* must be adequate throughout life, but even more during pregnancy as well as the first and last years of life, when living beings are more fragile. The standards characterizing this quality are defined among others by the World Health Organization, on the basis of epidemiological studies (WHO, 2000).

The habitat and workplace are important components of the microenvironment. Many writers have studied the link between the health of the occupants and the temperature and humidity prevailing inside buildings (see Boardman, 1991), quality of the air (Leslie and Lunau, 1992), and electromagnetic radiation (Hester, 1992). Tobacco smoke is probably the main domestic pollutant (Leuenberger, 1993). In developing countries, smoke from domestic homes is also an important pollutant (WSSD, 2002b). Reference to this subject can also be seen in Chapter 50.

b. Local Environment (Radius of about 10 km)

In a society that is little industrialized, it is the local environment (within a radius of some 10 km around the dwelling place) that provides food, water, and energy (firewood), whereas in rich countries, environment is less directly involved and used more as a source of recreational areas.

In towns, road transport and heating cause pollution, which in certain cases has immediate and serious effects on human health. In December 1952, for example, 4000 victims were recorded in London after

[7] Decrease in the size of households reduces the economies of scale that are possible in larger households.

a stagnant polluting fog (smog) over the town (McNeill, 2000). Apart from industrial catastrophes, often deadly (e.g., 3000 deaths in Bhopal, India, in 1984), chronic atmospheric pollution through certain components, sulfur in particular, is responsible for many attacks on human health. Reference to this subject can also be seen in Chapter 50.

This list should also be completed by evoking the pollution and degradation of soils, deforestation, etc.

c. Regional Environment (Radius of about 10 to 1000 km)

In developed countries, a large part of the resources that we consume—food, water, energy, and material goods—come from far away. The book *Factor Four* (von Weiszäcker *et al*., 1997a,b) cites a study by the Wuppertal Institute for Climate, Environment and Energy on the peregrinations of pots of strawberry yoghurt consumed in Germany. According to this study, each yogurt, its ingredients, and its glass pot represents an accumulated journey totaling 3500 km, to which must be added 4500 km for the materials of the suppliers. Our solid waste is often transported on this regional scale—not near enough to be seen daily, but not too far on account of high transport costs.

Many environmental risks are present on a regional scale: air pollution, acid rain, photochemical pollution (ozone, smog), pollution of ground water, rivers, etc.

d. Global Environment (Encompassing the Whole Earth)

Globalization of the economy, with the effect that goods are exchanged between widely separated regions (exotic foods out of season; minerals, oil, gas, or uranium transported thousands of kilometers), is accompanied by a globalization of environmental problems.

One of the first global environmental problems was that of the thinning down of the stratospheric ozone layer, consequent upon the emissions of chlorofluorocarbons (CFCs) used in refrigeration and aerosol canisters. In fact, it was only in 1985—when British researchers published for the first time some observations that the ozone layer had lost 40% of its depth over the Antarctic between 1977 and 1984—that human beings became aware that in acting locally (by using a spray in their bathroom, for example) every Earth-dweller could affect the global environment. This awareness led to the Vienna Convention and the Montreal Protocol, which have resulted in a drastic reduction in CFC emissions. The stratospheric ozone layer should in principle regain its normal state toward the middle of the 21st century (UNEP, 2002).

The second global problem is that of the climatic changes resulting from the gas emissions, principally carbon dioxide,[8] resulting in the greenhouse effect. The most optimistic scenario for the emission of gas having a greenhouse effect[9] is world population rising to a maximum of 8700 million in the middle of the century and then declining; economy oriented toward economic, social, and environmental viability (including greater equity), evolving rapidly toward services and a reduction in the intensity of the consumption of energy and materials, thanks to important technological progress. The Special Report on Emissions Scenarios (SRES) B1 scenario of Nakićenović and Swart (2000) associated with the least sensitive of the climatic models[10]—the Intergovernmental Panel on Climate Change (IPCC), a group of intergovernmental experts on climatic issues—assembled on the initiative of the United Nations, projects an average air temperature of the global surface for the year 2100 that is 1.4°C higher than in 1900, as well as a rise in the average sea level (mainly by thermal expansion) of 9 cm. At the other extreme, with the most sensitive version of the climatic models and the SRES A1FI scenario, characterized by the same population development but with a very rapid economic growth and an energy system based on a high intensity of fossil fuel consumption (Nakićenović and Swart, 2000), the figures are +5.6°C and +86 cm. The intermediate SRES A1B scenario,

[8] Carbon dioxide has the property of being transparent to solar radiation but does not afford an easy passage to the invisible infrared rays emitted by the earth's surface in response to heating by the sun. It is a gas with a so-called greenhouse effect, which plays a similar role to that of the glazing in greenhouses. If the percentage of carbon dioxide in the atmosphere increases, the Earth can no longer cool itself as much by infrared emissions. The heat is trapped at surface level. The climate heats up, the seas send more water vapor into the atmosphere, rain becomes more abundant on a global average, and subtle equilibriums that control the planetary climates are disturbed. In consequence, therefore, of human activities, the percentage of carbon dioxide in the atmosphere (its concentration, which constituted 368 parts per million in volume in the year 2000) has augmented by 30% since the preindustrial era. The present rate of increase is 0.4% par annum.

[9] It should be noted that none of the SRES scenarios (Nakićenović and Swart, 2000) considered by the IPCC envisaged supplementary initiatives taken after 2000 with the specific aim of protecting the climate, not even the work of the Kyoto Protocol. The reduction of emissions envisaged for certain of these scenarios resulted from other factors than those of a desire to protect the climate, such as the concern to reduce air pollution or preserve non-renewable resources.

[10] The sensitivity of a climatic model to an increase in the concentration of gases with a greenhouse effect is conventionally measured by the increase in average world temperature simulated by a doubling of the preindustrial concentration of carbon dioxide, when the climate of the model is expected to be stabilised at a new equilibrium temperature. This sensitivity is typically between 1.5°C and 4.5°C.

which has the same demographic base and postulates a balance[11] between the energy sources, gives +3°C and +38 cm when associated with a model of average sensitivity (Houghton *et al*., 2001). The hydrological cycle will also be accelerated by increased evaporation, with increased droughts in some areas, and more floods in others. To put these figures into perspective, it must be borne in mind that the speed of warming will most probably be higher than it has been at any other period since the end of the last ice age, 10,000 years ago.

Such rapid changes in climate will have effects on different aspects with regard to the habitability of our planet. Thus, the rise in temperatures will cause an increase in cardiovascular diseases during heat waves, and an extension in the geographical area of tropical diseases is equally to be anticipated (e.g., the possibility of malaria in Europe). Agricultural zones and ecosystems will move, if they are able to do so. A spatial redistribution of agriculture will take place, and water resources will be affected. The consequences of the rise in the average sea level will be increased flooding in the coastal areas and an invasion of the underground water by salt water.

The IPCC points out that the vulnerability of human health, socioeconomic systems, and (to a lesser extent) some ecosystems depends on economic systems and the institutional infrastructure. This implies that vulnerability to climatic changes is generally higher in developing countries, where the economic and institutional conditions are less favorable (McCarthy *et al*., 2001).

In demography, the predominant spatial reference is that of the state, and this observation is in agreement with what was stated above concerning the birth of the population concept and the Foucault analysis. Administrations, in particular national statistical institutions, have set up national systems for the collection of demographic data—mainly the civil registry, census, and national enquiries. Most of the analytical tools developed by demographers refer to these sources of national data.

Environmental problems, however, know no frontiers. Ulrich Beck (1992), a German sociologist and pioneer in sociological and environmental studies, argued that "an older industrial society, whose axial principle was the distribution of 'goods,' was being displaced by an emergent 'risk society,' structured, so to speak, around the distribution of 'bads'" (Szerszynski *et al*., 1996:2).

[11] Balance means that there is no excessive reliance on one particular source of energy, assuming that similar rates of improvement apply to all technologies concerning energy supply and end use (Nakićenović and Swart, 2000).

Demography, with its predilection for national reference, is therefore not well placed for studying environmental questions, and it is not surprising that few quantitative studies on the subject carried out by demographers should be on the global scale (Bongaarts, 1992; Lutz, 1992; Bartiaux and van Ypersele, 1993) or on the local or regional scale (Markos, 1997; see also the numerous case studies collected in *Les spectres de Malthus* by Gendreau and Meillassoux, 1991). There are few local studies on population and environment concerning the northern regions, and this appears to demonstrate the reluctance of demographers to abandon the national scale for their studies on developed countries, or the fact that the local level has little pertinence for these countries. For John Caldwell (1996:333), "Demography will remain a distinct discipline because of its approach: [. . .] that the study should be representative of sizeable or significant and definable populations." Demographers should nevertheless recall that the pertinence of the population chosen for study does not depend solely on the data and available analytical techniques, for the latter frequently channel the problems.[12]

It appears to us, however, that the spatial scale is not the only reason for the relative absence in developed countries of regional studies on the links between population and environment, and that, as we shall see later on, the relationship that demographers have established (consciously or not) between nature and culture also plays a part.

2. Time Scales

Environment is characterized by a great variety of time scales. Stocks of resources provided by the environment have often been accumulated over long periods. Oil, for example, results from the transformation of organic matter, such as plankton, over millions of years. The ozone layer that protects the Earth from an excess of harmful ultraviolet rays took almost 3000 million years to accumulate (Graedel and Crutzen, 1993:220), but its depth diminished through the emissions of CFCs, gases only invented around 1930. Soils are the outcome of very slow erosion and a physicochemical transformation of Earth's crust, but it requires only a few years of ill-conceived irrigation, for example, to make the soil sterile through salinization.

The climate of our planet has experienced a succession of glacial and interglacial periods in the course of the past 2 million years. The characteristic periods of

[12] As, for example, the study of households in demography (Bartiaux, 1991).

these variations, associated with astronomic factors, are 23,000, 41,000, and 100,000 years. It required 10,000 years for the 2-km-thick ice cap covering Scandinavia, Russia, and North America to melt 20,000 years ago, but the warming that will result in the 21st century from the gas emissions with greenhouse effect arising from the burning of fossil fuels will be at least 20 times faster.

The time scale for certain factors is short (carbon monoxide coming from badly ventilated stoves can kill within a few hours), for others it takes tens of years (exposure to radon, a radioactive gas arising from the soil and from certain building materials, causes cancer in the long term) (Lindvall, 1992).

As remarked by Jean-Paul Deléage (1991:247), "what characterizes ecological periods is the combination of the infinitely short and extremely long, from which has arisen the impression of very great stability that has shaped the perception of all generations up to the present regarding their relations with the environment surrounding them."

In demography, the time reference for calculating period indices is the year, which seems too rigid for studying, for example, the influence of environmental factors on death and fertility. Retrospective analysis is not to be disregarded, but prospective analysis by cohort appears more suitable. Research into epidemiology and public health concerns the influence of environmental factors[13] on health and death, and it is doubtless useful for demographers to see the extent to which their concepts and methods are compatible with those of demography.

In their demographic perspectives, demographers extend their time reference up to 20, 30, or 50 years and even longer, but then the degree of uncertainty increases rapidly. Over recent years, long-term projections of world population have been revised downward several times. For example, for 2025, the high estimations of the United Nations projections carried out in 1996 (8580 million earth dwellers) were much closer the 1992 average estimate of 8500 million.

3. View of the Links between Nature and Culture

The question of links between environment and society and between nature and culture is fundamental for our problem, even though it is only rarely approached directly by demographers. Yet one can recognize, as Jean-Guy Vaillancourt (1996) stresses for sociology, that demography is largely anthropocentric and functions principally according to the paradigm of human exemptionalism, according to which "humans are not considered as beings that are dependent on nature in their physical activities, but rather as cultural entities" (Vaillancourt, 1996:29–30). This is especially valid for demography as practiced in the north, as we have noted above with regard to the time scales.

Jean-Guy Vaillancourt (1996) has reviewed some trends in American sociology that are opposed to this paradigm and that adopt a contrary view by insisting on the role of the environment in social organization (that is to say, human ecology [close to the Chicago school], then environmental sociology and, in the 1990s, ecosociology). These tendencies, however, are marginal in sociology and especially in environmental sociology, in which the "constructivist" paradigm is dominant—environmental "problems" are nonexistent, they are merely social constructions set by lobbies (especially scientific) that have an interest in so doing (see Hannigan, 1995). Although at least two invitations to follow the paradigm of human ecology have been made to demographers in two major reviews of the discipline—*Population and Development Review* (Law *et al*., 1992) and *Population Index* (Namboodiri, 1994)—it seems that it has not been followed up and that demographers, who have up to now hardly studied the consequences of environmental factors for populations (E–P), at least for developed countries, continue rather (albeit rarely) to consider the inverse relation (P–E).

4. Causal or Systemic Perspective

This subject, which has divided certain demographers in passionate disputes, is scarcely a preoccupation in the natural sciences of the environment. Some causal and linear relations established by certain of them have been introduced by others into more complex models, with retroactive effects and the intervention of new processes.

No comprehensive model exists for the relationship between population and environment, as is the case in climatology, but the simulations of the Club of Rome and those conducted by Wolgang Lutz at the International Institute for Applied Systems Analysis are attempts in this direction. The question remains whether the simulation models of population and environment will provide a means of reconciling the causalists and systematicians. Only the future will tell, but it does seem that, irrespective of the hypothesis, the choice of a causal or systemic perspective is not a prerequisite for studying population–environment relationships.

[13] See especially the chapter by Francis Sartor (Chapter 50) of this treatise.

5. Research Action and Value Judgments

This topic is more complex, because it raises the question of the relationship between science (in this case demography) and politics. Michel Foucault (1976) would contend that since its origin demography has been linked to politics and has played a role of scientific legitimation, as can be maintained by comparing the efforts (relatively weak) in theorizing mortality to the advances in fertility.

As far as population–environment relationships are concerned, are demographers expecting a (possible) demand for a policy? Do they wish to participate in the management of the environment (just as certain demographers contribute to the town and country planning territory)? Do demographers, for example, wish to participate in quantifying the responsibilities between the north and south concerning the increase in greenhouse gases? Judging by some of the publications issued by demographers on the subject, the answer appears to be in the affirmative. The political implications of this are evident.

Can demographers participate in the management of the environment in a neutral way, without value judgments or ideological prejudices? Certain studies cited above appear to indicate the negative, and it is necessary to remain vigilant.

This idea that science must clarify political choices is, as Pierre Hamel (1996) has shown, inherited from the "Enlightenment" tradition and a component of modernity. But human behavior is not always predictable by the human sciences (as demographers well know), and philosophers and sociologists are telling us that we have entered the postmodern era. What then will be the role of science (and of demography) for studying the environment?

6. Interdisciplinarity

Study of the relations between population and environment necessarily requires interdisciplinarity, associating researchers from the social sciences with those from the natural sciences. Marcel Jollivet (1992) has termed those engaged in the interdisciplinary study of the relationships between nature and society "frontier runners," and has analyzed the theoretical and methodological question that surround these efforts.

Brigitte Dumas (1996), has defined interdisciplinarity (in relation to environment) as being "a combined employment of some disciplines, entailing reciprocal transformations in each of them." If this definition is accepted, then demography, with its blurred outlines, is closer to interdisciplinarity than are other social sciences such as social psychology, which has a more rigid theoretical framework and a well-standardized method.

Another advantage of demography for working on the relations between population and environment is doubtless its quantification and measurement equipment, highly esteemed by the natural sciences of the environment. It was indeed a demographer, Wolfgang Lutz, who was responsible for showing the risk of errors inherent in the celebrated equation ($I = PAT$) in the population–environment field, and this is very important.

But beyond quantification, demographers know, especially through their experience in the area of family planning, that values and modes of social organization have to be taken into account, in order avoid failure.

CONCLUSION

When they are interested in the interactions between environment and societies, environmental specialists from the natural sciences very often have a simplistic view of demographic phenomena. Little inclined to question the parameters A (for affluence,, i.e., the level of consumption) and T (technology) of the equation $I = PAT$, or the fact of dynamic demographic transitions, they often have the tendency to attribute all the ills of the Earth to the "population explosion." In so doing, they follow the expression introduced by the American biologist Paul Ehrlich (a butterfly specialist), whose book *The Population Bomb*, which appeared in 1968, has had an enormous and lasting repercussion.

In collaborating more with these researchers, demographers could doubtless show how their own knowledge enables a better understanding of the complexity of the interactions between population and environment.

Although, up to the present, demographers have little studied the influence of population(s) on environment, and even less that of environment on population(s), it seems to us that they could give these questions more consideration were they to reconsider their spatial scales, especially if they were prepared to abandon the paradigm of human exemptionalism (and not only for southern countries). In so doing, demographers could adopt the tradition of case studies and other monographs, or of demographic doctrines, by clarifying their value judgments and by being vigilant about the normative presumptions that guide their work.

The relations and interactions between population and environment are many and often call for collaboration with other disciplines (e.g., medicine for studying the effects of an heat wave; economics for studying energy consumption). Research into more sustainable development models (WCED, 1987; CNUED, 1988) in both the north and the south widens the context in which these studies are made. In this area, as in others, demographers will increasingly call for interdisciplinary study.

They will also have to (continue to) keep their distance from the economic paradigm of action (the individual acts rationally and the market controls supply and demand, including nonrenewable resources), without adopting the biological paradigm uncritically (and a concept such as carrying capacity) or even the constructivist paradigm of the sociologists. Is this a difficult balance or an impossible challenge?

Acknowledgment

APPENDIX: STATE OF THE ENVIRONMENT AT THE BEGINNING OF THE 21ST CENTURY

The following data are extracted from the *GEO-3* (UNEP, 2002) report, except where otherwise indicated.

Twenty percent of the richest of the world population account for 86% of the total private consumption expenditure; consume 58% of the world's energy (on the basis of 5 tons of oil equivalent per person per year) (WEHAB, 2002b), 45% of the consumption of meat and fish, and 84% of that of paper; and possesses 87% of the cars and 74% of the telephones.

Twenty percent of the poorest of the world population consume less than 5% of each of the goods and services. About 2000 million people have no access to electricity, mainly in the rural zone (WEHAB, 2002b).

Almost one-third of the world population live in a country that experiences moderate or high water shortage (i.e., the consumption of water is more than 10% of the renewable resources): 1100 million people have no access to drinking water, 2400 million have no access to sanitary installations, and 2200 million people die every year of diarrhea allied to the quality of the water.

Sewers constitute the most important source in volume of contamination of marine and coastal waters. Contributions of nitrogen and agricultural fertilizers from the sewers provoke outbreaks of eutrofication or explosive growth of toxic algae. The total volume of fishing is decreasing. The principal danger to the coastal environment is the direct physical destruction of the habitats. The latter is one of the main factors that bear down on coral, 58% of which are regarded as being threatened.

Nearly 2000 million hectares (mha), that is, about 15% of the continental surface, have been degraded by human activities (overgrazing, 35%; deforestation, 30%; agricultural activities, 27%; overexploitation of vegetation, 7%; industrial activities, 1%).

The net loss of afforested surface is 9.4 mha a year. Natural forests are losing about 16 mha per year, of which 15 mha are in tropical areas. About 70% of the deforestation has taken place in order to extend agriculture.

Biodiversity is decreasing at a speed that is several times higher than the historic rate. 24% of the mammal species and 12% of bird species are considered to be threatened on a global scale. The main factors in these changes are the degradration and loss of habitats (linked to agricultural development, exploitation of forests, construction of dams, mining activity and urbanization), climatic changes, pollution, nonsustainable exploitation of natural resources, and the introduction of exotic species.

Air pollution, both external and internal, is considered to be responsible for 5% of global morbidity. Air pollution aggravates (and perhaps causes) asthma and other respiratory allergic diseases. Almost 2 million people in developing countries die every year owing to exposure to the ultrafine particles of smoke from domestic biomass fires in dwellings. A third of the world's population depends on traditional fuels (wood, dung, and agricultural waste) to ensure their daily needs for heating and cooking (WEHAB, 2002b). The burning of fossil fuels is at the origin of emissions of sulphur components that cause acid rain and deposits. These emissions are rapidly declining in developed countries but are rapidly increasing in the Asia–Pacific region. Nitrogen oxide emissions lead to the formation of ozone in the lower atmosphere (where it is a pollutant that attacks both the lungs and vegetation).

Persistant organic pollutants, such as pesticides, which are chemically stable, are carried by the atmosphere over very long distances and accumulate particularly in the polar regions. They contaminate the food chain there and are to be found in animal fat, which constitutes a risk both for human health and the ecosystems.

The ozone layer in the stratosphere, which protects living organisms from an excess of ultraviolet radiation, has been reduced above the polar regions by chlorofluorocarbon gases (CFCs) used especially in refrigeration. Following the measures taken to progressively ban the production of CFC, the ozone layer in the stratosphere should recover its former state within some decades from now.

Because of the massive burning of fossil fuels, the concentration of carbon dioxide is 30% higher than its preindustrial value. The average global surface temperature has increased by 0.6°C during the 20th century. More than half the warming observed over the last 50 years is owing to the increase in the gases with greenhouse effect of human origin, of which carbon dioxide is the most important. Most of the rise in average sea levels observed in the 20th century (10 to 20 cm) is probably linked to the increase in temperature. The first consequences of these climatic changes for certain fragile ecosystems have been observed.

P A R T

II

THE POPULATION IN ITS BIOLOGICAL, ECONOMIC, SOCIAL AND CULTURAL SETTING

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

The determinants of change in demographic behavior were extensively discussed in Volumes I and II, and its consequences were more succinctly examined in Section II, Part I of this volume. Part II will now examine a set of relationships between population dynamics and various aspects of the biological, economic, social and cultural settings in which they take place; here it is more a matter of interactions than clear-cut causal relations. These contextual factors deserve demographers' consideration both in themselves and with a view to understanding their reciprocal influences. Here again, we have not attempted an exhaustive examination. That would be particularly futile since many fields that could be examined are virtually unexplored, and methods for studying others are still in their infancy. Our aim, once again, is simply to illustrate the range of possible approaches and to suggest some avenues for reflection.

As was said in Volume I, the basic principle of demographic analysis is to consider the population as a collection of individuals with no particular feature other than their membership of whatever category is selected for analysis. But we have also repeatedly pointed out that this is too reductionist a principle to enable us to grasp all aspects of the reality. It is sometimes even useful to take the opposite approach. Putting the individual at the center, we can obtain a more practical view of his or her development in time and space within the population(s) in which he or she is born, lives, moves, and dies. This is Paolo De Sandre's approach in Chapter 88, "From the Life Cycle to Life Paths and to Life Transitions."

A similar but more specific approach is to consider the way an individual's habitual environment changes as a result of the demographic transition. In Chapter 89, for example, Alain Monnier and Sophie Pennec describe how, at different stages of the transition, an individual (*Ego*) undergoes changes in "Experiencing Death."

The next two chapters examine households and families, the basic social units that structure all human populations and deserve the demographer's consideration for several reasons. They are the units of observation through which individuals can be approached to count a population or monitor change. They are also the units within which many economic and social decisions are formed and taken, and they can themselves sometimes be considered as elements of a statistical universe to which demographic analysis methods can be applied. They are also prime locations for new demographic behaviors to emerge or traditional behaviours to be conserved. Chapter 90, by Marc Pilon, sets out some general points and gives a practical illustration based on the experience of developing countries. In Chapter 91, Nico Keilman addresses the same question for developed countries.

But although the family (or household) is the basic unit of the social fabric, it is only one element. Four chapters examine different factors, all of which greatly transcend the individual and the family, and which are all more or less closely connected with population dynamics. In Chapter 92, François Héran addresses "Social Mobility, Then and Now"; in Chapter 93, Antonella Pinnelli reviews the relatively recent knowledge of relations between "Gender and Demography"; in Chapter 94, Giuseppe Gesano addresses the complex relationship between "Economic Activity and Demographic Behaviors"; in Chapter 95, Jean-Louis Rallu, Victor Piché and Patrick Simon discuss "Demography and Ethnicity: An Ambiguous Relationship."

To round off, referring back to the first chapter of this volume dealing with the genetic consequences of demographic change, in Chapter 96 Enzo Lucchetti and Alberto Soliani give a more general overview of the relationship between "Genetics and Demography."

CHAPTER

88

From the Life Cycle to Life Paths and to Life Transitions

PAOLO DE SANDRE

Dipartimento di Scienze Statistiche, Università di Padova, Padova, Italy

INTRODUCTION

Classical demographic analysis is characterized by a macrosocial approach based essentially on *officially exhaustive data* (censuses, vital statistics, registration of changes of residence). To investigate the mechanisms by which populations evolve, priority was given to the exploration of differences in behaviors, *beginning with specific events* (births, deaths, migration) and continuing with essential *prior states* (assumed to be closely correlated with or causally linked with the events). But causal analysis may also rely, in changing the perspective, on observation of populations (or subpopulations) that are *susceptible to experience* (or not) these events, in following the *principal biographic elements in the context of the temporal and spatial relationships that individuals maintain among themselves and with their life environment*. This approach is essentially based on exploitation of retrospective or prospective sample surveys, which, based on detailed questionnaires, are much richer sources of information than are the exhaustive sources.

The aim of this chapter is to lay out a sort of *inventory of points of contact* (at the level of *concepts*, of *information* to collect, of *methods of analysis*) between a microdemographic approach (that of the life cycle or life paths) and the macrodemographic approach. Hence, without claiming to be exhaustive, I will present a cross-sectional overview, with a number of elements in common with other chapters of this treatise.

We begin with the following empirical observation. In interaction with the radical evolution of population dynamics that has taken place in Western societies during the past 2 centuries, there have been important *structural changes in the stages of an individual's life*, very easily perceptible and still far from having produced all of their effects in the areas of life style, culture, or the economy. To have a broad knowledge of such radical transformations, it is sufficient to follow the evolution at the macrosocial level of a few key demographic variables. But to get to the heart of things, *longitudinal observation of individuals* and an in-depth *analysis of the systems* in which they live are required. Paradigms and conceptual categories need to be rethought and methodological approaches renewed, in order to combine, in an integrated and interdisciplinary manner, state characteristics, events, and individual behaviors, as well as the interactions among the individual paths and the contexts within which they unfold. From this last perspective, one should not lose sight that the contribution of demographic variables to the transformation of the society takes place in *an historical context of economic and social changes*: from the industrial revolution to postindustrialism (Coale and Watkins, 1986; Chesnais, 1986; Chasteland and Chesnais, 1997).

The chapter is divided into two parts, the first dealing with the empirical description of the life paths and the second presenting the methodological orientation appropriate for the study of these paths. After the first two sections devoted to changes in the nature of the different ages of life under the effect of the demographic transition and to certain consequences of this transformation of the *life cycle* that can lead to policy interventions, I will address several methodological aspects concerning the observation and analysis of life paths, including systems for collecting dynamic information and the opportunity to use multidimensional transition models that link up life trajectories and explanatory variables.

I. DEMOGRAPHIC REGIME AND STRUCTURAL EVOLUTION OF THE AGES OF LIFE

In thinking about the past 2 centuries or even, for the Mediterranean countries, the past 100 years (corresponding to from seven to three intergenerational intervals, respectively), one is struck by a certain number of major changes in the conditions of life linked to the evolution of the demographic regime and to that of the resulting population structures.

In the pretransitional regime with high mortality and high fertility (until the end of the 18th century for France and until the end of the 19th for Italy), the rules of population renewal were such that, from its birth until the mean age of childbearing, a cohort of women was reduced by half. The women who survived married, on average, at around age 20 years, and managed to give birth to 6 children before becoming infertile at around age 38 years, an age by which they had only about 20 years to live (80% became widows by age 50) (Livi Bacci, 1978).

In the current Western regime with low mortality and low fertility, nearly all women survive to the ages at which fertility is highest. On average, a woman only gives birth to less than two children. The mean age of first marriage of women has risen to 26 or 27 years (sometimes more), and although births are infrequent, they are also delayed. Conversely, at age 35 a woman's childbearing is 90% complete and her remaining life expectancy exceeds 45 years. Widowhood at adult ages has become quite rare, owing to improvement in the survival of the two sexes. However, voluntary disruptions of unions have become much more common (especially in the non-Mediterranean countries) (Véron, 1993, AIDELF, 2002).

The structural changes of the life paths underlying these transformations affect all of the traditional age groups.

1. Childhood

Childhood no longer represents a wager against death: to have a child born has become an irreversible choice, almost certainly durable over time. Although when mortality was very high more than one-third of newborns died before their fifth birthday, it is today only the case for one child in 100. Direct family and social investments in raising and educating children have become absolute and costly imperatives; at the same time, for the parents (and especially the mother), the opportunities they must forgo to confront these investment costs increase (in terms of employment and of different uses of time and money). Today, in certain countries of southern Europe (but also of central Europe and the ex-Soviet Union), the model of the only child is even gaining ground, alongside the two-child model, with profound changes in the ways of raising and socializing young children.

2. The Passage to Adulthood

Adolescence is extended to a *youth* who increasingly encroaches onto adulthood. With the passage from nearly direct access to the world of work at the time of preadolescence—typical of agricultural societies—to the *obligatory schooling* for all (most often to age 16, legally, but in reality up to the threshold of adulthood for most youth), which is characteristic of industrial societies, there has been a radical change in the social image of adolescents and of youth (INED, 1982, 1983). The increased educational investment seeks and often succeeds in guaranteeing upward socioeconomic mobility.

However, between the Scandinavian countries and the Mediterranean countries (two extreme situations), enormous *differences* exist in the forms of *passage to adulthood*. In the Scandinavian countries, the departure from the family of origin is *traditionally early*, with the formation of a family unit or of an own neolocal household (with an independent dwelling unit, whether living alone, as a married couple, or cohabiting). Entry into the world of work is likewise early, sometimes with study and work combined. All of this takes place in the context of an overall social insurance and public support system that contributes to maintaining this kind of behavior. In Mediterranean countries, by contrast, departure from the family is *traditionally late*; it still takes place almost exclusively for reasons of marriage, especially for women, and without any important public support (Corijn and Klijzing, 2001). The fertility and family surveys of the comparative European program Fertility and Family Surveys (UN-ECE, 1996–2001) have recently provided an overview of these differences: in Sweden in 1992–1993, only 8.4% of women age 23 were living with their parents, whereas in Italy in 1995–1996, 86.8% of women aged 20 to 24 still resided in their family of origin.

Nevertheless, in all Western countries, we have recently seen a general slowdown in the departure of youth from their families. Multiple factors seem to be at work in favor of a growing diffusion of the practice of staying in the family of origin for an extended period: (1) the reduction in the size of family units, which tends to maintain stronger centripetal cohesion between the parents (or the single parent) and the only child or only the two children (in contrast with large families); (2) the lengthening of periods spent as a student and the growing complexity of the connection between schooling and the evolving economic system and, furthermore, the difficulties of access in the labor market (more precarious prospects for getting established, less professional stability, stagnation of careers); (3) the tendency to delay marriage, whether because of new freedom to live affective and sexual experiences outside of traditional conjugal forms or the growing practice of nonmarital cohabitation; and (4) the emergence among the young of new needs that often cannot be satisfied by their own resources and are better covered by the economies of scale that can be realized within the family of origin. These are thus factors that accompany *a more complex and more conflicted passage to the autonomy and the responsibilities of adulthood*. At the same time that it is necessity to rethink what is meant by old age, because of demographic aging, and where a new schema of taking into account social, health, and economic aspects of the top part of the population pyramid is being laid out, it appears to be essential to not ignore the *extension of the ages* of youth nor the disquieting difficulties of the passage to *adult autonomy*, and to not penalize social investments in favor of youth (Cheal, 1983; Coale, 1987). The indeterminacy and precariousness of social norms concerning the transition to adulthood (Galland, 1984; Bozon and Villeneuve-Gokalp, 1994), which affect youth beyond simple short-term economic pressures, require a more precise knowledge and the definition of new equilibria in the *rules of intergenerational transmission of material and nonmaterial resources*, the old rules no longer being supported or legitimized by traditional demographic structures (Sgritta, 1995).

3. Adults

But *adulthood* is itself expanding and changing. At ages 60 to 65 years, can a person in good health and with 20 years of remaining life expectancy be considered as old? The high proportions of individuals in a cohort who attain this age in good economic and health conditions produce a new social stratum with its own expectations, an important capacity for consumption and investment, and non-negligible political power. But what has undoubtedly most completely changed the *lives of women*, in both timing and content, is the change in *ages of procreation*. Although the duration of their lives is getting longer, women have seen births reduced in number and concentrated within a shorter age interval, considerably reducing the portion of their lives devoted to reproduction and liberating them earlier from the direct obligations of child care. Assuming that these obligations last up to the end of adolescence of the last-born, about 60% of the remaining life after marriage (as opposed to 20% in the pre-transition regime) can thus be devoted to other activities. This is a *new condition*, which has made possible the massive presence of women in the labor market and has given women more continuity in their careers (conforming better to growing expectations in this area). More generally, this evolution has also given women a *different bargaining power between the sexes* in all domains, from access to *education* (new generations of women tend to have more schooling than men) and in decisions regarding *reproduction* (including decision on contraceptive means to use, on recourse to induced abortion, on access to assisted fertility), and the household. The emancipating pressure experienced by women is so strong that it becomes *difficult to reconcile maternal and professional roles* without first experiencing *a revision of the economic system regarding work* (flexibility of paid work time and of forms of support and of social and health services for mothers of small children), and without *also asking men* for greater flexibility on these same subjects and particularly a more equitable distribution of family tasks.

If the new reproductive paths offer new opportunities in life for women, the ways in which they are managed (control of all of the process of reproduction; segmentation of the stages of the reproductive process, which will be discussed again below) have also required profound cultural transformations that lead to the multiplication of models of sexual and conjugal behavior. Figure 88–1 reproduces a classical synthesis (Bongaarts, 1982) of the importance of the evolution of the principal intermediate variables in the change of potential fertility and in the lowering of effective fertility that marks the passage from traditional socio-economic contexts (level 6) to increasingly developed contexts (level 1).

4. Older Ages: Displacement of the Social Barycenter to Old Age

The aging of populations is well on its way to becoming the most visible and striking aspect overall of the demographic transition, whether it flows from

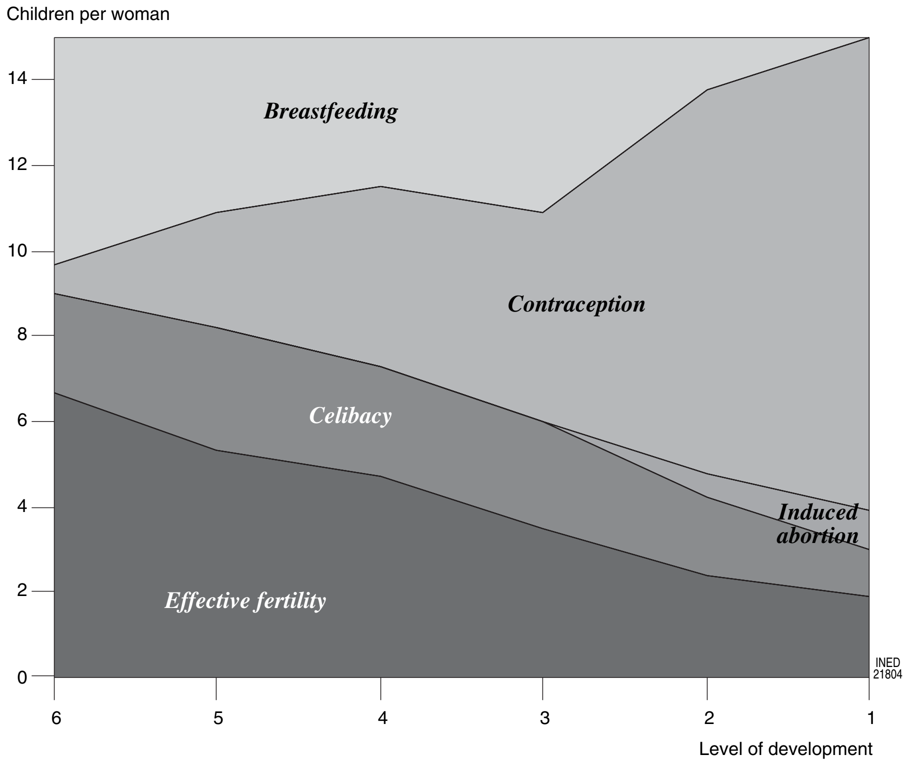

FIGURE 88–1 Effects of the intermediate variables on potential and effective fertility according to the level of development of a country. Scale: 6, less developed; 1, more developed. (From Bongaarts, 1982.)

the scarcity of births, which now tend to be below the replacement level and correspondingly reduce the base of the population pyramid, or the spectacular *increases in life expectancy being realized at older and older ages*. Before the transition, when mortality was high, only 20% of a generation reached age 65; with current survival conditions, it is now the case for nearly 90%. Life expectancy at birth has gone from 35 years, at the beginning of the transition, to 65 years, 50 years ago, and then to 75, 80, or higher (with differences by sex) at present. Just the effect of this prolongation of life, by itself, would have resulted in a demographic transition with more than a doubling of the population. Moreover, the number of people over age 60 has increased because of the prolongation of life and the growing concentration of deaths around the modal age at death (today close to 80). *The socioeconomic level* of the elderly has improved from one generation to the next, under the effect of the accumulation of human capital investments realized since the middle of the 20th century. At older ages health deteriorates, but the *severe loss of autonomy* only becomes important after age 70, becoming even more so after age 80. In France, for example, one-third of individuals over the latter age were estimated to be suffering from a medium incapacitation during the 1980s (Colvez and Robine, 1986). New thresholds need to be adopted for the description of the qualitative characteristics of the oldest age groups (e.g., ages 65 to 74, 75 to 79, and 80 and over for the very elderly), and a moving threshold should be used for old age (measured by the age at which remaining life expectancy is, e.g., 10 years), more consistent with the actual or expected conditions of good functional autonomy (life expectancy in good health; Fig. 88–2) (Caselli and Egidi, 1993). The conception of old age as a relatively brief and residual period of *passive enjoyment* of the goods accumulated during earlier years devoted to work and reproduction appears to be qualitatively obsolete and economically nonviable, in that it weighs entirely on the reduced numbers of people at the traditionally productive ages. The social and cultural adaptation of the idea of old age, in more *active* terms (Laslett, 1989), is getting started, albeit with great resistance and a lot of uncertainty.

5. New Links Regarding Intergenerational Exchanges

At the same time that it has contributed to transforming *individual life paths*, the change of demographic regime that has taken place in the course of the transition, in the economic context of the Industrial

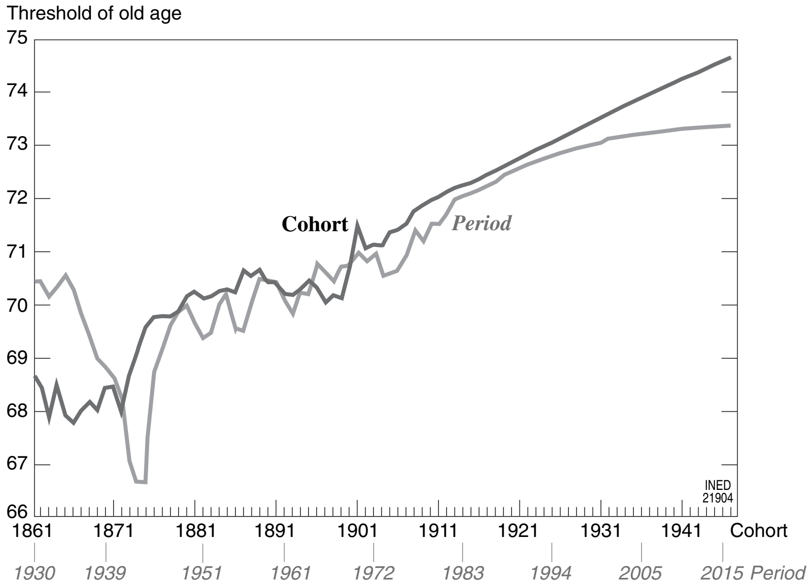

FIGURE 88–2 Threshold of old age (age with 10 years of remaining life expectancy). Comparison of Italian men's life tables by cohort and by period, the year of birth plus threshold of old age. (From Caselli and Egidi, 1993.)

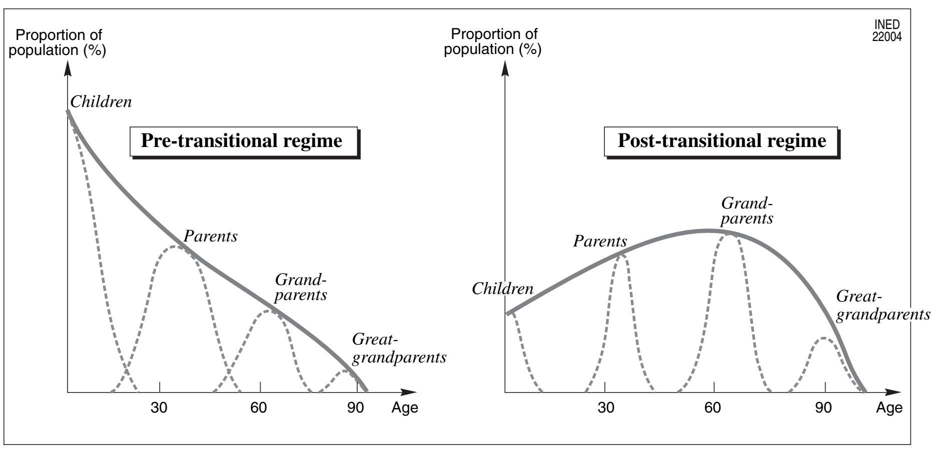

FIGURE 88–3 Chain of relatives.

Revolution, has also radically transformed *inter-generational relations* among children, parents, and grandparents.

The comparison (Fig. 88–3) between the age structure of a *young*, pretransitional population (sharp and regular reduction in numbers going from the youngest to the oldest ages) and that of a contemporary *aged* population (reduced number of the youngest, growing number of adults and elderly, sharp fall at the oldest ages) is eloquent. The *multimodal distribution* of the chain of *relatives* (children, parents, grandparent, great-grandparents), separated by about 28 years (the average interval between generations) and giving thought to the sequence of successive links, results in two major, inter-related observations.[1]

1. In traditional populations (with high fertility and high mortality), the *relatives* (children, parents, and grandparents; brothers and cousins; nephews and uncles), *are numerous and dispersed*, as regards a reference person, in terms of kinship groups and

[1] A good example of this was given by microsimulation, shaping the kinship network around a reference person (Ego) (Le Bras, 1982). For numerical data on the situation in Italy see Barbagli *et al.* (2003:201).

age classes, such that they are distributed with rather *regular frequency across age groups*, although rapidly reduced by mortality. In other words, kinship groups are numerous, especially related to young people. Conversely, in contemporary aged populations (low mortality, which is declining at the highest ages; low fertility, which is sometimes still declining), reproductive experiences are much less frequent and *concentrated* on a few ages, whereas mortality hardly eliminates individuals except at old age. The distribution of relatives is strongly concentrated around *three or four modal age values* and is characterized by successive waves of children, parents, grandparents, and great-grandparents (and relatives from parallel cohorts), spaced by the intervals between generations. The system of relationships within family networks is changing: horizontal linkages (brothers and cousins) are less frequent, vertical linkages (parents and children, grandparents, and nephews) are *more durable*, and in going from older to younger cohorts, there is a diminution in the number of descendants and an increase in the number of ancestors. At the same time, the ways in which children are socialized are changing, notably because of the changes in the structure of families and households (which are becoming simpler). The case of the only child, more and more common, is quite typical: in the absence of siblings, the child must broaden his relationships outside of the household, with cousins (if he has any) and especially with his adult relatives, and the child makes up for the absence of fraternal linkages by more friendly linkages. However, couples and young families find it more difficult to take in grandparents and great-grandparents.

2. In traditional populations, *young cohorts are proportionally much more numerous than those that gave birth to them*. The rules of intergenerational resource transfers, debit–credit relationships, and material and nonmaterial relationships all rest on this large demographic base. First, parents transfer resources to their young children, then these children become the intermediate generation, giving back to their now-elderly parents their filial debt accumulated in the previous stage (when the parents provided everything necessary for their children). *The viability of the filial debt* is assured, from the demographic point of view, by the reduced proportion of elderly compared with the number of adults and by the relatively short duration of life at higher ages and, from the economic point of view, by the rather reduced consumption requirements of the elderly. In current elderly populations, in contrast, *cohorts of parents have become more numerous than those of children*, at least so long as the reduction in annual numbers of births and improvement in survival at the highest ages continue. The changing of demographic relationships between cohorts is aggravated by the financial burden that weighs on the intermediate generations, at an age and condition to work, so as to pay the costs of assistance and retirement of the elderly (living to be older and with much more in the way of consumption needs than those previously, especially with regard to health). This happens especially in the countries where redistribution by the state is important (as is the case in nearly all European countries) (Esping-Andersen, 1999). In such a context, the traditional intergenerational system of the *filial debt becomes impossible* and is *fundamentally called into question*.

In any case, the exchange agreement of the pretransitional demographic regime (alternating between the filial debt accumulated by the young and then given back to the elderly by adults) was equally valuable for all generations in the cyclical evolution of their lives. The current demographic change no longer allows, with a perspective of a few generations, a guarantee to new generations that they will recover, in old age, the credits accumulated in the productive and reproductive phase of their lives, according to the traditional rule. Hence, there is concern about *iniquities regarding intergenerational transfers*. Reform of systems of pension funds, social security, and health—widening the subpopulation of taxpayers including raising the retirement age and drawing on other resources beyond wages and salaries—are among the paths to explore urgently in order to confront the crises heralded by the *conjunction between a regressive demographic dynamic and a new socioeconomic dynamic*.[2]

Throughout the evolution of the rules of intergenerational transfer of resources, it should be desirable to take advantage of a slowing up of the speed with which populations age. The issue is very complex, because it brings into play the cultural bases of collective life. This complexity can, however, be attenuated if it is possible to simultaneously meet the needs for investments in the young (in order to guarantee effective opportunities for education, employment, family autonomy) and support those who take care of children and family. In this way, some of the current obstacles to establishing new conditions for transferring material and nonmaterial resources between generations in the context of the redistributive policies of the welfare state, may be reduced (Demeny, 1987; Sgritta,

[2] We will not dwell here on the specific effects of the current postindustrial economic transformation, which, among other things, tends to reduce creation of employment and break the traditional national control barriers.

1995; Esping-Andersen, 1999; see also Chapter 81 of this Volume).

6. Multiplication of the Life Paths: Segmentation of the Conjugal and Reproductive Processes

Beyond issues related to the evolution of longevity, one can, from a demographic point of view, identify a plot of the changes that were just quickly described and that have been especially apparent during the recent decades, in considering three principal dimensions and their intersections (van de Kaa, 1987, 1988; Roussel, 1993, 1994):

1. The growing importance attributed to *the limiting of fertility* via a nearly complete mastery of the reproductive process (the radical nature of this control of fertility appears clearly in the recourse to induced abortion, which has become largely accessible and widespread in recent decades).
2. The priority given to the links of *the couple* compared with other family relationships such as the child–parent linkage, in a context of growth of women's economic independence. The importance of marital agreement is so great in and of itself that its weakening, even unilaterally, is legitimate grounds for dissolving the couple's union (the massive diffusion of *divorce* over the course of a few decades appears to be one of the most significant events of recent centuries, from a social point of view [Stone, 1994]); in addition, a couple's bonds can increasingly be established (or re-established, after a previous break-up) without *public contractual visibility* (consensual unions).
3. The simplification and the multiplication of *types of households, with or without a family nucleus*, have become highly dependent on individual biographies. From this point of view, the effects are strongly felt according to the way that, concretely, individuals realize and live the two conjugal and reproductive processes that were just alluded to (family adjustments after a divorce with minor children provide some varied examples) (Condran *et al*., 1994; Ni'Bhrolchain *et al*., 1994).

The *diversification of the life paths* in which conjugal and reproductive behaviors come together and evolve is an important phenomenon that also has methodological implications, notably with regard to observation (Roussel, 1980; De Sandre, 1981; Blayo, 1990). Figures 88–4 and 88–5 show possible paths for formation and dissolution of couples, fertility, and family building. In the pretransitional social and demographic regime, a *uniform idea* of marital and reproductive life prevailed, characterized by *biological constraints*: couples had a precise social mandate to have a large number of children to compensate for the high mortality and thereby guarantee both survival of the family and replacement of the population. The institution of marriage was strictly regulated so as to simultaneously ensure both the procreation function of the parents and the social identity of the child. Within the couple there was a hierarchy of asymmetric roles, with a very strong obligation for women to take care of domestic and reproductive tasks. Fertility control sought to space births rather than to prevent them. In recent decades, on the contrary, we've witnessed a *strong dissociation of ideas about marriage and reproduction*. Each dimension—concerning sex, coupling, reproduction—now follows its own path, both in terms of cultural representation and of behaviors, largely *autonomous* in relation to the others.

1. Sexuality, protected from the risk of unwanted conception, can be seen for itself—before, within, or outside of conjugal life.
2. The reproductive process, even when a conception is begun, can be fully controlled also via induced abortion; massive recourse to abortion is the sign, among others, of a cultural reversal *in the representation of the fetus* (someone who voluntarily has an abortion either resolves in this way a *conflict of subjective rights* in favor of the mother or else assumes that the fetus does not *have* any primary subjective *rights*, at least while abortion is allowed). Moreover, in addition to contraception and abortion, new forms of intervention on procreation have begun to appear, such as *assisted fertility* and genetic engineering.
3. The traditional conjugal model, legitimated by a public and legal pact, progressively moved away from its one-way and constraining pattern to give way to a free choice that couples make based on a private and reversible pact foreseeing a permanent search for consensus between the partners. Failure to achieve this consensus can lead to disruption of the union. The frequency of disruption of legal unions has greatly increased, as has already been noted, and may attain more than 50% of marriage cohorts, except in the Mediterranean countries, where this proportion remains clearly much lower.

The *interferences and interdependencies* between the particular types of management of each dimension of the conjugal and reproductive process—*combined in the life paths*—are numerous, complex, and not always easy to explore. Such interdependencies are engendered either *within individual biographies* or *at the intersection between biographies* of people who live together

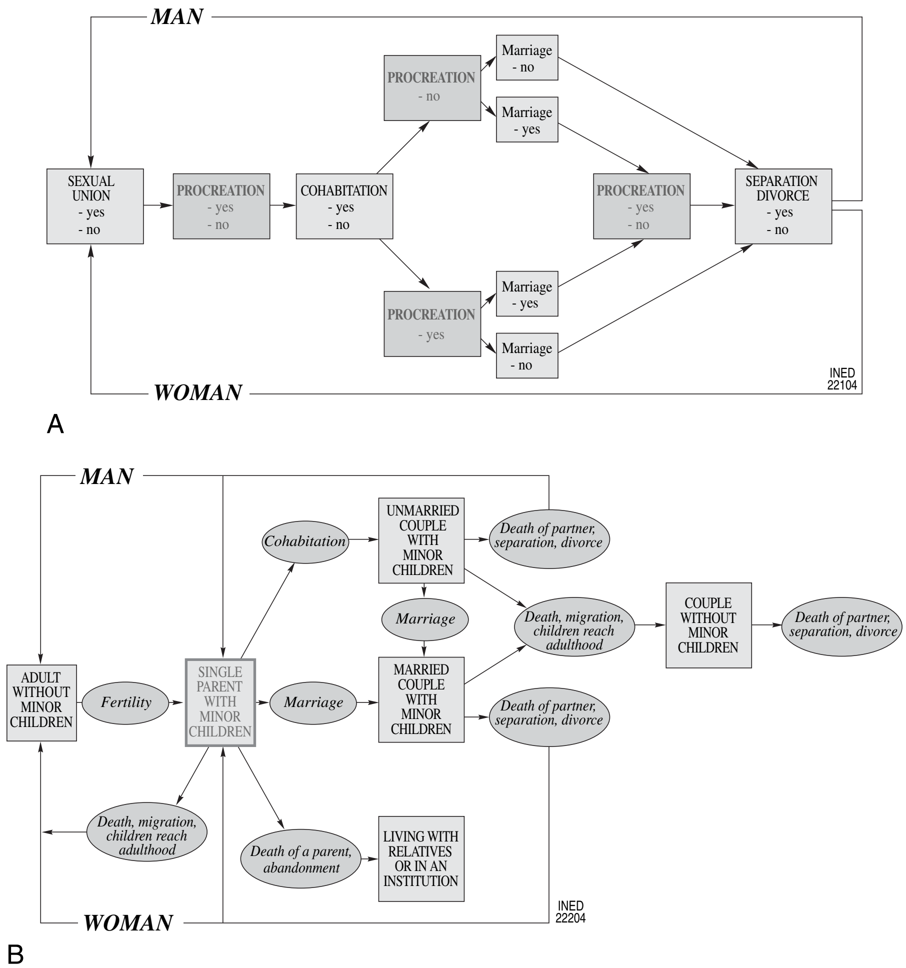

FIGURE 88–4 **(A)** Formation and dissolution of couples: diagram of principal possible paths (the effect of mortality, which can break up couples at any point, is ignored here). **(B)** Formation and dissolution of single-parent families.

during certain portions of their lives (e.g., couples and children). A good example of *interdependence internal to an individual biography* can be given by the adjustments of behaviors linked to a reduction in desired fertility, induced not only by an actual disruption of the couple but also by the simple sentiment of instability of the relationship (Bumpass, 1990). With regard to the *interdependence between biographies*, one example that can be cited concerns the family trajectories of children of separated parents (Hofferth, 1985) or the numerous economic woes of women with children after a divorce (Duncan, 1984; Bianchi and Spain, 1996). For the Western countries, recent data (including longitudinal data) document the deterioration of the well-being of minors involved in the union disruptions of their parents and justify the growing attention given today to the rights of children, even if there remains uncertainty about the long-term effects (Dumon, 1994). New consequences at the individual or collective levels may emerge from the *interdependencies between stages of life* in the difficult transition of the young toward adult status, especially in Mediterranean countries.

All things considered, the *segmentation of the conjugal and reproductive processes* implies a *profound discontinuity* between the institutional rules and the hierarchy that weighed uniformly and globally on couples, marriages, sexuality, conception, and birth (and extended throughout the life cycle) and *the emergence of new rules*. Their elaboration resides in the *sense that one gives* (at every moment) *to each of the dimensions of the process* and in the *protagonists' ability to negotiate* each of them (on the theme of the rights to formulate and safeguard as opposed to the duties to fulfill, and also on the capacity of individual control as opposed to being subject to social control, etc.). All of this evolves in a context of expanding *social tolerance* for different ideas that can lead to previously-stigmatized behaviors.

Such rules, which accompany other, more traditional ones and which don't only follow rational criteria of utilitarian calculation,[3] seem (1) to legitimate the *removal* not only of the material obstacles arising during an individual's life but also the interpersonal agreements (with the emblematical cases of recourse to divorce and to abortion); (2) to give priority to *reversible choices*, circumscribed in time and in their consequences; and also (3) *irreversible choices*, if in themselves they open new spaces of autonomy and opportunity. Whatever the causes of the differentiation of the paths and their rules, the fact is that *the possible paths are multiplying*, under the effect of different combinations of solutions concretely adopted, during their lives, in the domains of sexual experiences, the couple and reproduction.

Thorough investigation of the dynamics of marital life (or better, of life in a couple), reproductive life, family life, and linkages between generations should evidently account for the profound modifications of behaviors and attitudes, which in turn alter their empirical expressions in quantity, quality, and social meaning.

II. CONSEQUENCES OF CHANGES OF THE LIFE PATHS AND POLICY IMPLICATIONS

The structural changes of the components of demographic dynamics and how the population renews itself, the new disequilibria between young and adult generations, are so profound, new, and massively diffused that not only do they influence the persons directly involved, in changing life styles, but they weigh even more on *the evolution of social and economic rules and of the agreement between generations*, *on the basis of which this renewal is itself managed* (notably in terms of care and functions of old-age security and assistance) (Davis *et al*., 1987). In this context of change, the evolution of the rules happens because of *the initiative of individuals* who experience the changes and because of the *collectivity* (market, system of relationships, culture) and the *public sector*. New norms must be set forth regarding individual and social rights that require resources to be effective; the distribution of financial means must be modified, and services need to be reallocated to take account of the precarious economic conditions in which certain segments of the population—as a function of age, sex, family type, or number of children—are found. We must react to the perverse effects of aging of the age structure, for which the barycenter is made fragile by the decreasing share of the labor force in the population; the criteria for actions to equalize individual chances need to be revised. This entails important efforts that need to be innovative and that involve delays and lead to more or less coherent successive adjustments. To a great degree, this entails *a posteriori adjustments*, taking into account demographic modifications; sometimes interventions are explicitly decided on in the goal of *confronting demographic changes*. One must, therefore, evaluate the *economic impact* of certain demographic changes and notably their consequences for public finances (as well as the expected effects of interventions seeking to modify demographic trends by influencing fertility, health, migration).

[3] On the different types of logic of rational behavior, see Micheli (1995).

As a simple example, let us quickly emphasize the most current aspects of policy attention to the changes in this domain, a few interventions and international orientations, notably of the European Union, during the 1990s.[4]

1. The year 1993 was dedicated *to the elderly and to solidarity between generations* (CCE, 1994). In the context of maintaining the European social model (which gives more emphasis than do others to state intervention in favor of equalizing opportunities and addressing the struggle against social exclusion and poverty), it is noted that aging of the population requires improvement in the role and contribution of working retirees, that some form of insurance be provided for long-term care for dependent persons, and that old-age security systems be made more adequate. An *observatory of aging and of the elderly* was thus set up.

2. Since 1989, an observatory, renamed in 1999 the European Observatory on Family Matters, has also dealt, at the community level, with *national family policies*. Pertinent national policies assume a collective engagement (most often not systematic as the European Union would like) for increasing the value attached to families, which are essential social resources although partially compromised by difficult situations. In fact, households and families, in evolv-

[4] For an extension of the context to international policies, see Finkle and McIntosh (2002); Harbison and Robinson (2002); and, with regard specifically to fertility, Ofosu (1995). The subject of public policy seeking to adapt to changes in the life paths or to try and modify the demographic basis of these changes merits special and expanded attention, which is the principal focus of volume VII of the treatise. The stage of socioeconomic development here takes on crucial importance.

ing, have had to take on themselves numerous burdens, especially concerning the consequences of *divorces* (single-parent families, children with problems), *women's disadvantaged situations* (women with children in poverty, women without sufficient resources), and the *precarious positions of persons asking for support and care*. The measures proposed and adopted, in a very diversified manner and with variable intensity (Dumon, 1994), essentially deal with direct support for individuals so that their *family may satisfy its own needs* (e.g., support for the costs of minor children; facilitating women's work, especially for single mothers; forms of reconciling work and fertility; lightening of the burden of care, including health care). Initiatives are often public, but the growing difficulty of managing the welfare state requires solicitation of market services and voluntary associations. Special attention is paid to policy programs that can promote equal opportunity between women and men (CCE, 1994).[5] Interventions seeking to reduce the costs of children for the family and to reconcile work of mothers (and fathers) and care of children become more widespread as the number of births diminishes to well beneath the level of fertility necessary for replacement.

3. The *absolute priority* of the 1995–1997 community social action program was *employment*. In fact, this priority seeks not only to respond to the effects of the competition resulting from globalization of the economy and to the fact that technological innovations tend to reduce employment (reasons why one must *promote employment creation*), but also to facilitate the *access of the young to the labor market* thanks to new *training* programs and the immediate and future (permanent) improvement of the skills of those who work (EC, 1995). It would thus be possible that such a program could counter the current tendency of the young to prolong their stay in the family of origin and to delay their entry into a couple.[6]

[5] See also the specific contributions published on France, Hungary, and Sweden (Golini *et al*., 1991) and the papers presented at the Bologne Colloque on France (Chauviere, 1994), Germany (Ostner, 1994), England (Bradshaw, 1994), the United States (Kamerman, 1994), and Italy (Saraceno, 1994).

[6] To complete the information on the orientations of the European Union and the countries that constitute it, as well as to bring it up to date, it is useful to consult the European Union's Web sites: for society, demography, and family, see *www.europa.eu.int/comm/employment_social/eoss/index-eu.html*; for social security and social integration, *www.europa.eu.int/comm/employment_social/missoc_info_eu.htm*. One can also refer to the *White Book on Youth* (2000) and to the 2000–2006 program of action associated with it, as well as to *Social Policy in Europe* (2000), which gives particular attention to employment (which remains an absolute priority), to the problems of immigration, to equality between men and women, to social security, to the funding of retirees, to social integration, and to health.

III. OBSERVATION AND ANALYSIS OF THE LIFE PATHS (TOWARD AN INTEGRATED APPROACH)

This rapid proposed synthesis on the upsetting of the equilibria among age groups and the diversification of the life itineraries that characterize the replacement of Western generations (adorned by several notes on the interaction among socioeconomic components and on the asked-for policy adjustments) is based on solid and shared evidence. Emerging microdemographic knowledge integrates the macrodemographic background and context. It stems from conceptual research frameworks and modes of observation and analysis that add themselves to the macrodemographic approach (see Chapter 23 of Volume I), with convergent goals. How does one arrive at this knowledge? Can classical demographic methods be developed as a function of this type of observation? Some replies will be given in what follows, with emphasis on three aspects of microdemographic research: conceptual frameworks concerning (1) the individual life paths; (2) the spatial, temporal, social, and historical contexts in which they develop; and (3) appropriate methods of data collection and analysis.

The idea of distinguishing the different ages of life is rather old in the human sciences, whether it involves biomedicine (which extends from neonatology to auxology and to gerontology), psychology (which makes distinctions according to the stages of individual development), anthropology and sociology (which study the norms, roles, and forms of stratification by age), etc. The study of the evolution of generations or of intergenerational relationships has notably been the source of remarkable contributions in biodemography (from the description of mortality and fertility by age to measures of the intrinsic dynamics of the resulting generations) and in sociology (analysis of social mobility in comparing the social positions of parents and children or in following the evolution of their status so as to compare them in successive eras). A new step has, however, been taken recently with *the thorough analysis of biographies*. Since World War II and especially since the 1960s, scientific debates have developed between neighboring disciplines; useful field research has emerged, which has increasingly emphasized the importance of a longitudinal perspective, of analysis by generations or actual cohorts, at first *from aggregated data* and then in going more deeply (since the 1970s) into knowledge and analysis on the *life paths*, notably thanks to use of micro (individual) data with retrospective reconstructions, prospective locating of events, and development of specific methods of analysis (Elder, 1985; Courgeau and Lelièvre, 1989;

Magnusson *et al*., 1990; Mayer and Tuma, 1990; Trussell *et al*., 1992; Bogue *et al*., 1993). The observation of the life paths requires the possibility of *precisely situating events in their context* (environmental characteristics, groups to which people belong and reference groups, institutional and normative, social and economic, systems) to better approach the setting and the behavioral mechanisms (Anderton, 1993; Blalock, 1993; GRAB, 1999).

Some details of a conceptual nature can be useful, before recalling the most pertinent modalities of collection and analysis of biographic data of demographic and social interest.

1. The life paths form *elements of the social structure* produced by individual action, which is influenced by the processes of social and economic organization and by institutional and historical forces. It's not a question of considering them as isolated individual biographies, but as *socially modeled paths* (Mayer and Tuma, 1990): the complete representation of such paths requires the combination of observational and analytical approaches at both the individual and collective (micro and macro) levels.

2. The life paths are *multidimensional*, each one being a combination of complex stories (they are also called life domains, careers, or trajectories). Each of them is defined by a particular dimension of action, by a specific temporal structure, and by a particular sequence of events: history of schooling, professional life, life as part of a couple, reproductive histories (fertility and its control), health, migration and residency, military and civic life. The lesser attention given to certain of these trajectories for practical reasons should not make us forget the reality of the plurality of the set of trajectories, which are certainly interdependent. The *heterogeneity* of itineraries makes observation of the pertinent variables important, and it makes *unobserved heterogeneity* (measurement errors of explanatory variables, omission of key variables or important random period shocks) potentially misleading.

3. The recent diversification and increasing complexity of the life paths resulting from the multiple entanglements of trajectories at the level of individual experiences, leads to *abandoning the terms cycle and career*, which evoke regular and progressive sequences (or at least unidirectional ones) that are repeated from one subject to another or even sometimes for the same individual, whereas the actual dynamic can no longer be described in these terms. More precisely and in a more neutral manner, *trajectories* or paths will be used to describe the different stages of a life or a portion of life, or else *transitions from one state to another as influenced by an event or several competing events*, if only one of these stages is considered (Elder, 1985). From this point of view, it also seems reasonable, for example, to speak of the *family life cycle* (conjugal and reproductive), according to the classical expression of Paul Glick, only for the fraction of the population that is living the stages of family expansion and contraction via the sequence marriage–birth of children–departure of children from the family–widowhood. Table 88–1, using retrospective data from the Canadian censuses of 1971 and 1981, gives an example of the changes that took place in the course of several stages of the life cycle for family units with 15 to 35 years of marriage: stability of the unit, departure of children, couple without children. Overall, it is better to avoid using the word *cycle* for other types of sequences with disappearance, alteration, or conversion from one or several stages of the process (Fig. 88–5).

4. The *dates* at which the *state* conditions of the subject are observed and the *time intervals* during which the *events* that modify them take place can be identified in two ways: by the individual (biographic time) or with reference to the context (historical time). For isolated individuals *age* is a temporal variable of *major significance*, because it is a marker of the evolution of biological characteristics in a given context. But the *durations* spent in a state (e.g., as a spouse, mother of parity two, employed in the labor market) between the event that creates this state and the arrival of the event that will change it, also allow for, at a given age, following reality very closely and aggregating indi-

TABLE 88–1 Average Number of Years Lived by the Family Unit in Each Phase of the Life Cycle, after 15 Years of Marriage and before the 35th Anniversary (Women in a Couple), Canada 1971 and 1981

Family size	Duration of each phase of the cycle						
	Stability		Contraction		Without children (postparental)		1971
	1971	1981 (Δ%)	1971	1981 (Δ%)	1971	1981 (Δ%)	
1	11.1	6.3	—	—	8.9	–7.9	20.0
2	9.4	3.2	5.0	–4.0	5.6	–1.8	20.0
3	8.0	–3.7	8.7	–2.3	3.3	15.2	20.0

5	6.2	–24.2	12.5	8.0	1.3	58.0	20.0
6+	7.9	0.0	8.3	2.4	3.8	–5.3	20.0

Δ difference, in percentages, in years lived as of the 1981 census, in relation to the years lived as of the 1971 census.

From Pêron *et al*., 1986: table 3.

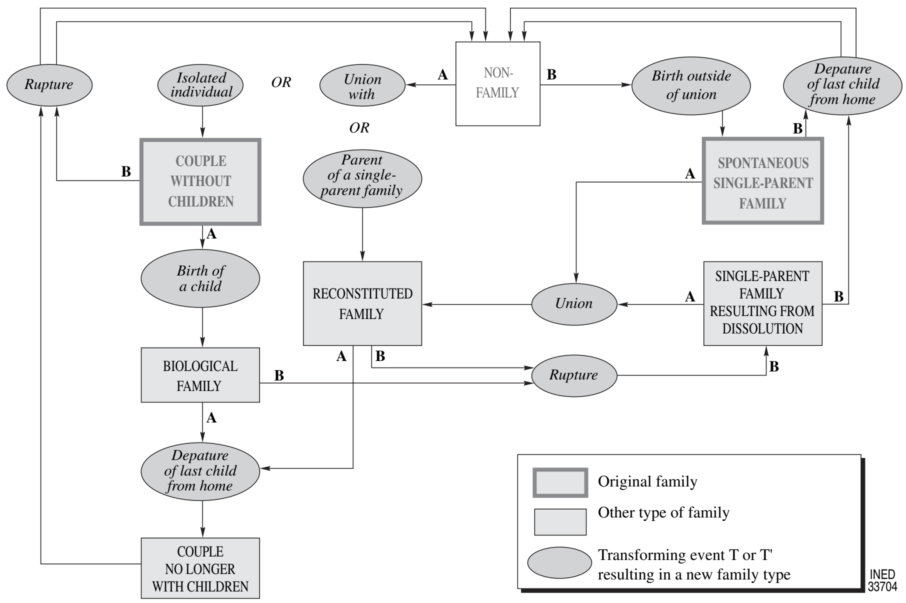

FIGURE 88–5 Family types and transforming events that constitute a family type. After a separation, the two partners in a family can form two single-parent families if each of the parents has at least one child, or one single-parent family and one nonfamily if only one of the parents is taking care of the children. To avoid overcrowding the diagram, the path of the parent going to the nonfamily situation is not shown. (From Blayo, 1990.)

vidual biographies that explain in part the heterogeneity of the population. *Historical*, *chronological time*, on the contrary, *both regarding individuals and the context*, has a *conventional meaning of proximate variable,* which incites us to study the underlying factors that are presumed to influence the life paths. Thus, attention *to the year during which a cohort of individuals is formed* (who all experience the same original event) makes sense not only for individuals but also for groups of individuals *exposed*, *at the same time*, *to the same environmental*, *economic*, *social*, *and institutional factors* that can give them a certain homogeneity at the outset and that may influence them for the rest of their lives. Moreover, individuals can be exposed to *specific* conditions that are important from a demographic point of view: as much as possible, it would be good to be explicit both about the general conditions (collective contextual factors) and about the specific conditions. In the same way, the *year in which an event takes place* can indicate propitious or unfavorable personal or contextual conditions, which should be measured by using pertinent indicators. To identify, with a goal of collecting data, the *factors underlying the stages of life* probably linked to the behaviors being studied is a complex exercise, open to debate and in continuous experimentation, which *results in the updating of personal characteristics* in the course of biographical time and *the construction of individual*, *environmental or social contextual variables*, which can be situated either all along individual biographies or as a reference to given periods. For example, at the *individual* level, asking interviewees the community or the type of family to which they belonged up to the end of adolescence seeks to capture contextual elements, important for explanatory purposes, during the phase when subjects were being educated. At the *collective* level, the study of events that affect individuals during a given year can usefully benefit from pertinent associated indicators, taken also from external sources, peculiar to the same period, dealing, for example, with the economic or labor market situation or with the political context.

5. In thus considering the *multidimensional* and *multitemporal* character of life trajectories, it is apparent that they require a *multilevel* frame of reference (Goldstein, 1995; see Chapter 24 of Volume I). It is necessary, therefore, in principle, to locate the data deemed to influence the variables that are the subjects of the study at multiple observational levels, not simply at the individual level, and also at the level of contextual units that may interact (family, social, normative, economic, territorial systems), which are themselves defined *in time and in space* in a coherent and pertinent manner.

1. Age-Period-Cohort and Beyond

The position acknowledged here implicitly takes part in the polemic on the supposed theoretical advantage of giving priority to cross-sectional (period) analysis compared with longitudinal analysis (by cohort) (Ni'Brolchain, 1992); the alternative here seems to be ambiguous. There is no doubt that the importance attributed by Norman Ryder (going back to the mid-1950s) to generations (cohorts) refers to the moment at which a group of subjects experienced an original event (and in the process refers to the interactive contextual conditions to which the members of the generation or cohort were exposed at that point) and focuses on the impact, generally specific and distinctive, of the historical vicissitudes on the life paths of different cohorts. The French demographic school was created and developed, under the direction of Louis Henry and Roland Pressat (INED, 1995), in harmony with this thesis. They emphasized that longitudinal description of sequential demographic behaviors (and other types of behaviors) constitutes the most *direct and natural* approach (i.e., closer to the unfolding of the life paths of individuals), whereas cross-sectional descriptions (across fictional cohorts) are purely conventional and lead to synthetic measures that are generally biased. But we do not see how this type of proposition, *from a general principle imposed on observation and analysis*, could be opposed to the empirical observation that, especially in periods of rapid behavioral changes, the variability of behaviors themselves is more attributable to a period effect than to a cohort effect. Nor is there opposition to the definition of current measures that draw a greater part from the *duration* in a state than from the *generation* (Rallu and Toulemon, 1993a,b). Such an observation should, if necessary, lead us to simultaneously and distinctly take account of the effects on behaviors both of the *generation or cohort* as well as the *period* in which the behaviors are expressed, rather than to neglect cohort measures, the importance of which can be felt in other temporal variations.

In this sense multivariate age-period-cohort (APC) analysis (Hobcraft *et al*., 1982; see also Chapter 18 of Volume I) of fertility and mortality (measured by year of observation and by age) seeks to distinguish, other than the (fixed) effect of the age structure of the phenomenon (strongly conditioned by biological factors), the (fixed) effect of the generation to which one belongs (variable across cohorts, but unaffected by period factors) and period effects. If the result was a nearly total absence of any period effects, this would mean that we are looking at cohorts for which the future life path is entirely predetermined from the outset. Such a drastic condition hardly seems reasonable. It is more realistic to think that a particular weight is exercised by the original context (there is more of a difference as the distance between successive generations is greater, because of the intervening historical changes), all the more so by *other significant moments* lived by the generations before they experience the events happening during the period of observation, which is equivalent to assuming that onto the specific history of generations is grafted *the influence of time throughout the life path and within the period during which the events being studied occur*. It is not surprising that APC analysis of the recent (1958–1982) variations in fertility by age in Italy show a period effect more distinct than the cohort effect at the time when first the *baby boom* and then the *baby bust* took place (the generations concerned being those born between 1918 and 1967), but in the same APC analysis *extended to other variables* (Martinengo, 1994), the result of the *differential effect of the education received in adolescence and the effect of territorial distribution* are still more distinct. This shows the importance of the influence of inequality of opportunity for access to education that they experienced in their youth, beyond that of the context in which they (in large part) lived the events studied. In the final analysis, it seems important not so much to reduce the time points taken into consideration but rather to *enlarge the scope* of investigation.

In this sense the question of the possible disappearance, owing to obsolescence, of simultaneous APC analyses (Mayer and Huinink, 1990) suggests some distinctions. The APC combination is a basic crossing of temporal references, for which the APC analytical techniques seek to discern the respective weights in exploiting macrodemographic data. This minimal combination may extend to other significant temporal variables that, if one has pertinent microdemographic data, can be exploited (with enhanced efficacity) via multidimensional analytical models of individual biographic data (see also Chapter 18 of Volume I).

2. Individual Trajectories (Life Course) and Family Trajectories (Family Cycle)

The demographic and social study of the evolution of the life paths thus requires observations as extended as possible in time and taking the context into account. Demographic events almost always bring into play the household and family contexts (Bongaarts *et al*., 1987). If *individuals* are the protagonists of behaviors, *families* (or households) appear themselves as the original context of demographic renewal, and it is reasonable to think that, via the systematic interpersonal relationships that characterize them, they influence the decision-making processes underlying individual conjugal and reproductive trajectories. But the development of data collection and analysis regarding individual and family units must follow different criteria. Is it possible, and how, to link the two approaches?

The tendency to reconstruct life paths cannot not *give priority to individuals*, *from the point of view of observation and of analysis*, although they will be gathered from the interactions with the higher-level pertinent social unit. In this sense the *family characteristics are used as an attribute* in the course of the personal life (e.g., in describing the types and characteristics of the household and the *family* of an individual: the family into which he is born, the family he left for the first time as a youth, the new family that he formed or in which he entered when he left his family of origin, the family in which he was living at the time of his divorce or after the divorce of his partner, the family in which he lives, or the family that he anticipates forming). It is also possible to seek to collect elements relative to the specific unit of the *couple* in which the individual may be a part. The *events* that change the configuration of families are thus considered as starting points of *transition* for individuals. One must acknowledge that, in this manner, a representation at multiple levels is supplied but focused on the individual himself, whereas the life paths of the family as a collective unit could be more appropriate to explain the specific individual paths. Nevertheless, the attempt to collect all of the important family changes assumes that complex distinctions have to be made among a multiplicity of nontraditional family paths, linked in particular to interferences between reproductive dimensions, on the one hand, and recent union types and union disruption of new couples, on the other hand,[7] but also to coresidential family passages (evolution of the household as such, as a higher-order unit compared with the component family nuclei).

Moreover, to simultaneously follow the entanglement of individual biographies that intersect with one another throughout the family paths (as unit of study), even if they can be reconfigured as operations of maximum adherence to the actual processes, brings with it specific data collection problems. And for the analysis, problems of *coherence between interdependent individual itineraries* (complicating the classical problems to reconcile, e.g., measures of male and female fertility) and of *identification in time of family units* (as sets of several subjects) must be resolved.[8] Identification of family units in time entails an arbitrary definition of the *rules of continuity*, of the type elaborated by the Survey of Income and Program Participation in the United States (McMillen and Herriot, 1985; De Sandre, 1986). The transition of individuals from one family type to another and, more infrequently, the transition of families from one type to another can usefully be studied with survival models, relying on different explanatory variables (White and Tsui, 1984). However, family typologies and the rules of continuity, even if only a little different, lead to substantially different results that are not comparable for the same situation and are difficult to reduce to the usual cross-sectional typologies.

One can quite rightly give priority to individuals, couples, or families (taken as units of observation and analysis) in research objectives, in either an alternative or integrated fashion. *Today it seems simpler to investigate the individual paths* by associating with them, as attributes (even to define a state or its variations), characteristics or events that take place at the collective level. The problems left hanging for the dynamic study of *units of two people or more* are constraining (measuring collective characteristics and interactions, identifying transitions and of competing risks, evaluating the selection of families that are outside of the field of observation, controlling heterogeneity, decomposing the effects linked to the stage of family life and to time, etc.), but that should not prevent us from seeking to disentangle them.

IV. DYNAMIC INFORMATION ON BIOGRAPHICAL STATES AND LIFE TRANSITIONS

The manner in which data collection is organized strongly conditions the possibilities for analysis of the life paths. This is why, quite fortunately, ad hoc surveys are organized. These surveys can provide information as appropriate as possible for the analytical methods. However, in certain cases, new analytical possibilities have been suggested, allowing for the use of information not specifically collected for the study of demographic and social biographies.

Exhaustive census or vital statistics data can be used to analyze partial biographies. For example, vital statistics data are often tabulated as a function of the

[7] Charlotte Höhn (1987), for example, considers it useful to take account of 12 to 40 types of paths.

[8] Nico Keilman and Nathan Keyfitz (1988), as well as Michael Murphy (1995), speak of dynamic definitions of families as elusive concepts.

cohort and the duration between consecutive events (marriage and birth) so that historical series by cohort can be constructed. However, the use of explanatory variables is then problematic, owing to the usual lack of annual information on the population according to exposure to the risk of experiencing the event being studied. The use of census microdata can allow for reconstruction of the births of women with minor children (who have not yet left the family of origin) in associating other characteristics of the woman or of the family pattern at the time of the survey. It is likewise possible to link individual (and family) microdata from successive censuses or census microdata and current birth data and data on subsequent deaths.

The most pertinent data for the study of biographical transitions and life trajectories come, however, from (1) retrospective or (2) prospective sample surveys of individuals or households (with or without a nucleus), which can be linked up to information from other sources. Prospective surveys include *panels* of representative samples of the population and of samples of birth cohorts. A well-known example of a panel of this type is the Panel Study on Income Dynamics, which covers 5000 to 6000 American families that have been followed and integrated since 1968 (Duncan, 1984; Duncan *et al*., 1994). An example of a sample by generation is the study that covers people born in 1958 in England, interviewed at 1-year intervals throughout their lives (Fox and Fogelman, 1990). It should be noted that even in these prospective surveys, interviews in each round include retrospective questions, but they are limited to the interval since the previous round. Although I refer the reader to other works for more detailed comments on the specifics of different types of data collection (Murphy, 1995; GRAB, 1999; see also, in Volume IV, the chapter by Dominique Tabutin (Chapter 121) on systems of observation), and with due emphasis on the care required regarding the sample frame when life histories in terms of transitions between states are being studied (Hoem, 1985), I wish to emphasize two points here.

In a number of Western countries during the 1980s, family *panels* were established in order to study the demographic and socioeconomic dynamics via follow-up observations at brief intervals (at least in Switzerland, France, Germany, England, Luxembourg, and The Netherlands). In some cases (Survey of Income and Program Participation in the United States, since 1983), the repeated data collection on the same individuals is limited to a small number of years so as to reduce one of the major drawbacks of panels (and even more of samples by generation)—the reduction of the sample (attrition), which over time biases the sample via a selection effect.

Retrospective cross-sectional sample surveys, which may be periodic but with independent samples, are, however, the most used. One of their principal limitations, the drawbacks of reconstructed data stemming from errors in memory (Auriat, 1996), does not seem to be a very pertinent objection for infrequent and very important events (such as marriage, divorce, or birth) for which there are means of verification, but they do present real problems for more frequent behaviors that are difficult to verify, especially for opinions and attitudes. The system of surveys that was the most profoundly innovative regarding retrospective data collection and that strongly stimulated applied analyses is the World Fertility Survey, carried out in more than 60 countries during the 1970s and 1980s (Cleland and Scott, 1987). Among the more recent surveys that constitute a new and important effort at retrospective description of different dimensions and trajectories is the National Survey of Families and Households of the University of Wisconsin (1988) (Sweet *et al*., 1989) and the Fertility and Family Surveys under the auspices of the Economic Commission for Europe of the United Nations (a survey done in the Economic Commission for Europe countries during the 1990s; see UNECE, 1996–2001). This latter set of surveys provides information, at the individual level, on retrospective characteristics pertaining to (1) the parents of the interviewee; (2) the parents of the interviewee's partner, (3) the places of birth and residence up to adolescence; (4) the first departure from the family of origin, in relation to the history of events with systematic dating; (5) schooling; (6) unions of couples and possible disruptions; (7) pregnancies; (8) contraception and induced abortion; (9) births and adoptions; (10) work; and (11) migration (UN-ECE, 1992). One of the major objectives of these surveys was, clearly, to reconstruct interrelated life trajectories, surveyed in much greater detail,[9] to evaluate their effect on marital and reproductive behaviors. Reference to variables other than at the individual level (couple, own family, family of origin, places lived as a youth) is only provided within the individual questionnaires, and not from collective variables measured in a comparable way in their context.

[9] The quality of the responses, above all regarding the exhaustiveness and the dating of events, seems to be satisfactory. With regard to the debatable international comparability of the surveys of the Fertility and Family Surveys project, see Festy and Prioux (2002). Concerning a new, longitudinal project, *Generations and Gender Programme*, see UNECE-UNPF (2000).

V. RELATIONSHIPS BETWEEN TRAJECTORIES AND DEPENDENT VARIABLES, MULTI-STATE TRANSITION TABLES AND HAZARD MODELS

There are two different analytical strategies that are used in the study of trajectories of events that follow one another in time (formation of a couple, contraceptive behavior, pregnancies, births, employment, etc.). One approach is to measure the *incidence of each nonrepeatable event* within a trajectory (unions, pregnancies, births, etc., *according to the order* of appearance) as a function of the *population at risk* (e.g., second-order births in relation to first-order births), in assuming, in this case, that the exposure to risk continues for someone who has experienced the initial event (first-order births, which defines the initial state of reference) even when he has experienced the event being studied. Appropriate analytical techniques are based on empirical probabilities and progressive rates, and they may partially alleviate the reduced attention to the temporal dynamic of the process in specifying it for periods before the state of reference (state dependence).

The other approach is to measure the *transition between one state and the following one* by virtue of *a nonrepeatable event* (or of several competing events), while taking account of the *duration between the initial state and the event* experienced. In this case it is assumed that the exposure to risk changes after the event being studied occurs. The appropriate analytical techniques are *survival functions by duration in the state* (life tables) and hazard or waiting-time models (Hobcraft and Murphy, 1986), with the useful specifications of the space of the states being studied and of the transitions between states.

The pertinent quantitative analytical models seem to have developed in a parallel fashion, only recently coming to a substantial integration: (1) one approach consists of analytical models of *relationships among variables* (linear models with latent variables based on the analysis of the covariance structure, linear structural relationships, and nonlinear extensions) applied to longitudinal data with a continuous metric; (2) another approach comprises the extensions of the classic demographic *survival functions* (multistate processes with multiple decrements, i.e., with several competing causes of exit or transition, and with multiple increment-decrements, i.e., with the possibility to increase the population at risk in addition to decrease it) applied especially to aggregated data; and (3) a third approach, based on the definition of the individual biography as a stochastic process with discrete states and continuous time, combines *survival models with regression analysis* (*hazard* models or multivariate survival analyses) and applies them to sample microdata. The last direction of research is destined to profoundly integrate the second. In particular, the exploitation of individual biographic data facilitates remarkable progress in linking up longitudinal and cross-sectional approaches (Palloni and De Sandre, Chapter 135): for example, by means of the application of multistate survival models to fertility by age-parity-duration and by other characteristics or in trying to separate out the effects of timing and intensity in synthetic period measures. Important methodological problems have been the subject of research into the riddle of what hypotheses may provide solutions (notably, measuring unobserved heterogeneity and evaluating the fitting of analytical models to biographies); the diffusion of technical applications, very modest at the outset (Trussell, 1992), is promising (Billari, 2000; see also Chapter 23 of Volume I). Innovative applications to complex real data, facilitated by the availability of biographic microdata and by the existence of manuals giving the methodology and providing directions for computer analysis (Courgeau and Lelièvre, 1989; Blossfeld and Rohwer, 1995; Lelièvre and Bringé, 1998), will enrich these techniques even more, techniques that have the merit of encouraging explicit dealing with a number of *sensitive problems posed both by the sample data* (exit of observations; selection of persons by the effect of the cross-sectional sampling frame; selection of the processes studied by the [right-]censoring of the life paths at the time of the survey; selection owing to sample attrition in panels; effect of omitted variables and omitted or erroneous responses) *and by the longitudinal approach* by transition durations between states, especially sensitive to biasing effects of an imperfect knowledge of the processes (Hobcraft and Murphy, 1986; Palloni, 1993; Blossfeld and Rohwer, 1995).

In a way, the rigor of the analytical procedures requires exercising a new vigilance even on the kinds of observations of behaviors, encouraging ultimately a *more prudent reading* of the underlying mechanisms of sociodemographic changes and *a more established and a more profound reading*.

CONCLUSION

The study of human behaviors, to progress in the analysis of causal mechanisms and long-term trends, should necessarily be based on multitemporal approaches (life paths and historical sequences), multidimensional approaches (taking into account multiple characteristics and factors and taking advantage of interdisciplinary synergies), and multilevel approaches (the results studied at the aggregate level depend on the integration of individuals into significant contexts of primary human relationships, of social, economic, legal, and geographic ties).

Demographic research has a rich and solid experience of studying vital processes based on aggregated data on actual cohorts (longitudinal analysis) or fictional cohorts (cross-sectional analysis). More recent is the direct utilization of individual biographic microdata. Reconciling the two research paths and making them converge represents a rather good investment, one that will take a long time. To link up demographic dynamics with their underlying factors, they must be studied by embracing the overlaps of the principal life trajectories of the individuals who produce them, reconstructing the significant contexts of human relationships (couples, families, communities to which individuals belong, and a reference system) at the level at which they develop. The field is open, especially today, to new contributions at all levels of research: conceptual revision of research projects, renovation and improvement of the ways of collecting information (and of using existing data), procedures and analytical models that are well-suited and pertinent, and updating of empirical reconstructions in terms of both time and space.

Experiencing Death

A Demographic Approach

ALAIN MONNIER AND SOPHIE PENNEC

Institut national d'études démographiques (INED), Paris, France

INTRODUCTION

Demography began with the study of mortality, which remains one of the main cores of the discipline. However, research on mortality focuses less on death than on the study of deaths, that is, on sudden events that have already happened; these events are seen as a collective fatality and are not considered from the point of view of the individual. Studies on medical, cause-specific mortality come a little closer to the reality of death, but nevertheless, they are just as limited as general mortality studies because they look at individuals only in terms of social identity, nationality, socio-occupational background, region, etc.

In reality, death is not an instantaneous or an abstract phenomenon but a concrete process, an experience corresponding to the last stages of life, *a process that concerns people*—the dying person as well as those who know him/her, that is, family, friends, colleagues, and, increasingly, the medical staff,—*and that has an impact on those who remain behind.* This point of view has been widely investigated in other disciplines, especially anthropology and history—in particular the work of Paul-Louis Vincent, Philippe Ariès, Michel Vovelle, and Edgar Morin—through studies on death rituals, or, in the field of psychology (in the line of research conducted by Elisabeth Kubler-Ross), through studies on the support given to the dying, to their family, and to the bereaved.

In demography, however, such an approach to death entails a conceptual leap, because it means considering death as a founding event, a starting point, and not as a final event as it is usually considered by demographers. Death, or its impending arrival, defines the dying person and has a specific impact on the persons close to him or her, who experience death in the sense that they become widows or widowers or orphans, or lose a grandparent, a brother, or sister, etc. Very few demographic studies have been conducted from that point of view. We can mention those concerning the death of relatives (Fourastié, 1959; Le Bras, 1973), on the consequences of widowhood on the mortality of the surviving spouse (Thierry, 1999), or on the subject of elderly persons (Delbès and Gaymu, 1999).

The way death, and all that accompanies it, is experienced by the dying person or by the survivors relies on social trends and, in particular, on demographic trends. In the first part of this chapter, we will examine certain basic characteristics of death from a macrodemographic perspective: in what ways ages at death, causes of death (and consequently the changes in the image of death tied to these trends), and places of death have changed. In the second part, thanks to a microsimulation model, we will describe how the experience of death has changed within families; these changes are due not only to mortality decline but also to changes in fertility trends and in family structures. As will be shown, the experience of death in families occurs not only at later ages but also more often.

Another reason why it is important for demographers to study death is that in the coming decades, the number of deceased and thus of dying persons (and very elderly dying persons), which in the past 50 years has not significantly changed in industrialized countries, will increase considerably. In France, for example, the estimate is that in less than 25 years from now, the number of deaths per year of elderly persons aged over 60 years will be about 550,000, that is, a little over the current number of deceased at all ages; in 2040, this figure will correspond to the number of deaths after 80 years. Overall, in 2050, there should be nearly 700,000 deaths of persons aged over 60 years, among which are 600,000 persons over 80 years. The number of deaths of very old persons, about 250,000 in France today, will more than double during the next 50 years, although the total population will not increase much.[1]

These trends will probably mean that there will be an increasing *presence* of death in society and also, probably, in the lives of individuals. This will entail new public health requirements and will have an incidence on ethical debates concerning the end of life, palliative care, the legalization of euthanasia, or medically assisted suicide.

I. THE DYING: AGE AND SEX, CAUSE AND PLACE

We do not have much statistical information on what is conventionally called the end of life, the last stage of life; in fact, it is difficult to determine when this last stage actually begins.[2] However, one can draw a general picture of how the individual characteristics of dying persons have changed, as well as the circumstances of their death: indeed, these have been considerably modified in recent years, owing to advances made in fighting mortality. Today, dying persons are mainly old persons, even very old persons, and in the latter case, they are often women. The hierarchy of causes of death has undergone a reorganization, differentiated according to age, with a sharp decline in deaths owing to infectious diseases, a rise in accidents and AIDS among young people, and a rise in cancers among mature men and women. Last, people now often die in a medical institution. The description of these changes will be based on macrodemographic data concerning deaths, which will be examined from the perspective of the information they also provide on the dying.

1. The Dying Are Increasingly Old

Today, the dying are most often old persons. This has not always been the case, and it may even be said that in the history of humanity it is a very recent phenomenon, observed only in the 20th century in the countries farthest ahead in the struggle against mortality.

If we look at the distribution of deaths (and thus of the dying) according to age in France (Fig. 89–1; Table 89–1), we see that in the early 19th century, owing to the high infant and child mortality rates, deaths after the age of 60 represented barely one out of three deaths. In 1825, there were more deaths before the age of 15 (37.6%, 20% during the first year) than after 60 (35%). The situation remained the same up to around 1880, with a proportion of deaths in each of the large age groups fluctuating between 30% and 40%. Thus, there were about as many deaths of children as of adults and older persons. With the decline of infant and child mortality at the turn of the century, this distribution changed quite rapidly, and just before World War II, the proportion of deaths of children under 15 fell below 10%, whereas that of persons over 60 reached 60%. As for the deaths of persons aged 15 to 59, the proportion remained remarkably stable at 30% for over a century, except during the periods corresponding to the 1870 war and World War I. Thus,

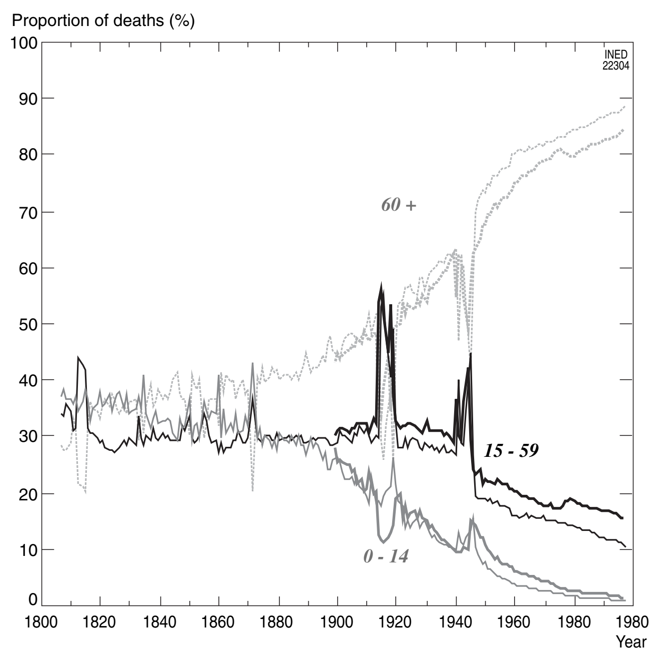

FIGURE 89–1 Age-specific distribution of deaths in France, 19th and 20th centuries. Fine line indicates distribution calculated on the basis of deaths recorded in life tables; bold line, distribution calculated on the basis of observed deaths. (From Vallin and Meslé, 2001.)

[1] These calculations were made on the basis of the mortality projections of Jacques Vallin and France Meslé (2001).

[2] Health economists avoid the problem by focusing on the last year or the last month of life and its costs.

toward 1940, the ages at death and thus of dying persons were still quite heterogeneous.

After World War II, the age-specific distribution of deaths once again rapidly changed: thanks to medical advances and the improvement of living conditions, infant and child deaths became very rare and deaths between ages 15 and 60 years diminished by half; today, the latter represent only 10% of deaths. The consequence of these trends is that the proportion of deaths of old or very old persons has considerably increased: over 80% of deaths occur after 60 years and even 50% after 80 years.

TABLE 89–1 Age-Specific Distribution of Deaths in France

Year	Age			
	0–14 years	15–59 years	60 years and over	
			Total	80 years and over
1825	37.6	27.4	35.0	9.1
1850	29.2	29.8	41.0	10.3
1875	30.1	30.1	39.8	8.6
1900	25.1	30.6	44.3	10.5
1910	20.4	32.1	47.6	11.3
1920	18.5	32.4	49.1	11.9
1930	14.5	32.2	53.3	13.1
1940	9.2	36.4	54.4	15.7
1950	10.4	22.2	67.4	20.8
1960	5.6	19.8	74.6	27.9
1970	3.9	17.4	78.7	30.6
1980	2.2	18.3	79.4	36.3
1990	1.6	16.3	82.1	45.7
1995	1.1	15.6	83.3	49.0
2000	1.0	14.8	84.2	47.1

Distribution in years 1825, 1850, and 1875 calculated on the basis of life tables.

From Vallin and Meslé, 2001; National Institute for Statistics and Economic Studies (INSEE) for 2000.

In addition, the age of dying persons observed through ages at death (bold lines of Fig. 89–1) is lower than that observed through life table (fine lines of Fig. 89–1), because throughout the 20th century the age structure of the French population was younger than that of the stationary population corresponding to the life table.

2. More Women among Very Old Dying Persons

Of course, the overall picture must be qualified according to sex, because the excess mortality of males has increased. Whereas in the beginning of the 20th century, the proportion of deaths over 80 was close to 10% among both men and women, the gap widened over the years, in particular between the early 1960s and the mid-1980s. Today, nearly two out of three female deaths (63.8% in 1995) concerns women aged over 80 (Table 89–2).

We can see that the proportion of women among very old dying persons has increased. Indeed, during the first half of the 20th century, there were about as many deaths of men aged 60 to 79 years as of women of the same age, because the proportion of women among older dying persons had increased from 56% to 61%. Over the second half of the 20th century, we observed a significant decline of the proportion of women among those dying between 60 and 79 years, (as well as under 60), whereas the proportion of women increased among dying persons aged over 80, up to two-thirds in the 1970s and representing about 63% in 1995.

To sum up this overall trend, we can underscore the fact that for those under 80, about two-thirds of the deceased are men, whereas for those over 80, it is the opposite, nearly two-thirds of the deceased are women.

TABLE 89–2 Age- and Sex-Specific Distribution of Deaths

Year	0–14 years		15–59 years		60–79 years		80 years and over	
	Males	Females	Males	Females	Males	Females	Males	Females
Per 100 persons of each sex								
1900	25.9	24.2	32.1	28.9	33.0	34.8	8.9	12.1
1950	11.7	9.1	26.0	17.1	46.2	46.9	16.0	25.8
2000	1.1	0.8	20.2	9.1	45.4	28.5	33.3	61.5
			No. of male deaths per 100 deaths: 64.6				No. of female deaths per 100 deaths: 63.7	

From Vallin and Meslé, 2001.

3. Medical Causes of Death and Changes in the Face of Death

Not only have the dying grown older, but the face of death has also changed over the past 50 years. Indeed, after World War II, the distribution of medical causes of death underwent deep transformations, in particular owing to medical advances. Indeed, the medical cause of death determines not only the circumstances under which the dying person spends the last moments of his or her life but also those experienced by the dying person's family and friends, both before and after the person's death. Dying suddenly in an accident, dying after several weeks because of an acute disease, or dying after a long and painful illness are obviously different experiences, both for the person who dies and for the survivors. To assess the changes that have occurred in the frequency of deaths (depending on medical cause) and to understand the main trends, we will study the changes that have occurred between 1950 and 1995 in the most striking causes of death among the large age groups corresponding to times of life: early childhood, childhood, adolescence, adulthood, old age, and very old age.[3]

If we calculate how the deaths that have occurred in France in each age group are distributed according to medical cause, we can get a picture of the relative importance of the main causes of death in 1950 and 1995.[4]

The contrast between the two periods is striking. In 1950, infant and child mortality was still dominated by infectious diseases, in particular respiratory diseases, which represented 48% of deaths during the first year of life and between the ages of 1 and 14. Deaths owing to congenital or perinatal causes were also quite frequent, whereas deaths owing to accidents seem to have been rather infrequent among children. In 1995 on the contrary, mortality during the first year of life is dominated by congenital or perinatal causes (70% of deaths), causes that concern the very first days of life, whereas accidental deaths dominate deaths from age 1 to 14. The sudden infant death syndrome had not yet been identified in 1950, and for that reason, it does not appear at that time (see below, for more on this issue). However, a new type of mortality owing to malignant tumors has emerged, whereas mortality owing to (usually infectious) diseases of the respiratory tract have disappeared.

In 1950, among adolescents and young adults, 40% of deaths were caused by an infectious disease, either general or of the respiratory tract (tuberculosis), and only 20% were caused by accidents. In 1995 however, accidental deaths represented 70% of the total number of deaths.

Depending on the medical cause of death, in 1950 adult ages and old age were still dominated by degenerative diseases, that is, diseases of the circulatory system, which caused one out of four deaths between 30 and 59 and one out of two or even more beyond that age. At those ages, deaths caused by malignant tumors represented, respectively, only one out of five and one out of ten deaths. Once again, the contrast is striking: in 1995, up to the age of 80 years 40% of deaths were caused by a tumor, and deaths owing to diseases of the circulatory system represented only 15% of deaths between 30 and 59 years and 30% between 60 and 79 years.

In the past 50 years, the overall picture of causes of death has been marked by the disappearance of young children's infectious diseases (and the near disappearance of children's deaths), the increase in the number of accidental deaths among young adults, and the newly leading place of cancers, up to the beginning of very old age. These general lines must be completed first by establishing a distinction between causes of death among males and among females and by specifying the role of certain specific causes as concerns 1995.

There are two main distinctions between female and male death causes, both in 1950 and in 1995: accidental deaths are less frequent among females than among males (however, in 1995 this cause predominates for both sexes), and mortality owing to malignant tumors between 30 and 59 years is a little higher among women, but the tumors have different locations for men and women. Among men of that age group, mortality owing to malignant tumors is caused mainly by smoking, whereas for women the tumors are mainly tumors of the genital system (breast, ovaries, uterus), which cannot be tied to any specific behavior.

Previous groupings according to large age groups and causes tend to conceal certain specificities tied to certain age subgroups or to one or the other sex. To provide an accurate rendering of the overall landscape of death in France at the end of the 20th century, several causes must be pinpointed more specifically. These causes are different from the others because they are particularly striking for public opinion, because

[3] The relative weight of each cause of death is calculated in comparison to the number of deaths, without standardization according to age, because the image of death at a given moment is precisely tied to the distribution according to the age of the dying.

[4] The groups of causes of death globally correspond to the section of the ninth revision of the *International Classification of Diseases*, and statistical continuity since 1950 was ensured to the best of our ability. The data are taken from a database on causes of death accessible on the Institut National d'Etudes Démographiques Web site (http://www.deces.ined.fr/).

their frequency makes them more visible, or both. We selected a few that seem to have a specific impact on the general perception of death today: the sudden infant death syndrome, suicide, AIDS, lung, and breast cancer.

The sudden infant death syndrome is specific in that although its etiology is unknown, it is quite prominent among parents' perceptions of the death risks threatening their newborn baby. This attributed importance corresponds to statistical reality since during the first year of life, one out of five deaths can be ascribed to this syndrome.

Suicide also represents a large share of adult deaths (20% between 15 and 29 years and 10% between 30 and 59 years). As to AIDS, it is not too frequent among young adults (5% of deaths), but it gains in prominence between ages 30 and 39 (one out of five deaths among men and one out of eight deaths among women).

As concerns all tumors, the prominent position of which for ages 30 to 59 years has been mentioned above, some are particularly visible owing to their statistical weight: cancer of the respiratory system (malignant neoplasm of trachea, bronchus, and lung) among men and breast cancer among women. The former represents 10% of deaths among men aged 30 to 79 years, and the latter represents 15% of deaths among women aged 30 to 59 years.

The impact of these transformations (the increasing weight of chronic diseases) on perceptions of death cannot be studied in detail in this chapter and would require specific observations obtained through interviews and surveys. However, it seems that two main images of death tend to predominate: on one hand, sudden death, something quite rare that strikes (accident, acute heart attack, sudden infant death syndrome) the individual or his/her relatives without warning and, on the other hand, death after a long disease, which goes along with serious physical and sometimes psychic alterations of the person. The fact that the latter representation of death is so widespread can be linked to the development of various movements in favor of the legalization of euthanasia and medically aided suicide.

4. Where People Die

In France, the changes in death mentioned above went along with a complete change in place of death—usually a hospital or other institution (clinic, nursing home, etc.), whereas only 30 years ago over half of all deaths still occurred in the dying person's home. The dying process has thus moved from the private to the public sphere.

The study of French statistics shows that people die in three categories of places: home, various institutions (mainly the hospital) and public places, with a miscellaneous category: other places and unreported places. One may leave aside the last two categories, which represent one out of twenty deaths, are closely linked to certain specific causes (accidents), and are special in the sense that the place of death has not been chosen. One must mainly consider the two alternatives: dying at home or dying in a medical institution, with a rather indefinite entity of nursing homes, which are both homes and institutions.

The place where people die has drastically changed over the past 50 years (Table 89–3): in 1950, people died mainly at home, a trend that continued until the mid-1970s, after which there was a change to institutions, in particular hospitals. Today, 50% of deaths take place in hospitals (compared with only 15% in 1950).

One can wonder about the reasons for this trend, which reflects a profound change in attitudes, in the sense that it marks the disappearance of the negative image of the hospital as a dying place for the poor, an image still strong in the 1950s. Various factors have been suggested: urbanization, the disappearance of extended families, isolation at the end of life, housing conditions, etc. An analysis of recent French data

TABLE 89–3 Distribution (%) of Deaths According to Place in France (1950–1995)

Place of death:	1950	1955	1960	1965	1970	1975	1980	1985	1990	1995
Home	71.6	68.9	65.8	62.6	57.1	53.2	32.8	30.4	28.6	25.9
All institutions	20.7	25.4	29.8	34.2	39.1	43.8	63.7	65.8	66.1	68.4
Hospitals and clinics	17.6	21.3	28.7	32.9	37.3	38.8	58.4	60.1	58.1	59.3
Nursing homes	0.6	0.7	1.2	1.5	1.9	5.0	5.3	5.8	8.0	9.1
Public places, roadways	0.9	1.0	1.2	1.5	1.7	1.5	1.9	2.0	2.3	2.2
Other places and unreported	6.8	4.8	3.3	1.6	2.1	1.4	1.5	1.7	3.0	3.5
All places	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0

Data from National Institute for Statistics and Economic Studies (INSEE).

shows that few differences depend on the characteristics of the deceased person or on the circumstances of death. Concerning deaths owing to illness, the proportion of persons dying in a hospital or institution are about the same regardless of whether the person is young or old, married or unmarried, and living in a rural town or in a large city.

However, to better understand the meaning of this change in behavior, it is necessary to know more about the period referred to as the end of life, from home (or nursing home) to hospital. Dying in a hospital does not mean that the entire end of life period was spent in a hospital, and conversely, dying at home does not mean that some time was not spent in a hospital. The opposition between dying at home and in an institution is not as clear-cut as it may seem, especially as new forms of hospital care dispensed in the person's home are now increasingly being developed.

In addition, very few countries publish data on the place of death, and one may surmise that situations in Europe still vary. In Greece, for example, at the end of the 1990s, nearly half of all deaths still took place at home.

On the basis of the observations presented above, a few general remarks can be made concerning the conditions under which dying persons experience their last moments. These observations should be completed by more precise measurements to better apprehend the reality of this ultimate experience. But the dying person's death is also an experience affecting the person's entourage, first and foremost his or her family.

II. DEATH AS EXPERIENCED BY THE DYING PERSON'S FAMILY

Although the dying process concerns the dying person and his/her close family and friends, in a sense, death is only an event for those who survive. As opposed to the usual conception in demography, whereby death is seen as a final event (the ultimate point of each life line of a Lexis diagram), one can also consider death as a starting point, an element belonging to the biography of the surviving relatives. This event, which can be termed "experiencing the death of another person" can take many forms and concerns death of friends, relatives, work relations, or (and this is what we will focus on) close family members. Each discipline that studies death has developed its own specific approach: anthropologists study rituals, psychologists study mourning processes, economists measure the cost of death, etc. The demographic approach to the experience of another person's death consists in measuring the frequency, over the years, with which a person, *Ego*, witnesses the death of his/her grandparents, parents, spouse, siblings, or even his own children.

The experience of a family member's death changed radically during the 20th century, owing to the mortality decline and changes in family structures. The traditional instruments of demography—calculations based on aggregated vital statistics and population observations—make it possible to assess some of these changes, in particular those concerning orphanhood. But to have an overall view of the experience of death within the family, it is necessary to use other approaches that take into account the numerous dimensions of the phenomenon.

1. A Simple Case: Orphanhood

To measure orphanhood, we have at our disposal the findings of Alfred Lotka (1939), who showed that the proportion of orphans in a cohort depended only on the mortality of the parents and could be easily calculated by using the appropriate life tables. Indeed, the probability of becoming an orphan at a given age is equal to the probability of the father or mother's death during the period lasting from birth to that age.

Lotka's equation was established by considering that during a given year, the distribution of births according to the age of the mother or father is correctly summed up by the mean age of mothers and fathers at birth (mean age calculated on the basis of the size of the birth cohort and not on rates). Thus the probability Ω_x for a child reaching the age x of losing his father or mother is equal to the complement to unity of the probability of survival of his mother or father between the mean age at childbirth and her or his age reached x years later.

$$\Omega_x = 1 - S(\bar{a} + x)/S(\bar{a})$$

with:

S = survivors of the life table;
$\bar{a}$ = mean age at motherhood/fatherhood;
x = age reached by the child.

Thanks to the existence of cohort life tables (Vallin and Meslé, 2001), we can add some precision to these calculations (Alfred Lotka only had period life tables to work with), and modern computer tools make it possible to perform complete calculations without simplifying by using the mean age. If we consider that the proportion of orphans is equal to the complement to unity of an average of survival probabilities tied to each age of the mother (father) between the birth and age x of the child, an average weighted by the distribution of births according to the age of the father (mother):

$$\Omega_x = 1 - \sum_{a-\min}^{Max} \frac{Na}{N} \cdot \frac{Sa+x}{Sa}$$

S = survivors of the life table;
N_a = Number of births according to the age of the mother (father);
N = total number of births;
a = age at birth of the child;
x = age reached by the child.

The descriptions of orphanhood thus obtained are taken from the point of view of a surviving *Ego*, thus the mortality of *Ego* is not taken into account. However, not all children become orphans, because some children die before their parents. Indeed, it is possible, if one combines the life tables of the children with those of their parents, to calculate the proportion of children who die before their parents; but the method is insufficient when one looks at other family relations, because other phenomena must be accounted for. Studying orphanhood is quite simple due to the extent that one necessarily has two parents and no more than two, if we limit ourselves to biological relationships. But if we look at other family relations, things are more complex and do not only depend on mortality: the proportion of persons who become widows also depends on nuptiality; the proportion of persons who lose a child also depends on fertility, just as the proportion of persons who lose a sibling, etc.

2. A Microsimulation Model

To take into consideration the numerous phenomena that together define the experience of another person's death as seen from the point of view of an individual *Ego* who is himself liable to die, one must refer to a microsimulation model thanks to which, for each type of family relation, one can measure the frequency of the three variants in the experience of another person's death, the other person being any member of *Ego*'s family:

1. The other person may have died before *Ego*'s birth.
2. The other person may die during *Ego*'s life, and it is thus possible to know *Ego*'s age at the time of his death.
3. *Ego* can die before the other person.

These possibilities can be observed when the other person is a grandparent, a sibling, an uncle, an aunt, father-in-law or mother-in-law, a nephew, or niece. However, the first possibility is not applicable to *Ego*'s mother (she can die during childbirth but not before *Ego*'s birth) or to *Ego*'s spouse or to a child, because they obviously cannot have died before *Ego*'s birth (before the union or the birth, respectively).

It must be noted that these data cannot be obtained through traditional surveys, in particular retrospective surveys. Indeed, by definition, the respondents of these surveys are necessarily survivors. In the first place, we cannot exclude that there is a dependence between *Ego*'s mortality and that of his relatives, and this can introduce a selection bias for the studied phenomenon. But above all, an important aspect of the phenomenon is lost to the extent that one cannot study the frequency of the cases in which *Ego* dies before his close relatives.

A microsimulation model makes it possible to reconstruct the family of an individual of reference and the deaths occurring within this family, including the death of the reference individual him/herself.

This simulation method was developed by Guy Orcutt in 1957 in order to simulate the American socioeconomic system. It has since been applied in various fields. Demographers also used this method in the 1960s and 1970s, first to study fertility trends and the impact of contraception (Perrin and Sheps, 1963; Jacquard and Leridon, 1974) and to integrate the different members of such networks as family, relatives, or the employees of a company. Thus we have, among many others, the Socsim model of Eugene Hammel and Kenneth Wachter, the more historical Camsim model of Roger Schofield, Peter Laslett, and Jim Oppen; and the Kinsim model of Wendy Post and Evert Van Imhoff (Le Bras, 1973; Wachter *et al.*, 1978; Smith, 1987; Hammel *et al.*, 1989; Reher and Schofield, 1993; Smith and Oeppen, 1993; Van Imhoff and Post, 1997). Microsimulation is based on the idea that studying the sum of individual behaviors provides a more accurate representation of reality than does studying changes in aggregates. In addition, the study of these networks requires the ability to recreate them, and that is not possible with more aggregating techniques. The method uses stochastic processes to determine for each person the events that he will experience during the simulated period. The probability of events is determined according to known or reconstructed trends when dealing with the past, or according to estimated trends when dealing with projections for the future.

The results presented here are limited to what could be called the first circle of the family: *Ego*'s grandparents, his parents, siblings, spouse, and children, but other relatives may also be included (e.g., grandchildren, in-laws, uncles and aunts). Of course, the simulations are sex specific. The model functions on the basis of individual microsimulations based on mortality and fertility data.

a. Mortality

The French data used here are age-specific probabilities of dying for each birth cohort since 1806, either calculated on the basis of observations or projected (Vallin and Meslé, 2001). For the cohorts born before 1806 (grandparents of *Ego* if the latter was born in 1850 or 1860), we supposed that their mortality was the same as that of the 1806 cohort. The mortality of cohorts born in the 20th century is based on observations and projections: thus, the mortality of the 1950 cohort was observed from the year of birth until 1997 and projected beyond; for the children of parents belonging to that cohort, the estimated part is even higher.

Table 89–4 shows life expectancies at birth of the cohorts of *Ego* only, but his/her parents, grandparents, spouse, children, etc. can belong to any other cohort: the simulation thus involves 300 series of probabilities (from the end of the 18th century, for the grandparents of an *Ego* born in 1850 to the end of the 21st century for the children of *Ego* born in 1950, for both sexes).

b. Fertility

We assessed, for each cohort born between 1850 and 1950, the age-specific and parity-specific fertility rates. The rates for the 1850 cohort were applied in order to reconstruct the cohorts born before 1850 (*Ego*'s parents, grandparents, siblings if any). The completed fertility of each cohort and the mean age at childbearing are shown in Table 89–4.

The reconstruction thus takes into account the real mortality of the different cohorts under consideration, as well as a partly estimated fertility (as concerns parity-specific fertility) whose general trend, in terms of completed fertility, corresponds to reality.

TABLE 89–4 Fertility and Mortality Parameters of the Model for the Cohorts of *Ego*

Cohort	Average life span		Completed fertility	Mean age at Childbirth
	Males	Females		
1850	39.8	43.2	2.78	29.8
1860	40.8	44.3	2.67	28.8
1870	38.8	43.4	2.54	28.9
1880	40.8	48.4	2.32	28.6
1890	38.7	51.5	2.09	28.3
1900	48.3	56.0	2.10	28.5
1910	53.1	61.5	2.27	28.6
1920	57.3	67.2	2.48	28.4
1930	64.0	73.6	2.62	27.4
1940	67.3	76.6	2.41	26.4
1950	72.9	82.0	2.11	26.5

Data from Festy, 1979; Vallin and Meslé, 2001.

3. Experiencing Death in the Family from 1850 to the Present

Thanks to the implementation of this model, it was possible to obtain data concerning the trends in the experience of death in the family for cohorts born between 1850 and 1950.[5]

The curves illustrating the experience of death in the family, that is, all the curves pertaining to each degree of relationship, provide a general picture for a given cohort. Graph A of Fig. 89–2 thus gives an overall view of the frequency of deaths in the family of a woman born in 1900.

In addition to period variations, owing to which this graph is a little difficult to read (in particular, World War I and World War II caused mortality peaks affecting fathers and brothers, respectively, spouses or children), three waves of deaths can be distinctly observed, corresponding to the deaths of the grandparents, parents, and contemporaries of *Ego*, whether the spouse or the siblings. We also observe the high impact of the death of children, either siblings or children of *Ego*.

A comparison with the same graph elaborated for the 1950 cohort (Fig. 89–2B) sheds some light on the changes that occurred throughout the 20th century, especially during the second half, even if some of the results shown here are still hypothetical (the 1950 cohort is not yet extinct). Still more clearly we can see the three waves, but whereas they were declining from the generation of the grandparents to that of contemporaries in the 1900 cohort, here their volume is about constant, if not increasing. In addition, advances made in the field of infant and child mortality have almost eliminated mortality at young ages, which was still high among the siblings and children of women born in 1900. This fact makes the graph more easily understandable. In fact, the graph illustrates the successive order of the deaths of close relatives, which follow each other in much the same order as the generations. It also provides a general overview of the overall aging of the age at death as concerns the death of other people, viewed as an event in the life of the survivors. Last, it seems to show that the number of deaths in the family of a woman born in 1950 is higher than that observed among the relatives of a woman born in 1900.

[5] Because of a different implementation of the microsimulation method, the results presented here differ from those we presented in various articles and papers.

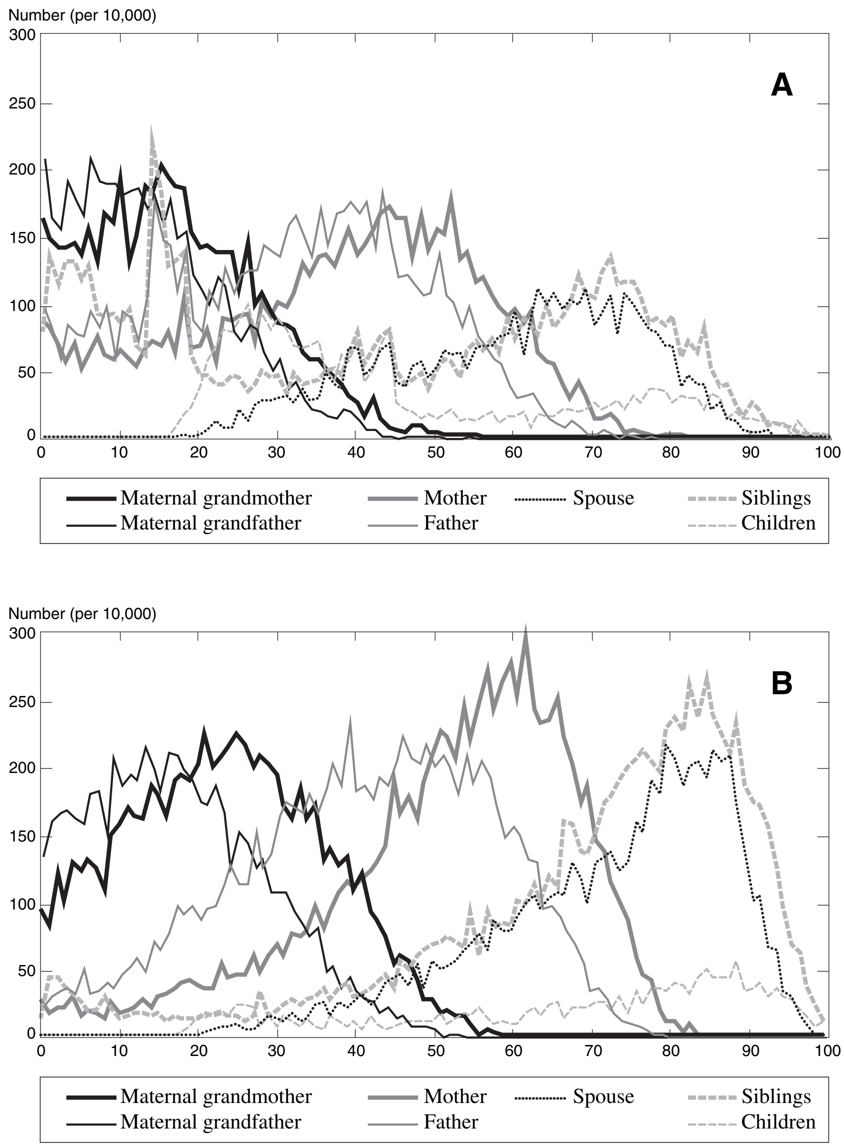

FIGURE 89–2 Numbers, according to age, of deaths in the family of a woman born in 1900 and in that of a woman born in 1950. **(A)** *Ego* is a woman born in 1900. **(B)** *Ego* is a woman born in 1950.

4. Death in the Family Is Experienced Later in Life

In this general context, in what way does the experience of death change when a person has reached old age? We will attempt to answer this question by looking at the deaths of *Ego*'s parents, spouse, siblings, and children (by the age of 60, for all cohorts, *Ego*'s grandparents have already died).

As concerns parents, there are two possible cases: either *Ego* dies after his/her parents or his/her parents die after him. The latter possibility was quite frequent during the 19th century, when infant and child mortality were very high. Thus in the 1850 cohort, we may assess that in more than 40% of the cases, the person died before his/her mother (42% of the females and 45% of the males). This proportion considerably declined, especially after 1900, and in the 1950 cohort it was only 11% (Table 89–5A). As concerns the death of the father (Table 89–5B), the trend was comparable. We can note that men die a little more often than do women before their parents and that this difference has increased over time with the rise in the excess mortality of males.

Alongside this trend, the mean age at which a person loses his/her father or mother has increased: in the 1850 cohort, a person was orphaned around the age of 30, whereas in the 1950 cohort the mean age of *Ego*

1950	92	8	41.7	13.9	87	13	41.1	12.7

at his/her mother's death was around 50 and at his/her father's death around 40. Last, the proportion of persons who are orphaned after 60 has also increased, in particular as concerns the death of the mother: for the 1850 cohort, only 2% to 3% of individuals lost their mother after 60, whereas this proportion represented, respectively, 35% and 38% for men and women born in 1950. As concerns the death of the father, the figures pertaining to the 1950 cohort are lower: 13% to 14% of men and women born in 1950 will lose their father after the age of 60.

The death of the spouse also occurs at later ages for both sexes, but the gap between the sexes has widened. We know that widowhood affects mainly women: in the cohort born in 1950, 75% of the women are or will become widows, against only 27% of the men (see Table 89–6). But for men and women, the mean age at widowhood has increased by about 20 years at least in the space of 100 years: the women born in 1850 became widows at 53 on average, and those born in 1950 at 73; for men the figures are, respectively, 54 and 77. Widowhood is now a phenomenon occurring mainly after 60 and even increasingly tends to happen after 80: for the 1950 cohort, 42% of the women and 54% of the men will be widowed after the age of 80, according to mortality hypotheses. As for the death of parents, these changes took place mainly after 1900.

The death of a sibling is an event that is similar to the death of a spouse in the sense that they are close to *Ego* in age. However (and this is a significant difference),

1950	57	77	40	72.0	42	71	30	67.4

siblings can die while *Ego* is still a child, which is not the case for a spouse. This explains why the mean age of *Ego* at the time of the death of sibling is always younger than that at the time of a spouse's death.

In addition, because the birth order of *Ego* has not been controlled (*Ego* can be of any parity), *Ego* is, on average, in the middle and thus witnesses the death of about one half of his siblings (between 46% and 57% for females, about 40% for males[6]). The dominant feature of this changing phenomenon is its aging: an individual born in 1850 experienced the death of one or several siblings before the age of 60 in 80% of the cases, whereas for the 1950 cohort, the death of a sibling happens after 60 in 77% of cases if *Ego* is female and 71% of cases if *Ego* is male (see Table 89–7). What was then the exception has now become the norm. This aging process is now clearly continuing: the death of a sibling after the age of 80 occurs in 40% of cases if *Ego* is female and in 30% of cases if *Ego* is male.

To experience the death of one or several children was quite frequent in the 19th century: 43% of the women and 40% of the men born in 1850 had lost at least one child (see Table 89–8). Today this has

[6] When *Ego* is male, the sex ratio of the other members of the group of siblings decreases (on average, *Ego* has more sisters than brothers); conversely, if *Ego* is female, the ratio increases. This, together with the excess mortality of males, is the reason why females experience the death of over half of their siblings and males less than half.

TABLE 89–8 The Death of Children

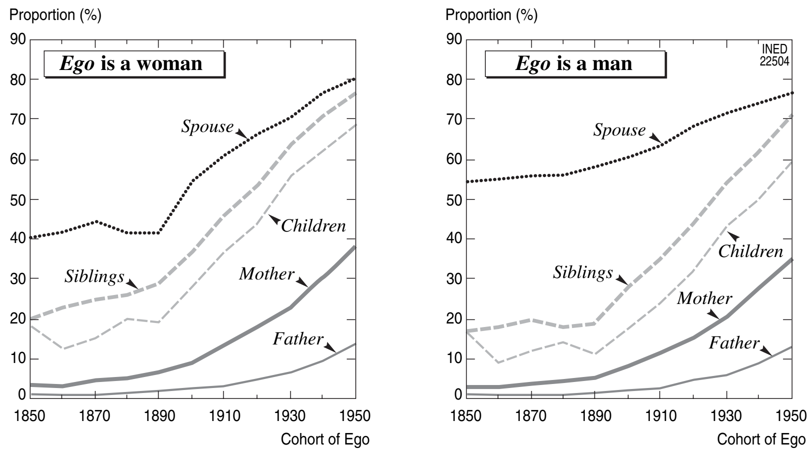

FIGURE 89–3 Proportion of deaths among close relatives when *Ego* is over 60.

become quite rare, because only 10% of the women and 6% of the men born in 1950 will have experienced it. But at the same time, not only has this phenomenon become more rare, but it has changed in nature. Indeed, in the 19th century, when parents experienced the death of a child, it was a small child, and these parents were thus young adults (the curve of deaths of children according to the age of the mother at the time of the child's death is thus very similar to the fertility rate curve). Today, the death of a child concerns older parents, even very old parents: for the 1950 cohort, 69% of the women and 59% of the men will be over 60 if ever one of their children dies (41% and 29%, respectively, will be over 80).

In all the cases examined above, the deaths of members of the family occur later in the life of individuals. The increase in the mean age of an individual, male or female, born in 1950, at the death of his/her mother, spouse, sibling or child is 20 to 35 years; the age at the death of the father has increased less, but it is still 12 years older for both men and women.

The changes in the proportion of deaths in the family occurring when *Ego* is over 60 shows that the age at which one experiences the death of another person has increased (Fig. 89–3). Beginning with the 1900 cohort, the curves rise quite clearly upward as concerns the death of the spouse, a sibling, and children, and a little less sharply upward as concerns father and mother.

5. Death Is a More Frequent Experience

These findings pertain to the trend in the schedule of the experience of death, at the time when *Ego* experiences the death of a close relative. But as we have seen, this phenomenon has other implications: *Ego* can die before any of his/her relatives (in which case he is no longer concerned by this schedule), and some of his/her relatives (a grandparent, brother, or sister) may have died before his/her birth (in which case they are not taken into consideration). The total frequency, the intensity of the experience of death, varies according to these factors: if *Ego* dies less often before his/her parents (father or mother), he will more often experience his/her parents' death; the same is true if the death of his/her grandparents occurs less frequently before his/her birth. In addition, over time, the number of parents (fathers and mothers) and of spouses (in this case the first spouse) remains, the same but the number of siblings or children can change. Here again we observe a factor that can change the frequency of the experience of death: mortality being equal, the greater the number of children, the greater the risk of losing a child.

To take into account these aspects of the phenomenon, one can calculate the mean number of deaths (converted for each individual at birth) for each degree of kinship; this calculation was made by establishing a distinction between deaths occurring when *Ego* is over 60 and those occurring before that age (Table 89–9). From females born in 1850 to those born in 1950, the total mean number of deaths within the family (as defined here) has significantly increased, especially during the 20th century, from 5.20 for the 1850 cohort to 5.43 for the 1900 cohort and 7.27 for the 1950 cohort. Thus, the experience of death in the family happens at a later age but has become more frequent.

OVERVIEW

In France and probably in other developed countries, from the point of view of the dying person and that of the persons close to him/her, the experience of death has considerably changed during a period that can be determined quite precisely: the second half of the 20th century. In 1959, Jean Fourastié wrote that "death was at the center of life in the same way as the graveyard was in the center of the village." One might say today that death is at the center of old age, because

TABLE 89–9 Mean Number of Deaths (for One Person)

those who die are mainly old but also very old persons, and their close relatives—their spouses or their children—are no longer young or are even close to old age. That death is no longer in the center of the village because nowadays, as a general rule, people die in hospitals or institutions.

Several aspects of these trends deserve special attention because the transformations observed have implications both for the individual and for society that should be examined in greater detail.

In the first place, a distinction was made according to the age of the dying persons; those of today are older than those of yesterday. In addition, dying women are much older than are dying men. But does this trend, which is positive as concerns the duration of life, have an impact in terms of the conditions surrounding a person's death? In other words, even though it is better to die at 85 than at 75, does the fact of being older make a difference for the dying person, for his family if he has one, and for the medical staff? As concerns the latter, whose thoughts on the subject are better known, we must remember that as Renée Sebag-Lanoë (2002) has pointed out, "age is one of the worst criteria for making a decision" as regards the choice of appropriate palliative care.

Given the increase in the age at death, brought about by the decrease of deaths at young ages, the succession of deaths within the family increasingly follows the order of generations. This ordering might seem to be a factor of greater *acceptance* in the general picture of death that we have briefly drawn, if we admit (but this remains to be proved) that death is more acceptable when it affects each in his own time. But conversely, because early deaths—deaths of children, adolescents, young people, or mature adults—happen more seldom, have they not become even more difficult to accept? What significance can be ascribed to the fact that we now live to experience a greater number of deaths in the family than in the past? Does this situation make it easier to accept death or, on the contrary, does it make it more difficult?

Next, we found that today, death occurs most often in institutions, because only a minority of persons now die at home. This trend seems to run counter to other trends that seem to give precedence to the private sphere over the public sphere. Thus, the decreasing frequency of marriages, the increasing frequency of consensual unions, and the rise in births out of wedlock are often interpreted as a sign that individuals prefer to withdraw their marital and family life from the influence of institutions. Are things different with death, in which the need for institutional support is very high, or can the fact that death is increasingly medicalized, that is, medical staff is needed, be seen as the sign of a more general phenomenon, that of the extension of the medical influence? This extension has been observed in the field of procreation, with the massive spread of contraception, the legalization of abortion, and the development of medically assisted procreation. Last, will the expected increase in the number of dying persons have an influence on medical practices pertaining to the end of life? It is to be expected that such issues as palliative care, staff resources, and the role of families in the dying person's last moments and euthanasia will become increasingly acute when a country such as France will be counting 250,000 more deaths each year.

Household and Family Demography

Application to Developing Countries

MARC PILON

Institut de recherché pour le development (IRD), Burkina Faso

INTRODUCTION

It has become increasingly important to demographers to place population behavior within its family context (Tabutin and Bartiaux, 1986). The capacity to statistically document family structure and dynamics, shed light on factors that influence them, explain their variations (within societies and between different societies), and follow their development over time has created a new knowledge base that has contributed to the emergence of household and family demography. This new field of research is important enough to justify significant space in this volume of the treatise.

Two chapters have been devoted to this subject in order to better emphasize the diversity of the situations, both sociological and statistical, of different cultures. The first chapter discusses developing countries and the second centers on the European experience. It is therefore appropriate for this first chapter to begin with a general introduction to the concepts, the theories, and the development of household and family demography, before applying this knowledge to developing countries.

I. HOUSEHOLD AND FAMILY DEMOGRAPHY

First of all it is necessary to agree on the terms used. This is all the more important for concepts that have very different meanings according to the circumstances and cultures in which they are used. This done, it is easier to evaluate the various current theories of family development and then introduce the relatively recent scientific dimension of household and family demography.

1. Concepts: Household and Family, What Are They?

Common sense could lead us to believe that the only difference between family and household is in their nature: the family being a natural biological unit and the household an economic and residential unit. However, common sense is not always enough and believing so in this specific case frequently leads to considerable errors in interpretation. The family is not a natural entity, and the household might only be a demographic tool for census officials.

a. The Family Is Not a Natural Entity

As stressed in the *Dictionnaire de l'ethnologie et de l'anthropologie* (Bonte and Izard, 1991:273), "everyone believes that they know what a family is: it seems to stem from the natural order. . . . But it is interesting to note that however vital, essential, and apparently universal the family institution may be, just as is the case for marriage, no strict definition exists for it."

Acceptance of the term "family" changes according to the protagonists and the institutional contexts, as well as according to society and era. It refers to representations within each society at a given period in its history; frequently not explicitly defined, the term family is an interpretation of the situation that is considered as the norm, the socially acceptable model (the extended family or kinship in Africa[1]), or is presented as such in cases in which the state has imposed itself and interferes in people's private lives. Indeed, the polysemic character of the family means that it only truly develops a meaning once it has been qualified.

Regardless of the definition, whether we consider a couple with children or a kinship group, it is necessary to remember that "the family is not, contrary to the belief of certain demographers and sociologists, a base unit or a cell of society. A family can not exist and be reproduced through generations independently of other families" (Godelier, 1973:8). The family is not an independent, autonomous unit.

We must agree with Pierre Bourdieu (1993:36) that although it is doubtless necessary to "stop considering the family as an immediate fact of social reality but rather as a tool for constructing this reality," we should also "ask ourselves who created these construction tools." In Western societies the state has played a crucial role in this area, so that the family appears as "the product of a long period of legal and political construction." Some even ask whether "the current statistical concept of the family still corresponds to an economic and sociological reality" (Desplanques, 1994:97); comparative studies on Europe are always faced with numerous obstacles (CEPR, 1991; Lefranc, 1995; Wall, 1996; see also the following chapter by Nico Keilman). A similar process, reinforced by the influence of international organizations, is underway in developing countries. Therefore, the family is not an immediate natural entity but a progressive "constructed category" (Bourdieu, 1993:36).

It can be defined or analyzed in terms of structure (family formation), through its functions (e.g., production, reproduction, socialization), and its relational and transactional dimensions (intra and extrafamily).

b. The Household: A Data Collection Tool That Has Become an Object for Analysis

The concept of household was created in Western societies by statisticians and demographers in search of a statistical unit for operational observation that makes it possible to identify individuals without omission or double counting during censuses and surveys; gathering information on kinship being above all a method of identifying individuals. The objective of these population collection operations was not (and is not) to study the family.

However, as Alain Collomp (1992:13) states "of the different meanings that can be given to the word 'family' (from a conjugal couple and their children to a large kinship group including uncles and cousins), it is that of household to which the history of the forms of the family refers." It is at the level of households that statistics on family are produced.

The pertinence of the household has been widely discussed (Netting *et al.*, 1984; AMIRA, 1987; Sala Diakanda, 1988; Lacombe and Lamy, 1989; McDonald, 1992; Burch, 1993). On the one hand, it is possible to cohabit without being related (particularly in urban areas); on the other hand, it is possible to be related and to live apart: for example, the phenomenon of noncohabitation of spouses and dependent children is relatively common in African cities, particularly in cases of polygyny (Locoh, 1990). Moreover, the residential unit does not necessarily coincide with production and consumption units, which themselves can be distinct and whose rules of composition vary according to societies; several levels of production and consumption can coexist within the same society (Gruenais, 1981). For the rural Bwa in Mali, the proportion of units headed by a female falls from 27% to 3% according to whether the household or the domestic group is considered (Hertrich, 1996). The reality thus observed is very different, particularly concerning the concept of the household head.

Conveying above all residential arrangements,[2] the household is one of the highly significant ways for grouping individuals: that individuals within a society, whether they are related or not, gather in one location to live daily for a given time does not occur at random; it definitely signifies something that is necessarily translated into *one* social reality and *one* real-life experience, a reality that can be both domestic and economic. Indeed, "the problem here is not so much the type of unit but the shifts in meaning to which it can be subject during interpretation" (Pilon and Hertrich, 1995:2).

Regardless of the society and the chosen definition, it is clear that household and family cannot be interchangeable concepts, nor can they be totally autonomous and independent of the rest of the kinship

[1] According to R. Mbuh (1994:64), "to bring this notion [of family] to traditional African society refers to a system of an extended family, favoring lineage." According to Christophe Sawadogo (1992:63), "in the traditional African context a definition of family should surpass the scope of household and home and should be placed at the level of lineage and clan."

[2] But which also convey different realities according to the reference population used during data collection: the approaches differ depending on the country as some consider the *de jure* population, whereas others consider the de facto population.

group and/or of society. Even if they coincide historically or occasionally, they are fundamentally different, but not exclusive, realities. It is therefore necessary each time to specify what is meant by the terms household and family.

2. Theories on Family Evolution

The family began to be studied in a scientific context during the second half of the 19th century (see the works of Le Play, 1871; Morgan, 1887; Durkheim, 1888; Engels, 1948) and was developed during the 1920s under the influence of American sociologists of the Chicago *interactionist* school (Michel, 1986). The post–World War II period saw the emergence and generalization of a global theory of social change, the modernization theory, of which the demographic transition theory (see Chapters 68, 69) and the nuclearization of the family theory continue to nourish scientific debate.

The argument of a convergence of family systems toward the nuclear model originated in Talcott Parsons' work on the American family, and from a structuralist-functionalist approach (Parsons and Bales, 1955), it was expanded by William Goode (1963), in particular in *World Revolution and Family Patterns.* According to this theory the modernization process, through industrialization and urbanization, ineluctably results in the transition from the traditional extended family to the modern nuclear family. This development is both a change in the structure and function of the family and a change in the male and female roles within it. The nuclear family, which is disconnected from the rest of the kinship group, is presented as the family model best adapted to the economic conditions of contemporary (American) society.

However, as stated by Patrice Vimard (1995:145), "Since 1970, family studies that have been developed according to relativistic and historical perspectives make it possible to strongly qualify or invalidate the nuclearization theory by showing that on the one hand, the extended family was the dominant, but not exclusive, model of the old family (Laslett and Wall, 1972), and on the other hand, that the nuclear family is not the ultimate and universal model of the modern family (Rao, 1973)." It is not necessarily where we expect to find it.

For industrialized Western countries, other theoretical avenues have been and are being explored in the light of significant and rapid changes in the family sphere over recent decades: the increase in the number of people living alone, of single-parent families (Lefaucheur, 1992), and of reconstituted families (Thery, 1987) are examples. The role of kinship and family solidarity has been rediscovered and reaffirmed: nuclear families do not seem so independent of the rest of the kinship group (Segalen, 1984, 1996). Some authors, such as Edward Shorter (1975, 1977), have announced the advent of the postmodern family, whereas others (Roussel, 1986) are leaning toward a theory of diversification and of multiplicity in family models.

For developing countries, family situations and their evolutions are also characterized by complexity and diversification that are a far cry from a linear path (McDonald, 1992; Vimard, 1993). In Nigeria (Oke, 1986), the Arab world (Behnam, 1985), and India (Lardinois, 1986), extended families and traditional family values can accompany the modernization process.

All things considered, we can only agree with Peter McDonald (1992:25) that the "Convergence theory not only failed to predict the path of changes in family systems in the non-Western context, it also failed to predict the movement away from the idealized version of the conjugal family that occurred in the West itself in the past 20 years." In the absence of a satisfactory new theoretical scope, much remains to be done in family studies before any certainties that do not reiterate the appearance of new myths and stereotypes can be put forward (de Oliveira, 1992).

3. Household and Family Demography

The study of the family is resolutely at the crossroads of several disciplines. In the wake of sociology and history, other social sciences have progressively joined this field: psychoanalysis, psychology, law, political sciences, ethnology, economy, and demography (de Singly, 1992) have all shed light on the issue.

Research in historical demography began in the 1950s (Henry, 1953–1955; Rosental, 2003) and has greatly contributed to improving the understanding of the dynamics and evolution of families in European countries, making it possible to expose a series of false impressions of the past and to call into question the myth of the extended family as a prop for high fertility, thereby rejecting the nuclearization theory (Le Bras, 1992; Segalen, 1996).

Demographers' more recent interest in the household and the family is partly associated with the need to contextualize demographic phenomena that are generally understood and analyzed at an individual level; this has meant crossing from a basically descriptive approach to a more explanatory approach in the hope of finding an observation unit that would be the entrance to an explanation of demographic behavior.

The relationships between family structure and fertility are assuredly those that have been most studied (Ryder, 1984; Bartiaux and Tabutin, 1986).

Demographic research on household and family as a separate research theme emerged in the 1960s and had grown in volume by the end of the 1970s. Meetings and international scientific programs dedicated to this theme multiplied: Committee for International Cooperation in National Research in Demography's program in 1979–1982 (CICRED, 1984) and the creation in 1982 of an International Union for the Scientific Study in Population (IUSSP) scientific committee on Family Demography[3] that organized two international seminars, the first in New York in 1983 on the methods and applications of family demography (Bongaarts *et al.*, 1987) and the other in Berlin in 1984 on the latter phases of the family life cycle (Höhn *et al.*, 1989). In 1986, the IUSSP created a new scientific committee on the same theme,[4] which in its turn organized three international seminars, the first in 1987 in Honolulu on changing family structures and life course in developing countries (Berquo and Xenos, 1992); the second in Vaucresson, also in 1987, on new forms of family life in developed countries (Prioux, 1990); and the third in Tokyo in 1988 on theories on family evolution.

An entire field of research called *household and family demography* that produced concepts and methods was thus progressively created. One of the leaders, Thomas Burch (1993:1), defined its outlines, "Union formation and dissolution; family and household structure and change; and kinship" (more details can be found in Burch, 1979). All the demographic phenomena obviously affect the size, structure, and dynamics of households and the family: fertility, nuptiality, mortality, and migration each have their own effects.

Although research is essentially centered around the household and the (conjugal) family, demographic sources make it possible to analyze different types of units of individual membership at a given time. We can list them as follows: the residential unit, the residential family group, the family nucleus (combination of husband/wife[s]/children that can be single parent, nuclear, or polygynous) residential or not (as it can be distributed between several residential units), the domestic group (that can be spatially fragmented), and the matricentric (mother–children) unit.

As a complement to other disciplines, demography seems better equipped to evaluate structures and their dynamics. For example, it can give statistical information on the proportion of individuals living in or belonging to a unit (residential or domestic) where polygyny is practiced (and this according to sex, age, and other individual characteristics), on the evolution of the residential forms of domestic units, on the significance and characteristics of situations of noncoresidence of spouses, on matched characteristics of spouses (age, ethnic group, religion, education, employment etc.), and on households with elderly people, etc. Such quantitative aspects if correctly interpreted, can be a mine of information. Demography can also grasp changes in the family and population structure of residential and domestic units, as a consequence of changes in demographic parameters (mortality, fertility, nuptiality, and migration), structural changes that can influence collective functions, roles, and individual status.

With reference to domestic groups the sociologist Martine Segalen (1996:34) rightly states that their "structure . . . is interesting as it reveals a certain form of organization that regulates the transmission of cultural values and practices which articulate family and work, family and power, family and knowledge." She then illustrates her words with a quotation by William Goode from his book *The Family*:

> "The various forms of the household have a number of implications for family interaction. They help to determine, for example, the chances of more or less intimate social relations among members of the kinship group. Thereby, these structural patterns shape in part the process of strain and adjustment among relatives. Various role relations may have to be spelled out in detail, if the household includes certain relatives. For example, if the household usually includes a man and his mother-in-law, there may be rules requiring much reserve or noninteraction between the two.
>
> Socialization patterns are also affected by who is included in the household. A mother-in-law, or a young boy may go to his mother's brother's house to grow up. A young child in a polygynous household sees a wider range of adult models intimately than he could observe in a nuclear family. Those who share the same household are likely to share the same budget, and thus economic exchanges are partly determined by the forms of the household." (Goode, 1964:44–45).

The 1980s produced "A plethora of formal methodological, as well as substantive-descriptive, studies of the family" (Höhn, 1992:4). Much progress was made in several fields: in conceptualization, notably with the recognition of the difference between household and family (Burch, 1993)[5]; in measurement, with the development of comparative indicators (Burch,

[3] This committee's president was John Bongaarts, and its members were Thomas Burch, Kenneth Wachter, Gustav Feichtinger, Hervé Le Bras, and Elza Berquo.

[4] Elza Berquo was the president of this committee, and the members were Charlotte Höhn, Louis Roussel, Jan Trost, and Peter Xenos.

[5] "A key step has been the full realization of the difference between household and family, a distinction somewhat blurred in early demographic work, due to a Western tendency to identify the two, and resulting census conventions . . ." (Burch, 1993:3).

1980; Burch *et al.*, 1987); in classification (Laslett and Wall, 1972); in modeling the interrelations between basic demographic factors and household and family dynamics at both the macro- and microlevels (Goodman *et al.*, 1974; Le Bras, 1992; Bongaarts *et al.*, 1987; Mason, 1987); and in attempts at generalization using empirical studies.

Despite this, all the problems are far from being overcome. Comparative studies of the household and the family in Europe, and more so at a global level, still come up against numerous obstacles: the great heterogeneity of definitions, classifications that are not always made explicit and that often make comparison very difficult, insufficient published statistics, etc. (Locoh, 1988a; CEPR, 1991; de Oliveira, 1992; Lefranc, 1995; Wall, 1996). Moreover, household and family demography essentially refers to Western societies and thus to the corresponding acceptance of the (nuclear) family. Many of these methodological and analytical tools have often been shown to be unsuitable for other societal contexts, particularly in Africa.

Research on household structures and their development remains rudimentary in developing countries, and the lack of knowledge is particularly evident in sub-Saharan Africa. This could be owing to several reasons: the weight of studies on kinship systems, the emphasis placed on fertility studies, and an often immutable perception of African societies as "eternally rural and traditional" (Pilon, 1996a; Cordell and Piché, 1997).

a. Kinship Ties: Essential But Neglected Information

Regardless of the definition retained for the household or the family, information on kinship ties is obviously essential in order to analyze family structures and household formation. Its degree of precision to a great extent determines the possibilities for elaborating classification, which then have varying degrees of analytical pertinence.

Kinship ties, combined with other variables—such as sex, age, marital status, and type of activity (educational or economic)—are required to identify family status and roles.

To know, as precisely as possible, who lives or resides within a household can thus make it possible to study certain phenomena, such as the circulation of children and the migration of adults that give an idea of the level of family solidarity. Who are the fostered children and the migrants within the household? To whom are they related: the household head, his (or one of his) spouse(s), or another member? What are their characteristics (age, marital status, level of education, activity)? These questions are particularly relevant to urban households, who often play host, and it is important for these households to be able to perform this role, if only partially.

Even though numerous societies experience high levels of matrimonial instability, and in Africa polygyny is widely practiced, it is important within households where the head is married to be able to distinguish the couple's children from those belonging to each spouse from a previous union, on the one hand, and those belonging to different spouses, on the other hand.

For censuses and large surveys, the fact that information on kinship ties is first and foremost collected in order to facilitate the identification of individuals during data collection and to help control the coherence of other variables rather than for analysis, largely explains both the loss of information and the underexploitation of data.

Very frequently, the types of kinship relations used for codification (in the absence of precodification) is far less detailed than is the information gathered during data collection; this inflates the figures of the "other relatives" category. The examination of 32 African censuses shows that for countries that have modified their systems between the last two censuses, the trend has been simplification rather than refinement.

Regardless of the precision in kinship ties, statistical tabulation on this variable remains rare and far below the possibilities. The simple cross-tabulation of kinship ties with age, sex, and marital status can be a method of refining the codification of kinship ties that are too basic and a way of helping to identify and characterize the family status of individuals within the household. A United Nations document (1980) on principles and recommendations for censuses proposes the production of several such tables.

b. Typologies

In a comparative, temporal, and spatial theorization perspective, sociologists and historians have attempted to define household and family types. But there is no unique universal typology. Depending on the phenomena or the logic that we wish to expose, the criteria used are very diverse and can be demographic, economic, social, cultural, etc.: for example, rules and practices regarding authority, inheritance, residence, kinship system, nature of interpersonal relations, family roles (in particular between husband and wife); duties undertaken by the household or family, production method, and external relations.

Although the study of household structure is not an end in itself and is not adequate to take into account all the dimensions of the family (a household or family

TABLE 90–1 The Typology of Households According to Peter Laslett (1972)

1. Solitary	a. Widows or widowers
	b. Single people
2. Household without a family	a. Brothers and sisters co-residing
	b. Other relatives co-residing
	c. Unrelated co-residents
3. Simple household	a. Married couple without children
	b. Married couple with children
	c. Widows with children
	d. Widowers with children
4. Extended household	a. Extended upward
	b. Extended downward
	c. Extended laterally
	d. Combination of the above
5. Multiple household	a. Multiple upward
	b. Multiple downward
	c. Multiple in both directions
	d. Frereches (coresident siblings)
	e. other
6. Household of indeterminate structure including some kinship ties	

cannot be reduced to its structure only), the household typology introduced by Peter Laslett (1972) at the beginning of the 1970s is a scientific contribution of great value (Table 90–1). Historical research that has resulted from it has shed light on the pre-existence of nuclear structures at the time of the industrial revolution, which has contributed to the nuclearization theory being called into question.

Demographers essentially use this type of typology in order to analyze the morphology of households and families at a given time (who lives with whom?); the term "structure" is also used. The expressions family structure, household or family types, and family system are often used indifferently but incorrectly.

Developed for a historical study of European societies, Peter Laslett's classification has some shortcomings and ignores a certain number of existing family formations (grouped in his no. 6 category). It does not take into consideration the practice of polygyny (an essential phenomenon in African family systems) and also leaves the status of "other relatives" and the unrelated unclear.

As Patrice Vimard (1995:9) states, "there are no typologies that are a priori good or bad"; it all depends on our objectives and the specificities of the populations studied. Multiple criteria can be taken into consideration: the number of generations represented and their organization, the number of conjugal families (and their monogamous or polygynous character), the presence of other related or nonrelated members, the marital status and sex of the household head, etc. As previously mentioned, the level of precision of the kinship ties determines the level of refinement for the typology. The number of categories used can also vary significantly (from two to several dozen), depending on whether a more descriptive or overall character is desired.

Typologies developed at the end of an analysis frequently aim to expose the level of nuclearization, which is conveyed by the opposition between nuclear or restricted households, on the one hand, and extended or enlarged households (or families), on the other hand, adjectives that are frequently not defined.

The diversity of the typologies used as well as the heterogeneity and the vagueness of the terms that define them frequently make comparisons between populations very difficult. Without undermining the value of this diversity (each classification is pertinent to the population under question, depending on the issue under discussion) and while waiting for a minimal typology acceptable to all, efforts to clarify the terminology should be undertaken in order to facilitate comparative studies, which are essential for increasing knowledge.

c. For a Dynamic Approach

Analyses of the distribution of household types at a given date are often justifiably reproached for causing incorrect interpretations, conclusions that are too hasty in terms of family models or in terms of changes by comparing the distribution at different dates (Carter, 1984; McDonald, 1992): "the typological classification annihilates the temporal dimension" (Segalen, 1996:37). Demographic dynamics, in particular, result in the fact that, even in a society marked by the predominance of the extended family system, there is always a greater proportion of simple families owing to life-cycle events (birth, marriage, mobility, death) and their timing, as well as constraints in the age and sex structure of kinship groups. Furthermore, the same family configuration can result from different processes and can also be accompanied by different functions, be it between different populations or different periods, and inversely. Therefore, "reintroducing the long-term makes it possible to understand whether the configurations . . . are structural or conjunctural. Are the households always multiple or always conjugal? Do they experience a typical succession of phases, and if so, what is its model? How can we explain the divergence between the norm and the average insofar as a determined model has been acknowledged as preponderant in a given society?" (Segalen, 1996:37).

The simple matching of household types with the household head's sex and age, too infrequently performed, makes it possible to undertake an initial evaluation of the dynamic character of their structures. But the longitudinal approach (and including other types of data) is obviously the best. Specific concepts and methodologies have been developed in this direction, by sociologists and historians: the concepts of "family life cycle," which refers to a succession of stages, and "life course," according to which the family experiences a process made up of transitions and in which individual, family, and social periods overlap (Hareven, 1977, 1991) (see also Chapter 88 of this volume, which discusses the life cycle).

II. HOUSEHOLDS AND FAMILIES IN DEVELOPING COUNTRIES: STATE OF THE ART

An attempt at producing a synthesis of knowledge on the size, composition, and evolution of households in the developing countries is confronted by the paucity and inadequacy of the existing quantitative data (under exploitation of census and survey data, heterogeneity of definitions, terminology, and classifications). Data on the past (even the recent past, but the more distant past in particular) is particularly lacking and limits the possibilities of a historical approach (de Oliveira, 1992; Cordell and Piché, 1997).

By using the most recent statistics available at time of writing,[6] I will attempt to describe the overall situation, incorporating household size, family composition, female household heads, and "fostered children."

1. Household Size

The three indicators used here to characterize the sizes of households, the average size, the proportion of one-member households, and the proportion of households with at least nine members[7] vary significantly according to the large developing regions of the world and between the countries.

The average household size is between four and six people for the large majority of countries (Table 90–2; Fig. 90–1). The countries of Latin America and east Asia have the smallest households, with relatively few variations between countries. In contrast, diversity is particularly significant in Africa (where the highest values are most frequently found) and in western and central Asia.

The average size of African households varies between 3.6 in Ghana and 9 in Senegal. Households seem to be generally smaller in east and south Africa compared with north and west Africa (with the exception of Ghana).

The differences between rural and urban zones also vary. They are quite small in Latin America; the greatest differences are in Africa and central Asia (Turkmenistan, Kyrghyzstan and Kazakhstan). It is moreover interesting that among the countries considered here, a significant proportion (40%) of them have larger urban than rural households.

The proportion of one-member households (Fig. 90–2) vary even more significantly than does the average size: it is only 1.1% in rural Bangladesh, but 30.2% in urban Ghana. This type of household is found most frequently in urban areas: this is the case for three-quarters of the countries and for nearly all the African countries. All the Asian countries (with the exception of the three central Asian countries) and the north African countries have lower proportions. sub-Saharan Africa has significant variations, both between the countries and between urban and rural areas. However the differences according to area of residence are greatest in Turkmenistan, Kyrghyzstan, and Kazakhstan, with much higher proportions in the cities.

The proportion of large households (made up of at least nine members) also varies significantly: from 1% in rural Kazakhstan to 47.5% in rural Senegal (Fig. 93–3). In the large regions, the lowest proportions are found in Latin America, Asia, and east and south Africa. The countries where the proportion of large households is more than 20% are mainly in west Africa: Yemen, Namibia, Guinea, Côte d'Ivoire, Burkina Faso, and Senegal.

Although rudimentary, the variations in these three indicators—whether between large regions, among countries within the same region, or between rural and urban areas—suggest a great diversity in residential family structures.

According to a study by the United Nations (1990), which makes a comparison between the 1970s and the 1980s, the average size of households has declined in every region with the exception of north Africa and west and south Asia. However, other studies (Locoh, 1988a) and the results of the most recent Demographic and Health Surveys reveal the opposite in sub-Saharan Africa, with an increase in household sizes, with the exception of Kenya, Zimbabwe, and Botswana, where fertility decline is now well underway.

[6] The Demographic and Health Surveys supply the database that offers the widest geographic cover (50 countries). See the Macro International Web site at *www.measuredhs.com*.

[7] Indicators from tables published in national survey reports.

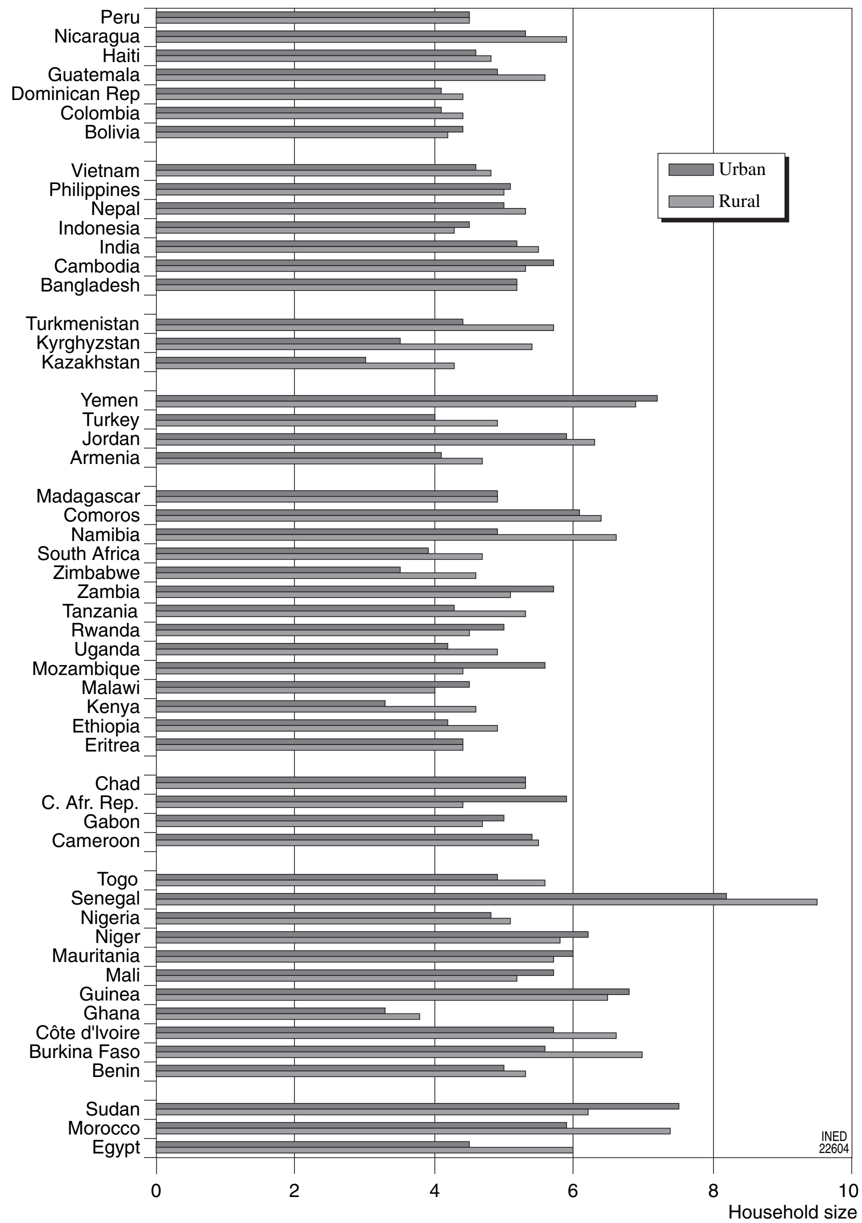

FIGURE 90–1 Average household size according to the Demographic and Health Surveys of 1990–2000.

2. The Family Composition of Households

The paucity of appropriate data is here again more apparent. Few publications of census and survey results provide tables on household structure and particularly tables that match it with the household head's sex and age. The United Nations' assessment (1993) published in its *Demographic Yearbook* is eloquent (Tables 90–3, 90–4).

Beyond this initial difficulty, the comparative approach also faces the problem of diversity in definitions and terminology. The possibilities for statistical synthesis therefore are very limited. In addition, books and articles offering an overall view of household and family, at a regional or world level, provide little quantitative syntheses on household composition, and they generally rely on the results of occasional studies or on limited data (Netting *et al.*, 1984; de Vos, 1987; Locoh, 1988b; Ekouevi *et al.*, 1991; Berquo and Xenos, 1992; Vimard, 1993; Cho and Yada, 1994; Pilon, 1996a; Adepoju, 1997; Pilon *et al.*, 1997). Generalization of the observed results involves obvious risks of once more producing stereotypes or misleading ideas. Nevertheless, knowledge that already makes it possible to draw

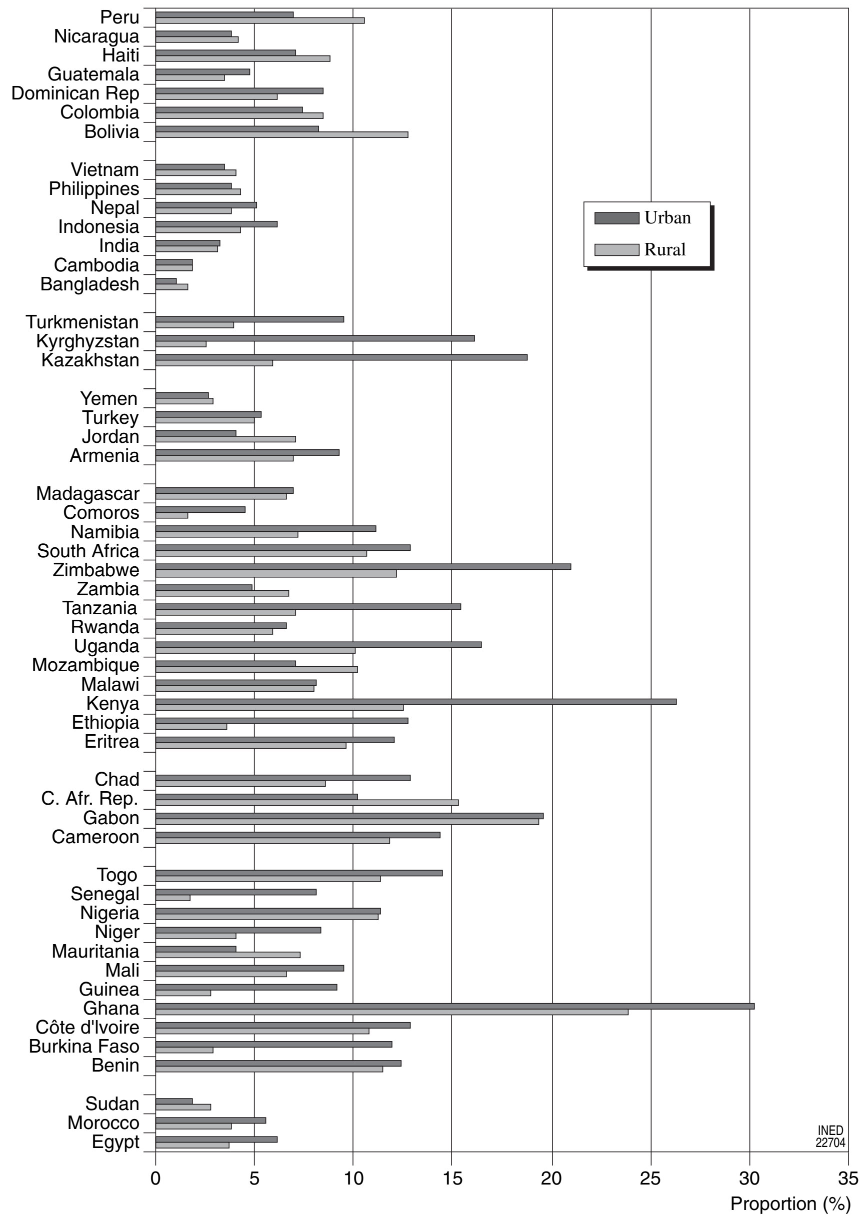

FIGURE 90–2 Proportion of one-member households according to the Demographic and Health Surveys of 1990–2000.

some conclusions, particularly concerning the convergence theory of family systems toward the nuclear model, is slowly building up.

In rural areas and particularly in private income economy zones, households and individuals are demanding more autonomy, be it financial or regarding marriage (Dozon, 1986; Berquo and Xenos, 1992; Gautier and Pilon, 1997). This process—which results in increasing tension in domestic group/rest of the kinship group, older/younger relations, and male/female relations—does not, however, result in the spread of the conjugal family model.

The role of host frequently performed by urban households, which maintains their interdependence with the rest of the kinship group (fostering of boys for schooling and girls for domestic help, which will be discussed below; accommodating adult migrants; etc.), often results in a structure that exceeds the nuclear structure. Generally smaller than those in rural areas, these urban households are easily composed of more extended and diversified relations. Furthermore, studies carried out in Abidjan show that "while the nuclear family is predominant at the lowest social levels (and here it represents more of a solution forced

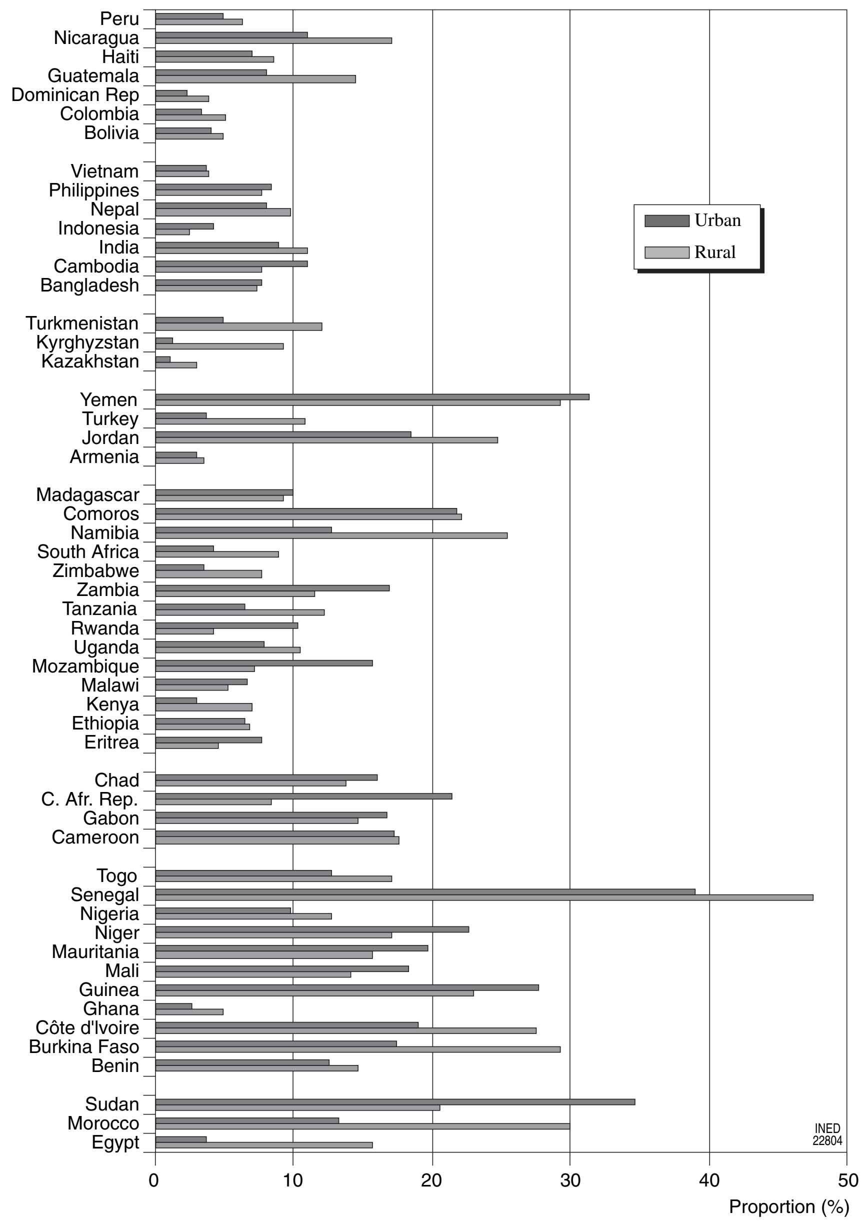

FIGURE 90–3 Proportion of households with at least nine members according to the Demographic and Health Surveys of 1990–2000.

by poverty than an actual choice), it is the groups that fit best into modern socioeconomic structures that perpetuate the practices of family interdependence and that recreate enlarged families" (Vimard, 1993:105–106).

However, the economic crisis significantly calls this logic into question. The stretching of host duties to the extreme in urban households affects children as much as it does adult migrants who arrive into an increasingly difficult and uncertain job market. Thus, the surveys conducted in the cities of Benin in 1990 and 1992 showed that the proportion of households that have accommodated people arriving from rural areas had fallen in 2 years from 24.1% in 1990 to 6.5% in 1992. Indeed, the situations are very diverse. According to the society and the context, the economic crisis has resulted in selective demographic offloads within the kinship group (Abidjan) (Vimard, 1997) and in the reinforcement of family relations (Dakar) (Antoine *et al.*, 1995).

The emergence of new types of unions, notably accompanied by non-coresidence of spouses but also by an increasing weakening of unions, the accentuation of temporary migration (male and also female) contributes, along with other factors, to the increase in the number of single-parent households in most countries (Ono-Osaki, 1991) and to the emergence of female household heads (see below).

Two other phenomena should also be mentioned because of their specific effects on household structure, namely, AIDS and the movement of refugees and displaced persons.

AIDS significantly affects households in multiple ways. The sexual aspect of the disease particularly contributes to the weakening of unions, especially for women; single-parent situations are increasing. Interfamily mobility is accentuated, whether of sufferers themselves or children being taken into the care of their grandparents or others. Circumstances can also force AIDS orphans on to the streets: whether it be as a result of exclusion or abandonment, the family's inability to cope financially, or the absence of other solutions. Faced with family destructuralization, strategies for reconstituting families are reactivating interdependence practices, but the increasing financial burdens are making this more selective and difficult (Hunter, 1990; Barnett and Blaikie, 1992; Delcroix and Guillaume, 1997).

The family consequences of the phenomenon of refugees and displaced persons (which has particularly increased in Africa) are also very significant: deaths, broken households, abandonment of the weakest, women raped and abandoned in camps, difficulty or impossibility of reconstituting conjugal families, and returning to the area of origin, etc. (Khasiani, 1989; de Renty, 1993). The increase in this phenomenon (UNHCR, 1994), and its near structural character in some regions, must lead us to further question its long-term effects.

Therefore, beyond the above-mentioned problems of the heterogeneity of definitions, plurality and complexity are without question the key words for the current state and development of households and families in the developing countries. A study by Economic Commission for Latin America and the Caribbean (ECLAC, 1994:78) on the social panorama of Latin America thus describes "the growing heterogeneity of household structure. Family structure is heterogeneous and varies according to the country, the urban or rural location of the family, and the level of poverty."

Nuclear households are not a new situation (Kabir, 1980; Charbit, 1987). Historical studies often call into question perceptions of the traditional family, particularly in terms of its structure. This was the case for China, for example, where it appears that the extended forms were not predominant in the past (Cho and Yada, 1994). The association between modernization and the nuclear family model is far from being confirmed everywhere. In the numerous countries experiencing a decline in fertility, the reduction in household size that it entails does not result in a process of nuclearization. Indeed, new domestic and residential arrangements and family reconstitution can be observed, associated with a redefinition of social relations and family roles (between sexes and between generations).

3. Female Household Heads

Although it has recently increased, this phenomenon is not new. It has existed in several societies since ancient times, notably in those in which matrilinearity is proven, in which women have the right to inherit and to possess land (Ono-Osaki, 1991; El Khouri, 1996). Diverse factors are behind it: husband's death, matrilinearity, marital instability, absence of migrant husband or the wife's own migration, practice of non-cohabitation of spouses,[8] households without an adult male (Charbit and Petit, 1996), and the woman's own decision (in terms of strategy of autonomy), and in a more artificial way, census and survey methods[9] contribute to females being considered as household heads, although sex roles usually confine them to a status of dependence on males. Indeed "according to the United Nations' recommendations, the male should systematically be declared household head within a couple" (Tichit, 1994:19) unless the female lives alone or without the presence of an adult male. These situations result in extremely diverse family and economic realities. Becoming a female household head can be the result of choice or circumstances, it can also reflect a strategy of autonomy as well as socioeconomic precarity (Locoh, 1988b; Ono-Osaki, 1991; Bisiliat, 1996).

Whatever the case, in both urban and rural zones an increasing number of women are taking on the role of household head. The development in male labor migration, growing marital instability, increasing practice of non-coresidence of spouses in cities, and a general female emancipation process make up the factors that explain the development of this phenom-

[8] In a study of the Bwa of Mali, who practice non-cohabiting polygyny, Vêronique Hertrich (1996) shows that the difference in the increase of "female households" could be considerable according to whether domestic groups or residential units are considered: the status of head is given to females in only 3% of cases for the latter, but in 27% of cases for the former.

[9] Because of the residential dimension of the household and the criteria of duration of absence, which leads to the statistical exclusion from a household of any person absent for more than a certain period (often 6 months).

enon over recent decades. However, the "tendency is possibly much older, dating to the socioeconomic changes initiated by colonization" (El Khouri, 1996:21).

The proportion of female household heads varies significantly depending on the region, the country, and the area of residence, from 5% in rural Burkina Faso to 51% in urban Botswana (Table 90–5; Fig. 90–4). In the majority of countries, the proportion of female household heads exceeds 20%, a fact that confirms the significance of the phenomenon. The proportions are highest in Latin America, east Africa, south Africa, and in the three central Asian countries.

The distinction according to residential area shows that the phenomenon is more marked in cities in nearly all the regions; this is particularly the case in South America and central Asia (as well as in Vietnam). Some countries in south Africa (Botswana, Zimbabwe, Malawi, Zambia, Kenya) are exceptions, with higher proportions in rural areas, a situation that is largely owing to the scale of male labor migration.

Although published statistics rarely provide information on the structure of female-headed households, three main types of composition can be identified: women alone, single-parent households (with or

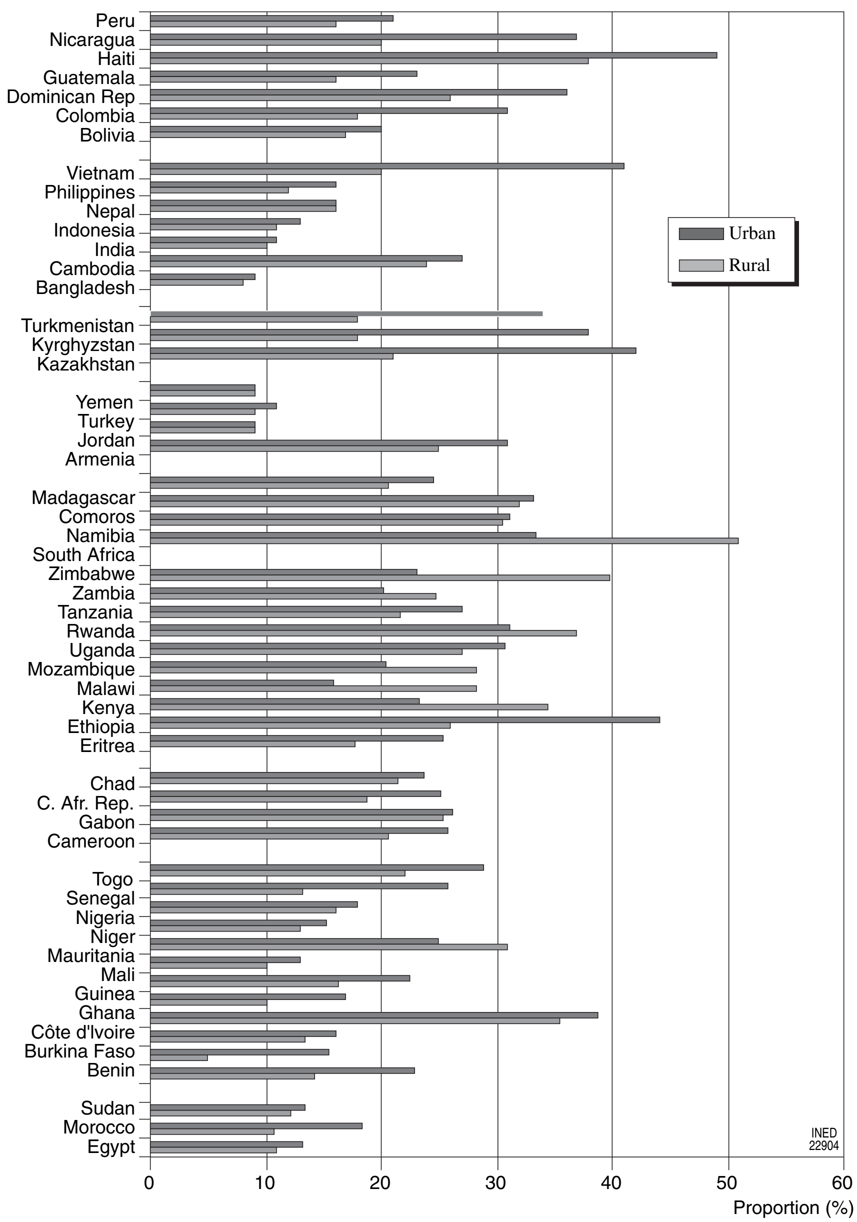

FIGURE 90–4 Proportion of households with a female head according to the Demographic and Health Surveys of 1990–2000.

without other persons, related or not), and women without children living with other persons (related or not). The specificity of female-headed households results in households being smaller than those headed by males.

The demographic profile of female household heads also varies significantly. Although their age structure generally shows a high proportion of elderly women (but it is generally lower than in industrialized countries), quite frequently there are also young women in some regions—in sub-Saharan Africa, Latin America, and the Caribbean (Arias and Palloni, 1999). Widowhood and spinsterhood are obviously associated with these two age categories.

According to a United Nations synthesis (1992:18) of the situation of females in the world, "In Africa, in the developed regions, and in the Asia Pacific region, approximately half of female household heads are widows. In Latin America and the Caribbean, only 28% are widows and 36% are single. In all regions, there are more married and single women than divorcees. The proportion of divorced female household heads is particularly low in Asia and the Pacific: 6% against 13% in Latin America and the Caribbean, 14% in Africa, and 16% in the developed regions."

4. Fostered Children

The common extended structure of households in developing countries is owing to the cohabitation of several family nuclei and/or the presence of others, related or not. Children are often among the former, notably owing to fosterage. The circulation of children is an old phenomenon found in numerous societies all over the world (Silk, 1987; Lallemand, 1993:41–48). Children who do not live with both parents fall into the following categories: mother present/father absent, mother present/father deceased, mother absent/father present, mother absent/father elsewhere, mother deceased/father present, and mother deceased/father deceased. A first distinction to establish is whether there is child mobility or not: does he/she come from another household, or have the parents left the household (or who are deceased)?

There are multiple reasons for all these scenarios, and the corresponding family situations are extremely diverse: illness, death, divorce, separation or parents' non-cohabitation, family support, socialization, education, relations through marriage, etc. (Lallemand, 1993). For the societies concerned, the circulation of children is a characteristic element of family systems and conforms to the logic of family interdependence and to the system of rights and responsibilities. In addition to a reinforcement of social ties, this practice, via a wider distribution of the economic costs of raising children, also appears to contribute to maintaining high fertility behavior. It is this association with fertility that has led demographers to become more interested in the phenomenon of fostered children. Regardless of the reasons for this, fosterage is one of the components of the structure and dynamics of households.

Adoption, loan, gift, exchange, transfer, circulation, mobility, and fostered child are some of the terms used[10] to indicate this plural reality; this is a little confusing because the same terms are used to describe different situations. The heterogeneity of the definitions makes comparative studies particularly difficult, as shown by the following examples taken from the literature:

Children aged 0 to 14 years, other than those of the household head, not living with their mother (Page, 1989)
Children aged 0 to 10 years, other than those of the household head, not living with their parents (Isiugo-Abanihe, 1985)
Children aged 0 to 19 years, other than those of the household head (even if one of the parents is present) (Vimard and Guillaume, 1991)
Children aged 7 to 14 years, other than those of the household head, not living with their parents but not orphaned (Ainsworth, 1990)
Children aged 1 to 12 years, not living with their mother (Bledsoe and Brandon, 1989)
Children aged 0 to 14 years, not living with their parents (Blanc and Lloyd, 1994).

In the absence of precise information on the situations observed, the expression "children's living arrangements" (Lloyd and Desai, 1992) seems the most appropriate, or at least the most neutral, term.

Specific studies and analyses carried out on demographic survey data have multiplied, shedding new light on the matter (Vandermeersch, 2000). Beyond the measurement of the scale of the phenomenon, authors have attempted to discover its principal determinants and to see to what extent this practice affects fertility behavior.

The results of the Demographic and Health Surveys currently provide the most comprehensive statistical information, with the possibility of temporal comparative analyses for a growing number of countries. The results published generally provide a household level indicator (the percentage of households in which children live without their parents), available according to place of residence, and a table giving the distribution of children according to survival and their parents' residence according to their age, sex, and area of residence. The percentage of households with children living without their parents (whether they are alive or deceased) gives an approximation of the scale of the phenomenon of child fosterage at the household level (Table 90–6; Fig. 90–5).

Existing studies concur that fosterage is particularly widespread in Africa (Antoine and Guillaume, 1986; Page, 1989; Isiugo-Ibanihe, 1991); which confirms the contents of Table 6 and exposes a large variety of situations within the African continent. The phenomenon seems to have a lesser importance in Latin American countries, even more so in Asian countries. In the majority of African countries, the percentage of households with at least one child aged under 15 years living without his/her parents is above the threshold of 20%.

CONCLUSION

This overview of household size and structure in developing countries does not really make it possible to come to any firm conclusions. On the one hand, the results available are still only partial, and on the other hand, the comparative analysis is limited owing to the data source; any interpretation must therefore be a

[10] Terms include fosterage, fostering, adoption, child relocation and transfer, child circulation, child migration, child rearing delegation (Isiugo-Abanihe, 1985, 1991), and exchange of children (Pennington and Harpending, 1993:171–199). Fostering and fosterage are the most commonly used terms.

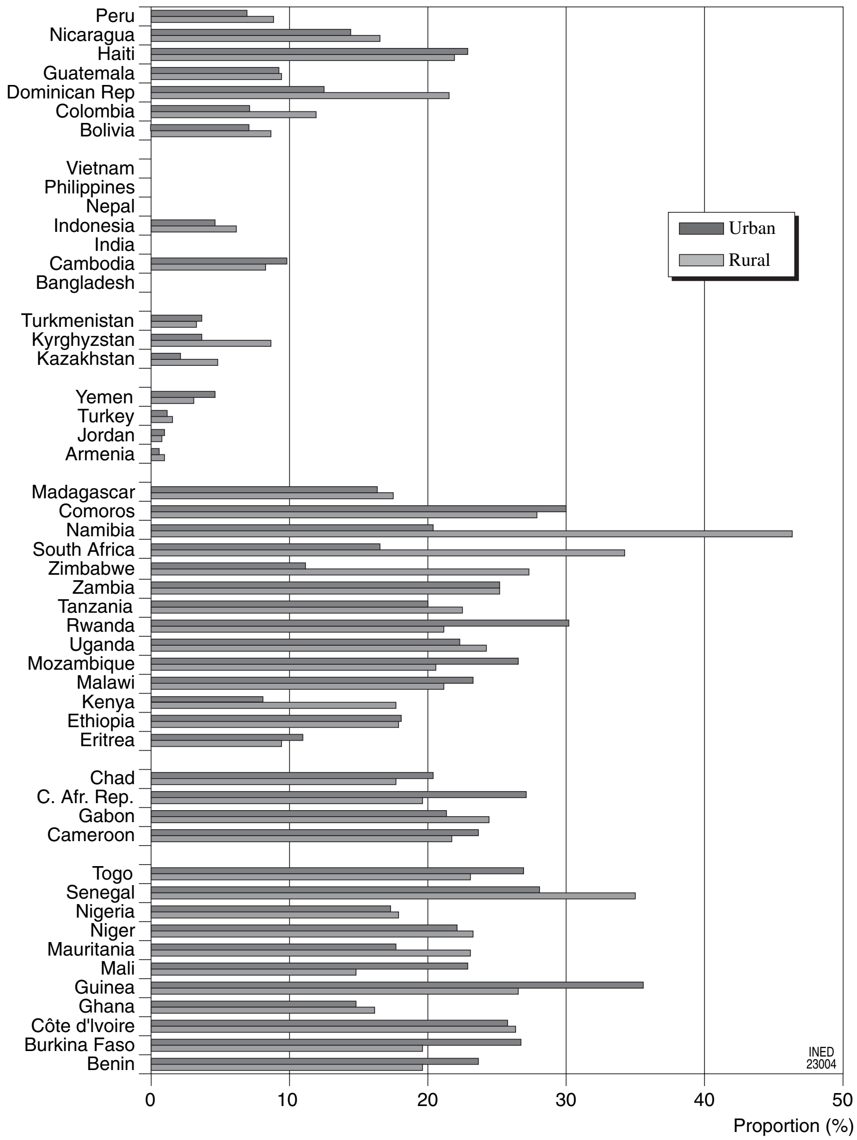

FIGURE 90–5 Proportion of households with children aged under 15 years without their parents, according to the Demographic and Health Surveys of 1990–2000.

TABLE 90–6 Proportion of Households with Children Aged under 15 without their Parents, According to the Demographic and Health Surveys of 1990–2000

cautious one. It is no doubt necessary to increase the refinement of analytical and data collection concepts which remains to be undertaken in the field of household and family demography in developing countries.

CHAPTER

91

Households and Families

NICO KEILMAN

Department of Economics, University of Oslo, Oslo, Norway

INTRODUCTION

Statistics Norway reported in its family statistics that there were 501,000 families consisting of a married couple with one or more children on January 1, 1999 (Statistics Norway, 2000). However, in another table the number of married couples with children for that date is much lower: 359,000 (Statistics Norway, 2000). Both figures are correct, but the definition of a family consisting of a married couple and one or more children differs between the two. For the first figure, children can be of any age, and for the second one, children must be younger than 18 years of age. Introduction of an upper age limit for children reduces the number of married-couple families by about 30%.

The November 1990 Population and Housing Census for Norway reported 102,000 consensual unions (Statistics Norway, 1999). But sample surveys carried out in 1988 and 1994 indicate that the numbers in those years were at least 130,000 and 200,000, respectively (Statistics Norway, 1995a).[1] The three numbers suggest a strong fall between 1988 and 1990 and a steep rise thereafter. In reality, this has not been the case: consensual unions have gradually become more and more popular in Norway since the end of the 1970s, and there are no indications for major fluctuations in the numbers. The main reason why the census number is much lower than what could be expected on the basis of the information for 1988 and 1994 is that the census number relates to the household situation according to the Central Population Register, that is, the *de jure* place of residence. However, the surveys are based on the de facto place of residence. The register does not always reflect the de facto place of residence accurately, and for partners in a consensual union in particular there is a strong underregistration in the register. This explains why the census figure is much lower than that obtained on the basis of a survey.

The two examples given above illustrate some of the difficulties one will encounter when family and household trends are investigated. Different definitions and different measurement methods make a comparison over time or across countries problematic. In this treatise, both the analysis and the synthesis of population developments are described. Therefore, the aim of this chapter is not only to give a broad overview of trends in family and household developments in Europe but also to discuss concepts and definitions concerning the household, the family, and their members: what constitutes a household, a family; what is a consensual union, a child, a one-parent family, a reconstituted family?

Next I review various issues connected to measuring household and family developments: de facto or *de jure* place of residence, measure of household and family structure at one point in time, measure of household and family dynamics over a certain period, the

[1] The estimate for 1988 has been computed on the basis of age-specific shares cohabiting women for ages 22, 27, 32, 37, and 42 from the survey (see Statistics Norway, 1995a). These shares were assumed to be the average shares for age groups 20 to 24, 25 to 29, 30 to 34, 35 to 39, and 40 to 44, and next these were multiplied with the registered numbers of women in these age groups for the country as a whole on January 1, 1988. This results in 129,000 cohabiting women aged 20 to 44. Cohabiting women outside that age group are not included in this estimate.

individual or the group as unit of measurement, the problem of longitudinal households, relationships between the events that several members of the same household may experience (e.g., a lone mother becomes a one-person household when her last child leaves the parental home), and the representativeness of the data. The strengths and weaknesses of various data sources often used to map household and family developments are discussed later in the chapter. Finally, the main trends in family and household developments in Europe after World War II are summarized. Notoriously lacking is a review of relevant behavioral theories. A decade ago, Burch (1995) noted that family and household demography have made considerable progress, but that theory has greatly lagged behind. This may reflect the complexity of the subject matter.[2]

I. DEFINITIONS AND CONCEPTS

The notions of household and family are closely connected, yet there are strong differences. A formal definition of both will be given below, but one can say that an important aspect of the household definition is coresidence irrespective of consanguinity or conjugality, whereas consanguinity and conjugality are major ingredients for the family definition, irrespective of place of residence. However, as we will see below, the family in the more restrictive sense is limited to persons related by blood or marriage, who live in the same household. In that respect every family is also a household, but some households are not family households, for instance, one-person households.

The 47th edition of the *Demographic Yearbook* of the United Nations (UN, 1997) contains summary tables for the definitions used by countries that participated in the 1990 round of censuses. The same type of information for the 1980 census is found in the 39th edition (UN, 1989). Much of the international experience that is given below is drawn from a survey among member and associated countries of the UN Economic Commission of Europe (ECE), which was carried out in the spring of 2004 (see Keilman and Kinsella, 2004). Forty-six countries gave details on their experience with the 2000 round of censuses.

1. The Household

For the 2000 round of censuses, the United Nations recommended using the following definition of a private household: a household is "(1) a one-person household, i.e., a person who lives alone in a separate housing unit or who occupies, as a lodger, a separate room (or rooms) of a housing unit but does not join with any of the other occupants of the housing unit to form part of a multi-person household as defined below; or (2) a multi-person household, i.e., a group of two or more persons who combine to occupy the whole or part of a housing unit and to provide themselves with food and possibly other essentials for living" (UN, 1998). This definition centers on two important notions: common housekeeping and living in the same house. Both conditions must be fulfilled when two or more persons can be said to belong to the same household, according to this so-called *housekeeping-unit concept* of the private household. A somewhat less restrictive definition centers on the *household-dwelling concept*, which says that all persons who occupy the same housing unit live in the same household (UN, 1998). Although in practice some countries use the household dwelling unit definition, the housekeeping unit definition may prove to be more useful in socioeconomic analyses of household structure. Two-thirds of the ECE countries applied the housekeeping unit definition in their census carried out around 2000 (Keilman and Kinsella, 2004). Many of the countries that used the household dwelling concept based their census on a population register, for instance, Denmark, Finland, France, Norway, and Switzerland. Similar shares (two-thirds of the countries using the housekeeping definition, one-third using the dwelling definition) were also observed in European countries for the 1980 round and for the 1990 round of censuses (Keilman 2004; Keilman 1995:table 5.1).

Household data may be obtained not only from a census, but also from other sources. Sample surveys are commonly used, for instance, a Labor Force Survey. Kormendi (1995:table 1) has shown that 8 of the 12 member states of the former European Community (EC) employed the housekeeping unit concept in their Labor Force Survey in the 1990s. Belgium, Denmark, Spain, and France based their household data on the household dwelling concept.

Whether one uses the housekeeping unit definition or the dwelling unit definition has little effect on the *total* number of households: differences of 2% to 3% have been reported for Austria, Germany, and Norway (see Ås, 1990; Galler and Ott, 1993; Gisser, 1995).[3] But

[2] Although, as Burch notes, a good theory makes things look simple(r).

[3] Although the numbers for Austria, Germany, and Norway cited here are small, this does not hold more generally, as is demonstrated by the case of Czechoslovakia: the difference in the number of households implied by the dwelling unit definition, as compared to the housekeeping definition was 8% in the Czech Republic, both in 1970 and 1980; in the Slovak Republic the difference was 9% in 1970 and 11% in 1980 (Kalibova 1991).

one-person households may be affected more strongly: lodgers are counted as one-person households according to the housekeeping unit concept, whereas they are member of the household that they share the housing unit with when the dwelling unit concept is used.

Housekeeping unit and dwelling unit are not the only two alternatives; other possibilities fall somewhere in between these two. For instance, Todd and Griffiths (1986) carried out a study into the effects of a household definition change on numbers of households in England. In many major household surveys of the Office of Population Censuses and Surveys up to 1981, the housekeeping unit concept was used to define a household. But in 1981 it was considered more appropriate to bring the instructions for interviewers in line with census practice, in which persons who shared a living room were also included in the household, even if they did not share catering arrangements. The effect of this change in definition was that the overall estimate of the number of households was reduced by 108,000, or 0.6%. Most of the excluded households were in the private rented sector in outer London and the southeast of the country, comprising one-person households and households with a resident landlord.

In addition to the private household defined above, the UN also has a recommendation concerning institutional households:

> "An institutional household comprises persons whose need for shelter and subsistence are being provided by an institution. An institution is understood as a legal body for the purpose of long-term inhabitation and provision of institutionalized care given to a group of persons. The institution's accommodation is by nature of its structure intended as a long-term accommodation for an institutional household. The great majority of institutions consists of one of the following: dormitories of educational institutions, hospitals, convalescence establishments, establishments for the disabled, psychiatric institutions, old people's homes, nursing homes, welfare institutions, hotels, motels, tourist homes, military installations, correctional and penal institutions, religious institutions, boarding houses, worker dormitories" (UN, 1998).

2. Head of Household

Until the 1990 round of censuses, the UN recommended using the notion "head of the household," that is, that person in the household or the family who is acknowledged as such by the other members. It implicitly involved the person who bears the chief responsibility for the economic sustenance of the household or the family. In a number of European countries, this concept is outdated. The UN formulated it quite cautiously: "In countries where spouses are considered equal in household authority and responsibility or shared economic support of the household, the concept of head of household was no longer considered valid even for family households" (UN, 1989). Thus, the concept of household head no longer reflects social reality in many European countries, and moreover, it is thought to be offensive to a large fraction of the population if they were asked to report one household member as head in a statistical enquiry (Murphy, 1991a). Therefore, starting with the 2000 round, the UN suggested that countries might prefer that the members of the household designate one among them as a *reference person* with no implication of headship:

> "There is some evidence though to suggest that the following criteria for selection of the reference person will yield the most fruitful range of explicit kin relationships:
>
> Either the husband or the wife of a married couple living in the household (preferably from the middle generation in a multi-generational household);
> Either partner of a consensual union couple living in the household where there is no married couple present;
> The parent, where one parent lives with his or her sons or daughters of any age;
> Where none of the above conditions apply, any adult member of the household may be selected" (UN, 1998).

Next, the structure of the household may be explored by tracing the relationship between the remaining members and the reference person, or the household head in countries where the traditional definition is considered appropriate.[4] Following UN practice, the term *householder* is used to denote household head or reference person.

Whether a householder is called head or reference person is of less importance than the fact that there is heterogeneity among countries in determining the householder. Among 46 ECE countries, all but two (Denmark and Norway) reported that they identified a reference person in the household (Keilman and Kinsella, 2004). However, for purposes of household structure mapping, the two countries just mentioned define the oldest person in the household as a point of reference. In 22 of the 46 countries, census respondents chose the reference person freely among the adults living in the household, using various criteria.

Does this large variability in the international practice concerning household head and reference person render international comparisons useless? Not for all cases, probably. First of all, in practice, the age distribution of householders seems to differ very little when alternative definitions are used (Murphy, 1991b). Second, many households consist of a married couple

[4] Brynin and Smith (1995) discuss various methods for mapping such relationships on the basis of the British Household Panel Survey.

(with or without children), a one-parent family, or a single person. In the case of a married couple, the husband will most frequently be denoted as (one of the) householder(s). In case a one-parent family is recorded, the householder will often be a woman. International comparisons are therefore still possible for a limited group of countries, provided that one distinguish between two-parent families, one-parent families, and other households, and that male and female householders be considered separately. When no such distinction is made, the comparison becomes hazardous, in particular for women. Indeed, as an UN review shows, female headship rates for Austria, Norway, and Sweden are almost consistently higher than are those in Italy, Portugal and Spain, and some of the differences may be interpreted in terms of economic criteria that are used to identify the householder (UN, 1989).

The ultimate solution is of course to standardize the definition of the reference person (Wall 1996). But this is virtually impossible to achieve in practice, and therefore Wall (1996) has suggested to base international household comparisons on a detailed set of standardized tables. The basic idea is to cross-classify age, sex, and marital status with a person's household position: whether he or she lives in a household as a couple, as a lone parent, as a child, as one person, etc. Such detailed tables have been compiled for Ireland (the Census of 1979) and Canada (the census of 1986), and can be constructed for a number of other countries as well (e.g., England and Wales, Great Britain, The Netherlands, Italy, Norway).

3. The Family

The UN recommend to define, for census purposes, a family as "two or more persons within a private or institutional household who are related as husband and wife, as cohabiting partners, or as parent and child. Thus a family comprises a couple without children, or a couple with one or more children, or a lone parent with one or more children" (UN, 1998). Among 46 ECE countries, 39 used a definition that complies with the recommendation. In Canada, England and Wales, and Northern Ireland, grandparent(s) living with one or more grandchildren but without the grandchild(ren)'s parents are also regarded as a family. Canada and Ireland restricted the family to those living in private households. Norway complies with the definition when compiling international tables, whereas persons living alone are also counted as families (one-person families) in national tables. The Swiss census did not include family information. The United States restricts families to two or more persons related by birth, by marriage, or by adoption to the householder. This differs from the recommended definition in two respects: cohabiting partners who are not married to each other are not counted as families, and a household consisting of a household reference person (householder) and two or more persons who form a family (according to the UN definition), but who are not related (birth, marriage, adoption) to the reference person, is not considered a family household.

Better comparability with previous censuses or with other statistical surveys was mentioned often as the main reason for a different definition.

4. Consensual Union

Starting with the 2000 round of censuses, the UN-ECE has formulated a recommended definition of a consensual union: "Two persons are understood as partners in a consensual union when they have usual residence in the same household, are not married to each other, and report to have a marriage-like relationship to each other." (UN, 1998). Note that partners can be of the same sex. Because of problems connected to developing criteria for marriage-like relationship, it must be left to the respondents to report themselves as partners in consensual union or not (for a review of issues connected to defining cohabitation, see Trost, 1988). All 46 ECE countries for which we have information practiced this so-called phenomenological definition (owing to Trost) in the 2000 round of censuses (see Keilman and Kinsella, 2004). Using a phenomenological definition will introduce a bias for various reasons (Trost, 1988): social acceptance, or tax avoidance, or differences in perception between the partners (one considers the relationship as marriage-like, the other one looks on it as more casual). As a result, two nonmarried adults living in the same household may be recorded as a consensual union at one occasion and as two nonrelated adults at the other. In case there are dependent children as well in the household, the alternative registration will often be a one-parent family, and a nonrelated adult living in the same household.

5. Child

The UN (1998) recommends to define a child "as any person with no partner and no child who has usual residence in the household of at least one of the parents." Children also includes stepchildren and adopted children, but not foster children. A child that alternates between two households (e.g., after the parents' divorce) is counted at only one of these households, for instance, on the basis of the *de jure* place of usual residence (see Section "De Facto or *De Jure* Place of Residence?") or the number of nights spent at either of the households. Only five countries among the 46 for which we have information deviated from the recommended definition (Keilman and Kinsella, 2004). The census in the Czech Republic required that children be economically dependent (economically not active) and not older than 25 years of age. There is no restriction on partners or own children. Denmark required that children be less than 25 years old. In Switzerland, sons-in-law and daughters-in-law living in the same household were also considered as children. Moreover, there was no restriction on marital status in the Swiss definition. Thus, a child could be married and living with his or her spouse in the household of the parent(s). The United States did not have any restrictions regarding the child's own children or partner.

The case of three or more generations living in the same household may create problems. A woman, who lives in the same household as her children *and* her parents, but without a partner, should be regarded as being member of the same family as her children, but not of the same family as her parents: "A three-generation household consists of two or more separate family nuclei or one family nucleus and (an)other family member(s). A woman who is living in a household with her own child(ren) should be regarded as being in the same family nucleus as the child(ren) even if she is never-married and even if she is living in the same household as her parents; the same applies in the case of a man who is living in a household with his own child(ren). Thus, the youngest two generations constitute one family nucleus." (UN, 1998).

6. One-Parent Family

The UN has not formulated a separate definition of one-parent family, but one possibility is one adult living in the same household with one or more of his or her children (by blood or adoption). Problems in connection with the notion of "child" have been discussed above. But other problems may arise when there is a second adult member in the household. When this person is a relative of the lone parent (mother, father), the situation is clear. But another possibility is that this person is the lone parent's cohabitee, and then there is the situation of a household consisting of a cohabiting couple plus the child of one of the partners. How can we distinguish between this household type and "one-parent family plus other adult"? A possible marriage-like relationship between the two adults is not enough for the household to be called a consensual union with child(ren). A further condition is that *both* adults take parental responsibility for the children. In Trost's words: the number of "parent–child units" should be twice the number of children, in addition to one "conjugal unit" (Trost 1990). If only one of the adults forms a parent–child unit with the children and a marriage-like relationship with the other adult, it will be unclear whether or not this is a one-parent family.

The situation described here is not at all hypothetical: Höpflinger (1991) indicates that in the 1980s in Germany, 10% of women who declared themselves as "lone mother" were in fact cohabiting; for "lone fathers" the figure might even have been as high as 28%.

7. Reconstituted Family

The UN regards a reconstituted family as "a family consisting of a married or cohabiting couple with one or more children, where at least one child is a non-common child, i.e., either the natural or adopted child of only one member of the couple. If the child (natural or adopted) of one partner is adopted by the other partner, the resulting family is still a reconstituted family" (UN, 1998). When a lone parent starts cohabiting with a partner who takes parental responsibility for the former lone parent's child(ren), we have one example of a reconstituted family or stepfamily. The other example of reconstituted family is when the two adults are legally married. Although such reconstituted families historically referred to family formation through remarriage after widowhood, we nowadays also regard separation or divorce, followed by the start of a consensual union, as events leading to a reconstituted family (Deven, 1995). Issues connected to reconstituted families have been discussed by Leridon (1993).

Only 19 of the 46 ECE countries for which information exists reported that they are able to identify reconstituted families by using census data. One possible explanation for the poor performance across countries on this item is the fact that many countries mapped household structures by means of the relationship of each household member to the household reference person, but not by means of the relationship to other household members. This implies that not all reconstituted families can be identified. For example, in case a father is the reference person and the mother is his second wife, this family can not be identified as reconstituted because the child is referenced to only one adult, viz. the father. It would be tallied as being a married-couple family with a biological child of the reference person but of unknown connection to the wife. However, if the father were listed as the "husband" of the reference person (the reference person being the second wife), then this child would be listed as the stepchild of the householder. This family could be identified as a reconstituted family in which the householder was not the biological mother of the child. Thus identification of reconstituted families requires more detailed mapping of household structures than by means of the relationship to just one person in the household. A full matrix of relationships between all household members is one possibility. Such a matrix was used by 13 of the 44 countries that reported that the relationship of each household member to the household's reference person was asked: Albania, Cyprus, Estonia, Greece, Hungary, Kazakhstan, Lithuania, Portugal, the Russian Federation, Serbia and Montenegro, England and Wales, Scotland, and Northern Ireland. An intermediate solution is to map, for every child in the household, the relationship with all adults (biological or nonbiological parent).

II. MEASUREMENT OF FAMILY AND HOUSEHOLD DEVELOPMENTS

Given a particular definition of the various household and family variables, the analyst can start measuring them. Before doing so, however, several questions have to be answered.

1. De Facto or *De Jure* Place of Residence?

Do the data to be measured refer to the *de facto* or the *de jure* situation? A number of countries have a population register, which is used directly or indirectly for collecting information on households and families. The situation according to the register (*de jure*) may differ from the actual situation (de facto). An important aspect in this respect is the place of usual residence. The UN (1998) recommends defining as place of residence: "the geographic place where the enumerated person usually resides; this may be the same as, or different from, the place where he/she actually is at the time of the census; or it may be his/her legal residence. A person's usual residence should be that at which he/she spends most of his/her daily night-rest."

Of 46 ECE countries, 43 reported that they complied closely or completely with this definition. Scotland applied a different definition, because a person's usual residence was preferred to be at their family residence if they worked away from home during the week. In Austria, the usual residence of a person is her/his main residence as registered in the population register. Week commuters are registered at the family's residence, similar to the case of Scotland.

Given this recommendation it must be concluded that the UN recommend collecting de facto information regarding membership in families and households. In practice, a number of countries have probably used a *de jure* definition of place of residence and hence of family and household membership, most often based on a population register. Although this may be good practice in case there is little difference between *de jure* and de facto place of residence, it creates difficulties when the register shows considerable differences with the actual situation. Below I give some examples for Norway, Switzerland, and Germany connected to the 1990 round of censuses. For these countries, we have detailed statistical data on the differences between *de jure* and de facto places of residence.

Registration rules for the Norwegian population register until 1998 stated that a never-married person who resides outside the home of the parents because of education should be registered as living at the parents' address (Statistics Norway 1985; Skiri 1995). Data collection for the November 1990 Population and Housing Census of Norway was closely linked to the register. One of the census questions was "With whom do you share this dwelling?," and respondents had to answer *in conformity with the register*, irrespective of the persons actually living in the respondent's dwelling. One consequence was that the census severely underestimated the de facto number of consensual unions and the number of one-person households: an estimated 22% for consensual unions (Keilman and Brunborg, 1995), and 19% for one-person households (Schjalm, 1996). At the same time, the census reported far more young adults living with their parents than in reality. The overall result was that the 1990 census underestimated the de facto number of private households by 4% to 6% (Statistics Norway, 1994). Registration rules were changed in 1998, when students were given the possibility to register as their *de jure* place of residence the place where they actually lived. But the 2001 census found that still 83,000 students had not done so. The consequence was that the census underestimated the share of persons living in a one-person household by two percentage points.

The December 1990 Census of Switzerland distinguished, for the first time, between legal and economic residence (M. Buscher, personal communication). The economic residence is the place where the individual concerned usually (the largest part of the week) lives.

The legal residence is where taxes are paid, political rights are exercised, etc. The legal place of residence is different from the economic one for 3% of the population.

Finally, note that difficulties may be encountered when a child alternates between two households, for instance, after the parents' divorce. In general, an individual may theoretically be a member of two households, but with different degrees of membership (Berge, 1988). In practice, however, when classification is attempted, only one household will be assigned to each individual. But in German household statistics, persons with two residences are counted twice (Linke, 1988). The population in private households in a certain municipality includes all persons counted there, even if some of them live most of the time in a different municipality. Schwarz (1983) estimates that the number of one-person households in 1961 had to be adjusted downward by no less than 30% in order to reflect reality.

2. Individual or Group Level Data?

Do the data apply to *individuals* or to the *group* level? One should clearly distinguish between an analysis for persons and an analysis for households (or families or married couples). For instance, whereas 38% of private households were a one-person household in Norway in 2001, only 17% of the population lived in such a household (see *http://www.ssb.no/emner/02/01/fobhushold/*).[5] Both types of data have their merits: for instance, some purchases are directly linked to the individual level (food, clothing), others to the group level (housing, capital goods). Furthermore, the household can make decisions as a group (e.g., the decision to marry taken by a cohabiting couple) or by individual household members (e.g., home leaving of young adults).

Data that reflect the household and family situation at one point in time (stock data) are routinely given both at the individual and the household level. For instance, the UN recommend to tabulate, among others, the *population* by household status (persons in various types of households) and, at the same time, *households* by various types. Note that knowledge of the type of household an individual lives in is not sufficient for determining this person's individual household status. For example, a person living in a household of type "married couple with children" may have household status "child" or "spouse." Conversely, age, sex, and marital status may be added to an individual's household status, and this often helps in determining that person's household type given household status, but not always—it depends on the actual classifications chosen for both household type and household status.

Contrary to stock data, the individual level may be preferred when information is collected concerning household and family *dynamics* over a certain period (*flow* data). The reason is that the group level perspective may create some problems; compare the discussion below on longitudinal households.

In between the individual and the complete household is what Ermisch and Overton (1985; see also Ermisch, 1988) have called the minimal household unit (MHU). It is the smallest group within the household that constitutes a demographically definable entity. This means that an individual, over his lifetime, moves from one type of MHU to another by means of simple demographic events only. The four MHUs defined by Ermisch and Overton are (1) childless, nonmarried adult; (2) one-parent family; (3) childless married couple; and (4) married couple with dependent children. Demographic events that cause individuals to move between MHUs are marriage, loss of spouse, birth of child, loss of last child, and divorce with loss of children. The status "married" and the event "marriage" are to be interpreted as including de facto marriage. Hence MHU types 2 through 4 are equivalent to a narrow definition of the family, whereas type 1 corresponds with a person living alone. Households can be viewed as consisting of one or more MHUs.

3. Adult or Child as the Unit of Analysis?

When family or household structures are investigated, the focus is often on the relationship between children and adults. If the data apply to individuals, the choice is between the perspective of the child and that of the adult. Most often, the adult is chosen as the unit of analysis, because most data are supplied in that form (OECD, 1979). But in a few cases, the focus has been on children. The results may differ, sometimes considerably, according to which viewpoint is chosen. The first reason is that most children live in families and households with only one or two adults, whereas the range in number of children seen from the perspective of the adult is much larger: from one to six or even more. The second reason is particularly relevant when *relative* numbers are compared, for instance, the share of lone parents among all parents to the share of children with a lone parent compared with all children. In this case the findings will differ because the reference groups differ (all parents versus all children).

[5] Note that the ratio of these two numbers equals mean household size; for Norway 38/17 is 2.3 persons per private household on average.

As an example consider the Children Statistics compiled by Statistics Norway (1996:table 1), from which we can compute that 17.3% of all *children* (under 18) lived with a lone parent on January 1, 1995. On the other hand, only 13.7% of all *parents* (with children under 18) were lone parents at that time (Statistics Norway 1995b:table 3).

The few demographic family and household studies in which children are the unit of analysis have most often analyzed family break-up and the extent to which children experience divorce by the parents. Examples are findings reported for Denmark, England, France, The Netherlands, New Zealand, Norway, and the United States.

4. Structure or Dynamics?

Is the interest in the household and family *structure* at one point in time or in *dynamics* over a certain period? Cross-sectional data can only give a snapshot of the situation. Changes in that structure may be mapped at two levels: that of the population as a whole, and that of the individual or the household. Repeated cross-sectional surveys can provide us with repeated measurements for population indicators, for instance, the development in the number of households of various types, in the share of children living in a one-parent family, and so on. Only the net change between two points in time is measured this way—hence we may also speak of comparative statics. Yet this will generate useful data. For instance, changes in the composition of households by size and type may help us in understanding developments in housing preferences, or consumption patterns. But when the interest is in a more causal analysis, data on net changes obtained from repeated cross sections are only of help during a first stage in the analysis—changes at a continuous time scale (gross flows) measured for individual persons or households should be analyzed next. This would facilitate exploring the consequences of certain policy actions for subsequent household and family behavior, or to study the impact of events in one arena of life (e.g., education) for those in a different arena (e.g., childbearing). The point is that the *timing* of certain events is recorded for *the same* individual or household during a particular time period.

The amount of household change that is found during a particular period increases when more detail is distinguished in the breakdown by household type or household status. When households are only divided into family households and nonfamily households, a woman who becomes a lone mother will not change household type. This will only be the case when an additional distinction is made between couple households and lone-parent households. Compare the distinction between interregional migration and intraregional migration in studies of regional mobility.

5. Longitudinal Households

An individual person is born, dies, and experiences during his life several events such as home leaving, start of a partnership, marriage, childbearing, etc. Events of this type reflect household and family dynamics at the *individual* level. We can also define events at the *group* level: household formation, household dissolution, and household change. When the focus is on the development of households at the group level, one may be confronted with the problem of *longitudinal households*: when a household splits, it is often difficult to determine which part is the original household and which part constitutes a new one. In other words, when can two households that exist at two points in time be considered as the same household (McMillan and Herriott 1985)? For example, when a married couple with four children separates and the man leaves the household, the result is a lone mother and a one-person household. Are these two truly new households? Or is the one-parent family a continuation of the old household (although of a different type)? To answer such questions, continuity rules have to be formulated. One possibility is to call a household a continuous one as long as 50% or more of its members are the same at two points in time. In that case the lone mother and her children mentioned above would not change household. Another one is the rule that two households that have the same head are the same household. This may lead to the decision (depending on the definition of head of household) that the man who now lives alone in fact lives in the same household. The continuity rule chosen for a particular situation is often arbitrary, and an important objection is that different rules lead to different results (Citro, 1985; McMillan and Herriott, 1985). Therefore, when household dynamics are investigated, the unit of analysis is likely to be the individual rather than the household (Duncan and Hill, 1985; Murphy, 1995). In such an approach, individuals move between household states. As an example, consider the following sequence: from “child with two parents” to “cohabiting” to “married” to “married, one child” to “separated” to “deceased.”

6. Interrelated Events for Members of the Same Household

To focus on individuals rather than on households when analyzing household and family dynamics circumvents the problem of longitudinal households, but it leads to another problem: many household events for members of the same household are interrelated. An event for one household member often induces an event for other members. To continue the example given in the previous section, when a person moves from “married, one child” to “separated,” the spouse becomes a lone parent. If we want to understand household dynamics at the individual level, these and other links between events experienced by members in the same household must be taken into account. How complex these interrelationships are depends on the level of detail in the household state classification for individuals. For instance, with only four marital states (never married, currently married, divorced, widow[er]) we just have to trace marriage and divorce for both partners, and death of one spouse together with transition to widowhood. But with a reasonable set of proper household states (e.g., child, living alone, cohabiting, married, in institution, and other) there are many interrelationships of various types.

7. Representativeness

When the data come from a sample survey, one should consider carefully which larger population they represent. At survey date, the sample should be representative of the population both in terms of individuals *and* of households. In other words, the distribution of sample members by household status should be reasonably close to the corresponding distribution for all persons in the population, and at the same time, the distribution of households by some characteristic should be close to the corresponding distribution for households in the population. This may be problematic when the sample frame is in terms of individual persons, of which a sample of persons is drawn who next report on the household situation of all other members in their household. This leads to an overrepresentation of large households, because a randomly drawn person is more likely to live in a large household than in a small household. Thus, a representative sample of individuals will not give a representative sample of households. The same problem may occur when generations are linked. A representative sample of children will not give a representative sample of the previous generation: mothers with large families will be overrepresented, and childless women will not be included at all (Murphy, 1995). Weights by household size or family size (sampling proportional to size) must be used to achieve representativeness in such situations.

The problem becomes even more complex when the data do not apply to one point in time, but when they cover a certain period, for instance, in the case of a panel survey. Because of selectivity in the exit and entrance processes for the relevant population, the sample may become gradually less and less representative of the whole population. Selective panel nonresponse only adds to the problem. Time-dependent (longitudinal) weights may be necessary to achieve representativeness for each wave, both at the individual and at the household level (Duncan, 1994). This may also be useful for retrospective data—there is no nonresponse, but exit and entry processes in the past may have been different for the population compared with the sample.

In any case, one has to decide whether the sample should be representative of the larger population:

1. Only in terms of individuals, or also in terms of families or households
2. Only at one point in time or over a longer period

III. DATA SOURCES

1. Census

A large part of the data that we have on families and households stems from censuses. Indeed, as was indicated in the previous sections, the UN formulates recommendations for measurement and tabulation of such kind of data. Important aspects of census data are (Eggerickx and Bégeot 1993):

1. The characteristics of the whole population are mapped, not just a sample.[6]
2. Measurement in the form of a snapshot takes place at regular intervals, typically every decade.

These aspects point at the same time at a number of advantages and disadvantages. Because census data cover the whole population, they can be broken down by region, socioeconomic group, etc. Regular measurement facilitates an analysis of changes in household and family structure over a relatively long period. However, these changes can only be investigated in the form of net flows, as argued above. And although regional and socioeconomic detail can be given for the household and family variables, the huge undertaking each census is implies that it is rather costly and, hence, that only a few variables can be measured. Most often will we be able to give the household and family structure at census time only and not changes at the

[6] This is not the case for the few countries in which the census is a sample survey. This was the case in Norway in 1990 (sample of between 8% and 20%), and in 1991 in Germany (the 1% microcensus).

level of individuals or households. Another problem is that because of its administrative character, some household variables may be difficult to measure accurately, for instance, whether or not a person cohabits. Consequently, numbers of consensual unions based on a census have been underestimated by 30% to 50% in Norway, France, and England and Wales in the 1980s and 1990s (Keilman, 1995).

2. Cross-Sectional Sample Survey

A cross-sectional sample survey can be held just once, or it can be repeated a number of times. A one-time cross-sectional sample survey is relatively cheap, and therefore, it usually contains a large number of questions. The survey is most often organized for a specific purpose, and hence, it will be relatively easy, compared with the case of a census, to build up good rapport between respondent and interviewer. This increases the quality of the data. Yet well-known problems connected to the sample character remain: the sample can be biased, and the nonresponse can be selective. For instance, the proportion of women aged 20 to 24 years in Norway who live in a consensual union varies between 24% and 34% in five sample surveys around 1990 (Gulbrandsen and Gulbrandsen, 1993).[7] Another drawback is that the information obtained from a pure cross-sectional sample is limited: no information is obtained concerning changes. If the interest is in dynamics, and not only in the structure at one point in time, retrospective elements have to be included or the survey has to be repeated. If the same sample is used for each round, we speak of a panel. In case a fresh sample is drawn in each round, we have a repeated cross-sectional survey. An example is the annual household statistics for The Netherlands, which started in 1988 and is based on annual averages of data from the monthly Labor Force Surveys (Visser, 1995).

There are numerous cross-sectional sample surveys repeated on a regular basis that routinely collect past and present household information. The main difference with a multiround panel survey is, of course, that links between the household situations between two subsequent interview dates can only be given for the aggregate, not for individuals. Klijzing (1988) noted that few trend studies attempt to link up the differences in household composition, as observed between subsequent rounds. Part of the problem is that, from round to round, sample designs are frequently adapted to changing research objectives.

A repeated cross-sectional survey for which the household data are certainly not underutilized is the General Household Survey (GHS) in Great Britain. Established in 1971, the GHS has a standard sample size of around 10,000 private households each year (Harrop and Plewis, 1995). Originally, the GHS primarily produced stock data on household composition, but since 1979 questions on family formation were included as well. These questions covered aspects such as length of current cohabitation and type of premarital cohabitation (Brown and Kiernan, 1981; Haskey and Coleman, 1986). Hence, since 1979 the GHS may be typified as a multiround retrospective survey.

3. Retrospective Survey

In a retrospective survey, the sample is approached only once. However, the questions cover not only the present situation but also a certain period in the past. Retrospective surveys have gained popularity among demographers in the past few decades, not the least because they provide life-history (biographical) data. Murphy (1995) provides a useful overview. A prime example is the set of so-called Family and Fertility Surveys carried out in several European countries and co-ordinated by the UN-ECE (ECE 1992; Klijzing 1995). During the period 1988–1997, 20 countries in Europe, plus the United States, Canada, and New Zealand carried out the field work for such a Family and Fertility Survey, and all of them have included life-history data on partnership formation and dissolution (although with somewhat variable level of detail).

Compared with its competitor the panel survey, a retrospective survey is relatively cheap, and it produces immediate data on dynamics. A problem, however, is the quality of the data. In particular, retrospective data may be subject to errors of omission and misplacement—in particular for events that the respondent experienced as unpleasant (divorce, abortion), for which the timing is not clear-cut (start of a consensual union, leaving the parental home), or for which the occurrence took place in the remote past (Courgeau, 1991; Poulain *et al.*, 1991). In addition, to collect reliable retrospective information on individual values is next to impossible, except for those values that are so fundamental to the individual (characterizing perhaps his or her personality) that they are constant or almost constant over time. A final problem is

[7] Although the surveys cover a long period (1987–1992), this fact can not explain the large differences in the proportions. The high share of 34% dates from 1988 and the low one (24%) from 1992. Moreover, the earliest survey (1987) reports 30%. An apparent ***decrease*** in cohabitation is not plausible; it must be caused by sample errors of various kinds.

that of sample selection bias (Tuma and Hannan, 1984). Only persons alive and living in the region of interest at the time of the interview can answer the retrospective questions, and thus, the sample may become selective because of survival and emigration. Even if the sample is representative of the population *at interview time*, the *retrospective data* may be biased when the process of interest depends on mortality and emigration. When the sample is restricted to a special subgroup of the population (e.g., only married couples), the problem becomes even larger because there are additional exit processes (divorce and transition to widowhood in this example).

4. Panel Survey

If one would want to improve on the quality of retrospective data, one could rely on a panel instead. Panel data record the situation of sample members at two or more points in time. Sometimes, retrospective questions are added, which cover the period between two panel waves. This reduces memory effects clearly and facilitates the collection of data on current norms and values. Drawbacks, however, are that a panel is relatively costly, that the panel has to be followed-up over time, that selective panel drop-out may introduce a bias in the estimates, and that repeated interview may distort the answers or even the actual behavior of the respondents (Kasprzyk *et al*., 1989).

Usually a panel comes in the form of a sample survey, but the sample size varies a great deal. For instance, in the panel investigation on changing fertility, parenthood and family formation in Nordrhein-Westfalen (Federal Republic of Germany [FRG]), the sample dropped from 2620 women aged 18 to 30 years in the first round (late 1981/early 1982) to 1472 women 2 years later (Kaufmann *et al*., 1982). In contrast, we have the British Panel Household Survey, with annual waves between 1991 and 1994 (Buck *et al*., 1994). This source contains household and family data from nearly 13,000 individuals in about 5000 households in the first round. Other examples of panel surveys that may be used to trace family and household developments are the annual Panel Study of Income Dynamics in the United States, with a sample size of 5000 to 6000 families since 1968 (Duncan and Morgan, 1976), and the German Socioeconomic Panel, with annual waves for 6000 households since 1984 and an additional 2000 households from the former German Democratic Republic since 1990 (Ott, 1995).

During the years 1994–2001, the European Union (EU) carried out the so-called EC Household Panel, a multipurpose survey that covers demographic characteristics as well as a number of other topics (income, labor force, health, education, housing, migration) in the EU. Annual waves have been carried out based on a sample of approximately 61,000 households (about 127,000 individuals) in 12 EU countries. All members in the sample household aged 16 years or over were interviewed. The achieved sample size ranged from some 3500 households in Denmark to nearly 7500 households in Spain (except for Luxembourg, where the sample size was 1010 households). Austria, Finland, and Sweden were also included in wave 3 in 1996. An illustrative analysis based on the results of two waves of the pilot survey shows how data of this kind may be used to map dynamics in household composition and in individual relationships within households, among others (Verma, 1994).

A specific type of panel data is that which is obtained by linking the records of successive censuses. Data of this type are available for Sweden for the period 1975–1980 (Dellgran *et al*., 1984), for France for 1968–1995 (the so-called *Échantillon démographique permanent*), and for England and Wales for 1971–1991. The latter data source is known as the 1% Longitudinal Study. It is a record linkage study covering about 500,000 people in England and Wales (1% of the population). It includes a sample of the census records from 1971, 1981, and 1991. But register information for sample members regarding births (women only), deaths, and cancer has been linked to the census data (Murphy *et al*., 1988; Craig, 1990; Dale, 1993). The French *Échantillon démographique permanent* covers a little over 1/200 of the population. It is based on the census forms from the censuses of 1968, 1975, 1982, and 1990 and the civil registration forms for major demographic events (births, marriages, deaths, adoptions) for the years 1968–1975 (Ekert-Jaffé *et al*., 2002).

5. Register

Another possibility is to analyze population register data. There is no selectivity connected to this approach, but there are other problems. For instance, the *de jure* situation that the register reflects is sometimes only a crude approximation of the de facto situation that one is interested in. (This has implications not only for statistics on household membership, but also for migration statistics.) Furthermore, the number of variables is usually very limited. As most of the existing population registers record (changes in) formal marital status but not (those in) household status, only limited information on families and households can be obtained from such a source. Informal living arrangements such as consensual unions are difficult to measure with a register.[8] But exceptions are the Scandinavian countries (Denmark, Finland, Iceland, Norway, and Sweden) and The Netherlands. Concerning families, statistics in the form of stock data are published with regular intervals for the Scandinavian countries, for instance, annually for Finland and for Norway. Statistics Netherlands carried out register counts in 1987 and 1992 with ample information on families (Prins and Levering, 1994). Concerning households, Denmark has a household register (Noordhoek and Petersen, 1984; Petersen, 1985). Finally, Statistics Sweden combined data from the censuses of 1980 and 1985 with information from the registers of marriages, that of internal migration, and that of deaths. This resulted in stock and flow data for couple formation and dissolution (Statistics Sweden, 1992; Prinz *et al*., 1995).

IV. MAIN TRENDS IN FAMILY AND HOUSEHOLD DEVELOPMENTS IN WESTERN EUROPE AFTER WORLD WAR II

The main developments in numbers and types of households in Western Europe and other industrialized countries after World War II have been documented extensively (Hall, 1986; Burch and Matthews, 1987; Hoffmann-Nowotny, 1987; Keilman, 1987; Schwarz, 1988; Linke *et al*., 1990; Gonnot and Vukovich, 1989; Höpflinger, 1991; Haskey, 1993; Kuijsten, 1995, 1996). Therefore, I can restrict myself to a short summary. The extent to which the various countries experienced these trends is not always the same—in some countries the *levels* are lower than in others. This may, at least partly, be explained by the fact that definitions, concepts, and measurement of household and family variables differ among countries and within countries over time. However, the *direction* of the trends seems to be similar (except for a few policy-induced temporary effects, such as marriage peaks in Austria in 1983 and 1987 and in Sweden in 1989). However, at the end of this section,, I shall discuss the apparent uniformity of the trends.

[8] Previous address of both spouses is recorded when a marriage takes place in Austria, France, or Spain. This is one possibility for compiling statistics on consensual unions (De Santis and Santini, 1995), but the application is restricted to cohabiting couples who eventually marry. A second possibility is the practice followed by Statistics Finland and Statistics Denmark. When two persons of opposite sex are registered at the same address, do not have a common biological parent, are not married to each other, and have an age difference of less than 16 years (and, for Denmark, no other persons live at that address), the two are considered as a cohabiting couple.

1. Falling Average Household Size

There has been a continuous *fall in average household size*. Two demographic causes stand out: (1) numbers and proportions of persons living alone have greatly increased, and (2) family sizes were reduced, owing to the fall in fertility rates, especially those of higher birth orders (in addition to a modest increase in voluntary childlessness in some countries). Changes in the age structure of the populations concerned have also contributed to this development. An aged population has relatively many couples whose children have left the parental home and also relatively many elderly persons who live alone, but such changes contribute much less to the fall in the average size of households than the first two factors.

Information on average household size covering Europe as a whole is only available since 1950. Estimates by MacKellar *et al.* (1995) indicate that average household size in Western Europe dropped from 3.5 in 1950, via 3.1 in 1970, to 2.6 in 1990. The figures for eastern Europe were higher by 0.2 to 0.3 persons per household for those years. The average for developed countries in the year 2000 was 2.5, with a range between 2 and 4 (UN, 1995; UN Centre for Human Settlements, 2001). Country-specific data for the old EC indicate that average household size was between 2.5 (Denmark and the FRG) and 3.7 (Ireland) in 1980 and dropped to between 2.2 (Denmark) and 3.3 (Ireland, Spain) in 1991 (EC, 1993). Households in Europe are smallest in Sweden (2.1 persons on average in 1990), closely followed by Denmark (2.2) and Switzerland (2.3) (see Eurostat, 1995). Whereas the fall in birth rates and excess mortality among men are among the main demographic explanations for the falling household size in Western Europe around 1970, the recent drop is caused to a large extent by more frequent divorce and separation and by increasing longevity. Countries in eastern Europe had relatively high and stable fertility until the mid-1980s, when strong declines occurred (Coleman, 1996). This explains the somewhat larger households in that region, compared with the western part.

MacKellar *et al.* expect a modest further decrease in average household size for eastern Europe, to a level of 2.4 to 2.8 persons per household on average in the year 2030. For Western Europe a slight increase might occur to a level of 2.7 in the year 2030 when fertility would increase again, but in three other scenarios the authors expect a further drop by 0.1 to 0.3 persons per household by 2030. This agrees with Bumpass' (1990) view that sociological factors such as a shift in tastes toward privacy, and economic factors such as higher income, all lead to more atomized living arrangements in industrialized countries. Indeed, the following factors are related to shrinking households:

First, all other factors remaining the same, falling birth rates reduce population size but do not affect the number of households; hence, household size is reduced.

Second, social, economic, and cultural theories of demographic behavior point to a variety of reasons why individuals prefer to live in small households. These include less adherence to strict norms; less religiosity and increased individual freedom on ethical issues; female education, which has led to women having greater economic independence and also facilitates divorce; more assertiveness in favor of symmetrical sex roles; the contribution of women to the labor market; increased economic aspirations; and greater residential autonomy among young adults (Van de Kaa, 1987; Lesthaeghe, 1995; Verdon, 1998).

Finally, population ageing reduces household size. This is a direct consequence of two facts: increased longevity leads to longer periods of time when children do not live with their parents and the greater mortality of men, together with the usual age difference between spouses, results in many widows who live alone.

Smaller households, then, are the result of processes that cannot be reversed (such as modern contraception and liberalization from norms) or that we value for a number of reasons (such as women's emancipation).[9]

2. Increasing Importance of Consensual Unions

The *traditional family* has lost its dominant position. Marriage has been postponed to higher ages, and ever lower proportions of successive birth cohorts have ever married (or may be expected to do so) at age 40, say. Griffin *et al.* (1995) note that the increase in mean age at marriage has been stronger for women than for men in many European countries.

Consensual unions have become accepted widely—not only as a prelude to marriage, but in some countries also (and increasingly so) as an alternative to married life. De Santis and Santini (1995) have analyzed trends in observed age-specific shares of women living in consensual union for nine industrialized countries between 1975 and 1990. In seven of these, they noted an increase over time in the average share (the average taken over 35 ages between 15 and 50 years).

[9] Some processes are irreversible *and* appreciated at the same time.

The rising popularity of consensual unions went together with increased levels of extramarital childbearing in some countries. In other countries childbearing remained largely restricted to married couples. Lesthaeghe (2000) plotted national percentages of nonmarital births against proportions of cohabiting women aged 20 to 24 years and found the following groups of countries:[10]

1. *Low extramarital fertility together with a low incidence of cohabitation* in Mediterranean countries, Poland, and Japan
2. *Low prevalence of cohabitation but high nonmarital fertility* in Eastern Europe, Portugal, Ireland the UK and the US;
3. *High prevalence of cohabitation but low nonmarital fertility* in Western European populations such as Belgium, The Netherlands, the FRG, and Switzerland;
4. *High prevalence of cohabitation combined with parenthood* in Scandinavian countries, and, to a certain extent also in France, Austria, Estonia, Slovenia, the former German Democratic Republic, and Canada.

The picture is not static, as Lesthaeghe notes. For instance, Portugal has recently moved from the first to the second group, and Belgium, the Netherlands, and the FRG are on their way to the fourth group.

At the same time De Santis and Santini (1995) have noted an increasing tendency to live without a partner (neither cohabitee nor spouse) in Sweden (1975–1985), Canada (1984–1990), The Netherlands (1982–1988), Austria (1981–1989), Italy (1983–1988), and the FRG (1982–1986). For Norway a similar rise has been observed in the age group 25 to 44 years (1980–1995) (see Barstad, 1996). Also, Klijzing and Macura (1997) note increasing shares of women who, by the age of 25, never had entered a first partnership. The increase is observed for women born between 1950 and 1970 in Italy, Spain, Belgium (Flanders), the FRG, New Zealand, France, and The Netherlands.[11] Hence the fall

[10] Information stems from the Fertility and Family Survey project, with data collected in the various countries between 1988 and 1999. Note that Lesthaeghe's fertility indicator applies to women of all ages, whereas cohabitation is restricted to young women.

[11] The indicator used by Klijzing and Macura is different from that employed by De Santis and Santini. Entrance into partnership *after* age 25 will not be reflected by the former two authors' indicator, as opposed to the latter two authors' indicator. This explains why Sweden, Canada, and Austria appear in De Santis and Santini's list, whereas Klijzing and Macura note *no* increase for these countries. Nor is it observed in Eastern European countries such as Poland, Lithuania, Latvia, the German Democratic Republic, Estonia, central Europe (Switzerland, in addition to Austria), or northern Europe (Norway and Finland, in addition to Sweden).

in marriage rates generally observed for European countries has not fully been compensated by increasing shares of women living in a consensual union (see Haskey, 1993). Part of the rise in the proportions living alone is an indirect consequence of the increased popularity of consensual unions, as these unions have relatively high separation rates. This has been documented for Sweden (Hoem and Hoem, 1992; Trussell *et al.*, 1992a), The Netherlands (Klijzing, 1992; Manting, 1994), and Norway (Keilman and Brunborg, 1995; Texmon, 1999). But also the role of education and of psychological factors has been stressed (Van Hoorn, 1994).

Several authors have noted that cohabiting couples do not form a homogeneous group. Rindfuss and VandenHeuvel (1991) have stressed that the behavior of some cohabiting couples is close to that of married couples, whereas that of others is much more similar to the behavior of persons who live alone. Noack (1996) discusses whether a cohabiting couple should be regarded as "just lovers," as "engaged to be married," or as a de facto married couple.

3. Growing Numbers of Lone Parents

The nature of *one-parent families* has changed dramatically. Decreasing mortality and increasing divorce has led to fewer lone parents who are a widow(er), and many more divorced lone parents, in particular lone mothers. Although the share of births outside marriage went up sharply since the 1970s, this is not a major cause for the increase in one-parent families. The reason is that most of these children are born in a consensual union.

Data for the former FRG on the distribution by marital status of lone mothers indicate that the share of divorced lone mothers went up from 24% in 1961 to 46% in 1985. The share of widows dropped from 46% to 18% over the same period. For Switzerland the figures show a similar development between 1970 and 1980; for The Netherlands the changes during the years 1960–1983 are even stronger: from 14% to 60% for married lone mothers and from 71% to 21% for widows.

As a consequence of the growth in divorce rates, larger shares of children spend more and more time of their childhood in a one-parent family, usually with their mother. Studies have been carried out for Denmark, England and Wales, France, The Netherlands, Norway, and the United States, among others (Hofferth, 1985; Brown, 1986; Kuijsten and Voets, 1986; De Jong, 1989; Voets and Kuijsten, 1989; Haskey, 1990; Jensen *et al.*, 1991; Villeneuve-Gokalp, 1993; Duncan *et al.*, 1994; Festy, 1994). Longitudinal data collected for adolescents indicate that roughly between 15% and 30% of them will have lived in a one-parent family, depending on the age limit for these young adults (often between 18 and 21) and the type of family they were born in (two married parents, two cohabiting parents, or a lone mother). The figures are particularly high for blacks in the United States.

4. Higher Levels of Childlessness

A number of countries in northern, western and southern Europe experience growing levels of childlessness for subsequent birth cohorts of women.[12] Among the 11 countries listed by Höpflinger (1991), there are five in which women born in the 1950s have higher shares with parity zero than do women born around 1940. Prioux (1990a) notes that seven countries in western and northern Europe experienced low childlessness for women born between 1935 and 1947 (between 8% and 15% of these women are childless). Later cohorts have higher levels. Beets (1995) showed that for 17 European countries, the mean percentage childless at age 30 increased from 16% for women born in 1945 to 22% for the 1955 cohort and 27% for the 1960 cohort. Childlessness at age 30 *decreased* between cohorts born in 1935 and 1945 for England and Wales, France, Italy, The Netherlands, Norway, and Portugal. De Beer (1995) found that the share of childless women is particularly high in southern Europe in the early 1990s: over 30% as measured on a period basis, compared with 20% in Nordic countries. De Jong (1995) has analyzed births by parity in the 17 countries of the European Economic Area (EEA)[13] and notes that first birth rates were high around 1970. Then a decrease took place that lasted until the mid-1980s, with southern Europe following the pace set by northern and western Europe. In Ireland, Spain, and Italy the fall continues at least until 1990. Because of the period perspective adopted by De Beer and De Jong, these figures exaggerate the fall in cohort shares, particularly as the age at birth of the first child is rising in many European countries.[14] This implies that some of the women born

[12] Leridon (1999) presents evidence that suggests that proportions childless were more or less constant at a level close to 10% for women in Hungary, the Czech Republic, Poland, the former German Democratic Republic, and Yugoslavia who were born between 1940 and 1960.

[13] The 15 member states of the European Union plus Iceland and Norway.

[14] When birth generations 1950 and 1960 are compared, the mean age at motherhood (irrespective of parity) went up from 26.7 to 27.8 years for the average of the 17 EEA countries. Greece and Portugal are the only countries in which no rise took place. (see De Jong, 1995:table 4).

at the end of the 1960s and during the early 1970s may still have a first child after age 30. Indeed, first birth rates went slightly up again in the 1980s in Sweden, Norway, Denmark, Portugal, West Germany, The Netherlands, and France. Yet the figures indicate that a rise in cohort childlessness has to be expected, as current period levels of first birth rates are lower than those 20 years ago. This is also confirmed by recent data compiled by Prioux (2002). She suggests that shares of childless women born in the early 1960s in countries in northern, western, and southern Europe may increase to 15% to 20%.

How can these developments be explained? Prioux (1990a) discusses strictly demographic factors: the strong fall in first marriage rates, the relatively low marital first birth rates early in marriage, and, as a factor counteracting the latter two trends, the rise in extramarital fertility. Beets (1995) stresses the fact that postponement of the first birth may lead to higher infecundity: 30-year-old women who wish to become pregnant will succeed after approximately 3 months, but for women aged 35 it will take about 7 months. Hobcraft and Kiernan (1995) present a thoughtful discussion of the existing literature about the transition to parenthood from various perspectives: they elaborate both pronatalist forces and constraints on becoming a parent, involving biology, time, money, ideas, and security. They argue that fertility was high in the 1950s and 1960s for several reasons: costs of rearing children (education, health, welfare) were increasingly covered by the state rather than directly by the parents themselves; economic growth and permanent employment added to the anticipated security for parenthood; reconstruction of housing after the war improved quality and access; and the accelerated establishment of independent living, which usually involved marriage, contributed to earlier entry into parenthood. After 1970, the scene changed fundamentally (although Hobcraft and Kiernan also argue that some of the key changes can be dated back to the war time period or even further back). Increased female labor force participation reduced the time available for childrearing. Reliable means of fertility control broke the intimate connection between sex and reproduction. Patterns of partnership changed, with marriage becoming a more fragile institution and cohabitation becoming more widespread. In addition, employment insecurity delayed the achievement of the basic requirements for becoming a parent and increased the levels of uncertainty about future security. The authors are rather pessimistic for the future, although they assume that generous provisions by Scandinavian welfare states have led to higher entry rates into parenthood than in southern Europe, where commitment to marriage for women is relatively great, attachment to the labor force is lower, and state support for parenthood is less.

The analysis by Hobcraft and Kiernan confirms that prolonged education for women and their increased labor force participation per se are insufficient explanations. Indeed, Hoem (1992, 1995) argues for the case of Sweden that mothers with high levels of education also had the highest fertility in the 1970s and the first part of the 1980s. And in subsequent years, the labor force participation of women has increased (further), simultaneously with a substantial rise in fertility for *all* birth orders. Hence she questions the roles of improved educational level and higher labor force participation as the main explanatory factors in the intensity and timing of childbirth. Instead, she argues that new attitudes as to what is suitable at different ages in life should be analyzed further as potential explanations: childbearing is regarded as an important part of full life, but it is a part that many young people see as belonging to a later phase than earlier cohorts did. This argument points into the direction of *activity status* as an important determinant for childbearing, rather than educational level. This is confirmed by Kravdal (1994), who finds that the effect of educational level on first birth rates of Norwegian women is small, whereas being in education has a strong fertility-inhibiting impact. In other words, what matters for childbearing is not educational attainment, but educational participation. Being employed reduces the chances to become a mother somewhat.

5. Fluctuations in the Age at Leaving Home

During the 1960s and 1970s, young adults left the parental home at progressively younger ages. This has been documented for Sweden, Germany, The Netherlands, Great Britain, France, and Norway (as well as the United States and Australia) (for a summary of the literature, see Texmon, 1996). Among the reasons that explain this trend are changes in attitudes and values, increasing individualism, a decreasing tendency for living in families, improved economic conditions, and the increased availability of (student) dwellings. This trend stopped up in the 1980s, and it has turned into an increase in home leaving ages for some countries (Sweden, The Netherlands, the FRG, and England), in particular for men. Moors and Van Nimwegen (1990) present figures for the EU as a whole in 1982 and 1987 that show a trend toward later home leaving at ages between 21 and 24 for men, and at all ages between 15 and 24 for women. Economic difficulties in the housing market and the labor market are mentioned as factors behind this reversed trend. But part of the effect may also be explained by the fact that surveys are not always comparable (*first* or *final* leave, problems with measuring living with parents, etc) (see the particularly thoughtful analysis by Texmon, 1996). It is unclear whether the tendency for young adults to leave the parental home at higher age as observed in the 1980s has continued in recent years. Figures presented by Visser (1995) for The Netherlands indicate that at least for men this seems *not* to be the case: in 1988/1989 63% of men aged 20 to 24 lived with their parents, and in 1993/1994 only 60%. (For women the decrease was only two percentage points.) On the other hand, Italian men and women *did* leave their parents at a higher age between 1983–1985 and 1995–1996 (Manting and Alders, 1998).

6. Two Qualifiers

It should be stressed that many of the trends noted here have a long history, which started well before World War II. Drops in fertility and family size, and an increase in divorce were first in evidence in the 19th century. The movement of women in the labor force and the growth of sexual permissiveness became noteworthy in the first half of the 20th century (Popenoe, 1991). More surprising, however, was the fact that in the 1930s birth rates began to rise, and that immediately after World War II many Western countries experienced a "family renaissance." Although family life was also valued before 1950, there was an increasing emphasis in the decade thereafter on marriage and parenthood as central to fulfilling life. Popenoe argues that one explanation for this phenomenon is that the unparalleled affluence and upward mobility after the war gave the working classes the opportunity to achieve the bourgeois family ideal. With less education and access only to inferior jobs, which they held out of economic necessity, the women of the working class had long looked with envy at the nonworking wife middle-class wife. Other explanations point to political circumstances, such as the Allied victory, which led to a renewed confidence in the stability of the democratic state, or the Cold War, which undermined confidence in the future and led people to retreat to the safety of home and family (Cherlin, 1992). However, it is problematic that all these arguments point to circumstances after the war. They fail to explain why fertility and marriage rates began to rise in the 1930s already, immediately after the Great Depression, and why the increase continued during the war in a number of western countries. More generally, when one tries to explain developments in household and reproductive behavior, attention should also be given to what happened to families and households between 1930 and 1950 and not only to the events since the mid-1960s. But others have argued that the 1960s *did* imply a break. Lesthaeghe and Van de Kaa have been among those who most strongly have stressed the role of tastes and aspirations and of norms and attitudes in the explanation of family and fertility changes in industrialized countries after World War II (Lesthaeghe, 1983; Van de Kaa, 1987; Lesthaeghe and Surkyn, 1988). During the 1960s and thereafter, a strong shift in norms toward progressiveness and individualism, and a focus on self-fulfilment implied increased individual freedom from religious and political institutions, from peers, and from parents. At the same time, the economic position of young men has deteriorated (Oppenheimer, 1994). These developments, which have been in operation for the past 3 decades, have had led to lower levels of fertility and marriage.

A second qualifier is that the family and household trends described above are rather similar for various countries as long as an analysis at only a superficial level is employed, for instance, in the form of aggregate demographic rates for family and household dynamics. But more detailed investigations reveal a great deal of pluriformity. Hobcraft and Kiernan (1995) stress the difference between Scandinavia and southern Europe when they analyze the constraints around parenthood. Lelièvre (1994, 1995) gives a detailed comparison of couple formation and the birth of the first child in Great Britain and France. She concludes that the recent rise of births outside marriage and the extent of extramarital cohabitation are very different between the two countries, despite apparently similar trends. Mellens (1999) notes that female labor force participation is high both in eastern and in northern Europe, but for different reasons. In former communist countries, many women belong or belonged to the labor force out of economic necessity—in the north, the explanation is to be found in nontraditional sex roles. Kuijsten (1996) criticizes expectations of a continuing convergence of demographic and family trends in Europe toward uniformity, as expressed by various authors. The material he presents for ten European countries on combined family status/labor market status for women shows a picture of substantial variation between the countries. These differences cannot be explained as intercountry differentials in the speed toward a uniform model of family and household patterns. This leads Kuijsten to the belief that the Swedish model—with high shares of cohabiting couples, lone mothers and one-person households, and high labor force participation among women—does not necessarily predict the future situation in other countries. For instance, the family life in Germany (in particular in the former FRG) is highly polarized. There is a strong and growing nonfamily sector (consensual unions are not interpreted as families in Kuijsten's analysis), but at the same time there are fewer employed married mothers aged 25 to 29 than traditional housewives in that group. In general, Kuijsten endorses the view that industrial countries have entered an era of new biographical models with a pluralization of life styles, both over the life course of the individual and in the cross-sectional picture at one point in time.

Social Mobility

Then and Now

FRANÇOIS HÉRAN

Institut national d'études démographiques (INED), Paris, France

INTRODUCTION

The sociology of networks has turned the study of social mobility into the most formalized branch of quantitative sociology and, as a result, the most international. Specialists in the field have a reputation of forming a closed circle. As quantitative sociology is, itself, a minority branch of sociology as a whole—in both Europe and America—the analysts of social-mobility now form a minority within a minority among sociologists. Hence the temptation to attach value judgments to this singular status: what some observers will see as a subsect of the discipline, others will describe as the elite of the elite.

Fortunately, this stark choice seems ever less valid. On the contrary, recent advances in the study of social mobility have promoted a broad opening of the specialty by lowering the entrance barriers that had been steadily erected in the 1970s and 1980s. The technical revolution introduced by the application of log-linear models simplified the approach to social mobility. It rapidly made obsolete most of the research efforts hitherto expended in an all-out race to sophistication. The change also made it possible to reintroduce social-mobility phenomena into the wider analysis of *life chances*—Max Weber's predilect *Lebenschancen*—which include educational attainment, the school-to-work transition, working career, and life expectancy, while allowing time comparisons at lower cost. It is no exaggeration to state that, after the log-linear turning point, the tool had ceased to hide the object and now enables it to be problematized with unmatched clarity.

As a result, social-mobility studies can once again attract interest from a social science such as demography, without reconnecting in any way with the dubious approaches (to say the least) that drove the first explorations of social heredity between the 1880s and 1930s—investigations that conjured up the specter of prolific proletarians overwhelming the Malthusian elites.

In the interest of full disclosure, it should be said at the outset that I am hardly a specialist of social mobility: my incursions into the field are remote. My viewpoint here is that of a practitioner of sociodemographic surveys who has had occasion to observe at a distance the growth of social-mobility studies while examining the history of social statistics. My attitude is one of a sympathizer, so to speak, but of a critical sympathizer who, after a period of discouragement, has regained hope.

I. GROWTH OF SOCIAL-MOBILITY STUDIES: QUALITY OF HISTORICAL RESEARCH

Someone seeking an overview of the history of studies on social mobility in the Western world can rely on a high-quality literature in French without equivalent in English.[1] Four authors currently dominate the field.

Charles-Henry Cuin, an academic close to Raymond Boudon, has examined the seminal book by Pitirim Sorokin, *Social Mobility* (1927), as well as the reasons why French sociologists from Émile Durkheim to Pierre Bourdieu overlooked or rejected the study of social mobility, until Raymond Boudon himself became directly involved in it (Cuin, 1987, 1988, 1993, 1995).

Laurent Thévenot, an *administrateur* (senior statistician) at the French National Institute of Statistics and Economic Studies (INSEE) who later joined the École des Hautes Études en Sciences Sociales, follows a totally different approach. He has focused on identifying the principles of political philosophy that underlay the first French surveys on social success and social mobility. These surveys were conducted at International Network of Economic Developers (INED) by Marcel Bresard and Alain Girard and at INSEE by Jacques Desabie (Thévenot, 1987, 1990).

By using a historical, critical, and pedagogic approach, Dominique Merllié has reconstructed the development of social-mobility surveys, starting from the first Italian, French, British, and Scandinavian experiments (Merllié, 1990, 1994, 1995; Merllié and Prévot, 1991). He takes his study up to INSEE's 1985 survey on education and occupational skills (Formation-Qualification Professionnelle: FQP). He was unable to include *The Constant Flux*, the wide-ranging international synthesis published in 1993 by Robert Erikson and John Goldthorpe. In all, he devotes only two pages to the introduction of odd ratios and log-linear models, which profoundly transformed the comparative study of social mobility (see next section and Appendix 92–1).

Gilles de La Gorce tried to fill this gap. His doctoral thesis, defended in Paris in 1993 at the École des Hautes Études en Sciences Sociales and still unpublished, gives an intellectual and technical history of social-mobility models in Western countries. The author's scholarship is less sure-footed than is that of Dominique Merllié, but perhaps it has a keener sense of the prevailing currents and significant breakpoints. In the current context, it is no doubt the best introduction to the subject. The article published before the thesis (La Gorce, 1991) reports only part of the findings.

[1] The historical summaries by Gosta Carlsson (1963), Anthony Heath (1981), and John Goldthorpe (1976) are less detailed.

II. RECENT DATA: A CONFIRMATION OF THE LOG-LINEAR MODEL

Since these historical and critical studies, the flow of empirical publications on social mobility has not ceased. To continue with the French example, the decisive role of log-linear modeling (see Appendix 92–1) in social-mobility analysis was fully vindicated by a remarkable series of theses and publications that echo the work being done in other Western countries such as Switzerland (Lévy *et al*., 1997) and Italy (Schizzerotto *et al*., 1995).

Louis-André Vallet, one of the few French academics to have been involved in official statistics before joining the French National Center for Scientific Research (CNRS), was the first large-scale user of the log-linear model in France, which he applied to the study of female social mobility. He has helped generously to disseminate the method in the research community (Vallet, 1991, 1992, 1995). More recently, he has switched to log-multiplicative models.

John Goldthorpe, who used surveys dating back to the 1970s in *The Constant Flux*, widened his analysis to include French and United Kingdom data of the 1980s, and amply corroborated his earlier findings (Goldthorpe, 1995).

Two INSEE statisticians with a keen interest in sociology, Dominique Goux and Éric Maurin, used the same techniques to analyze INSEE's latest FQP survey (1993) and, retrospectively, the complete series of previous FQP surveys since 1970 (Goux and Maurin, 1995, 1997a,b,c).

In the same spirit, Louis Chauvel, a researcher at a Paris-based economic institute, Office Français de Conjoncture Économique (OFCE), and a graduate of the INSEE statistics school (ENSAE), used the same methods to analyze the changes in social mobility in France between the 1964 FQP survey and the 1995 Labor Force survey. He separates the cohorts, however, into 5-year groups (Chauvel, 1997).

III. FRANCE–ENGLAND: THE DUAL ORIGIN OF THE SOCIAL-MOBILITY TABLE

The most widespread approach to social mobility relies on a simple technique: the construction of a *social-mobility table* that cross-tabulates sons' occupations with fathers' occupations (the occupations of daughters and mothers were seldom used until recently).

The first such table was published in England in the journal *Biometrika* in 1904. Prepared by Emily Perrin, an assistant to Karl Pearson, it draws on 750 entries of the *Dictionary of National Biography*. The cross-tabulation did not yet involve social categories but occupational sectors or disciplines (medicine, literature, theology, art, politics, military, etc.). The goal was to compute an association index derived from chi-square, the *contingency coefficient*, and measure the extent of its possible divergence from the coefficients previously determined for physical measurements, which ranged between 0.45 and 0.50. Emily Perrin (1904) found a value of 0.63, which led her to conclude without any further verification that biological inheritance accounted for nearly three-quarters of total occupational heredity. In its design, Emily Perrin's mobility table was not new. It was inspired by the contingency tables for physical measurements, which already tabulated sons' characteristics against their fathers'.

It would be wrong, however, to establish an intrinsic link between the emergence of the social-mobility table and the hereditarist or even eugenicist ideology. The counter-proof of this was supplied in the same year in Third Republic France by Paul Lapie (1869–1927). This heterodox disciple of Émile Durkheim, who became administrator of the elementary-school system, published a social-mobility table in 1904, without being aware of the work of Karl Pearson's team (Cherkaoui, 1979:250–251; table partly reproduced in Merllié, 1994:127). Lapie classified into nine categories the occupations of 772 alumni of an elementary school in Champagne, cross-tabulated them with their fathers' occupations, and calculated the access rates by origin. In 1911, he extended the analysis to two other schools, taking the opportunity to remove orphans from his classification.

The contrast with Karl Pearson's approach is striking. Paul Lapie spontaneously offered an interpretation with no trace of biologism. Interestingly, he introduced a third variable by duplicating the mobility table so as to distinguish between children possessing the "elementary-school certificate" (*certificat d'Études primaires*, or CEP) and those who did not. Comparing the two series, he concluded that "school sometimes succeeds in breaking the links of the net in which economic causes trap our fates."

But the overall inspiration of Lapie work's is consistently ambiguous. On the one hand, he ardently defended the meritocracy principle in his book entitled *La justice par l'État* (*Justice through the State*), arguing that children of poor families should be given scholarships to facilitate access to jobs compatible with their merits. On the other hand, he wanted to reassure the critics of the Third Republic's education policy, who opposed general compulsory schooling, by demonstrating that school did not foster excessive ambition among children of "the people": it did not "declassify" them up the social scale. Reversing the value judgments conveyed by the liberal approach to the issue, Lapie does not speak of *social mobility* (the term was first used by Pitirim Sorokin in his 1927 essay), but of "social instability." "Occupational heredity" was measured by "stability coefficients" or "instability coefficients," which are, in fact, the rates of access to current positions determined by social origin (Lapie, 1904).

IV. BENINI'S TWO INDICES

A third source for the mobility table was Italian (see Capecchi, 1967:297; Jones, 1985; Merllié, 1994:138, 142). It consists of the marriage tables combining the characteristics of the two spouses.

By 1897, the economist and demographer Rodolfo Benini (1862–1956) was teaching his students at the University of Pavia how to construct an index, called the "sympathy coefficient," which measures the ratio of the number of individuals in each cell to the number that would result from the assumption that spouses' origins were independent of each other. Benini used this initial index in an article of 1898 on "sympathetic combinations in demography."[2] But, in 1911, he corrected it in his *Principii di demografia* by deciding to bound it to the smaller of the table's two margins. He called this second indicator "index of attraction or repulsion." Benini was thus the first author who sought to neutralize structural effects in the measurement of social reproduction.

Benini's double contribution went largely unnoticed because it did not directly concern social mobility but was confined to marital mobility. Frank Jones (1985) and Dominique Merllié (1994), who rehabilitated this pioneer, show that most of the indices later used to study father—son mobility would be identical to the ones developed by Benini.

This is true of Benini's first index: the ratio of the number of observed individuals to the theoretical number under the independent-origins hypothesis. It was reinvented in 1948 by the American statistician Herbert Goldhamer under the name of *social distance mobility ratio*—more simply, *mobility ratio* (see also Goldhamer, 1968) His compatriot Natalie Rogoff, author of a social-mobility survey in Indianapolis, mentioned this origin in an article in *Population* in 1950. During her stay at INED in Paris, she communicated the index to Marcel Bresard, author of the

[2] *Le combinazioni simpatiche in demografia*, 1898.

first French social-mobility study, who used it immediately (Bresard, 1950). She then popularized it in the United States through several publications (Rogoff, 1953).

Benini's first index, also known as the Goldhamer-Rogoff index, was cited next in the publication of the first Anglo-Welsh survey on the topic, conducted by David Glass (1954). The British demographer states that he discovered it independently of Natalie Rogoff. Curiously, he mentions Benini (apparently a second-hand reference via the articles by Natalie Rogoff and Livio Livi in *Population*) without realizing that this was the same index, which he named *index of association or dissociation*. In his critical review of mobility indices, Raymond Boudon was to discuss "Glass's index" without being aware of its pedigree (Boudon, 1973).

Benini's second index had the same clandestine posterity. Glass's disciples criticized it without understanding it: they saw it as an imperfect version of the first index. Later, several authors, in an attempt to neutralize the effect of margins on the measurement of mobility, proposed adjusted indices that allowed for the differences in population size between rows and columns.

In a 1955 article in *Population Studies*, Wladyslaw Billewicz cataloged the shortcomings of the initial index: if N is the total sample size and max the larger of the two populations in the category of origin and category of arrival, the index will never exceed N/max. The article was followed by commentary by Elizabeth Durbin, who proposed an adjusted index called I for "inertia." In 1964, the Japanese Saburo Yasuda, in an often cited article of the *American Sociological Review*, repeated the operation by suggesting a "coefficient of openness." He acknowledged in passing his debt toward Elisabeth Durbin (his index being merely the complement to unity of Durbin's inertia index). But the literature would now refer to the *Yasuda index*, neglecting the contributions of Durbin and—before her—Benini.

V. SOROKIN: A MULTIPLE APPROACH TO SOCIAL MOBILITY

Rodolfo Benini's technical advances were all the more remarkable for having been unknown, 25 years later, to the man who would make the greatest contribution to defining the subject of *social mobility*: the Russian-born American sociologist Pitirim Sorokin. In his *Sociology of the Revolution* (1925), he described the "abnormal" forms of mobility introduced by the revolution, which had expelled him from Russia in 1922. He broadened the scope of his investigation to all forms of mobility in his 1927 treatise, *Social Mobility*.

Sorokin, however, was severely short of technical resources. When he set out to comment on a series of mobility tables culled from several sources, including his own monographs produced in Minneapolis, as well as data already published by the Italian Federico Chessa (1912), he was clearly unaware of Benini's indices of association (Sorokin, 1927:429–434). His indicator of "transmission of occupational status" was simply the percentage of immobile individuals of a given origin (Sorokin, 1927:419). He did not think to complement the table of destinations with a table of origins, although he provided a "literary" commentary on the latter. His conclusions oscillate between the strength of the link and the significance of dispersion: Western societies can be described neither as a caste system nor as a disorderly flow.

Of his five propositions on social mobility, the last is still quoted today: "As far as the corresponding historical and other materials permit seeing [. . .], there seems to be no definite perpetual trend toward either an increase or a decrease of the intensiveness and the generality of social mobility. This is proposed as valid for the history of a country, for that of a large social body, and, finally, for the history of mankind" (Sorokin, 1927:152). But Sorokin's horizon was not a few decades, as it is for John Goldthorpe or for Dominique Goux and Éric Maurin today: he was taking a multicentury view.

Another central theme of *Social Mobility* is that social mobility operates through "selection agencies" such as the family, school, the army, trade unions, occupations, and so on. This notion was hastily rejected because of its functionalism, but it deserves to be explored and tested. Sorokin developed a prophetic idea: the function of schooling is to sort and eliminate. Those who imagine that the expansion of education will inevitably increase social mobility are mistaken: the greater its spread, the more it will help to perpetuate inequality.

VI. SOCIAL MOBILITY AND DIFFERENTIAL FERTILITY

The first systematic investigations of social mobility, in the late 19th century, were haunted by the issue of differential fertility. Because they are more fertile than the upper classes, the lower classes may eventually submerge them. How can one protect the elite from the invasion of the masses? How can one shelter quality from quantity? Francis Galton (1869), Arsène

Dumont (1890), Alain Girard (1961), and many others have played variations on this theme.

Pitirim Sorokin fits into this approach. For him, the lesser fertility of the elites creates an imbalance that jump-starts the upward-mobility engine by triggering a gradual rise of the lower classes. He mentions (Sorokin, 1927:138) Arsène Dumont's famous "social capillarity." The abundant European data that he accumulated on the topic give no hint of a "U-curve" or "J-curve" that would indicate efforts by the middle-class to reduce costs in order to ensure their ascent (Charles Westoff described such a curve in 1953). Despite the detailed nature of the occupational classifications he refers to, Sorokin generally reduces his commentary to a dichotomy between upper classes and lower classes—the elite versus the masses—as Vilfredo Pareto had already done (1916). However, he intuits that mobility spreads from neighbor to neighbor, so that the inward currents generated in the upper strata of society initially benefit the strata immediately below it, that is, the middle classes (Sorokin, 1927:450). This "staircase mobility" concept was formalized by Daniel Bertaux (1977) and consistently validated by later studies.

While loudly proclaiming the need for a quantitative approach free of value judgments, Sorokin often freely indulges in ideological considerations: among the authors he cites most often are Otto Ammon and Georges Vacher de Lapouge, who later became references for racist theories of social reproduction (see Béjin, 1982, 1989). Another source of inspiration was Pareto. For lack of proof, Sorokin rejects the theory of the intrinsic superiority of the Nordic race, but he regards as "likely to be true" the negative social selection process "so brilliantly depicted" by Georges Vacher de Lapouge. *Social Mobility* concludes with two obsessive worries: by steadily reducing its fertility, the upper class will "waste" the high-quality genetic stock of which it is the depositary; meanwhile, the steady reduction of infant mortality among the lower classes in large cities will enable the weak elements of the population to survive at the expense of the strong elements, preventing the latter from periodically compensating the deficits of the upper class (Sorokin, 1927:499, 506).

By accumulating quantitative data from a wide range of sources demonstrating that the upper classes are healthier, taller, and longer-lived than are the lower classes, Sorokin concludes that "Social stratification, with some exceptions, is correlated and considerably coincides with *biological* stratification of the same population from the standpoint of the physical superiority" (Sorokin, 1927:268, author's emphasis). This correlation, he asserts, is "likely to be permanent." But whereas today's sociologists would see this as proof of an influence of living conditions on physical condition, he inverts the causality: "Other conditions being equal, physical superiority has been the condition which has favored the social promotion of individuals and has facilitated their social climbing, while physical inferiority has facilitated the 'social sinking' of individuals and their location in the social lower strata" (Sorokin, 1927:275). If this correlation should weaken, a circulatory mechanism consistent with Pareto's law will restore it naturally: an elite that loses its physical superiority is on the road to "degeneration" and will promptly be expelled by parvenus from the lower classes, provided that the latter are physically superior (Sorokin, 1927:275). Sorokin notes, however, that the physical factor no longer plays in our societies the role it still plays in societies without writing. His thinking on this point remains unsettled; he finds solutions based on voluntary action appealing but unrealistic. "Eugenics exists still only on paper, and there are not great hopes that it will be practiced efficiently in the future" (Sorokin, 1927:499).

Sorokin follows a similar line of argument in regard to moral and mental superiority. Drawing on Nietzsche, Michels, and Pareto for inspiration, he proclaims that, in ordinary times, members of the upper class are merely brutish, ambitious, cynical, and hard-hearted. In periods of decadence, they sink into limpness and humanitarian sentimentalism, at the risk of being overthrown by stronger-minded minorities of plebeian origin (Sorokin, 1927:312). In a revealing footnote, he accordingly prophesied the capture of power by fascists, monarchists, communists, and labor unions. That is what happened in Russia and Italy. Soon would come the turn of countries such as Germany, France, Spain, and even England (Sorokin, 1927:316).

The book ends with a dream of perfect mobility: "In a mobile society, in order to know a man, we cannot rely any more on the information he is a member of a given group [. . .]. Under the conditions of intensive circulation, to say that 'Mr. Smith is a business man, or mechanic, or clerk,' means almost nothing because Mr. Smith yesterday might be a minister and to-morrow may become a millionaire or a senator. We need to know his whole curriculum" (Sorokin, 1927:542). Yet extreme mobility carries the danger of a rootless cosmopolitanism that, by way of compensation, would seek to lock other people into fixed, abstract "social boxes," with no regard for human individuals. That, says Sorokin, is the driving force behind communist collectivism. The book concludes on a bitter note by describing the foreign intellectuals who, when the Red Terror is mentioned, do not want to hear anything about the "15 millions of lives, at least, sacrificed to this God of 'humanitarian communism'" (Sorokin, 1927: 546).

VII. 1948: A BREACH OPENED BY INED

Sorokin's book relied on an accumulation of monographs, which still relied mainly on the extraction of data from biographical dictionaries of eminent persons. Its publication did not trigger a significant series of surveys on the topic. Natalie Rogoff's 1950 panorama of mobility surveys in *Population* is based on two incomplete samplings whose size she carefully refrains from disclosing; she amalgamates them in her presentation, giving the average numbers. At the time, the United States had been overtaken by France.

In November 1948, INED launched France's first-ever sample survey of social mobility. The project was managed by Marcel Bresard, who released the initial results in 1950. The survey would be cited for many years by American sociologists in their international comparisons (see Lipset and Bendix, 1960; Blau and Duncan, 1967).[3]

Discussing Bresard's survey, Charles-Henry Cuin emphasized the fact that its purpose was not "to measure and analyze mobility flows in France, but rather [to assess] the influence of family size on the odds of its members' social ascent, and more precisely to study the relationship between social origin and educational attainment, which was only the first step in a mobility process" (Cuin, 1995:38). Cuin's assertions seemed to downplay the impact of this initial work, his main goal being to show that French sociology had missed every opportunity to study social mobility before the arrival of Raymond Boudon.

Reading Bresard's pioneering work today, we are surprised to note that, far from restricting the scope of social mobility, he addresses it in very open-minded manner, incorporating aspects that would still be worth exploring today.[4] The influence of family size on the odds of social ascent is only one of them. Bresard also analyzes the components of the occupational scale, career-choice factors (family business, personal calling, search for security, financial emergency, etc.), the inheritability of differential fertility from one's grandparents, and marital mobility.[5]

These topics are admittedly lined up in a row rather than interconnected. When Bresard built three-dimensional tables, it was to measure the influence of the number of siblings on the link between the son's occupation and the father's occupation, then the link between the father's occupation and the father-in-law's occupation (Bresard, 1950:546, 551). There was no technical obstacle to his using the same approach for the length of schooling, but he did not do so. The latter variable is effectively included in a three-entry table, but only at the intersection between social origin and family size. Incidentally, this table is most enlightening, because it shows that for an identical origin, a large family reduces the mean length of schooling, except among management-level workers and professional people.

With hindsight, we can assume that Bresard had the means to deepen his analysis of interactions between social mobility, fertility, and educational attainment; we can also regret that he was interested less in the link between education and employment than in the unfavorable status of large families. But if we bear in mind the historical context—the sorry state of French empirical sociology in the late 1940s—the most striking aspect of Bresard's undertaking is its innovativeness: his three-dimensional intersections were a major novelty in the sociological literature of his day. Bresard also contributed another key innovation, well known to historians of social classification: he was the first French researcher to build and use a classification of socio-occupational categories, before INSEE prepared its famous *nomenclature des catégories socioprofessionnelles*, introduced in the 1954 census.

VIII. 1953: INSEE TAKES UP THE BATON AND KEEPS IT

The 1948 survey was the first and last that INED would be able to conduct on social mobility. In 1953, INSEE took up the baton for good by introducing a one-time question on the father's occupation in that year's Labor Force survey (it did not reappear in the questionnaire until 1982). The results were published rapidly by Jacques Desabie in 1954. Convinced of their usefulness, INSEE administrators decided to repeat the same questions in the first survey on education and

[3] The survey, which covers 3076 economically active males aged 18 to 50, was not properly representative—a deficiency underscored many years later by Daniel Bertaux (1969:451, 1971:88): manual workers are substantially underrepresented owing to inadequate enforcement of the quota method, which resulted in greater overall mobility for the sample.

[4] Sibling social mobility is an issue that few authors have addressed in recent years. Two who have done so are Nicole Tabard (1984) and Bernard Zarca (1995a,b).

[5] In so doing, he introduced the term *homogamie* (homogamy) into French statistics (Bresard, 1950:542), well before Alain Girard's *Le Choix du conjoint*, "choosing one's spouse" (1964).

occupational skills (FQP), which followed the 1962 census.

Charles-Henry Cuin gave a curious interpretation of the interval between the 1953 Labor Force survey and the 1964 FQP survey. He saw it as proof that the social-mobility issue had remained "dormant" at INSEE for about 10 years, because the State Planning Commission (Commissariat au Plan) had assigned other tasks to the Institute, such as the assessment of skills levels (Cuin, 1995:39). But this reading neglects the fact that the timing of FQP surveys was closely linked to that of population censuses. Unlike standard surveys, based on address samples, the FQP survey took a sample of individuals stratified by social group. This could not be done until detailed census results were available. However, one could not wait too long, as this would entail a greater number of changes of address, and the cost of tracking down respondents at their new locations would become excessive. Hence a routine gap of 2 years between a specific census and the corresponding FQP survey. The year 1964 was therefore the first possible date for launching such a survey, which, as all census operations, obviously required several years' preparation.

Moreover, the FQP launch coincided with the financial bonanza from the State Planning Commission, which suddenly allowed INSEE to broaden its social-survey program in a spirit of great intellectual freedom. Without the conjunction of these new resources and the INSEE social statisticians' abiding sociological interest in changes in living conditions, the institute would never have been able to undertake the impressive series of FQP surveys, which continues to this day and provides a matchless source for social-mobility developments.[6] In reality, INSEE's interest in the topic has been remarkably constant since the 1950s, even though its pace has been set by the fluctuations in the census calendar.

IX. BOURDIEU'S CRITIQUE AND BOUDON'S WORK

In 1965, Michel Praderie, senior statistician (*administrateur*) at INSEE, presented the results of the FQP survey at the Arras colloquium, jointly organized by a sociologist, Pierre Bourdieu, and an institute statistician, Alain Darbel. In keeping with a principle that INSEE would consistently follow in the future, Praderie dedicated two separate contributions to the survey findings on *social* mobility (intergenerational) and the findings on *occupational* mobility (changes in occupational category during the respondent's working career, over a 5-year period).

The proceedings were published in 1966 under the title of *Le Partage des bénéfices* (*Sharing the Profits*). The volume was signed by the collective pseudonym Darras, an allusion to the conference venue. The organizers' goals included "examining how the economic and social privileges that hinder the equalization of chances are transmitted from one generation to another" (Darras, 1966:18). As a companion piece to Michel Praderie's article on "Social Inheritance and the Odds of Ascension," Pierre Bourdieu contributed a paper on "The Transmission of Cultural Heritage."

This text is remarkable in many ways. First, it is Bourdieu's clearest précis of his own thought, which was already highly structured. It is thus strongly recommended to all readers seeking a rapid introduction to this difficult author. Second, it is the text in which Bourdieu most openly acknowledges his debt toward INED research on school tracking, published in a series of articles by Alain Girard and Paul Clerc in *Population* in 1963 and 1964.[7] Third—and we shall focus on this aspect here—it took an explicit position on the classic approach to social mobility.

Pierre Bourdieu relies on INED data to emphasize that the school system, far from being a factor of social mobility, is "one of the most efficient factors of social conservation," because it legitimates social inequalities by giving its seal of approval to cultural heritage, treated as a natural gift. Even at this early stage, he stressed that families' cultural capital includes not only "verbal proficiency" and "the nonformal culture acquired in extra-curricular experiences," but also "information from parents on curriculum choices and careers"—a resource whose importance would rise steadily as the system became more diverse and complex (Bourdieu, 1966:394–395, 404). Consequently, Bourdieu argues, the study of social mobility is worthwhile only if it tests the egalitarian ideals of a "democratic society." This, however, requires "measuring the chances of accessing the institutionalized instruments of social ascent and cultural salvation that it offers to persons of different social classes" (Bourdieu, 1966:240). Chances of access imply unequal access costs. Bourdieu criticizes the analyses based

[6] There have been five FQP surveys to date, in 1964, 1970, 1977, 1985, and 1993, following the 1962, 1968, 1975, 1982, and 1990 population censuses. The survey consecutive to the 1999 census is due in 2004.

[7] In particular, Bourdieu used the three-variable tables such as scholastic achievement as a function of the father's educational attainment for an identical income level, and extension of child's education as a function of father's social category for an identical scholastic achievement. At the time, few French sociologists were capable of fully exploiting such tables.

exclusively on father-son social-mobility tables for bracketing these inequalities. He regards the "perfect mobility" postulate—which asserts total independence between fathers and sons—as, basically, an abstraction that ignores reality; however, he admits that this "myth" can serve a critical purpose by objectivating the gap between reality and democratic ideals.

To grasp the logic of this approach, it is useful to refer to the typology of political philosophies that, according to Luc Boltanski and Laurent Thévenot (1987), inform the different models of possible *polities*. Bourdieu's sociology of education consists in denouncing the contamination of the *civic* model of the school polity by a *domestic* model. Although the education system thinks it is assessing students on the basis of scholastic criteria, the education system actually classifies them on the basis of their family strengths, starting with the cultural proficiency forged in early childhood (Thévenot, 1990). This diagnosis of Bourdieu's position seems more interesting to us than that of Charles-Henry Cuin, who merely tags it with a hastily contrived sociopolitical label: a "structuralist metamorphosis of Marxism." We can better understand Bourdieu's special interest in Paul Clerc and Alain Girard's three-variable tables, which introduce the notion of a differential return on the diploma or educational attainment by social origin; the simple two-variable mobility table, as typically presented in the available literature, seems feeble indeed by comparison. On this point, Bourdieu is not far removed from Sorokin, who already saw education as the main *selection agency* capable of preserving the range of social-mobility odds.

By using a different approach, Raymond Boudon also set out to enhance the analysis of social mobility by introducing educational-achievement variables (Boudon, 1973). But the task was technically complex. He sought to catalog the second- and third-order interactions between the main variables of social and educational mobility, including differential fertility. He concluded his work with some 40 partial conclusions that cannot give a clear overview of the issue for readers in a hurry. (Significantly, Charles-Henry Cuin gave up on summarizing Boudon's theory, because he claimed that it could be stated not in natural language but only in model form.)

Paradoxically, we can now provide simple answers to the two French sociologists' questions by means of the log-linear interaction model applied to three-dimensional tables (Goux and Maurin, 1997). Bourdieu's model postulates that the relationship between social origin and social destination (which we shall denote as O and D, respectively) is concentrated by the school, in the form of a diploma or educational attainment (written E) that certifies social origin and determines destination. This is a simple-interactions model: (OED) = (OE)(ED). Dominique Goux and Éric Maurin show that it regresses the FQP survey data far better than a purely meritocratic model of the (OED) = (O)(ED) type, which postulates a relationship between education and destination that is independent of social origin. However, the model remains inadequate.

In other passages (not mentioned by Goux and Maurin), Bourdieu suggests on the contrary that, for the same diploma, social origin continues to differentiate social destinations (there exists a "differential return on diploma"), which gives an undersaturated model of the (OED) = (OE)(ED)(OD) type: social origin continues to weigh directly on destination, even if schooling acts as an intermediary factor. This model proves to be far more consistent with the facts observed in France in recent decades. It was used by Claude Thélot (1982), whose book *Tel père, tel fils?* (*Like Father, Like Son?*) was a landmark in social-mobility studies in France. The model was also the final choice of Dominique Goux and Éric Maurin. The two authors note that it contradicts one of Boudon's hypothesis, namely, that the social return on education differs from one period to another, depending on whether we are dealing with high-rank or low-rank graduates.[8] In reality, the combined impact of family heritage and educational attainment on social destination is corroborated for diplomas and degrees of all levels.

X. SOCIOLOGY/DEMOGRAPHY: IDEOLOGICAL OR INSTITUTIONAL DIVIDE?

In his history of social-mobility studies, Charles-Henry Cuin (1993, 1995) emphasizes the ideological impediments to the expansion of research by French sociologists. Similar to Merllié (1994) and Thévenot (1987, 1990) before him, he reminds readers of how the young Alain Touraine, still imbued with a Marxist-inspired sympathy for the working classes (*ouvriérisme*), had thwarted France's participation in 1954 in the planned international survey on social mobility launched by David Glass at the International Association of Sociology. For Touraine, the survey conveyed an individualistic concept of mobility. What counted, in his view, was "collective" social mobility, that is, the improvement of the fate of the working

[8] Indeed, under this hypothesis, family heritage would not be a factor for selecting highly educated candidates unless they were in oversupply in the labor market. If supply is weak, cultural heritage would be a selection factor among low-qualified candidates.

class obtained through labor-union struggles (Touraine, 1954). In a similar spirit, but 20 years later, the political scientist Nicos Poulantzas (1974), a disciple of Louis Althusser, denounced the "bourgeois" approach to social mobility.

These ideological taboos are indeed real, but do they suffice to explain the weakness of social-mobility studies among French sociologists? Factors of a more structural kind—concerning the organization of research in France—also played a role. When social mobility is described as having long remained "a preserve of economists and demographers" in France (Cuin, 1995:38), the term should be taken to mean a preserve of sociologists and survey statisticians working in the main official statistical institutes, INED and INSEE—a field that sociologists affiliated with universities or the CNRS did not enter.[9] But this separation is hardly specific to social-mobility analysis. It applies, more broadly, to all social statistics, including family expenditures, consumption surveys, fertility surveys, and the sociology of the family.

Unlike in the United States, United Kingdom, and Germany, there is a radical divide in France between academia and the official statistical system. The latter not only holds a monopoly on the collection resources needed to produce data with large-scale representativeness. It also analyzes the data, largely relying on its own staff, who are proficient in statistical methods and demographic analysis. And the system publishes the results itself, in institutional media. This is a far cry from the situation in the United States, where, as far back as the 1950s, official agencies such as the Census Bureau simply collected social-mobility data, subcontracting the data tracking and analysis to specialized academics (Robert Centers, Peter Blau, Otis Duncan, David Featherman and Robert Hauser, and others).

The French situation has admittedly begun to improve, but only recently. INSEE and CNRS did not begin exchanging a limited number of specialists until the early 1980s. The framework agreement signed by the two organizations on survey-file transmission, including FQP surveys, was implemented in the mid-1980s. And it is only in the mid-1990s that INED and INSEE began including doctoral students in their research teams.

As a result, French academics working on social mobility have never tackled the subject directly, either by taking part in INSEE questionnaire development or by conducting their own analyses of the data files.[10] Some have skillfully examined the history and epistemology of the specialty, at the risk of irritating practitioners, who readily view them as amiable arbiters of elegance. An even smaller number—for example, Raymond Boudon in his 1973 book—engaged in the secondary processing of the data. But harsh reality forced them to confine their analysis to the existing social-mobility tables, and they soon veered toward the construction of abstract models that were impossible to validate in the near term. Some of Raymond Boudon's central assumptions, for instance, were not submitted to experimental testing by INSEE researchers until 25 years later (Goux and Maurin, 1997).

The author of *L'Inégalité des chances* was himself aware of the limits of the exercise; he made an impassioned plea for the production of empirical materials covering the long term: "A satisfactory theory of mobility cannot be designed until we have mobility surveys repeated at fairly regular intervals over time. Only thus will we be able, for example, to introduce in a precise manner a fundamental variable into the mobility process, namely, the change in social structure. For our part, we have confined our work in this area to analyzing the consequences of the cautious and spare hypothesis that the social structure changes less quickly than the educational structure" (Boudon, 1973:219).

With hindsight, it is striking to see the extent of the divergence between the research strategies of Raymond Boudon and John Goldthorpe in the field of social mobility. Although the French academic remained dependent for data on the official statistical system, his British colleague tackled the data head-on. Boudon's work has been continued in France by young researchers who, similar to Louis-André Vallet, Michel Forsé, Louis Chauvel, Dominique Goux, and Éric Maurin, master the new techniques of mobility analysis. Boudon himself eventually switched to cognitive sociology: he decided not to update his textbook on mobility indices, published in English and never translated into French. John Goldthorpe, by contrast, has

[9] The distribution of authors by discipline is not as clearcut as Charles-Henry Cuin makes it out to be. Why classify Nicos Poulantzas among sociologists and Alain Girard among demographers? Poulantzas was a political scientist who never conducted an empirical survey—a good example of the "materialists without material" pilloried by Bourdieu. Girard played an important role at International Network of Economic Developers, but was not a demographer himself. He studied demographic behavior as a sociologist, with a predilection for sample surveys that sought to identify perceptions and opinions.

[10] Except for two sociologists at universities in western France, François de Singly (1977, 1983, 1984, 1986) and Louis-André Vallet (1991), who cooperated productively with Claude Thélot when he was working with the National Institute for Statistics and Economic Studies regional office in Nantes. Both de Singly and Vallet specialize in the analysis of female mobility.

sought to maintain contact with social statisticians. His team established links with a wide international network in order to collect—and, sometimes, inspire—the main mobility surveys in Western countries in the 1970s. He was helped in this task by the organic connections between social statistics and academic research in the United Kingdom, Germany, and the United States, whereas Bourdon remained a prisoner of his isolated status.

XI. THE "CONSTANT FLOW": GOLDTHORPE

Following the work of Leo Goodman (1979), Robert Hauser (1978), Michael Hout (1982), and a few others, John Goldthorpe imposed the use of *odds ratios* in the sociological profession as an indicator of overrepresentation of groups in a social-mobility table. Odds ratios offer two advantages. First—unlike any of the mobility indicators used until then—they remain independent of variations in the size of marginal groups. Second, they can be incorporated into a very simple modeling of mobility tables, that is, log-linear models, which use a logistic metric in which effects are additive rather than multiplicative as previously. In such a model, the number of individuals in each cell is obtained by adding together several effects (or multiplying them, if one renounces logarithmic transposition): a scale effect (parameter taking into account the total number of individuals in the table), a row effect (destination or origin, depending on the table's arrangement), a column effect, and an effect of the row-column interaction. The same logic can apply to tables with *n* dimensions. These properties make log-linear models the ideal choice for international and time comparisons. For his project, John Goldthorpe has steadily gathered individual files from the main industrialized countries (most notably thanks to funding from the Volkswagen Foundation in Hanover): United Kingdom, France, Netherlands, Sweden, United States, and Canada, soon followed by Japan and several countries of central/eastern Europe.

As a result, in his analyses and those of his critics, we have seen a recent flowering of some odd expressions (to say the least) consisting of dual metaphors, such as "inertia of social fluidity" and "core social fluidity." These alliances of words are incomprehensible if we refer to first-order truths. They denote second-order truths that require reasoning on a "some things being equal" basis.

John Goldthorpe calls the core assumption the "FJH hypothesis," in homage to the three U.S. researchers who formulated it back in 1975: David Featherman, Frank Jones, and Robert Hauser. It consists in stating that if the Western industrialized countries display an unquestionable overall mobility, the relative mobility (or social fluidity) is fairly stable from one society to another, just as it is stable in time. It is not the quantity of mobility that remains invariable, but the *competitive structure of flows* or, if one prefers, *differential mobility*.

Let us take, for example, two neighboring countries at very different stages in the process of reduction and concentration of the rural population—one with, say, a 20% share of farmers in its total population, the other with only 2%. Despite the gap, the access of farmers' sons to urban social strata will follow the same hierarchy in both countries. At the other end, the number of managerial jobs or higher-level intellectual professions may increase in different proportions and at different paces in the two countries, but the demand created at the top of the social ladder will be filled in different ways depending on the social origin. Applicants from each group will access these new positions in accordance with very similar odds hierarchies in both countries. Social groups do move, but without significantly modifying the system of connections or distances that unites them. A final example is the risk of downward mobility represented by exposure to unemployment, which now justifies introducing the unemployed into mobility tables: this phenomenon chiefly affects the most vulnerable groups, at the bottom of the ladder.

The thesis of a *constant flow* of social mobility goes back a long way. Sorokin had already intuited it (admittedly in the context of a multi-century time frame). It crops up more or less explicitly in the observation made by sociologists of all persuasions in the 1960s and 1970s: contrary to all expectations—most notably those of U.S. sociologists of social mobility, such as Richard Bendix and Seymour Lipset—the massive spread of education in the years of expansion was not matched by an equivalent reduction of economic and cultural inequalities; nor did it generate an overall rise in the odds of upward mobility. Twenty-five years later, Dominique Goux and Éric Maurin said the very same thing: "the level is rising, but the classifications are not changing. "And Michel Forsé gave the following title to an article published by OFCE: "The Decrease in the Inequality of Education Odds Is Not Enough to Reduce the Inequality of Social Odds" (Forsé, 1997). The more recent studies by Louis-André Vallet (1999), based on log-multiplicative models, show the following pattern for France over the long run (4 decades): the relative link between social origin and access odds has loosened very slightly, but not on a scale proportional to the changes in social structure during the intervening period.

Raymond Boudon's essay on social mobility took this observation as its starting point. This was the central significance of the "Anderson paradox" that he chose to showcase: as the school structure, driven by the pressure of education demand, evolves faster than the social structure, the length of schooling increases without changing the mobility structures. Consequently, a child whose educational attainment exceeds that of his or her father has no guarantee of rising higher than the father's position on the social ladder (Boudon, 1973:207). Formulated in a period when long-term data were scarce, this analysis has stood the test of time.

At the risk of reconciling authors commonly viewed as irreconcilable, we can say the same about Pierre Bourdieu's verdict on the issue, despite his different approach. In *Le Partage des bénéfices* (1966) as in *La Distinction* (1979) and some intermediate analyses (Bourdieu, 1973), Bourdieu consistently stressed that the preservation of intergroup competition structures entailed the constant renewal of content in the ranking struggles (e.g., in France, parents seeking to make their children study German in order to obtain the same result formerly achieved by opting for Greek, i.e., access to the more prestigious high schools). The notion of 'conversions" or "field homologies" that preserve relative statuses is a means for Bourdieu to identify the invariant elements concealed under the apparent fluidity. Can we say that, in so doing, he is distancing himself from social mobility? In fact, he only extends it—as Sorokin had already done (and as has since been forgotten)—to all the phenomena of unequal and distinctive diffusion of goods, information, habits, and tastes; in turn, these are incorporated into a general sociology of "access odds," of which social mobility in the strict sense is merely a specific expression. The overall process does indeed resemble a "constant flow." The discussion on this point would take us too far. Let us draw a provisional conclusion by suggesting that John Goldthorpe's general result contains nothing bluntly incompatible with Bordieu's sociology of social structure. More precisely, Goldthorpe's success has demonstrated that Bourdieu's presumptions against mobility analysis were no longer justified.

XII. A POSSIBLE CONVERGENCE: DIFFERENTIAL MOBILITY AND DIFFERENTIAL DIFFUSION

Why has *relative* social mobility remained so constant in our societies? We need to compare it with other differential diffusion phenomena that leave the overall pattern of inequality unchanged. For example, the uneven diffusion of medical innovations—new therapies, new equipment, and new knowledge, via the selective diffusion of recourse to specialized doctors—may partly explain the persistence or *relative* gaps in health or life expectancy. The current diffusion of personal computers in homes is recreating, before our eyes, new social inequalities between children of school age. Every innovation tends to initially favor the best-equipped social categories.

The identification of *constant flow* should not accredit the existence of an eternal sociological law. Constant flow is a remarkable regularity (which is already a lot) that will hold true as long as it has not been disproved. As Louis Chauvel rightly noted, we should not rule out the possibility that Goldthorpe's constant flow may one day undergo the same fate as the alpha coefficient of Pareto's wealth curve, which stood the test of fact for nearly a century before succumbing to it very recently. For the moment, constant flow applies to all cohorts born between 1900 and 1960. By chaining the data from FQP and Labor Force surveys produced by INSEE from 1970 to 1995, Chauvel established that social fluidity remained broadly unchanged in France for all male cohorts entering the labor market from the 1930s to the present.

In other words, there seems to be little change in the structure of mobility in time and space in the main Western countries—as demonstrated recently for Italy and Switzerland. The demonstration also disproves the widespread notion that North American society is more mobile than are European societies.

The criticisms directed at John Goldthorpe have spared the bulk of his work and focused on what he has called, not without humor, "core fluidity." What does this consist of? Goldthorpe takes the logistic comparisons of selected cells in the table and subjects them to a series of effects. For example, mobility out of or toward the category of farmers and farm workers is slowed by a "sector effect" that can be estimated (all other things being equal, switching to a farming occupation is particularly difficult, as is exiting from one). Other paths are influenced by effects that counteract mobility from a short distance or a long distance, and so on. The structure of attractions or repulsions between classes modulates the general phenomenon of relative fluidity via eight effects that, according to Goldthorpe, form the "core fluidity" of industrialized countries. France and England are the best embodiments of this core; Sweden diverges from it because of a slight excess fluidity that may be owing to its long-term implementation of a social-democratic social policy (but this needs to be demonstrated).

We are now witnessing an interesting reversal of approach, effectively noted by Dominique Merllié and Jean Prévot (1991) and Gilles de La Gorce (1993). A social-mobility study would typically begin by setting aside structural mobility in order to concentrate on net mobility, equated with true mobility. Because of the abundantly repeated observation of constant flow, the latest research starts by verifying the existence of a constant relative mobility before moving on to the study of absolute mobility tied to changes in social structure. Let us return to our earlier example of two countries in which farmers make up 2% and 20% of the population, respectively. However hard they try to distribute the social-mobility flows while preserving the structures of interclass competition and ranking—which are similar in both countries—the fact of the matter is that life is not the same in a country where farmers represent 2% rather than 20%. The portion of the population that changes economic sectors and ways of life is not the same. The log-linear analysis of social mobility thus seems to have completed a long side-trip in order to discover that, ultimately, social-mobility analysis is but a chapter of a broader venture: the study of the changes in social hierarchies in general.

APPENDIX 92–1

A Log-Linear Model of the Association between Educational Attainment and Social Origin[11]

Let $F_{i,j,t}$ be the number of individuals aged 25 to 34 of social origin i and educational attainment j at date t. We can decompose $\mathrm{Log}\,F_{i,j,t}$ in a unique way (see Gouriéroux, 1984), as follows:

$$\mathrm{Log}\,F_{i,j,t} = \mu + \lambda_i^O + \lambda_j^D + \lambda_t^T + \lambda_{i,j}^{OD} + \lambda_{j,t}^{DT} + \lambda_{i,t}^{OT} + \lambda_{i,j,t}^{ODT} \quad (1)$$

where O denotes social origin, D educational attainment, and T the survey date. The γ coefficients meet the following identification constraints:

$$\begin{aligned}
\sum_i \lambda_i^O &= \sum_j \lambda_j^D = \sum_t \lambda_t^T = 0,\\
\sum_i \lambda_{i,j}^{OD} &= \sum_j \lambda_{i,j}^{OD} = \sum_j \lambda_{j,t}^{DT} = \sum_t \lambda_{j,t}^{DT}\\
&= \sum_i \lambda_{i,t}^{OT} = \sum_t \lambda_{i,t}^{OT} = 0,\\
\sum_i \lambda_{i,j,t}^{ODT} &= \sum_j \lambda_{i,j,t}^{ODT} = \sum_t {}_{i,j,t}^{ODT} = 0.
\end{aligned}$$

μ is a constant representing a parameter of scale. The λ_i^O, λ_j^D, and λ_t^T coefficients stand, respectively, for the effect of the distribution of individuals by social origin O, educational attainment D, and survey date T. The $\lambda_{i,j}^{OD}$, $\lambda_{i,t}^{OT}$, and $\lambda_{j,t}^{DT}$ coefficients stand, respectively, for the effect of the specific associations between social origin and educational attainment, between social origin and survey date, and between educational attainment and survey date. The $\lambda_{i,j,t}^{ODT}$ coefficients stand for the impact of the changes in the associations between social origin and educational attainment over time.

The advantage of this type of model is that it allows a simple test of the independence and conditional-independence hypotheses. In the study of social mobility, most of the key questions can be framed in terms of independence. For example, testing the stability of educational inequality over time is the same thing as testing the independence of the OT association and DT associations. This involves testing the simultaneous nullity of the $\lambda_{i,j,tt}^{ODT}$ parameters in Eq. 1, that is, verifying the statistical validity of the model:

$$\mathrm{Log}\,F_{i,j,t} = \mu + \lambda_i^O + \lambda_j^D + \lambda_t^T + \lambda_{i,j}^{OD} + \lambda_{j,t}^{DT} + \lambda_{i,t}^{OT} \quad (2)$$

An abridged representation of Eq. 2 is $(OD)(OT)(DT)$. This is consistent with the standard practice of describing log-linear models by means of a summary outline of the effects and interactions to which the model is confined.

To test the compatibility of Eq. 2 with the data, we can simply estimate the γ and μ parameters by using

[11] From Dominique Goux and Éric Maurin (1997a).

TABLE 92–A Change in Association between Education Attainment and Social Origin, 1970–1993: A Log-Linear Model

Models	Degrees of freedom	G^2	rG (%)	p
Benchmark model: *(OD)(OT)*	36	1,788	—	0.0001
Uniform democratization: *(OD)(OT)(DT)*	27	156	91.3	0.0001
Effect: *(DT)*	9	1,632		0.0001

1. T stands for the survey date. Four-category classifications are used for social origin (O) and educational attainment (D). The distance G^2, combined with the number of degrees of freedom, provides a measure of the difference between the observations and the model. The probability p measures the test's significance.

Interpretation: Between 1970 and 1993, 91.3% of the increase in educational attainment was uniformly distributed across all social strata.

Field: young adults aged 25 to 34 in 1993.

From Formation-Qualification Professionnelle surveys (INSEE, 1970, 1977, 1985, 1993).

TABLE 92–B Change in Association between Education Attainment and Social Origin, 1970–1993: A Log-Linear Model

Models	Degrees of freedom	G^2	rG (%)	p
Benchmark model: *(OD)(OT)*	60	870	—	0.0001
Uniform democratization: *(OD)(OT)(DT)*	50	104	88.0	0.0001
Effect: *(DT)*	10	766		0.0001

1. T stands for the survey date. Six-category classifications are used for social origin (O) and educational attainment (D). The distance G^2, combined with the number of degrees of freedom, provides a measure of the difference between the observations and the model. The probability p measures the test's significance.

Interpretation: Between 1970 and 1993, 91.3% of the increase in educational attainment was uniformly distributed across all social strata.

Field: young adults aged 25 to 34 in 1993.

From Formation-Qualification Professionnelle surveys (INSEE, 1970, 1977, 1985, 1993).

the maximum-likelihood method and then assess the distance between the observed data and the model forecasts by means of the likelihood statistic G^2.[12] Another method, which typically yields very similar results, consists in estimating the parameters by minimizing the distance of Pearson's chi-square.[13] Here, the two methods lead to the same results (Goux and Maurin, 1995).

Table 92–A summarizes the results. It reports a log-linear analysis of the mobility table whose elements are the $F_{i,j,t}$ values. These are obtained by combining education and social-origin classifications into four categories and by separating four dates. The $F_{i,j,t}$ vector studied has $4 \times 4 \times 4 = 64$ degrees of freedom.

Table 92–B shows the same analysis, but using the more detailed six-category classifications. The vector studied has $6 \times 6 \times 6 = 216$ degrees of freedom.

To study the dissemination of diplomas (i.e., school democratization), we chose the (*OD*)(*OT*) model as the benchmark. This model postulates that (1) inequality has remained stable (no *OT* or *DT* interaction), and (2) educational attainment has remained stable over time within each social category (no *DT* interaction). The model does not, of course, provide a statistically acceptable description of the changes in the distribution of individuals by social origin and education ($G^2 = 1788$ and the probability p that the omitted coefficients are null is a very small 0.0001). The distance between this model and the observed data is consistent with the full impact of school democratization on the shift in the mobility table over time. This is precisely the influence we are trying to isolate and analyze, and we have accordingly adopted this model as the benchmark in our study.

We next estimated the (*OD*)(*OT*)(*DT*) model. Here, only the $\lambda^{ODT}_{i,j,t}$ interactions have been constrained to zero. We kept 37 parameters (μ, (μ, $3\lambda^O_i$, $3\lambda^D_j$, $3\lambda^T_t$, $9\lambda^{OD}_{i,j}$, $9\lambda^{OT}_{i,t}$, and $9\lambda^{DT}_{j,t}$), leaving only 27 degrees of freedom. This model is based on the hypothesis of a uniform dissemination of diplomas, that is, no *OT* or *DT* interaction. The (*OD*)(*OT*)(*DT*) model is far more realistic than the previous one. It explains more than 90% of the differences between the frequencies predicted by the

[12] If $F^*_{i,j,t}$ is the estimate of the frequency $F_{i,j,t}$ by the log-linear model M, the quality of M's fit with the data can be estimated by

$$G^2 = 2\sum_{i,j,t} F^{Log}_{i,j,t}\left(F_{i,j,t}\middle/F^*_{i,j,t}\right)$$

This statistic displays additivity properties: if M' is a model nested in M, then

$$G^2(M') = G^2(M) + G^2(M,M').$$

[13] The chi-square statistic has the minor disadvantage of not being additive. The distance between two models is not quite identical to the difference between those models and observed data.

TABLE 92–C Main Differences between Observed Changes *(ODT)* and the Uniform Democratization Model *(OD)(OT)(DT)*

Educational attainment	1970	1977	1985	1993
1. Farmers' children[a]				
Higher education	0	0	0	0
Bacclaurêat or equivalent	–	0	0	+
CAP, BEP, BEPC	0	0	0	0
CEP or dropout	+	0	0	–
2. Manual or clerical workers' children[b]				
Higher education	+	0	–	0
Bacclaurêat or equivalent	+	0	–	0
CAP, BEP, BEPC	0	–	+	0
CEP or dropout	–	+	+	0

Bacclaurêat, senior-year high-school diploma; a prerequisite for admission to university; CAP, *certificat d'aptitudes professionnelles* (vocational training diploma); BEP, *brevet d'êtudes professionnelles* (vocational training diploma); BEPC, *brevet d'êtudes du premier cycle* (diploma at the end of fourth year of secondary school); CEP, certificat d'êtudes primaires (primary-school diploma, now abolished).

Field: young adults aged 25 to 34 in 1993.

[a]*Interpretation:* The estimates of the $\lambda^{O}_{i=farmer,}{}^{DT}_{j,t}$ coefficients that measure the differences between the *(OD)(OT)(DT)* model and the observed data *(ODT)*. Only the signs of the coefficients are given; 0 denotes a value not significantly different from zero. If democratization had been strictly uniform, there would have been more dropouts and fewer *Bacclaurêat* holders among farmers' children in 1993.

[b]*Interpretation:* The table reports the estimates of the $\lambda^{O}_{i=manual\ or\ clerical\ worker,}{}^{DT}_{j,t}$ coefficients that measure the differences between the *(OD)(OT)(DT)* model and the observed data *(ODT)*. Only the signs of the coefficients are given; 0 denotes a value not significantly different from zero. If democratization had been strictly uniform, there would have been fewer dropouts and more *Bacclaurêat* holders among manual and clerical workers' children in 1993.

From Formation-Qualification Professionnelle surveys (INSEE, 1970, 1977, 1985, 1993).

(*OD*)(*DT*) model and the observed frequencies (this is expressed in the formula $rG^2 = 91.3$). In other words, more than 90% of the dissemination of diplomas has occurred uniformly in each social category, without modifying inequality. Only the residual 8.7% is owing to changes in the association between education and social origin over time.

The differences between the (*OD*)(*OT*)(*DT*) model and the observed frequencies are weak but significant: in other words, the probability that the order-three interactions neglected by the model are all null is itself practically null. The analysis of the differences between the model and the observed frequencies allows us to locate the frequencies of the $\lambda^{ODT}_{i,j,t}$ interactions, whose nullity can be ruled out. Table 92–C reports the estimated values of these non-null interactions. They concern only the most modest social categories: farmers versus manual and clerical workers. For greater legibility, only the signs of the significantly non-null $\lambda^{O}_{i=farmer,}{}^{DT}_{j,t}$ and $\lambda^{O}_{i\,=\,manual\ or\ clerical\ worker,}{}^{DT}_{j,t}$ interaction are given; the others are equal to 0. Table 92–C thus shows that, if the children of manual and clerical workers had benefited as much as other children from school democratization, they would have included more holders of the *baccalauréat* and higher-education degrees, and fewer dropouts (Table 92–C-2). In contrast—again assuming strictly uniform democratization—we would now find more dropouts and fewer *baccalauréat*-holders among farmers' children (Table 92–C-1).

CHAPTER

93

Gender and Demography

ANTONELLA PINNELLI

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

INTRODUCTION

This chapter sets out to illustrate the main insights that can be expected from adding a gender perspective to demographic research and training. As has already happened with sociology, demography is shifting from often implicitly feminist-oriented studies on women to studies on gender, which looks more at male-female relationships and how they evolve over time. This is because changes in women's status clearly entail changes in that of men, so their respective agendas and conditions, and the interactions between them, must be examined to understand the trends and determinants of demographic behaviors.
