General Introduction

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Six hundred million Chinese in 1950, and double that today. Eight hundred million Africans on the eve of the third millennium, and probably three times that in 40 years. Humankind under threat from a third world population *explosion*. Industrial societies enfeebled by *depopulation* and the opposing risk of a *population implosion.* Pension systems hard-pressed by aging populations. Northern societies living in entrenched fear of invasions from the east or south, be it history's *yellow peril* or the more recent *open floodgates* from across the Mediterranean or Rio Grande, turning a convenient blind eye to their own ancestral past as invaders, with their most overwhelming wave (toward North America) being a matter of recent history. For the past 50 years, population issues have dogged our contemporaries and they remain as live an issue as ever.

There is nothing new in this. Populations have been counted since the start of recorded time. But rational scientific methods to do so are of fairly recent date. Back in the 17th century, John Graunt (1662) tried estimating the population of London from registrations of deaths, while the late 18th century found Thomas Malthus publishing the first edition of his *Essay on the Principle of Population* (1798). But it was not until the 20th century that Alfred Lotka (1934, 1939) gave us a general theory of population dynamics, and Adolphe Landry (1934) a general explanation of the *demographic revolution,* which we now call "demographic transition" (Kirk, 1944; Notestein, 1945).

I. SCIENCE AND ITS PURPOSE

The problem with how demographers relate to the public may be that they now have so many different sophisticated tools for analysis that they risk shutting themselves up in an ivory tower of overtechnicality, even to forgetting what their science is all about: population. Too many handbooks give a sterile purchase on demography and, after lengthy expatiation on the relationships of *rates* to *probabilities*, the differences between *occurrence—exposure rates and frequencies,* or even the pros and cons of the n^{th} *parameter* of a descriptive or explanatory *model* of fertility or mortality, stop just where things start to get interesting: explaining the phenomena measured and assessing their impact on other aspects of economic and social life. The aim here is to combine a comprehensive and comprehensible presentation of all these methods of demographic analysis with a discussion of how they can be used to understand general population dynamics and the relationships (causes and effects) between them and their natural, economic, social, political, and cultural environments. In other words, we need to look not only at the science (demography), but also its subject (population) and not just what we can know about the latter, but what we can do with it.

The aim of scientific inquiry is not just to describe the universe and the laws that govern it; but also to try and tell us how it works. What it tells us enables us to act directly on the real world in some areas and change it for our benefit. So, modern physics has given us control of atomic energy and laser beams and medicine has produced antibiotics. In other areas (meteorology and astronomy, for example), science has only—at least as yet—enabled us to predict certain developments so that we can better accommodate them. For some scientific topics, we must be much less ambitious and content ourselves with describing past or current events and trying to understand their root causes. This, surely, is where we must class economics and politics, with the caveat that these disciplines are firmly geared toward action and control of the material world and the future, whereas the ultimate goal of science, regardless of performances, is to increase humankind's ability to take its own destiny in hand. Where does demography stand in this? Is it predictive? Can it be used for action?

Knowing, understanding, predicting, and controlling population development . . . Can this be done in isolation from other disciplines like history, geography, economics, sociology, psychology, medicine, biology, and genetics? Absolutely not. But, attempting to include every discipline would be as doomed to failure as would limiting our study to the techniques of demographic analysis alone: Co-opting everything potentially related to demography would lead us off course and risk muddying the paths we are trying to clarify.

The term "demography" first appeared in a work by Achille Guillard (1855), "*Eléments de statistique humaine ou démographie comparée*." Although more of a crusading pamphlet than a scientific discourse, and offering too narrow a definition, he must at least be credited with having coined the word used to describe the discipline today. But, it was more a late baptism than a birth. The foundations of the scientific edifice of demography were laid in the 17th and 18th centuries by a series of scientists working along the same lines: England's John Graunt (1662) and Edmond Halley (1693), Germany's Peter Süssmilch (1775), Holland's Willem Kersseboom (1742; INED, 1970), France's Antoine Deparcieux (1746), Sweden's Per Wargentin (1766). This nascent science as yet had no clear name or object. It was often referred to as *political arithmetic*. In fact, while its founding fathers came from quite different backgrounds (a cloth merchant, an astronomer, a theologian, an actuary, and two mathematicians), they agreed on at least one point: the need to address their *political* problem (the study of human populations) with *numerical* sciences—mathematics, statistics, and probability theory. And, that is precisely what Achille Guillard meant by linking his neologism with the expression *elements of human statistics*. We, too, must start by reducing reality to calculable and measurable elements in order to describe, analyze, and understand the mechanisms that govern the composition and development of a population. This is the foundation on which Alfred Lotka (1939) developed his general theory of *population dynamics* and this process is central to demography, even if it also seeks to study the dynamics of population from all angles connected with the various qualitative and quantitative aspects of the population at both individual and societal levels.

II. HUMAN POPULATIONS

What populations are we referring to? This is not a trivial question because in strictly statistical terms, a *population* is generally defined as a set of unspecified individual elements meeting a single definition. Once that group becomes subject to an ongoing process of entries and exits capable of changing its size and structure, it can be studied with the tools of demographic analysis. In this way, one can just as easily calculate the life expectancy of a *population* of electric light bulbs as measure the fertility of a *population* of butterflies, and so study the overall dynamics of these specific populations. *Animal population studies* in particular are a special field in which the principles of demography are widely used. Nevertheless, we exclude it from our area of study by limiting our discussion to human populations only. This is less because *human demography* is already a broad enough field in itself to be the subject of encyclopedic treatment than to highlight its singularity: Humans are not just statistical units, simple living beings, or merely social creatures like bees and ants; in Aristotle's[1] phrase, man is a *political animal* thinking and influencing his or her own individual and collective destiny, which situates the study of human population dynamics clearly in the field of social sciences rather than biology.

The most easily defined human population is all the human beings inhabiting the earth: All humanity, taking the term "humanity" in its full demographic sense of not just all human beings alive today, but also the entire course of the history of settlement, which is the core issue of population dynamics. Here, population dynamics relates only to one kind of entry and exit: births and deaths. But demography can just as easily apply to a small part of that group, set apart by reference to one or more criteria by which the individuals selected to form part of it can be identified: territory, religion, language, nationality, education, economic activity, disease, sex, blood group, and so forth. Any group thus defined can constitute a *population* in the demographic sense of the term. In many cases, the dynamics of this population will then be

[1] In his "Politics" Aristotle (384–322 BC) was seeking to emphasize the sophistication of humankind's social organization, embodied in the organized state. As Marcel Prélot (1961, p. 6) puts it: "Ancient man, as Aristotle defined him, was only a being or 'creature of the city.' The import of the definition is severely curtailed by translating 'zoon politikon' as 'social animal.' Animals are also social, but only man is political. His nature is not to live in flocks, herds or hordes but as an integrated part of that social organization represented by the Polis, the City; which is, for him, both a natural need and an ideal."

governed by more complex rules, according to many different types of entry and exit. In addition to the *natural changes* of births and deaths, we must take into account other events through which the individual characteristics defining the group studied are acquired or lost: crossing a border, acquiring or losing nationality, taking up or leaving an occupation, illness or cure, and so forth, unless they are (biologic or other) characteristics acquired through birth and lost only with death (gender, blood group, birthplace, etc.).

Of all the criteria used to identify a subpopulation whose dynamics are a matter for demographic study, the most important is residence in a socially significant territory. First, it must correspond to the simplest definition covering all humankind, which is self-defined by residence on a territory (the planet) whose social significance is beyond question in these times of globalization, the only difference being that this territory represents the entire area so far inhabitable by humankind. In addition, the concept of territory is inseparable from the social organization of human life, taken here as a building block of the subject of demography. So, territory is not just about geographically bounded areas—the area concerned must still be connected with the organized community life of human beings. Admittedly, the boundaries of that area may be determined by strict physical geography (the population of the Andean plateaux or the middle Senegal valley, for example) but the significant fact is that the ecologic conditions governing these territories influence the collective way of life. Consider too that these ecosystems are not the only source of socially organized territories: remember how many states of the United States are delimited by imaginary lines representing latitudes and longitudes!

III. POPULATION DYNAMICS

Whatever the population studied, demography focuses on its dynamics. Although it may attempt to identify the determinants and assess the impacts in the economic, social, cultural, political, and other fields, these factors and impacts fall within its purview only in so far as they offer explanations of these dynamics in view of informing government and society of the implications for the future. However, developing the specific analytic tools to do that has enabled demographers to acquire experience and skills in equally useful fields of study outside the specific focus of the discipline, not directly connected to population dynamics. Mortality, for example, one of the key factors of population dynamics, is obviously related to health and thus is a touchstone issue of demographic research in which demographers were interested even before the word demography was coined. But, the demographic study of health is supremely relevant to the social system and policy makers, be they general government, the medical profession, welfare funds, or charitable agencies. As a result, demographers are encouraged to engage with studies or research on subjects completely independent of the relevance they may have to explaining population dynamics or the effects of growth. For example, having developed abilities to measure morbidity, which has a clear impact on mortality (and hence population dynamics through tuberculosis, cancer, or cardiovascular diseases), the demographer may just as easily be prompted (by a study sponsor or simply to further his or her own scientific interest) to evaluate diseases or disabilities such as the common cold, vision problems, or mental illnesses whose connection with mortality are much more tenuous and in any event not the major concern.

Likewise, marriage entered the ambit of demography prima facie because it was or still is in many societies a factor for formally organizing the expression of fertility. However, it has subsequently remained a subject of demographic inquiry even where the marriage rate and fertility are increasingly uncoupled by the rise in nonmarital fertility and contraception within marriage. Demographers are increasingly working with sociologists, psychologists, political scientists, and lawyers in studying the diversifying forms of marriage, including those that clearly no longer have a link with fertility, such as same-gender unions.

The fact is that anything connected with fertility or mortality, however remotely, can have a direct bearing on population dynamics and it is only well upstream (factors) or downstream (consequences) that it can be considered completely outside the specific field of demographic research.

Migratory moves are another consideration. It is clear that what has just been said about mortality and fertility can readily be applied to external migrations—those across the boundaries of the area in which the study population lives. Internal migrations, which are a zero sum for the population concerned and so do not affect its dynamics directly, are a different matter altogether. Should they simply be excluded from the scope of demography? There are at least three good reasons why they should not.

First, the concepts and methods of analysis of migrations are self-contained, for one very good reason: The same migration flow can be considered as external or as internal according to how the study population is defined. A migration from Ohio to Oklahoma is an internal migration for the United States, but external for each of the two states concerned. The same argument can be applied at all levels and applies even more so where the study population is defined not by territory but by any other distinguishing criterion (school population, occupation, legal categories, etc.). Occupational, social, and legal migratory moves may be internal or external, depending on the study population profile. Such rapid change in the distinction between internal and external alone would justify including the study of all migrations of whatever kind in the scope of demography.

But, also, even restricting discussion to the strict confines of a given population—in the broadest case of the population of a geographic area—internal migrations are usually not just indirect factors. Rather, they are are also a direct consequence of population dynamics. The spatial reorganization effected through internal migrations, especially between town and countryside or relatively different cultural areas, is rarely without consequence on demographic behavior, health, and fertility. To this extent, internal migratory moves contribute at least indirectly, and often significantly, to the overall movement. But, even more clearly, internal (and external) migrations are often the consequences of population dynamics effects. Population pressure exerted on certain strata or regions of the territory (the countryside, for example, or areas with a higher natural increase) are often the source of internal migration flows, which, as a result, fall within the field of general population dynamics.

For all these reasons, far from excluding internal migrations from the scope of this book, external and internal migrations will be distinguished only according to methodologic or conceptual needs. It is quite clear that although only external migrations are central to the dynamic, internal migratory moves are equally important in studying determinants and consequences and that in the final analysis, they will in most cases be methodologically inseparable.

The division between the components of population dynamics and their relations with other aspects of social dynamics may be unclear, but so are those of the wide range of populations that can be the focus of demographic study. It was said earlier that the focus of this text will be on resident populations living in a socially constructed area, but that is not to exclude other populations susceptible to demographic analysis. However, other examples will be cited only briefly and selectively to illustrate the varied range of possible applications, which is so wide as to rule out a comprehensive approach.

IV. INDIVIDUALS AND VITAL EVENTS

As stated above, demography is about the study of the *human population*, although its techniques can be applied to other subjects. However, any population consists of a group of individuals. While demographic research does not focus on the individual *per se*, unlike psychology for example, demographers must bear in mind the obvious facts that a population's mortality is due to the death of some of its members during a given period, *natality*[2] is the result of births engendered by men and women, and migration stems from the mobility of human beings within or outside borders. The correspondence between population changes and individual vital events, however, is more complex than it appears at first sight. Take the case of mortality, for instance. In any year, an individual may die or survive; so his or her survival probability will be 0 or 1. During the same year, general mortality may be characterized by the ratio of the number of deaths to the population exposed to the risk at the start of the year. This ratio gives a frequency or probability of dying that will never be equal to 0 or 1 other than in the exceptional case of everyone surviving or dying in the year. When we say that a person has a 0.083 probability of dying in the year, we are actually applying a group characteristic to the individual that will *never* occur on an individual level. The fact is that if the person survives during the period of time, its probability of dying will be 0, and if the person does die, it will be 1; it will never be equal to 0.083. An individual probability cannot be estimated unless there are at least two individuals; we then apply to the individual a probability calculated for the group by assuming that the population is homogeneous in relation to the risk of dying. This is the basic principle of life insurance, enabling a measure taken on the population to be transposed to a specific individual.[3]

Another example of the differences between a population and an individual relates to the fact that a person may age comparatively quickly or slowly, but can never get younger. The *arrow of time*, as philoso-

[2] We generally talk of natality in relation to a population, and fertility for individuals of childbearing age.

[3] This principle depends on the concept of probability itself. Do we assume that a probability is the result of a series of identical experiences, where events are repeated in the same conditions (a barely tenable position for human events), or do we instead consider that probability expresses the degree of certainty about the truth of a proposal in the light of the available information? This second "Bayesian" approach seems to correspond more closely to the needs of demography.

phers call it, is a one-way street.[4] But a population can get younger if the birth rate rises. In this case, the proportion of young people in the population will rise (to the detriment of the other age groups) and the mean age of the population will fall. So a population may rejuvenate following a rise in the birth rate even if individual life spans lengthen. Conversely, populations have historically aged as a result of declining fertility and not because the mean life span of individuals increased.

A population is a point-in-time cross-section of a multitude of individual life paths. In a given period of time, people are added to this population through birth and immigration, while others die or emigrate. The total population will increase or decrease as a result of these events. To properly understand the period change in the population, therefore, we need to know how many people were born in the period under review, how many died, and how many emigrated or immigrated (as will be seen in more detail in Chapter 3). The cross-sectional *demographic structure*, therefore, will depend on the characteristics of the individuals comprising the population at that time (e.g., their age, marital status, gender, etc.). *Population change* will result from the number of births, deaths, emigrations, and immigrations occurring in that population during a period of time.

There is an infinite variety of possible demographic structures according to the number of characteristics selected. Individuals do not differ only by age or marital status; they also differ in dietary patterns, musical tastes, hair and eye color, and so forth. Not all of these characteristics and associated structures are useful to demography; only those characteristics capable of affecting population change must be taken into account. So, fertility, mortality, and migration vary with the individual's age, sex, and marital status; but educational level and social or ethnic group often affect an individual's fertility or life span too. On the other hand, a love of tulips or Sibelius symphonies probably has no impact on the components of population change, although these characteristics may be more specifically *associated* with certain social or ethnic groups. Any putative correlation between a passion for tulips and individual fertility would probably be spurious, therefore, and would almost certainly be eliminated by controlling for the social or ethnic group.

Generally, for an individual characteristic to be meaningful for demographic purposes, it must be individually discrete and affect at least one of the components of population change, after controlling for potential common causes. For example, individuals differ in age, and age influences fertility, mortality, and migration. The same applies to gender and many other variables. By contrast, musical tastes may vary from individual to individual, but do not influence population change; any correlation will be eliminated by controlling for *confounding variables* such as social status. Musical tastes may interest sociologists and musicologists, but are utterly irrelevant to demography.

Demographic behavior (i.e., giving birth to a child and dying or migrating within or outside of the area concerned) is clearly an individual characteristic. The aggregation of these events is what produces population and structural changes. The causes of these types of behavior may be physiologic. Sexual desire is important for the reproduction of the species; death is probably imprinted in our genes. Most behavior, however, is learned during life or childhood (i.e., it stems from factors related to the individual's past, family and social environment, and culture). Even gender may depend on assignment and upbringing, such as whether parents and peers treat the child as a boy or girl. This individual gender identification may even lead to pseudo-hermaphroditism (Fantino and Reynolds, 1975). The decisions to get married, have children, and/or migrate are very much dictated by learned behavior, parental and peer influence, social membership, and group culture. Dietary patterns, which have a significant influence on health and survival, are also largely culturally determined, as lovers of snails or frogs' legs will testify! Smoking and drinking, two major causes of death, are also socially conditioned.

Thus, inquiring into the possible causes of demographic behavior means going beyond individual factors and looking at the human being as a member of a household, family, social category, ethnic group, and so forth. In recent years, targeted surveys have enabled demography to sharpen its focus not just on individual characteristics (age, sex, education, etc.) that influence demographic behavior, but also on the multilayered aspects of demographic change stemming from the individual's membership of different networks of groups and institutions.[5] The subject of demographic research, therefore, is the individual *and* the society in which he or she lives. Explanations focused just on individual behavior, like the rational behavior of economic agents beloved of economists, cannot encompass the broad spectrum of influences

[4] Although some philosophers consider the forward march of time to be only a subjective characteristic of life as lived, and not an objective reality; they would argue that time stands still (see, for example, Michael Tooley, 1997).

[5] See D. Courgeau (1996).

and incentives that rule human needs and motives; the same would apply to a purely macrodemographic explanation (see, e.g., de Bruijn, 1999).

As will be seen throughout this book, demographic explanations and theories are increasingly incorporating the social value systems and factors that predicate demographic behavior. This is not to say, however, that all individuals act in an identical manner; even in very homogeneous societies, some individuals adopt nonconformist attitudes and styles of behavior. So, some couples in a low-fertility country may have large families, just as some couples may practice contraception in countries where fertility is highly valued. Nevertheless, behavior in most societies is sufficiently homogeneous for aggregated measurements like life expectancy and average parity to be meaningful.

V. DEMOGRAPHY AND SOCIETY: THE GREAT CHALLENGES

Demographers, therefore, cannot rely only on demographic variables to describe and explain population dynamics. Their conceptual framework must necessarily accommodate all individual and collective factors likely to influence the demographic processes of the individuals—and hence the population—studied.

Recent developments in the field are intertwined with the broader changes wrought to knowledge and practice in all the social sciences by turn-of-the-century political, economic, social, and demographic developments. Society today is in the throes of rapid change, which is affecting some geographic areas and population groups more than others and creating new (social, economic, and demographic) divides or reviving old inequalities. As a result of the rapid pace of social and cultural changes, major technologic advances, the growing power of the market economy, the decline of the welfare state, globalization, adaptability to new situations differs from one population to the other, even within countries, according to their cultures, access to new technologies, and, of course, economic performances. In almost every case, the strongest win out over the weakest. As a result, the gap—including the demographic gap—between the leaders and the laggards is widening. These processes have aggravated the world north/south split, just as economic globalization has widened the welfare divide between an increasingly developed north and the different components of an increasingly riven South. The most dynamic southern countries, which are also those with the earliest onset demographic transitions, have managed to make the best of the situation, and even compete with northern countries, whereas others, resource-starved and still tackling the consequences of overrapid population growth, are sinking deeper into crisis.

Population trends in the wealthy countries could become a new source of concern. The received wisdom that the sweeping historical change represented by demographic transition—the shift from high levels of fertility and mortality to the low levels attained between the two world wars—would be followed by a situation of equilibrium—near-zero growth and unchanging structures—seems not to have to been borne out in reality. Far from stabilizing, the distribution of the population between its three large components that typify the individual life cycle—childhood, adulthood, and old age—seems more fluid now than ever. In the classic posttransition scenario, the population aging that is inherent to the change from pre- to posttransitional stages could have stayed within reasonable enough limits to require only tinkering at the edges with the social systems established over the century; but the collapse of fertility levels and the unexpected decline in mortality among the oldest old is distancing the situation from the accepted model. Furthermore, short-term cyclical reasons have created an unprecedented accumulated potential among northern populations for the demographic aging process to accelerate. Basically, the working age populations have so far remained virtually stable thanks to the size of the post–World War II *baby boom;* before long, however, these large numbers of cohorts will reach retirement age, while the working population dwindles as the less populous cohorts reach working age.

It is easy to predict when the two waves of baby boomers—immediately postwar and the 1960s—will leave the labor force. With retirement ages of 60 or 65, the first wave will start exiting around 2005 to 2010, the second around 2025 to 2035. Logically, this will put immense pressure on health and social protection systems. Here, the veritable revolution in health care brought about by major advances in treatment and prevention, which give most people with degenerative diseases or cancer a longer life expectancy than before, must be taken into account. The possibilities of survival amongst the oldest old are expected to increase considerably in the coming decades, because today's older people—and the next generation even more so—are (or will be) of the generations that have drawn far more of the positive benefits of welfare than their predecessors: proper diet, improved quality of life, occupational health and safety, cultural development, and, especially, the goods and services necessary to stay in good physical and mental shape until entering the oldest age group. The increased number, and especially proportion, of the old elderly, however, will begin to push up not only social protection but also health costs: the prevention and treatment of chronic and degenerative diseases, assistance for disabled people, and, more generally, care for very old people with physical and mental disabilities. So, demographic analysis must accommodate not only declining mortality and lengthening life expectancy, but also the development of different disease patterns and morbid conditions affecting the population.

Entrenched very low fertility also has a major bearing on the increase in the proportion of old people. Basically, where the top of the population pyramid gets wider under the effect of increased longevity, the bottom part narrows each year with the declining birth rate. Furthermore, that low fertility is itself the result of shrinking generations, because women born after the baby boom and falling birthrate are now the child-bearing-age generation: Even supposing an average parity equal to that of their mothers, these women would produce fewer children in total than preceding generations. Fertility decline thus creates a dual cause of the falling birthrate. Were this knock-on effect to continue, it would produce an inescapable decline in the total population. Although immigration might provide a stopgap solution, only a significant rise in fertility can halt the process in the long term. The steadier the decrease in the youngest cohorts entering at the bottom of the pyramid, the harder it will be to turn the situation around and the longer any possible resurgence in fertility will take to restore age structure balance in the population. But it is far from certain that any such turnaround in the situation is imminent, so greatly does it depend on the position of women in society and, more generally, children's place in their scale of priorities.

Historically, women's lives were taken up with bearing and raising children; now, these activities occupy only a small part of their lives: More women work, leaving the labor force only for short periods (confinement and delivery), and have many fewer births, being more intent on pursuing their careers in historically male jobs. The world of work has not yet fully adjusted to the growing number of women, which is a competitive handicap to those trying to balance work and motherhood because job characteristics (working time and procedures) and promotion prospects are still patterned on male lifestyles. In many areas, therefore, career opportunities are dictated by the early years of working life and generally fixed around 30 years, just the age at which personal and family choices—partners and family size—are played out. Basically, women today want financial independence and a professional career and spend most of their youthful years in education and establishing a foothold in working life, which means deferring or abandoning plans to start a family. Obviously, until such time as work and fertility can be fully reconciled, women will almost always choose the former over the latter.

Overlaying this are the consequences of changing family patterns. Demographic transition evidenced a shift from the patriarchal family to the nuclear family; but far from being a foundation of permanent stability, the latter is now being called into question in turn by marriage break ups and new living arrangements. Rising divorce and separation rates are almost automatically increasing the proportion of lone, often marginalized, mothers. This severing of parental bonds has affected the postwar generations, especially the baby boomers (i.e., those who will soon be adding to the oldest age group). Rising insecurity related to the loosening of traditional ties of solidarity, places new demands on social protection, which could further undermine existing systems. Failure to address this new situation may hinder a return to demographic balance, as the fear of marriage breakdown may depress fertility. All in all, the only-child option, perhaps combined with deferred childbirth or even voluntary infertility, could well become an established societal norm with a series of repercussions on the future population dynamic.

This concern about the demographic future of the developed world may seem out of place, given the magnitude of the problems pulling in opposite directions today within many developing countries. Yet it appears likely that the globalization of demographic processes will turn it into the key issue for all humankind within the next few decades. However, this must not eclipse the fact that a significant proportion of the world's population will still have to contend with the problems of rapid population growth for some decades to come.

The completion of the demographic transition, foreshadowed and confirmed by each new United Nations (UN) population projection for the past 20 years, is naturally a great relief compared with the acute fears aroused less by the UN's late-1950s forecast of 6 billion people by 2000 and the resultant rash of far-fetched extrapolations made beyond that date. Right as it may be to condemn the overblown rhetoric of the past that sought to stigmatize rising births in the developing world as irresponsible or support the introduction of fertility regulation policies, it is equally important now to consider that although the impending end of the demographic transition is proof positive of the groundlessness of some past fears, many crucial problems remain to be solved.

With 6 billion men and women in 2000, the hardest part may seem to be over. We have gone from 2.5 to 6 billion in 50 years and have still to go from 6 to 9.5 in the next 50 years. We have therefore experienced an increase of 3.5 billion in a half-century, from a starting point of 2.5—a 140% rise—while the 3.5 billion still to come, also in a half-century, is a mere 60% increase over the current 6 billion! Granted, but two problems still remain. One is that the results to date are hardly impressive: 20% of the world's population has 80% of its income, while the overwhelming majority share the crumbs that remain. This is not a matter for pride, especially given the very unequal division of that remainder. Poor countries increasingly have to be divided between genuinely developing countries and very poor countries whose extremely fragile economies are on the brink of collapse.

Above all, however, a large share of the 3.5 billion people added in the last 50 years accreted directly to developed countries with growing populations (especially North America and the former Union of Soviet Socialist Republics [USSR]) while the bulk of that in the south was added by the most dynamic countries or regions (China, Southeast Asia, Latin America). By contrast, the next 3.5 billion will be almost entirely added to the world's poorest countries or areas, especially in sub-Saharan Africa and some South Asian countries. Setting this further increase against the current total population of the regions most affected (under 2 billion), we get a real growth figure of nearly 200%. However, not only are these countries the world's poorest, but unlike most of Asia or Latin America whose highest population growth came during the "30 boom years," today's poorest countries will incur theirs in adverse international economic conditions (Vallin, 2000).

Arguably, there is every reason for consigning to history what in fact we should never have feared, but there is now all the more reason to look seriously at what, all rhetoric aside, we have consistently put off to later: the economic and social development of the poorest regions. This remains a live and very urgent issue, like finding environmentally sound development models that respect the broad balance of nature on the planet.

VI. FUTURE POPULATION DYNAMICS

It is a racing certainty that once this exceptional growth period has peaked, all the world's populations will more or less attain a mortality—fertility equilibrium in the near or relatively near future. However, there are no guarantees that it will remain stable. What is most likely is that the end of the great historical process dubbed "demographic transition" will also see the end of the like-named paradigm.

Barely had the UN ventured to produce its fine simulation of a general stabilization of the world population based on the transition theory in the early 1980s than the fault lines began to show everywhere. Less because of its failure to predict the acquired immunodeficiency syndrome (AIDS) epidemic in Africa or the health crisis in Eastern Europe (which, however appalling, are finally just adverse developments that cast no doubt on the fundamentals of the model) than because of the growing body of evidence that "the end of the transition" will be anything but that expected. The postwar baby boom experience should have sounded the alarm bells, but the fact is that World War II upset so many apple carts that it might be reasonably thought to be only an interlude in the unfurling of an inevitable historical process. And that is how it was seen.

But, how could it be thought that declining mortality and fertility, the period of exceptional growth due to the time lag between the two, and the resulting upheaval in age structures, would end up in a period of general stability? How could it be thought that after the storm would come the eternal, untroubled calm on nothing more than the belief that life expectancy at birth would never extend beyond 85 and that fertility would inevitably level off at 2.1 children per woman? There was nothing, absolutely nothing, to suggest that it would be this way. To the contrary, all the signs today are that things could go very differently. Sadly, there is no new paradigm, model, or theory with which to accommodate not the end of the demographic transition, but its expected consequences. All that can be done when imagining the long-term future, therefore, is to devise possible alternative scenarios for fertility and mortality and their expected consequences for the total population and age structures. Admittedly, it can be done on the basis of currently observable facts, but the future import of those we cannot tell.

As to fertility, first, two facts give pause for thought. First, in a number of northern countries, the total fertility rate has been significantly below the replacement level of 2.1 children per woman for the past 20 years. In some, it has even been far below: 1.3 in Germany, Italy, and Spain, for example, and even 0.8 in Northern Italy! Second, mean age at childbirth is rising significantly. These two facts may not be unrelated. It could readily be assumed that a late first birth would reduce period fertility to very low levels simply as the combined result of very low fertility among women who completed their fertility when younger and the continuing very low fertility among younger women who are putting off motherhood. Overall lifetime fertility aspirations may be unchanged, but, in these conditions, period fertility could actually fall to very low levels at least for a certain time. Obviously, it may equally well be that what has really changed is desired family size.

On the basis of these different possible interpretations of the changes in progress, one chapter of this treatise will seek to explore various fertility trend scenarios that combine assumptions about level (from a return to replacement level to the only-child model) and timing (early or late, with one or two key family formation periods).

Still on the basis of current facts, questions arise about the lasting quality of a parameter that demographers have in the past always taken as stable—the sex ratio at birth. It is a universal fact that until very recently the number of male births was always slightly above female births (105 males to 100 females), with excess male mortality redressing the balance at childbearing age. Now, in some societies where male preference is particularly strong, this successful balance is being seriously undermined by antenatal gender diagnosis and the possibility of selective abortion. In some parts of India and China, the sex ratio at birth has now risen to 120, 150, and above. What would be the result of a long-term spread of such behavior?

But fertility is not the only question mark for the future. Contrary to expectations, the future of average duration of life is little more certain than that of fertility. Disregard the possibility of humankind being simply wiped out by a nuclear war, or an epidemic even worse than AIDS is proving for Africa. Leave to the gloom merchants the idea that life expectancy could fall on a long-term basis worldwide as it recently has in the Eastern European countries. The game still remains wide open. There are, in fact, two theories today setting biologists and demographers at odds with one another.

The first says that we are fast approaching the absolute limit of human longevity. Having raised life expectancy from 25 in the 18th century to 80 years now, all we have done is to bring the average (life expectancy) closer to the maximum possible life span (longevity). Only the former is susceptible to change, while the latter is irreversibly fixed by the initial life potential written in our genes. It is clear that the closer one gets to the maximum, the harder it is to raise the average. Furthermore, because of the variations in individual gene pools, the upper limit itself varies widely between individuals, and the absolute record recently set by Jeanne Calment, who died in 1997 slightly older than 122 years, is just that—a record (i.e., a score that only a tiny number of individuals will ever be able to match). This line of reasoning has led biologists like James Fries (1982) and demographers like Jay Olshanski (1990) to conclude that it is virtually impossible for life expectancy to exceed 85 years. This, indeed, is the underlying assumption of the most recent UN projections.

There is, however, another theory that human longevity is not immutable. First, we have no evidence that it has not increased in the past. Methuselah aside, anecdotal evidence of extreme longevity is not uncommon in historical records, but singularly lacking in hard proof (Vaupel and Jeune, 1994). No proof has ever been produced of any man or woman before Jeanne Calment attaining the age of 120 (Allard *et al*., 1994). However, there is a well-established tendency in almost all societies to exaggerate the age of very old people. By contrast, there is circumstantial evidence that human longevity may have increased in recent decades (Robine *et al*., 1997). The highest age at death has risen each year in the most advanced countries over the past 40 years (Wilmoth and Lundström, 1996). Also, since the 1970s, mortality among the oldest age groups (over 75 years), which had been relatively stable suddenly, began to recede (Kannisto, 1994, 1996; Meslé and Vallin, 1998). Finally, some biologists, like Roy Walford (1984), for example, believe that we are on the threshold of effectively delaying the human aging process. If so, anything becomes possible.

Without going as far as André Klarsfeld and Frédéric Revah (1999) with their suggestion that immortality does not exist, not because of biologic imperatives, as had always been thought in the past, but simply because serving no biologic purpose, it did not evolve, should we not, for example, admit the plausibility of Roy Walford's proposition that life expectancies of up to 150 years should not be beyond imagining in the 21st century? What effect would that have on populations?

All these scenarios would obviously have very different consequences in terms of total populations and demographic structures. The world population, for example, could just as easily continue to grow rapidly after 2050 or collapse to pre-Neolithic levels with the risk of being wiped out altogether. Alternatively, "reasonable" aging leading, for example, to 30% of the population aged over 60 is just as likely as a radical upheaval in age—sex structures going far beyond even the most radical predictions so far: Life expectancy of 150 years and a single-child family trend could, for example, produce a population with only 2% of "young people" (younger than 20 years) and 7% of "adults" (aged 20 to 60 years), but 91% of people older than 60 years and 74% older than 100 years! Obviously, the descriptions young person, adult, and old person could not then be applied to the same age groups as today. Regardless, given the difficulties we now have contemplating the prospect of living tomorrow (in 2050) in a society where at least 30% and perhaps even 40% of the population will be older than 60 years, how can we envisage a world where three fourths of the people will be centenarians? It is easy for demographers to make population forecasts, but it is much harder to envision the kind of society that they would produce. Sociologists, psychologists, economists, and political scientists would also have to think hard! Much will depend on their respective abilities to communicate and create synergies of knowledge. In any event, the size of the challenges, the complexity of development factors, and the still largely uncharted possible consequences require a new demography with a broad cultural focus capable of addressing issues holistically. The next stage will probably see new developments increasingly tracked through in-depth surveys that pave the way for research into the linkages between socioeconomic and environmental changes and the demographic—and even biologic—components of the population and the development of a framework of theories and assumptions capable of connecting all the components of demographic thought and experience with those of life as it is lived in an overall approach. For that to happen, demographers will obviously have to be more skilled in combining macroanalysis with microanalysis, moving from the forensic analysis of types of behavior and their determinants to interpreting them at the holistic level of the complex systems in which we live.

In relation to the state of the art in methods and knowledge, this view of demography lies more in the realms of science fiction than today's realities. At the very outside, it may perhaps be incipient. This book, therefore, does not seek to offer its readers what does not yet exist. Its aim is less lofty: to report on what does exist, pointing up the consistencies but also the emerging inconsistencies that may foreshadow the future shape of our discipline.

GENERAL LAYOUT

This treatise on demography comprises four volumes. This volume, the *first* in the series, falls into two sections. Section I discusses population dynamics and focuses on the essence of demography: the analysis of the components of population change related to changes in total population and age–sex structure. It falls into five parts, themselves directed by the overall approach taken in this treatise progressing from analysis to synthesis. Part one covers population growth, with an initial overall view of the principles of population dynamics. Part two is given over to the analysis of the three specific components of population change (fertility, mortality, migration) in the context of the life experiences of cohorts. In part three, the measurements made are reconstituted as period indicators to track demographic trends. This paves the way for an initial synthesis followed, in part four, by the construction of population models. Part five looks at ways in which to take account of the dependency between demographic phenomena and of population heterogeneity.

The following chapters analyse the factors of each of the three building blocks of population change: fertility, mortality, and migration. There are separate parts of each component, where the different types of factors (biological, socioeconomic, cultural) and levels of explanation (baseline variables and intermediate variables, theories, frameworks, and explanations) are addressed. The determinants of fertility are covered in Section II of Volume I, while those of mortality and migration are successively discussed in the two sections of Volume II.

The first section of Volume III addresses the history and consequences of demographic change, i.e., the history and geography of human settlement but also population forecasts. Section II considers the consequences of demographic changes in the biological and health fields, in the socioeconomic and cultural ones, on development, and on the environment.

The fourth and final volume covers, in Section I, population theories and doctrines and population policies. Section II falls into three parts and considers observation systems, auxiliary methods in demography, and the history and teaching of demography.

POPULATION DYNAMICS

Introduction

GRAZIELLA CASELLI AND JACQUES VALLIN

In statistical terms, a population is a set of individuals defined by the same criteria but possessing various values for different attributes. A population can also be considered at all times as consisting of *groups* of individuals possessing the same value for given attributes. The main characterization of a population, therefore, is its size (the number of individuals comprising it) and its composition (the frequencies of the various values attaching to the attributes). On the face of it, this clearly applies to human populations, which are the subject of demography. However, human populations are not frozen in time but are in a state of constant change. Demographic analysis primarily studies the underlying mechanisms of that change (i.e., to understand *population dynamics*).

A first characteristic of the dynamics of a population is its capacity to increase or decrease at a certain rate. For that reason, part one of this section looks at *population growth*. Chapter 1 looks in more detail at what demographers mean by populations and individuals; Chapter 2 considers the dynamic nature of human populations, whereas Chapter 3 examines how population growth depends upon its natural (birth and death) and migratory components. These three short introductory chapters lead on to a problem analyzed in Chapter 4: The fact that the mechanisms of growth cannot be understood independently of the age-and-sex structure of a population. Population movement and structure are inseparable: not only is population structure constantly altered by changing fertility, mortality, or migration patterns, but structural changes themselves influence how these factors of change are reflected in the population growth rate.

To understand this interaction, we must first look more closely at each component of change. The approach taken to do that, the *longitudinal approach*, which is the subject of part two, may initially seem to be leading away from the strict definition of a population, but is nevertheless central to demographic analysis. Each phenomenon (fertility, mortality, migration) will be considered as it is actually experienced by the individuals during their life cycle. So, a benchmark set of individuals born in the same year (a *birth cohort*) will be taken to describe their age-specific mortality from observed deaths in that cohort or a cohort of women to profile their age-specific fertility based on successive childbirths. This somewhat extended section will fall into nine chapters: the first discussing the baseline data (Chapter 5), ways of accounting for them (Chapters 6 and 7), and the theoretical and practical bases of measurement (Chapters 8, 9 and 10). The three final chapters will analyze in detail each of the three components of change: mortality (Chapter 11), fertility (Chapter 12), and migration (Chapter 13).

Although the longitudinal approach can accurately describe the components of change and their underlying trend, it cannot account for year-over-year observable changes in a population. Demographers commonly do this by *period* analysis on the basis of the idea of a *hypothetical cohort*. Instead of describing lifelong mortality, fertility, and migration in a real birth cohort, a hypothetical cohort is designed, and its age-specific death, fertility, and migration rates are calculated for the same single calendar year. This is done at the beginning of part three (Chapter 14). *Standardization methods* will then be used to compare total or synthetic indicators (Chapter 15) and perform age-specific and total differential analyses (Chapter 16). The following two chapters will examine the varying degrees of linkage between period and cohort analyses: *translation models* (Chapter 17), and *APC (age-period-cohort) models* (Chapter 18).

Using this array of instruments to analyze population change, part four *consolidates dynamics and structure*. This is done in two chapters in which *population replacement* (Chapter 19) and *population models* (Chapter 20) are discussed. These will show that, in the final analysis, population structure is entirely determined by the history of its changes, because although structure has a strong duration-specific influence on change, it progressively forgets its past.

In order to analyze the fundamental mechanisms of population dynamics, the realities have had to be oversimplified through two basic working assumptions: (1) all the individuals in a population are, if not identical, at least exposed to the same mortality, fertility, and migration risks, and (2) the probabilities of dying, procreating, and migrating are completely independent events. This is obviously not the case in real life. So the analysis needs to be fine-tuned in order to clarify exactly how the *heterogeneity of a population* can distort the measurement of natural (Chapter 21) and migratory (Chapter 22) changes. We will then consider how to go beyond the independence assumption (Chapter 23). It will quickly be seen that the *life history analysis* used to account for interaction of events has to consider multiple possible levels of aggregation, leading to *multilevel analysis* (Chapter 24). This will be a major step toward understanding demographic phenomena, and the approach to the determinants of change, which will be looked at in Section two of this volume and in Volume II.

I

POPULATION GROWTH

CHAPTER

1

Populations and Individuals

JACQUES VALLIN

Institut national d'études démographiques (INED), Paris, France

To a parent's eyes, a newborn baby, especially a firstborn, looks like no other. Genetic science bears out that conviction: The probability of two (nontwin) human beings being identical is vanishingly small, close to zero. And genetics is not all! What goes for the formation of a person's genotype doubtless goes double for personalities—neither psychologists nor ethnologists would take issue with that. Yet, demography basically invites us to disregard these differences. Individuals can only be counted and turned into statistics by working on the assumption that they are all the same.

I. NUMBER AND COMPOSITION

Essentially, demography is simply the *statistical study of human populations*.[1] In statistical terms, a population is basically a group of individuals who fulfill a definition. The population of France, for example, is everyone living in France, regardless of gender, nationality, religion, skin, or eye color. We can look at this set of people in two different ways: size and composition. In the former, they are simply counted, disregarding any attributes that may differentiate one individual from another. The 1999 census, for example, recorded 58,518,748 people living in Metropolitan France; each of these—regardless of age, size, weight, intelligence, and so forth—counts for one and one only. With typical black humor, the cartoonist Reiser[2] thought the world leper population—estimated at the time by the World Health Organization (WHO) as 14 million—would be more accurately assessed by discounting the hands, arms, feet, or legs rotted off by this dreadful disease, which he calculated would reduce the number of lepers to an estimated 12 million. Not so, however! The size of any population is always and only the total number of its constituent individuals, however great the individual differences between them may be.

From the latter angle—composition—differences between individuals are clearly relevant. And yet, the principle remains unchanged. To determine the distribution of the population according a specific attribute or characteristic, *classes* are created to which all the individuals with the same definition, the same statistical *value*, for that attribute are assigned and a frequency table is constructed for the different values assumed by the *attribute* studied. Suppose that we wish to study eye color in the American population and assign four values to the attribute *eye color*: blue, green, chestnut brown, and black. The inhabitants of the American continent will be assigned to one of four classes according to these values and the number of individuals listed in the corresponding class, disregarding all other attributes, will give the frequency of each value. In fact, what we have done is to distinguish, within the American population, four *subpopu-*

[1] So defined by Achille Guillard, who first coined the word demography for the title of his book: *Éléments de statisque humaine ou démographie comparée* (Paris: Guillaumin, 1855).

[2] Jean-Marc Reiser. La léproserie du dimanche. In: *Les Copines.* Paris: Albin Michel, 1981:20.

lations by reference to eye color and measured their size in exactly the same way as the size of the French population was measured in the 1999 census. There is no essential difference between measuring the frequency of each of the four eye colors in this way and the more usual method of counting the population of each state making up the United States. Only the attribute definition changes.

Clearly, many other attributes of varying degrees of complexity may be observed. The most basic of these is obviously gender, for which there can be only two values (male or female). Others, by contrast (e.g., occupation, birthplace), lend themselves to a vast or even unlimited number of values, where continuous variables like age, weight, size, and so forth are concerned. Distributions that intersect multiple attributes may be studied. Cross-studying sex and age, for example, allows us to produce, as we will see in a subsequent chapter (see Chapter 4), a population pyramid that offers many insights not just into a population's demographic history and predicted development, but also on a host of societal issues such as school, work, health, and so forth. We can take this further and cross-study three, four, five . . . *n* variables. The principle will always be the same—statistically, the individuals will be grouped within a single definition to constitute a population or to distinguish multiple subpopulations within the population. All individuals who satisfy this definition are presumed identical, and so available for being counted and computed, although the heterogeneity of the groups so formed may have to be factored in at a more advanced stage of the analysis.

It is clear that by cross-studying a sufficient number of variables, each containing a sufficient number of classes, we could arrive at a subpopulation of one individual. However, it is equally clear that this will not account for the extreme variations between the individuals who make up humankind (from a purely genetic point of view, the possible number of combinations is infinitely greater than the number of individuals currently alive in the world), but this would have taken us beyond the reach of statistical reasoning (and demographic analysis), which is essentially based on the law of large numbers.

II. SIZE, COMPOSITION, AND DYNAMICS: STATE AND CHANGE

What does demography offer us beyond statistics? Each of the previously described aspects (size and composition) can be approached from two angles: state (What is its size and composition at a given moment in time?) and dynamics (How is it and its components changing and what are the driving forces of those changes?). Demography really starts with the second question.

Admittedly, all literature on methods and materials of demography take as their subject size, composition, and dynamics (state *and* change). But demography would not have been needed simply to measure the distribution of a population between its various constituent categories defined by attributes or characteristics to be studied on the basis of census data or sample surveys. The techniques of descriptive statistics were more than enough for that. Analyzing population change and understanding its mechanisms gave rise to a specific body of methods. That said, the study of change might aim to describe a state in situations where the latter is not directly observable. This, indeed, is the origin of demography. Before censuses became a matter of administrative routine and a reliable source of demographic information, there was no easy way to determine even the total population size of a country or province. Our forefathers believed that, under the dominion of the laws of God and nature, whose purpose was to ensure the proper balance between births and deaths, population sizes varied little if at all. Accordingly, they thought that the tangible embodiment of those laws—baptismal and burial registers—was enough to estimate the population and its principal components. Demography, therefore, originated in the myth of population stability and now enables us to comprehend its dynamics. However, other situations exist in which the analysis of change aims to describe a nonobservable state. For example, attempts to forecast the size and composition of the population 10, 20, or 30 or more years hence. The same process is often applied in a bid to reconstitute past populations. Conversely, as will be seen, the development factors of a population during a given period of its history are closely tied to certain aspects of its initial composition. Without change, therefore, demography, would not exist but state *and* movement are central to the analysis.

This kills two birds with one stone. First, regardless of whether all or each discrete component is concerned, the central overarching question that minimizes individual differences will always be the following: How does the size of a population subject to perpetual change through the entries and exits of the individuals comprising that population increase, decrease, or remain stable? But, because entries and exits may be partly dependent on the population composition, it is not enough to say that what is true of the whole population (of France or America, for example) is also true of its components (the blue-eyed subpopulation, women, senior managers, for example). Not only are entries and exits not necessarily of the same nature among subpopulations as in the whole population (one is *born* a woman, one *becomes* a senior manager), but also change in the whole may be dictated by certain elements of its composition. This means distinguishing those constituent elements that are decisive to the future of the total population, and hence essential to demographic analysis, from those that predicate only that of the subgroups. Thus, it will readily be imagined that gender distribution may play an essential role in the population dynamic because there can be no births (the most ordinary *entry* route into a population) without women. By contrast, the proportion of blue-eyed individuals will have no influence and probably interest the genetic scientist more than the demographer. Between these two extremes, some individual characteristics may play an intermediate role. Arguably, for example, the proportion of senior managers is chiefly of interest only to sociologists and economists. But if senior managers were to have a longer survival rate than others, they would *exit* later. Their share would influence total population development. In other words, we cannot stay at the highest level of aggregation indefinitely.

2

Population: Replacement and Change

JACQUES VALLIN

Institut national d'études démographiques (INED), Paris, France

In the previous chapter we defined the field of demographic analysis as the study of a human group made up of people corresponding to the same definition, whether it be according to the criterion most commonly used in identifying a population (people residing in a given territory) or to any other criterion making it possible to distinguish, within such populations, subpopulations made up of people sharing a specific characteristic (blue eyes, male sex, manager, residing in a town, etc.). We have also chosen population *movement* or change as the main subject of this analysis. This does not only concern human demography. The statistical approach, in the more general sense of the word, usually concerns populations made up of transient individuals who are continuously replaced through a process of entries and departures, which may, at the same time, change their dimension or modify their composition. According to the nature of populations, however, two types of processes may come into play: those which ensure replacement in an endogenous manner, without calling upon outside help from a neighbouring population (by bringing in new individuals or by exporting excess numbers of individuals), and those, which on the contrary, rely on exogenous exchanges with other populations.

The most common way of maintaining a supply of objects, whatever their nature, is to draw from outside reserves of new individuals and to reject those which have become undesirable. Thus, the grains in a pile of sand which a mason uses to make his cement will be continuously replaced by regular deliveries from outside to make up for the sand used in his work. In the case of goods produced by human beings, instead of drawing on natural reserves one may produce new objects to increase the collection or replace the items that have become undesirable. The production source, however, is not the collection itself, but an outside manufacturer. This is an example of exogenous replacement.

The living world, to which human populations belong, has the capacity for endogenous replacement which, on the contrary, enables a population to engender new individuals itself. However, the individuals in question are mortal and can also leave the population without adding to the ranks of another population.

One of the fundamental aspects of demography, in the wider sense of the term, is that it has to deal with complex modes of replacement associating endogenous and exogenous processes. More precisely though, demography, which deals with human populations, has developed according to the characteristics of this dual process as it occurs among human beings. In fact, in human societies, as in other forms of societies, these replacement processes are subject to constraints imposed by the environment and biology; they are also, to a great extent, controlled by mankind which has managed to create for itself a certain amount of room to maneuver, allowing the expression and influence of individual or collective decisions. And this is the case in both endogenous and exogenous processes.

I. EXOGENOUS REPLACEMENT: ENTRIES AND EXITS BY MIGRATION

The most common definition concerning a population in demography, and which also gives the most meaning to the discipline, is that of a group of individuals residing within the limits of a territory endowed with a social significance. And among the different types of socially organized territories, national territories organized as States contain populations which, by definition, fall within the realm of demography. Upon this basis, the notion of exogenous replacement through entries into and exits from a territory (international migrations) is clear and relatively easy to define, even if certain clarifications remain necessary. By extension, the same principles may just as easily be applied to any other territorially defined population. However, most of the other populations falling within the field of human demography are also subject to an exogenous replacement process, even if the analogy with the entries and exits through a geographical border may seem a little tenuous.

1. National Borders: Migrations and Simple Visits

To define a population in the usual sense of the term (a group of people living within the boundaries of a socially organized territory) and whether or not entries and exits are exogenous, the notion of "living in a territory" needs to be clearly defined. Two notions are possible at this point. One may rely on the simple observation of a physical presence at a given moment in time and therefore all individuals in this territory at that time are considered as belonging to the population. In this case reference is generally made to a "*de facto population*." This might be, at least in appearance, the simplest solution. It would, however, be entering, in a way, in contradiction with the idea that the territory of reference is only interesting if it has a social significance attached to it, if the individuals in it are socially organized. Would it not be preferable to consider as a part of a population only those individuals who truly maintain social links which organize the population? In that case, visitors who find themselves at a given time in the territory and who have no permanent ties with its "*inhabitants*" and who maintain permanent social relations with another population should be excluded. One must therefore define what is meant by "inhabitant." Usually, reference is made to the notion of residence, of permanent place of residence, which generally relies on criteria of duration, sometimes associated with declarations of intention. But, if one only refers to "*permanent residents*", one must also include in the population being studied, permanent residents momentarily outside the territory. In this case reference is made to "*de jure population*" even if the definition of a permanent resident used for statistical purposes does not generally cover a legal category so to speak.

The evaluation of the exogenous replacement process of a population will of course be made according to the type of definition used for the population. If this concerns the de facto population of a territory, any crossing of the border must be considered to be a migration modifying the population. All entries, even those of outside visitors, will increase the size of the population whereas any exit, even for the shortest period of time, will reduce it. On the contrary, in the case of a de jure population, only changes of permanent residence will play a part in the replacement of the population.

2. Entries and Exits at Other Geographical Levels

The need to make a distinction between de facto and de jure population is also valid, and even more so, when the population is defined by another territory than the national territory, since the problems are then often more complex. The specially strong tie which links inhabitants from the same country usually leaves little room for any ambiguity concerning the notion of permanent residence (or at least, ambiguous cases are quite rare). The smaller the internal administrative area considered, the more migratory exchanges will become frequent, diverse and ambiguous: commuting or seasonal movements for work or studies, main residences and second homes, or even multi-residences, etc. So much so that the definition of de jure population, as well as that of migrations to be taken into account for evaluating exogenous replacement, becomes both difficult and necessary. In most cases, important political, social and legal issues are linked to the total size of the population and its variations. Demographic analysis should therefore be able to deal with de jure population as well as de facto population.

The notion of population as defined by a territory to which a social significance is attached may extend to physical entities that can be considered as part of a territory. A micro-demographic approach will, for example, take into consideration the population of a school, a company, or a hospital. The buildings concerned may then be considered as territories, and populations and migratory movements will be defined in relation to the walls of the buildings . . . But the notion of territory tends to give way to that of the status of the individual person. Individuals belong more to the population considered in terms of the functions they fulfil than in terms of their presence in the place, which in most cases is not permanent but lasts only for the time needed for the person to fulfil his or her function. In the same way, exogenous replacement of a given population may be evaluated more in terms of accession to a function or ending an activity than in terms of observed physical moves. It has more to do with migrations from one category to another than with moving from one place to another.

3. Generalization of the Notion of Migratory Entries and Exits: Extension to Non-territorial Populations

The notion of exogenous replacement through entries and exits extends therefore to the case of populations defined without any reference to a territory.

A first group of populations, the definition of which is largely if not totally independent from the notion of territory, concerns groups of people established on the basis of the family, the clan, the tribe, etc. In many traditional societies, especially in nomadic societies but also often among sedentary populations, the territory is not the main criteria of belonging. It is not even necessarily taken into account. Ties of kinship are the main factors for identifying the limits of a population, since it is on the basis of these ties that the society and its political life are built. It is thus not rare to find situations where—depending on geographical migrations, which in this case do not contribute to replacement—several populations, clearly defined socially and politically, overlap in a very complex manner in the same territory and, in spite of this, are perfectly distinguishable from one another. Such populations, in the same way as territorial populations, fall within the province of demographic research.

The contours of such populations having been established by definition according to ties of kinship, one might think that any idea of exogenous replacement by immigration should be excluded. This is not so. In fact, two factors of exogenous replacement must be taken into account: the exchange of women and processes of adoption. Except for the theoretical hypothesis of an entirely endogamous society totally closed to any outside influence, entry within (or exit from) such a population may occur through the acquisition or the loss of kinship ties. More generally, one may shift from the notion of the clan or of the tribe to that of the ethnic group and, without the notion of territory being primordial, define a population according to its belonging to an ethnic group mutually recognised by the people within it. One will therefore have to take into account for the demographic study of such populations their capacity for filling their ranks from external sources or on the contrary for reducing their numbers through changes in ethnic membership. Therefore, in all of these cases and despite all appearances, the criteria for belonging to a population do not exclude changes in membership of a group and therefore exogenous replacement, even though, of course, endogenous replacement remains prevalent.

The notion of populations based on membership of a category is also to be encountered in what may be termed as "*sector-related sub-populations*". From a demographic point of view, specific groups of individuals may be studied within a whole population corresponding to one of the earlier definitions, according to individual characteristics. Sex, for example, makes it possible to make a distinction between a male and a female population. Marital status, social category, level of education, etc. and, why not . . . the color of the eyes, provide criteria for making distinctions between subpopulations, the size, composition and dynamics of which one may wish to study exactly as if it were a population in its own right. This time, replacement will in most cases be essentially, if not entirely, exogenous.

The question of sex should be left aside as an attribute used in defining a population since it is too closely connected with reproduction to be considered as a case in kind. In all of the other cases, the criterion defining a population being an individual characteristic, one must in fact distinguish two possibilities. Either the characteristic is likely to change (marital status, level of education, socioeconomic category) and therefore the main replacement factor of the population will be a change of the characteristic in question, resulting in the individual moving from one category to another and therefore from one subpopulation to another. In this case therefore it is indeed a migration, which may be considered as similar to a geographical migration (change of status, social mobility, etc.). Or on the contrary, the attribute for a given individual cannot change (the color of the eyes) and the population will not be directly subjected to any exogenous replacement process. However, in every case, these sector-related subpopulations are indirectly subjected to the consequences of replacement flows, whether exogenous or endogenous, affecting the parent-population. Through the latter, the results of the conventional processes mentioned above may be observed. The special criterion used to isolate the subpopulation only adds, in certain cases, to a supplementary replacement process which may just as well be exogenous (marital status, for example) as endogenous if the characteristic is a support for a certain endogamy and may be transmitted to the following generation (nationality, religion, for example).

II. ENDOGENOUS REPLACEMENT: BIRTHS, DEATH

For populations defined by a territory in the strongest sense of the term (country, State) or by a clan, migration usually only plays a secondary role in the replacement process. This is essentially endogenous. Notable exceptions such as the Vatican and the Republic of Mount Athos only confirm the rule, since even if these entities are sovereign states, they more closely resemble subpopulations based on individual criteria rather than on subpopulations residing in a territory or belonging to an ethnic group. To a large degree, demographic reasoning is developed within the framework of "*closed populations*," which, although their use is often well-founded, remain purely theoretical since, as we have just seen, most populations are subject to exogenous replacement processes. In many cases not only does the endogenous replacement process dominate human population dynamics but also, and maybe above all, one of the essential characteristics of these populations—and no doubt the one which establishes demography as a discipline in its own right, distinct from statistics—is their endogenous capacity to reproduce.

1. Reproduction and Death

The capacity living people have of reproducing and giving birth to new living beings, similar to them and endowed with the same abilities, fundamentally distinguishes a population, as defined here, from any other collection of objects the replacement of which can only be ensured from the outside. The pile of sand mentioned earlier can only be supplemented by an outside source which itself depends on the (natural or artificial) transformation of larger rocks into grains of sand. The ability to reproduce, which is a characteristic of the living world, is at the heart of demographic analysis, directly associated with its corollary, death. The ability to procreate has as its counterpart the need to die. And in the same way that procreation is fundamentally different from migration or the modification of a characteristic which introduces a pre-existing individual within the population, death differs from the simple loss of an attribute or from emigration to another population since it makes individuals disappear without them being able to fill the ranks of any other population (except for the fictional one of cemeteries). On the contrary, the grain of sand which as it is worn down becomes too small to be of any use to the mason, thus losing its attribute of belonging to the group being studied, emigrates to another group (finer sand or dust). Thus prevalent in human populations as with all living species, is the endogenous replacement process based on reproduction and death, generating specific entry and exit flows which are generally described as *natural*.

Here again, however, a number of points need to be clarified concerning borders. Where exactly are these natural entries and exits to be situated? Concerning death there is only a little margin for hesitation. Doctors have indeed delayed in adopting a universal definition of death, in choosing a decisive symptom (the stopping of the heart obviously being insufficient), and in the past errors have indeed been made with people being buried alive. On the other hand, the discussion is closed in demographic terms: death is definitely the final event by which an individual exits a population.

On the contrary, can one be so sure that birth constitutes the point of entry? Human beings are mammals, the mother carries her offspring in her womb for nine months and can breastfeed them for two years. What is more, children only become adults after approximately fifteen years of life. When can a new human being thus created be considered to have "entered" the population? At his/her conception? After a certain time in the mother's womb? At his/her birth? When weaned? At puberty? The question may seem trivial since we are used to thinking of birth as the event marking the arrival of a new individual. Yet the point could be discussed. Let us suppose one is studying insects, butterflies, for example; egg, caterpillar, pupa, fully-formed insect: which stage marks the arrival of a new living being? The fully-formed insect is nothing more than a reproductive organ. The caterpillar has done all the work of accumulating the reserves needed to ensure the cycle of life is completed. Can one exclude such active individuals from the population? On the other hand, the pupal state closely resembles a new stage in the gestation of the insect (after that of the egg) making it possible to transform the larvae into a magnificent sexual subject. To which population should the entomologist demographer refer to? Should he exclude the eggs and the pupa because they are only beings in gestation? What strange populations in which each individual could die twice and live two lives!

But one must face the fact that for demographers, life only begins at birth. No doubt because what happens before has more to do with the mother's, or the couple's, sphere of influence than with that of society, although society has long denied the mother any choice in deciding whether or not to continue her pregnancy and the law sometimes attributes rights to the *infans conceptus*. However, let us consider once and for all that for the demographer, the point of entry is birth. Let us draw conclusions from this.

On the one hand, birth must be defined. And on the other hand, one must nevertheless study what happens before.

Although entry within a population occurs at birth, the distinction between who is alive and who is not must be made. A stillborn child can never be considered as having belonged to the population. But the law varies in different countries and may even change with time. In France, for example, only children who were alive at the moment when they were declared to the civil registrar are legally considered as born alive. This declaration must be made within three days following the birth of the child. A child may therefore, theoretically, have lived for nearly three days and never have legally belonged to the French population. The deadline of three days is theoretical since most declarations are made on the first day. However, a substantial number of children born alive and having died after a few hours are considered from a legal standpoint as stillborn. Statisticians and demographers are forced to make corrections in order to base their research on births and deaths.

Moreover, to decide to fix the entry within a population at birth does not in any way dispense the demographer from studying what preceded birth: conception, gestation, fetal morbidity and mortality, late fetal mortality, etc. But none of these aspects will be counted in terms of population. They will only be taken into account as being a part of the reproduction process.

The real future of the individual within the population only starts at birth, at age 0.

2. Age

Because of the very nature of the endogenous replacement process, of life and death, from the outset age presents itself as an unavoidable differentiating characteristic between individuals. One might, in fact, perfectly imagine populations to be in perpetual replacement through external exchanges totally independent from age, for the analysis of which the age reached by the individuals would be of no particular interest. On the contrary, with the endogenous replacement process, in a closed population, entry only occurs at age 0 and from then on starts a cycle of life which will command the expression of the capacity to reproduce and set off the natural process of elimination by death. Age soon appears as an indispensable variable for measuring and analyzing these natural entries and exits which are a part of population dynamics.

Age does not only determine the different phases in the life cycle: maturing of childhood leading to puberty and accession to the ability to reproduce, reproductive activity of the adult ages arriving at its term with the menopause, at least among women, biological ageing and wearing of the body, leading ultimately, naturally, to death, unless death occurs sooner because of external events. Age also determines, in counterpoint, the modes of integration of the individual within society: upbringing and education, productive activity, retirement, to mention only the major stages in life as they operate today in our modern societies. Not only is age the key to natural population dynamics but it is also at the heart of demographic, economic and social phenomena. And finally, simply because of its biological and social connections, age is also at the heart of migratory processes. We will clarify the different meanings of the term in Chapter 6.

3. Sex

Lastly, and we will see further on in this treatise at which point this complicates the analyst's task, human reproduction is sexual and sex is therefore a second fundamental variable. It should even be said that it is just as unavoidable as age. Regarding certain points which remain crucial, however, demographic science has so far only been able to skirt around the problems that this simple reality (two people of opposite sex are needed to create a third person) poses for demographers. This will appear clearly in Chapter 20 concerning population models.

Nevertheless, the numerical balance between the sexes will prove to be a decisive factor in the expression of a population's reproductive capacity. But even more important than the numerical balance is the nature of the psychological, social, economic and political relations between the sexes and, notably, the rules governing the formation and the separation of couples, the respective roles of men and women in the family and society, etc. Without mentioning the fact that, according to their gender and the role they play, individuals have demographic behaviors which differ in terms of reproduction, health, death and migrations.

Population Increase

GUILLAUME WUNSCH, JACQUES VALLIN, AND GRAZIELLA CASELLI

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Institut national d'études démographiques (INED), Paris, France

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

At each instant of time, a population is composed of a certain number of individuals: the population *stock* as economists would say, or the population *prevalence* according to the terminology in epidemiology. This number changes with time under the impact of inputs (births or immigrations) and outputs (deaths or emigrations) (i.e., *flows* in economic terms or *incidences* in epidemiology).

Before distinguishing between different types of flows, first consider the total population increase. Afterward we will distinguish between *natural* flows as they are called (births, deaths) and *migratory* flows[1] (immigrants, emigrants).

I. TOTAL POPULATION INCREASE

Let P_t and P_{t+h} represent population numbers at two different dates, times t and $t + h$. The total population increase between those two dates is as follows:

$$A_{t,t+h} = P_{t+h} - P_t$$

For example, between the census of March 4, 1982, and that of March 5, 1990, population size of France changed from 54.3 million to 56.6 million inhabitants, an absolute increase of 2.3 million. However, the comparison between this increase in absolute numbers with that observed between the last two censuses in China or in Luxembourg would be meaningless. The intercensal periods are not the same. In particular, the population numbers are very different. To compare these increases, one must convert to the same unit of time and population size.

1. The Time Unit

The year is the most common time unit used in demography. However, the study may also cover periods of several years, often rather arbitrarily taken as 5-year periods, or less frequently periods shorter than a year to examine seasonal variations and so forth. In the latter case, months, weeks, or even days can be taken as the unit of time, as for example in the study of infant mortality. On the other hand, few demographic studies use data collected by the hour, minute, or second, although the latter time intervals are often used in other fields, such psychology or physics, which uses time units ranging from a billion years to the nanosecond.[2] The length of the period should be chosen for its relevance to the problem at hand[3]: a 20-year period for the study of mortality would conceal too many important temporal variations, whereas a 20-minute period would not be pertinent for most, if not all, demographic studies, and it would also lead to a very small number of deaths and therefore to a lot of chance fluctuations (or random

[1] More precisely, one should distinguish between the moves themselves (migrations) and the people who actually move (migrants). A same person can move several times during a given period (see Chapter 22, this volume, by Daniel Courgeau).

[2] One billionth of a second.

[3] On this topic, see the book by Janice R. Kelly and Joseph E. McGrath (1988).

noise) in the data. In many studies, the demographer has no control on the length of the time unit, especially if he or she uses data collected by others, such as from administrative sources or existing survey data. For example, data on internal migration might be collected and published by year. In this case, demographers interested in possible seasonal patterns of migration would not be able to obtain needed data. One could interpolate the yearly data to evaluate the number of migrations by month, but this would require knowing the seasonal migration pattern—the object of the study itself!

2. The Rate of Increase

To simplify, consider a 1-year unit of time and suppose one knows the population numbers P_t on January 1, year t, and P_{t+1}, on January 1, year $t + 1$. The rate of increase is obtained by dividing the difference $P_{t+1} - P_t$ by the population size. What denominator should one take, as the size of the population is continuously changing over the year?

One could use the population size at the start of the year, P_t, and compute the yearly *relative increase* as follows:

$$a = \frac{P_{t+1} - P_t}{P_t}.$$

Supposing this relative increase remains constant over time, the population P would increase every year by the quantity aP. Starting from year 0, the population size 1 year later would be:

$$P_1 = P_0(1 + a)$$

and 2 years later:

$$P_2 = P_1(1 + a) = P_0(1 + a)^2$$

Finally, t years later, one would have:

$$P_t = P_0(1 + a)^t$$

Coming back to the intercensal increase of the French population, one can use this formula to compute the average relative increase per year during this period, as one has:

$$a = \sqrt[t]{\frac{P_t}{P_0}} - 1$$

and with the French data of the 1982 and 1990 censuses:

$$a = \sqrt[8]{\frac{56.6}{54.3}} - 1 = 0.005199 \cong 0.5\%$$

Actually, this yearly average increase is not the true measure of the rate demographers wish to estimate. Dividing the absolute increase by the population at the beginning of the year does not take into account the fact that the population is itself the source of events (births, deaths, migrations) that lead to population change. As the size of the population continuously changes during the year, the number of events produced each day by this population also changes. Therefore, at the end of the year, the net population increase (or decrease) does not depend only on the size of the population at the beginning of the year but also of its successive modifications during the year. One should therefore divide the absolute change by an average of all population sizes observed during the year. If the population does not fluctuate too erratically during the year, an estimate of this rate can be based on the simple arithmetic average of the population at the beginning and that at the end of the year. One obtains for the year t the *rate of population increase r*:

$$r = \frac{P_{t+1} - P_t}{(P_t + P_{t+1})/2}$$

If the period of observation is greater than a year, one simply multiplies the denominator by the number of years concerned. For example, the average rate of population increase per year of the French population between the censuses of 1982 and 1990, a period of 8 years, is equal to:

$$r = \frac{56.6 - 54.3}{8(54.3 + 56.6)/2} = 0.005185 \cong 0.5\% \text{ per year}$$

One sees that the difference between this result and the one obtained previously is very small. One can show that for levels of the rate of annual increase of less than 5%, the difference between the results of the two formulas is negligible. Human growth rates for total populations usually remain below 5% per annum, except for certain subpopulations where this rate can be exceeded. For example, one knows that at the beginning of an autoimmune deficiency syndrome (AIDS) epidemic, the population affected by this disease doubles every 2 years on average. In this case, the relative annual increase is 100% but the rate of increase is significantly lower:

$$r = \frac{1}{(1+2)/2} = 67\%$$

When computing the relative increase a one assumes that all the flows depend on the initial population P_t. In the case of the rate of increase r, taken as the ratio of the absolute change to the average of the populations at the beginning and end of the year, one implicitly assumes that the flows going in or out of the population occur at mid period or that they are evenly spread over the period. In other words, one assumes that the population size changes linearly over the year or period. This assumption is not truly correct, as the population is continuously changing and, if the rate of increase is constant, the number of incoming and outgoing events increases (or decreases) relative to the population size.

Thus, as a result of these discrepancies, a precise definition of population growth rate should be based not on discrete units of time but on the continuous values taken by the size of the population over time and the *instantaneous growth rate* occurring during an infinitesimal fraction of time.[4] In other words, we wish to define the rate of increase in the case of a population size changing between times t and $t + \Delta_t$ when Δ_t tends toward 0. If $r(t)$ is the instantaneous rate of increase, one has:

$$r(t) = \lim_{\Delta_t \to 0} \frac{P(t) - P(t+\Delta_t)}{P(t) \cdot \Delta_t}$$

or

$$r(t) = \frac{\mathrm{d}P(t)}{P(t)\mathrm{d}t}$$

which can also be written:

$$\mathrm{d}P(t) = P(t)r(t)\mathrm{d}t$$

Integrating, one obtains:

$$P(t) = P(0)e^{\int_0^t r(\tau)\mathrm{d}(\tau)}$$

Finally, in the finite interval of time $(t, t + h)$, assuming that $r(t)$ is constant over the whole interval, one has:

$$P_{t+h} = P_t \cdot e^{r*h},$$

showing that under this assumption the population grows exponentially during the interval of time $(t, t + h)$.

According to this definition, the rate of increase r^* is thus equal to:

$$r^* = \frac{\ln(P_{t+h}/P_t)}{h}$$

and in the example of the French population, one has:

$$r^* = \frac{\ln(56.6/56.3)}{h} = 0.005186 \cong 0.5\%$$

The difference with r is very small, which is why one usually approximates the growth rate, by convenience, using the average population as denominator.

From one country to another, the growth rate presently varies from –1% per annum to +3.5%. Even within a country the rate can vary greatly for a number of reasons. Crises sometimes lead to dramatic declines in population sizes and long troubled periods of time can lead to durable population reductions. Alternatively, some developing countries recently have experienced periods of very high population growth, with rates above 4% per year. However, total increase rates can be much higher for subnational populations due to migration, which in this case is an important component of growth. This is clearly the case for the rate of increase of the population of urban areas in many less developed countries. For example, the urban population of Tanzania grew at the rate of 6.1% per year during 1990 to 1995, while its rural population grew at the rate of only 2% (United Nations, 1994).

3. Doubling Time of a Population in an Exponential Model

Knowing the annual rate of increase of a population, one can calculate the time needed for a doubling of the population size assuming a constant growth rate. Using the following formula:

$$2P = Pe^{rh},$$

taking logarithms, one obtains:

$$h = \frac{\ln 2}{r} \cong \frac{0.693}{r}.$$

For example, with the average annual growth rate of the French population of the period 1982 to 1990, this population would double every 0.693/0.005 = 138.6 years.

Table 3–1 gives the doubling time of a population for various values of r. Thus, with a rate of growth of 3.5% per annum, a population would double every 20 years. With a population of 10 million in the year 2000, this population would increase to 20 million in the year 2020, to 40 million by the year 2040, to 80 million in 2060, and so forth. A small growth rate can therefore lead to a tremendous increase in population size over a relatively small number of years. Using the growth rate of the Tanzanian urban population as constant, one obtains a doubling time of only 11.4 years. In this case, the population size would be multiplied by 500 in a century!

[4] Though basing the discussion in the present chapter on the number of individuals and events observed during discrete time intervals, it is important to develop at the same time the relationship using calculus, in order to take advantage of the mathematical convenience and power of the latter. Those not familiar with calculus may skip this paragraph if necessary.

TABLE 3–1 Doubling time of a population according to annual growth rate

Annual rate of growth, *r*	Doubling time, y
0.005	139
0.010	69
0.015	46
0.020	35
0.025	28
0.030	23
0.035	20
0.040	17
0.050	14
0.060	12
0.070	10
0.080	9
0.090	8
0.100	7

Exponential population growth of this type led Thomas Robert Malthus (1798) to argue that population has a natural tendency to increase after a geometric (exponential) progression, outstripping the means of sustaining it which grow only following an arithmetic (linear) progression. Although this argument will be examined in Chapter 97, one can already point out that populations never experience constant growth rates for long. Other models of population growth, such as the *logistic* one discussed below, are therefore more suited to actual population trends.

4. The Logistic Model of Population Growth

Some authors propose replacing the exponential growth model with one that supposes that population experiences an accelerated growth over time that progressively decelerates and tends toward 0. This so-called logistic function equation is as follows:

$$P_t = \frac{k}{1+e^{a+bt}} \text{ with } b < 0,$$

where k, a, and b are constants. The Belgian mathematician Pierre-François Verhulst introduced this equation in the 19th century. The equation was then reinvented in the 20th century by the Americans Raymond Pearl and Lowell Reed.[5] If one has three observations in time equally separated from each other, one can compute the values of the constants k, a, and b characterizing the logistic function adjusted to these three time points (Duchêne and Vilquin, 1992). A logistic population increase is probably more suited to sustainable economic development than the exponential model, which leads to implausible results in the long run.

[5] See the interesting discussion by Piero Manfredi (1995).

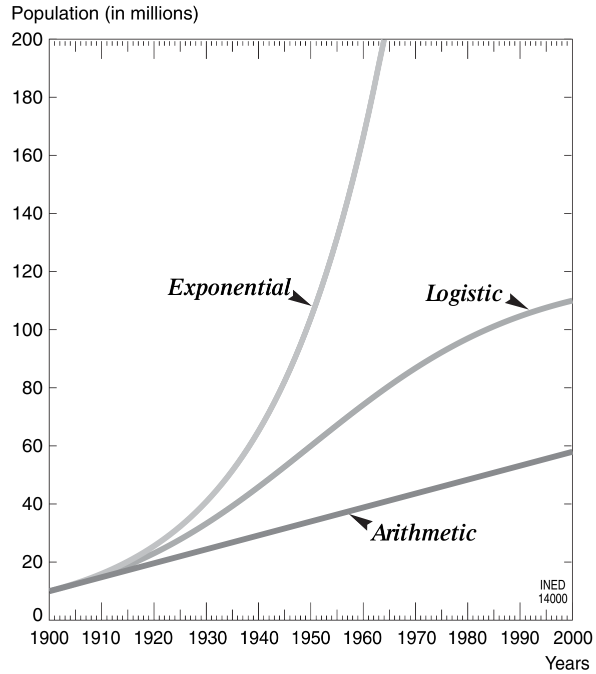

FIGURE 3–1 Evolution over a period of 100 years of a population of 10 million inhabitants with the same initial growth rate of around 5% per annum but following three different models of growth.

Figure 3–1 illustrates the case of a population having a size of 10 million inhabitants in 1900 and a rate of growth of around 5% that year. According to the results of an arithmetic (linear), logistic, or exponential (geometric) growth model, the population would reach in the year 2000 respectively 56 million, 110 million, or 1.1 billion inhabitants.

To conclude this topic, the growth rate is a useful summary indicator of population dynamics, as it shows the differences in population change over time or space. However, population growth results from the combination of various entries into and departures from the population, which must be disentangled to improve one's knowledge of population trends and development of better models of population evolution.

II. NATURAL AND MIGRATORY INCREASE

In the general case of a population of a country or region, there are two types of entries and departures, of inputs and outputs: birth and immigration and death and emigration. During a 1-year period, total population increase can thus be written:

$$A_{t,t+1} = P_{t+1} - P_t = B_{t,t+1} - D_{t,t+1} + I_{t,t+1} - E_{t,t+1}$$

where $B_{t,t+1}$, $D_{t,t+1}$, $I_{t,t+1}$, and $E_{t,t+1}$ represent the number of births, deaths, immigrations, and emigrations, respectively, observed during year t (between January 1, year t, and January 1, year $t + 1$).

One sees that population P increases by the two quantities $(B - D)$ and $(I - E)$. The first is called *natural increase* and results from the two so-called natural components of population growth (i.e., births and deaths), whereas the second is called *net migration* and is simply the balance of immigrations and emigrations. Population changes can therefore be classified into those due to natural increase (or decrease) and those due to net migration, both being the difference between entries and departures. In the case of a *closed population*, without migration, population change results, by definition, from natural increase only. In actual populations, change occurs from both natural increase and net migration, the latter being in some situations more important than the former, such as in the case of many urban populations.

Data on stock or prevalence are usually obtained from censuses or population registers; where they exist, data on flows or incidence such as births, deaths, and migrations come from systems of continuous (e.g., civil [or vital]) registrations or population surveys (see Chapter 121). In countries where the civil registration system works well, current data on births and deaths are routinely collected. If the vital registration system is defective, as in most developing countries, information on births and deaths is obtained from population surveys. It usually is more difficult to obtain reliable data on migrations, especially international migrations. Several countries now have population registers incorporating changes of residence, which yield adequate information on moves inside the country at least. If this type of registration does not exist, the number of migrations can be evaluated thanks to retrospective questions at a census or at a survey (see Chapter 22). In the absence of such data, net migration can be computed as the difference between total intercensal growth and natural increase during the same period. In fact, many developed countries now estimate annually their population size at the beginning or end of each year and the amount of net migration occurring during the year. Some even evaluate their annual flows of immigrations and emigrations.

The relative level of the four flows of entries and departures is measured by *crude rates* of natality,[6] mortality,[7] immigration, and emigration, obtained by dividing the number of events (births, deaths, immigrations, emigrations) during a period by the average population size, following the same approach as for computing the total growth rate of the population. As a first approximation, in discrete terms, one may assume the equal distribution of flows during the year. In that case, the crude birth rate, b, during the year is taken as:

$$b = \frac{B_{t,t+1}}{(P_t + P_{t+1})/2}$$

Replacing the numerator by the number of deaths, D, immigrations, I, or emigrations, E, one obtains the *crude death rate*, d and the crude rates of immigration, i, and emigration e.

Although computed here for a 1-year period (t, t + 1), all these rates can also be derived for longer or shorter periods (t, $t + h$), as was the case for the rate of increase. To bring these rates back to a 1-year period, for comparative purposes, one weights the denominator or average population of the rates by the time interval h expressed in years or fractions of years:

$$b = \frac{B_{t,t+h}}{h(P_t + P_{t+h})/2}$$

The difference between the crude birth and death rates gives the *rate of natural increase*, whereas the difference between the crude rates of immigration and emigration yields the *net migration rate*. One observes, this time at the level of rates, the same decomposition into the two components of change:

$$r = (b - d) + (i - e).$$

Thanks to vital statistics data produced by the civil registration system and to the yearly estimates of population size at the beginning or end of the year, evaluated by the national statistical institutes, one can compute the values of the annual crude birth and death rates (at least in the developed countries) and, taking their difference, that of the rate of natural increase.

In France, for example, in 1989 the crude birth rate was equal to:

$$b = \frac{765{,}473}{(56{,}017{,}000 + 56{,}303{,}000)/2} = 0.01363 \cong 13.6/1{,}000$$

and the crude death rate to:

$$d = \frac{529{,}283}{(56{,}017{,}000 + 56{,}303{,}000)/2} = 9.4/1{,}000$$

[6] Or *crude birth rate*.

[7] Or *crude death rate*.

The rate of natural increase was therefore equal, for the same year 1989, to $b - d = 13.6 - 9.4 = 4.2/1{,}000$.

One cannot usually do the same for migration, in the absence in most countries of a reliable registration system of in- and out-migrations. Often one falls back on estimating intercensal net migration by subtracting natural increase from total intercensal population growth. Similarly, one obtains a rate of net migration from the population growth rate over the period and the crude birth and death rates on the basis of the so-called *growth balance equation*:

$$s = i - e = r - (b - d)$$

One notices that the same net migration value can be produced by very different amounts of flows. For example, a net migration of ten moves can result from the difference 20 immigrants minus ten emigrants or from the difference 10,010 immigrants minus 10,000 emigrants. In fact, as Andrei Rogers (1990) has pointed out, there is no such thing as a *net migrant*: the latter results from the difference between two flows.

Similarly to the rate of increase r, crude rates b, d, i, and e of natality (crude birth rate), mortality (crude death rate), immigration, and emigration, respectively, can also be defined with greater precision using calculus (Keyfitz 1968, Pressat 1995).

In the time interval t to $t + \Delta t$, population increase results from the number of births $B(t,t + \Delta t)$, deaths $D(t,t + \Delta t)$, immigrations $I(t,t + \Delta t)$, and emigrations $E(t,t + \Delta t)$ occurring during the interval:

$$\begin{aligned} P(t + \Delta t) - P(t) = {} & [B(t,t + \Delta t) - D(t,t + \Delta t)] \\ & + [I(t,t + \Delta t) - E(t,t + \Delta t)] \end{aligned}$$

When Δt tends toward 0, one may write for the number of births:

$$B(t) = \lim_{\Delta t \to 0} \frac{B(t,t+\Delta t)}{\Delta t}$$

The number of births occurring during the very small interval of time $(t, t + \mathrm{d}t)$ is therefore $B(t)\mathrm{d}t$ and is dependent on the conditions of time t and the population size $P(t)$ at that instant. This number of births divided by the number of person-years in the interval $(t, t + \mathrm{d}t)$ (i.e., $P[t]\mathrm{d}t$) yields the *instantaneous birth rate* (or *force* of natality) $b(t)$ at times t:

$$b(t) = \frac{B(t)}{P(t)}$$

Assuming that the population size varies exponentially during the finite time interval t, $t + h$, and that the instantaneous birth rate is constant over the same interval, the crude birth rate b^* over the same interval is equal to:

$$b^* = -\ln\left(1 - \frac{B_{t,t+h}}{P_t}\right)$$

Coming back to the French example, one obtains:

$$b^* = -\ln\left(1 - \frac{765{,}473}{56{,}017{,}000}\right) = 0.01376$$

Once again, this result is not very different from the value of b obtained previously and this is the reason why, for convenience, one usually computes b instead of b^*. The smaller the finite interval, the closer the approximation.

Similarly one can compute the instantaneous rates or forces $d(t)$, $i(t)$ and $e(t)$ of mortality, immigration, and emigration under the same assumptions and the corresponding crude rates d^*, i^*, and e^* during a finite interval of time.

The instantaneous rate of growth of the population $r(t)$ can then be shown as follows:

$$\frac{dP(t)}{P(t)dt} = r(t) = [b(t) - d(t)] + [i(t) - e(t)],$$

and therefore

$$r^* = (b^* - d^*) + (i^* - e^*)$$

which is similar to the relation derived previously for the crude rates.

Among national populations, the crude birth rate varies from 10 to 45 per thousand. However, in the recent past, some developing countries have had crude birth rates in excess of 50 per thousand. Yet, birth rates as low as those prevailing today in various developed countries have never been observed in the past. The crude death rate, varying today between 5 and 20 per thousand, has always been much higher. If a crude death rate of more or less 40 per thousand was usual in normal times, it could reach much higher figures in times of crisis. For example, in Finland in 1868, it reached 80 per thousand during a severe famine. In Ukraine in 1933, it nearly reached 100 per thousand for the same reason.

Crude birth, death, and migration rates do not adequately reflect population behaviors as the latter are age dependent and the crude rates are influenced by the age composition of the population. More refined measures of population growth therefore have to take the age structure of the population into account.

Population Dynamics: Movement and Structure

GRAZIELLA CASELLI AND JACQUES VALLIN

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

Institut national d'études démographiques (INED), Paris, France

In the absence of migration, variations in a population's size are the result of the algebraic sum of births and deaths, and its growth rate is equal to the difference between its crude birth rate (CBR) and its crude death rate (CDR).

In such a population, known as a *closed* population, renewal depends on the two components of natural increase, and one might be tempted to consider that CBR and CDR are synthetic indexes that are representative of its propensity to, respectively, procreate new individuals and to lose population. In fact, procreation and mortality, which determine the evolution of a closed population, are the outcome of a complex set of behaviors closely linked to the sex and age of the individuals: to conceive a child, one must be a female of a certain age and have been fertilized by a male; the risks of dying vary across the life course and also between men and women.

Each life history, from birth to death, is written into a biologic time frame that governs both the capacity to procreate and the capacity to stay alive. Even if one considers that all individuals have exactly the same life history, two populations of same size may thus produce different numbers of births and deaths and different birth and death rates, since this will depend on the age–sex structure of the individuals who form the population. The birth rate will be higher when the proportion of women of childbearing age is higher, the death rate will be higher when the proportion of elderly is higher. Thus, in a given population, the propensity to procreate and the risks of dying are, at each moment, translated into births and deaths through the filter of the age–sex structure of the population present at that particular moment. Fertility and mortality dynamics therefore depend, indirectly, on changes in the age–sex structure.

Inversely, changes in the birth and death rates will modify the population's age–sex structure. An increased birth rate will immediately raise the share of infants in the population, and subsequently, as they age, the share of adults then of the elderly. Similarly, a sharp infant mortality decline will produce a similar effect by immediately increasing the share of child survivors, whereas a reduction of mortality risks at older ages will directly increase the share of the elderly. One can also imagine changes in birth and death patterns modifying the population's sex structure. Regarding births, this is no longer pure science fiction, because it is no longer impossible to select offspring on the basis of gender. Regarding deaths, the trends may differ for men and women, not merely in war years, thereby altering the proportions of men and women in the population.

Such modifications in the population's age–sex structure will in turn have an impact on the crude birth and death rates. For instance, the inflated birth cohorts mentioned previously will, given a same reproductive behavior, produce more births when they reach childbearing age than the preceding cohorts, and will, given the same mortality risks, produce more deaths, notably at older ages.

Thus, at each moment, the evolution of a closed population is determined by a continuous process of interactions between the three key elements of its natural dynamics: propensity to procreate, mortality and age–sex structure. The pattern is naturally more

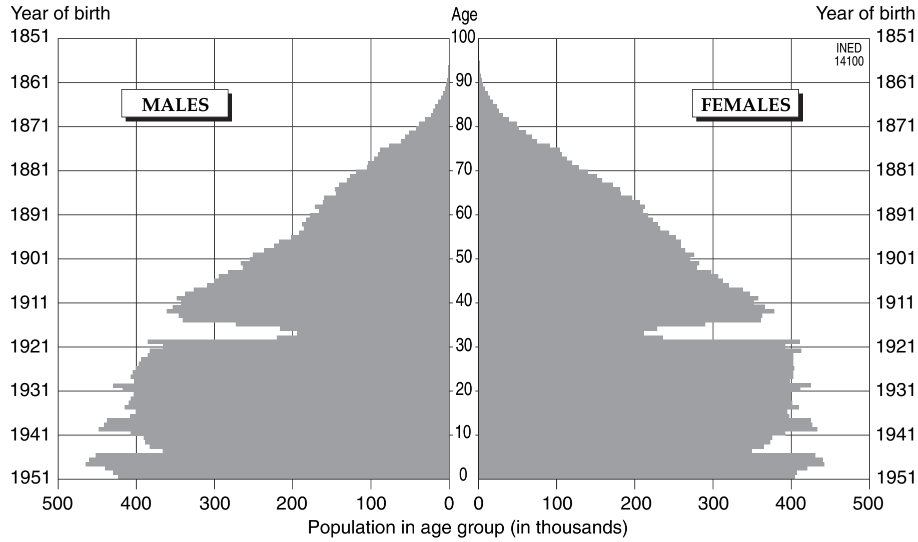

FIGURE 4–1 Population pyramid, Italy, 1951.

complicated when in- and out-migration intervene, but the principle remains the same: Migration also affects the age–sex structure, which in turn acts upon migration.

I. THE AGE–SEX STRUCTURE

To visualize the features of a population's sex and age structure, demographers conventionally construct its *population pyramid*. The definition and utilization of this tool are precious for revealing a number of phenomena and suggesting possible interpretations. We shall therefore make a general presentation of the population pyramid, which will then lead us naturally to the specific issue of the balance between males and females.

1. The Population Pyramid

The population pyramid, whose popularity has spread outside the realm of demography, is constructed by placing side by side the histogram representing the male age structure, generally on the left, and the one representing the female age structure, on the right (Figure 4–1).

a. A Pyramid by Individual Years of Age

For each sex, age is represented on the *y*-axis and the size of the population in the age group on the abscissa. Note that whereas the female pyramid reads normally, from left to right, the male pyramid reads from right to left. Figure 4–1 illustrates the pyramid for the 1951 census population in Italy.

In fact, the Italian 1951 census data were only published by individual years of age from 0 to 79, then by age groups (Istituto Centrale di Statistica, 1956). To construct the complete pyramid, we estimated the population of each individual age beyond 80 by using the year-of-birth distribution published together with the census findings.

b. Unequal Age Groups

Indeed, the complete distribution of the population by sex and individual years of age is frequently lacking, and there is rarely another source of data to fill in the gaps. However, a population pyramid illustrating the structure of the population can be constructed by taking variations in the age scale into consideration. To do so, the population in each age group will be weighted by a coefficient, which is the inverse of the ratio of the size of the age group to the reference age group. Consider the example of the 1951 Italian census data. In Table 4–1 and Figure 4–2, we have grouped them into the unequal age groups commonly used to present census and survey results. In this case, one divides the number in each class by the size of the age group (e.g., the population number in the 1–4 age group will be divided by 4, the number in the 5–9 age group by 5, etc.). For the open age group 85+, we assume that the number of centenarians can be neglected here and divide the number by 15 (i.e., 100 – 85).

c. Proportional Distributions

In absolute numbers, the population pyramid illustrates the age–sex structure while also giving an idea

TABLE 4–1 Italian population by sex and unequal age groups, 1951

Age groups	Population of age groups		Coefficient	Values plotted on the abscissa

*Since the number of centenarians is negligible here, the group 85+ is taken to extend from 85–100 years.

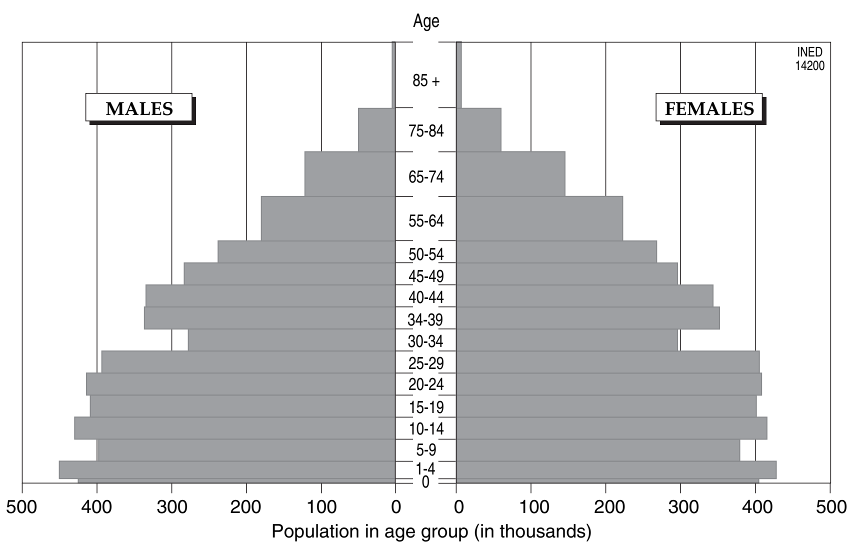

FIGURE 4–2 Population pyramid, Italy, 1951, by unequal age groups.

of the total population size. This may be useful for comparing different populations or the same population across time. However, it may also hamper the comparison if one wishes to focus on differences in the age–sex structure. In this case, a proportional distribution is preferable to absolute numbers (Table 4–2, Figure 4–3A and 3B).

The caveat here is that the population of each age and sex should be related to the total population for both sexes combined. Otherwise, if related to the total population of men or women separately, the result would be two independent histograms and the image of the sex-specific population structure would be lost.

Figure 4–3A and 3B contrasts these two ways of displaying the three sets of country data for comparison. When absolute numbers are used, the differences in population size are so great that this dominates the image, which remains clear even when the three pyramids are superposed (Figure 4–3A). However, the differences in age–sex structure are flattened. By giving a

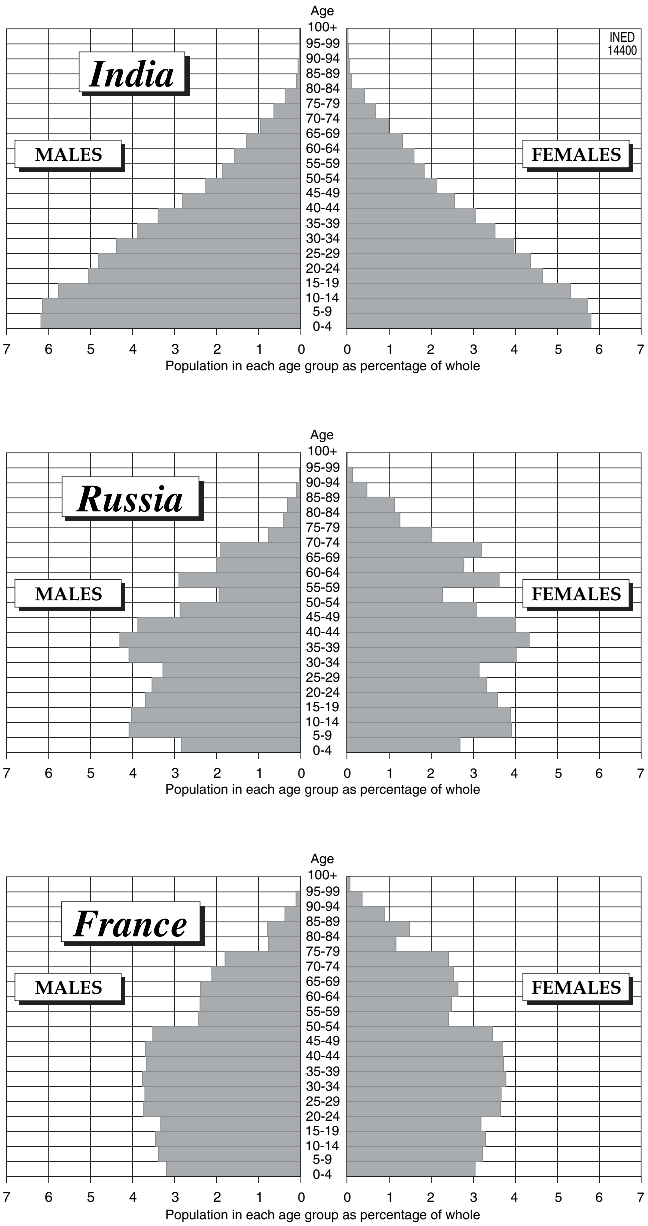
same dimension to all three countries, the proportional distributions are more revealing of these differences (Figure 4–3B).

d. Observation Problems

The population pyramids illustrate survey or census results, but these may be imperfect. Some types of error are immediately visible on the population pyramid, which, for a trained reader, becomes a very useful tool for checking the quality of the data. This is clear from Figure 4–4, which illustrates the Moroccan census of 1960 (Service Central de Statistiques, 1964). All the *round ages* (those ending in zero) are protuberant. The numbers at these ages are overestimated by an effect known as *age heaping*. This problem is common among populations that have no reliable vital registration system and age is not known with accuracy. In this case, enumerators or respondents tend to report the age as the most probable round digit. In some cases, other digits, those ending in five in particular, attract the imprecise cases (Roger *et al*., 1981; Clairin and Lohlé-Tart, 1988; Tabutin, 1995). The instructions given to interviewers to remedy this type of error may be so strict that they have the opposite effect and produce a marked deficit at the round ages: this occurred with the 1960 census in Niger (Roger *et al*., 1981). The heaping effect may also concern years of birth, when the questionnaire focuses on date of birth rather than on age. Thus, cohorts born in years ending in zero (or five) will be overestimated, as was the case in the Zambian census of 1969 (Ohadiké and Tesfaghiorghis, 1975).

In this case, the heaping effect will naturally appear on the pyramid at ages other than multiples of five or 10, unless the census or survey was held in a round year. Finally, if a historical calendar is used to help respondents to locate themselves in time, the heaping will be determined by major events in the calendar and will concern ages that are neither round nor resulting from a round year of birth (Waltisperger, 1988). Age heaping, so blatant on the Moroccan population pyramid for 1960, continued to mar most European censuses throughout the 19th century. It is clearly visible on the French population pyramid for 1851, for instance (Tabah, 1947; Meslé and Vallin, 1989).

The population pyramid may also reveal other forms of error. In some developing countries, for instance, the numbers of nubile girls are often underestimated, because their age tends to be inflated when they are married and understated when they are not (Simonet, 1974; Roger *et al*., 1981). This is quite clear in the case of Morocco (Figure 4–4). Another common example of age misreporting that can show up on the population pyramid concerns the first year of age. Indeed, age 0 is a very abstract notion, and infants who have not yet reached their first birthday may well be reported as being "age 1." The result is a sharp indentation at the base of the pyramid for those younger than 1 year. Another sign of underestimation detectable on the pyramid concerns elderly women, who often escape the enumeration when they are widowed or divorced (Négadi *et al*., 1974), or men in the armed forces, who are systematically excluded. However, it is important not to confuse these



B

FIGURE 4–3 (*Continued*) **B:** Comparison of three population pyramids using proportional distributions (India, Russia, and France, 1995).

systematic errors due to age misstatement with actual perturbations resulting from specific historical events. It is not because the population studied is a developing one that every unusual feature of the pyramid is a sign of age misreporting (Picouët, 1969).

2. How to Read the Population Pyramid

Not only does the population pyramid reflect an image of the current composition of the population by age, with all the implications for expression of the needs of the different categories of population (preschool and school-aged children, working population, pensioners, balance of the sexes, etc.), it also, by placing side by side 100 successive birth cohorts, traces the history of these different generations. Indeed, the current population of each individual age or age group is the combined result of an initial number of births in the cohort and the deaths or entries/exits by migration that have occurred since. The interpretation of the pyramid calls on two kinds of historical events that have each left their mark. First, the bumps and hollows trace the memory of the hazards of history experienced by specific birth cohorts. Second, the general shape of the pyramid reflects the major trends that have shaped the course of fertility, mortality, and migration.

a. The Hazards of History

In the last decades, some countries have lived through a terribly tormented history, so tormented that the distortions produced on the population pyramid are staggering. Three of the most remarkable examples to date are shown in Figures 4–5, 4–6, and 4–7. Let us just consider the spectacular impact on specific birth cohorts of three major events: World War II in Russia, the ban on abortion in Romania, China's "great leap forward."

World War II caused almost 20 million deaths in Russia[1] and the crude death rate suddenly soared from 20.1/1000 in 1939 to almost 60/1000 on average in the period 1941 to 1944.[2] This trauma concerned many birth cohorts simultaneously, which makes its impact less visible on the population pyramid (Figure 4–5). The trace it leaves is less a clearcut break in the dimension of successive age groups than a break in the balance between the male and female populations—although the imbalance produced by the war tends to blur with time, mixing into the structural effect of the very high excess male mortality which characterizes the Russian population. Nonetheless, on the 1997 pyramid, the hollowing out of the male population aged 69 to 78 is a permanent scarring caused by the tragedy.

The most visible impact of the war, however, is the indentation of the population at ages 46 to 49, men and

[1] On the basis of recent studies (Andreev *et al.*, 1990), Alain Blum (1994) estimates that World War II produced 26 to 27 million more deaths than there would have been in peacetime. According to Alexandre Avdeev (personal oral communication May 1999), 20 million of these war deaths concern Russia alone.

[2] Supposing the majority of the excess mortality (20 million deaths) can be attributed to the years 1941 to 1944 and that, without the war, the number of deaths per year would have been much the same as in 1939.

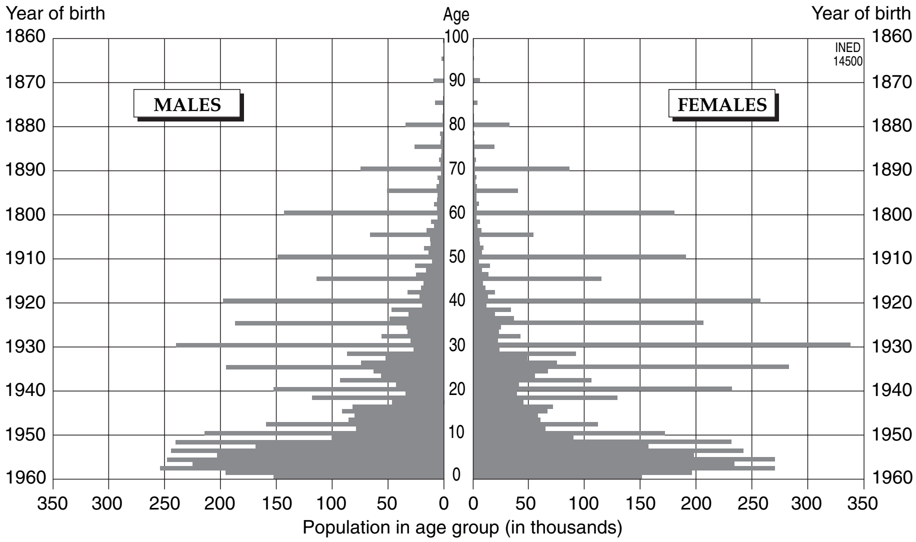


FIGURE 4–4 Moroccan population pyramid based on the 1960 census data.

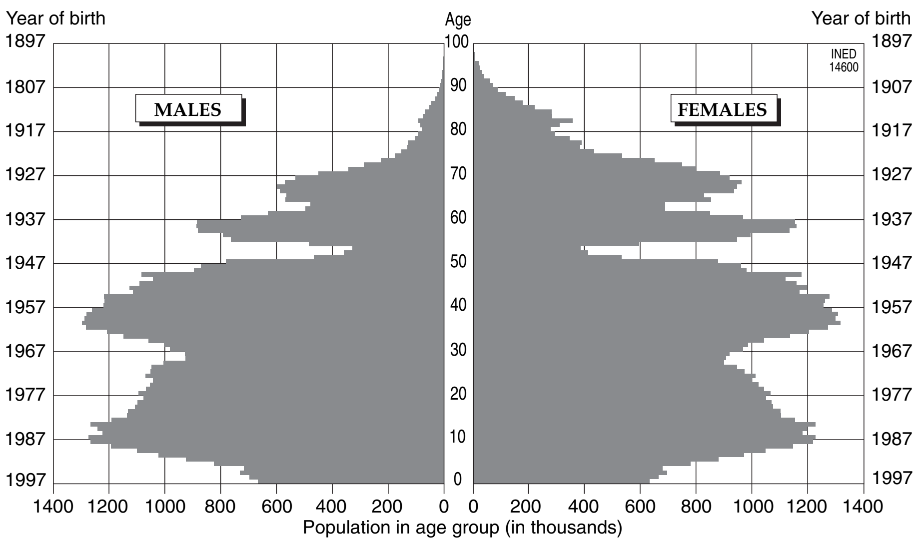

FIGURE 4–5 Population pyramid of Russia, January 1, 1997. (Source: estimated by Goscomstat, data kindly communicated by Alexandre Avdeev.)

women alike. These are the cohorts born during the war years, depleted compared with the earlier and later cohorts because so many couples were separated by the war. Indeed, the annual birth rate plummeted from 37/1000 in 1939 to 13/1000 in 1943.[3] This *deficit of births*, which relates to a precise number of cohorts, leaves a more striking mark on the pyramid than the more devastating, but more diffuse, effect of the 20 million war victims. The impact of the deficit was such that a second indentation can be observed on the pyramid marking the moment when the cohorts born during the war years entered the reproductive ages: In turn, these depleted cohorts produced depleted cohorts, in the mid 1970s. This is a striking example of the interaction between the structure of a population and a component of its natural dynamics, births. First, in the 1940s, a sudden change in the birth rates profoundly modified the age structure, compared with what it would have been had the previous birth rate level been maintained. Then, one fourth of a century later, because of this anomaly in the age structure, the

[3] These estimates refer to the USSR, but they are probably not so different for Russia. The births estimated by Serge Adametz *et al.* (1994), 7.3 million in 1939 and 2.6 in 1943, were related to a total population of about 195 million.

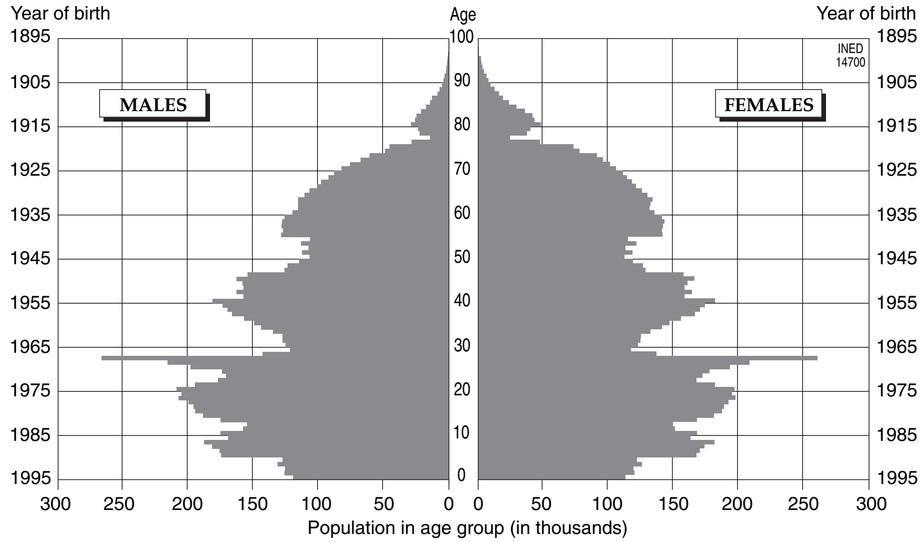

FIGURE 4–6 Population pyramid of Romania, July 1, 1995. (Source: United Nations, 1997.)

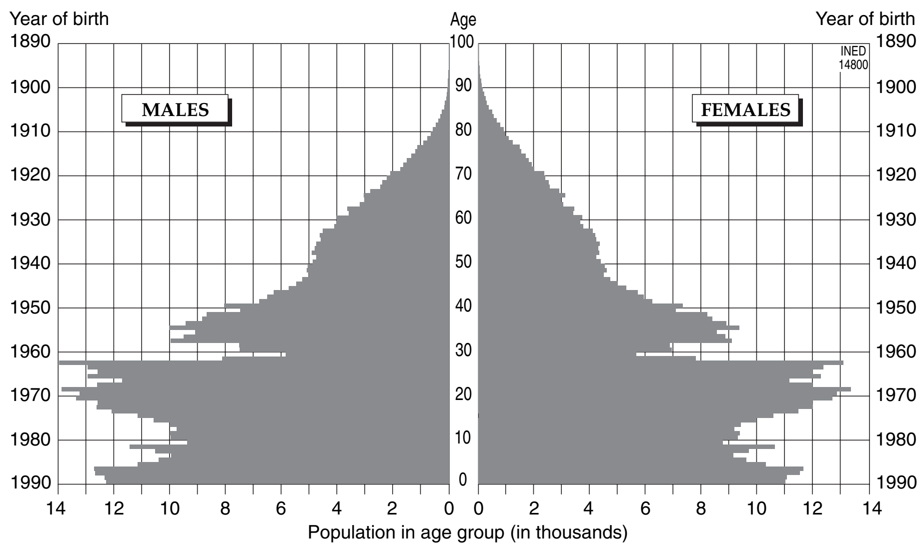

FIGURE 4–7 Population pyramid of China based on the 1990 census (Source: PCO, 1993.)

birth rates fell, producing a new indentation of the age structure. And so on . . . because another quarter century on, another sudden drop in fertility is observed, just emerging at the base of the 1997 pyramid, which will produce another set of depleted cohorts. This new phenomenon is not, however, merely the backlash of history: The erosion at the base of the pyramid, observed since the end of the 1980s, is enhanced by an actual decline of the propensity to reproduce. The cyclic effect of the shortfall of births during the war tends, on the contrary, to become diluted, as the births in the years concerned are not the offspring of depleted cohorts only, but also of neighboring nondepleted cohorts who are also of childbearing age. Yet, in the present case, the impact on the Russian population pyramid has been so great that it will be a long time before the slate is wiped clean.

The population pyramid for Romania (Figure 4–6) is marked by the same kind of cyclic perturbations related to the war (even the impact of World War I, which was more devastating in Romania than in Russia, remains clearly visible).

However, we have chosen this example to illustrate an inverse effect. In 1966, the Romanian government suddenly decided to ban abortion, which was at the time unrestricted and widely used as the principle method of birth control. As a result of this sudden decision, many women who were then pregnant had no choice but to keep their baby. The outcome was a sharp *excess of births* in the following year (Gethau, 1970, 1983; Lévy, 1990; Muresan, 1996). The birth rate leaped from 14/1000 in 1966 to an extraordinary 27/1000 in 1967, thereby doubling the size of the 1967 birth cohort compared with the preceding one, and creating a lasting and unprecedented anomaly in the Romanian population pyramid. This was also a one-off increase, since in the following years women resorted to alternative methods of birth control (illegal abortion or more systematic contraception) and the birth rate fell back to below 20/1000 (18.2 in 1973). Despite the extent of this upturn, the fact that the excess of births was limited to the years 1967 to 1968 means the cyclic shockwave has been slight compared with the Russian deficit of births during World War II. Indeed, 20 years after this extraordinary baby boom, only a slight increase in births is observed.

Looking at China's population pyramid for 1990 (Figure 4–7), we find an example of birth deficit, not a wartime one in this case, but the consequence of the terrible crisis engendered by the Great Leap Forward decreed by Mao Tse Tung in 1957. This brutal political change not only caused 15 to 30 million deaths between 1957 and 1961[4] (Banister, 1997, p. 85), but also a sudden downturn in birth rates, owing to the forced separation of many couples and to the fact that the others were unwilling to have children who were doomed to famine. The birth deficit was made all the more acute as the rise in mortality targeted infants in particular. Thus, the population pyramid constructed from the 1990 census data shows a marked indentation at ages 29 to 32 years. Once more, these depleted cohorts produce, in turn, another anomaly in the pyramid 20 years later: The number of children born around 1980, aged 9 to 13 in 1990, was visibly reduced, even if this particular deficit is combined with the effects of the one-child family policy.

b. The Shaping of the Pyramid: The Role of Births, Deaths, and Migration

Such specific historical events that have a brutal impact on the population pyramid are but one aspect (and no doubt not the most important one) of the interaction between population dynamics and population structure. In a much more general and fundamental way, the long-term trends in births, deaths, and migration give their overall shape to the pyramid. This explains why the population pyramids of different countries display such a great variety of shapes. Figure 4–8 shows five examples of the most classic situations.

In ancient Europe, but also until quite recently in southern Europe, population pyramids were almost perfectly triangular in shape, which explains why this representation is called a "pyramid." This situation, illustrated by India in 1951, corresponds to a demographic regime of very high mortality and fertility, but relatively slow population growth. The population is very young, with very few elderly: in India in 1951, 47.5% of the population were younger than 20 years, 48.9% were adults aged 20 to 65 years, and 3.6% were older than 65 years.

In comparison, in Kenya in 1969, the pyramid is still triangular but its base is broadened and the sides are concave. This difference is because birth rates increased in Kenya during the 1950s and 1960s because of a reduction of breast-feeding and postpartum abstinence, and at the same time infant and child mortality began to decline. Consequently, the population growth rate accelerated rapidly, which greatly broadened the base of the pyramid. Compared with India in 1951, the proportion of those younger than 20 years is even higher (58.6%), and the proportions of adults and elderly are lower (37.9% aged 20–65 years and 3.5% 65 years or older).

The population in France in 1911 illustrates a situation in which birth rates were falling for a long time (see Figure 4–8). Despite the concomitant decline in infant and child mortality, which has slowed down the process, the base of the pyramid has narrowed to the extent that the cohorts of young adults are barely smaller than the cohorts of children. The proportion of those younger than 20 years is much lower than in the previous examples (33.3%) and those of adults and elderly are higher (57.5% and 9.2%, respectively). The French pyramid is typical of a population in which the decline of birth rates has constantly offset the mortality decline and maintained a very low rate of population growth.

The base of the Italian pyramid for 1995 is narrower than the French. Indeed, for the last two decades Italy has experienced an unprecedented fertility decline. So, the crude birth rate is exceptionally low, in the region of 10/1000, which is even lower than the crude death rate and means that natural increase is negative. Consequently, the proportion of those younger than 20 years is even lower than that in France in 1911. The share of those older than 65 years is, on the contrary, higher: It even exceeds the share of those younger than 15 years (16% versus 14%).

[4] According to Judith Banister (1987), the excess mortality due to the crisis is about 15 million deaths if the death rate recorded in 1957 (10.8/1000) is taken to be correct. She considers, however, that there must have been substantial underregistration of deaths and that the excess mortality may be as high as 30 million.

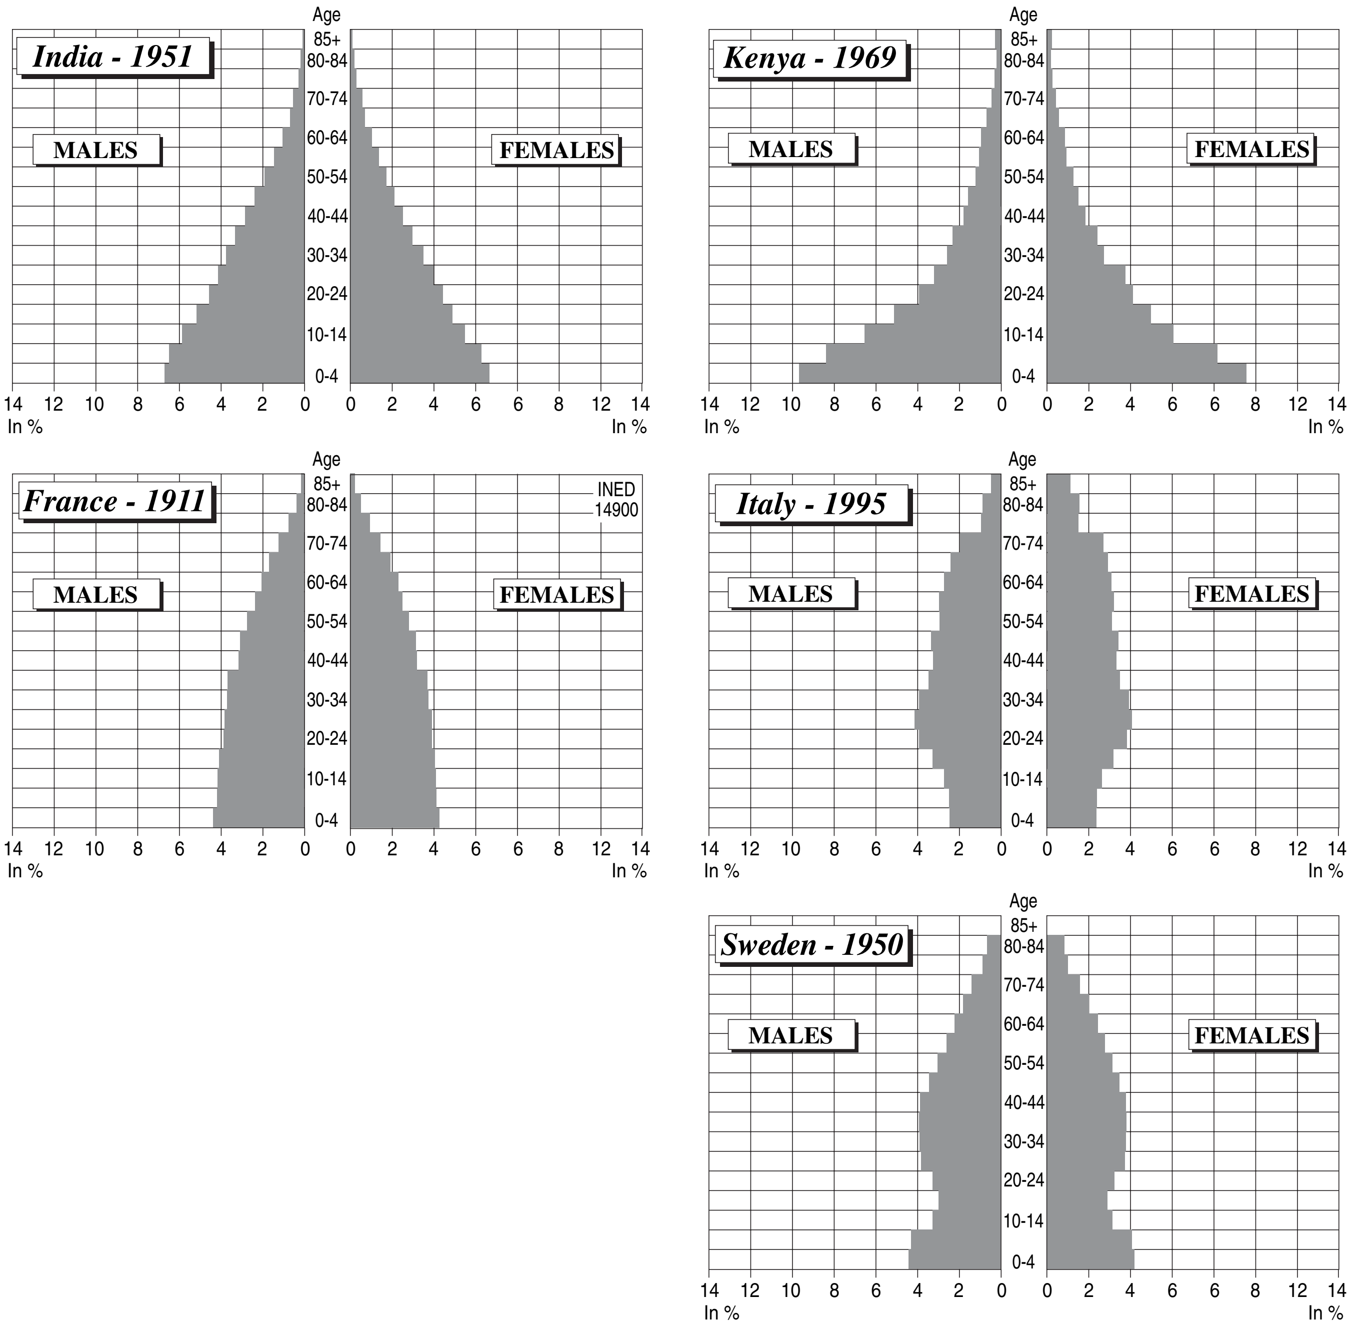

FIGURE 4–8 Population pyramids of India in 1951, Kenya in 1969, France in 1911, Italy in 1995, and Sweden in 1950. (Source: Population censuses)

In the case of Sweden in 1950, we observe a trend that led, as in France and Italy, to a narrowing of the pyramid, but which was then followed by a baby boom in the 1940s and 1950s, which expanded the base again (Figure 4–8). The result is a characteristic ace-of-spades form.

In Figure 4–9, we show two even more pronounced patterns illustrating the last two situations: Emilia-Romagna and Catalonia. These two regions are known for the extent of their recent fertility decline and the very low levels reached at the end of the 1980s, particularly in Emilia-Romagna. Here, the proportion of those younger than 5 years had fallen well below 2% in 1991.

The two regions differ, however, in the general aspect of their population pyramids. In Emilia-

Romagna, the population had already aged considerably before the recent fertility decline, which explains the pyramid's barrel shape. In Catalonia, on the contrary, the decline has modified the base of a more classic pyramid, giving a Christmas-tree shape.

Migration generally plays a lesser role in shaping the population pyramid than fertility and mortality, which explain most of the population growth. However, in specific countries and specific periods, international migration has been so strong, and so selective by age and sex, that it has had a notable impact. Figure 4–10 shows three such examples: Italy in 1911, Algeria in 1974, and Kuwait in 1980.

Because of very high emigration, the Italian population had a clear deficit of young adults at the turn of the century. In 1911, the pyramid shows a clear discontinuity around the 20th birthday for women as well as men, a sign that emigration concerned both in roughly equal proportions. The situation is different for Algeria in 1974, where emigration visibly affected men more than women. Lastly, Kuwait illustrates the impact of particularly high immigration of (mostly male) adults.

The impact of migration on the population pyramid is more pronounced at the local level, when very specific internal migration flows leave their mark. The French city of Toulouse, for instance, like many towns whose economy is based on an active university life and modern, dynamic industry, has recently attracted a flow of young adults who have swollen the central part of the pyramid, which elsewhere is rather monotonous since the age groups below 35 and above 60, up to about 85, are of comparable dimension (Figure 4–11). The contrary is noted in an extreme example,

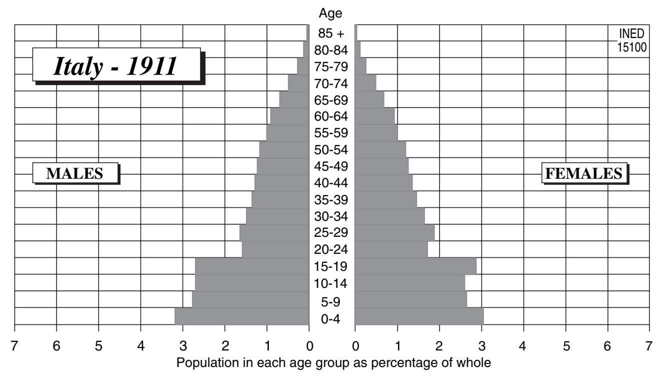

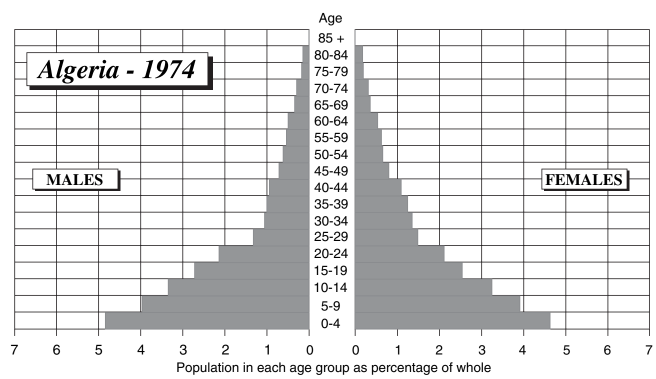

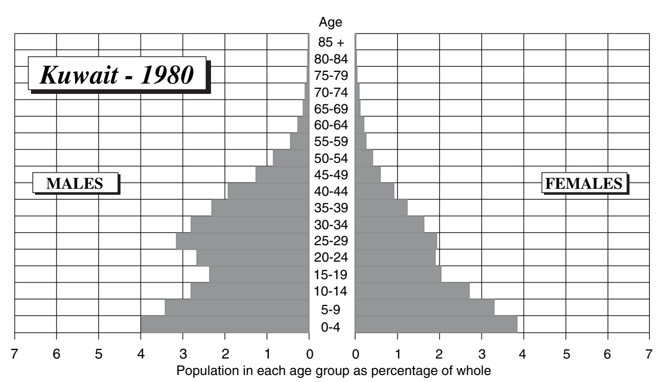

FIGURE 4–10 Population pyramids of Italy in 1911, Algeria in 1974, and Kuwait in 1980. (Sources: Algeria: ONS 1975; Italy: DGSL, 1914; Kuwait: 1994.)

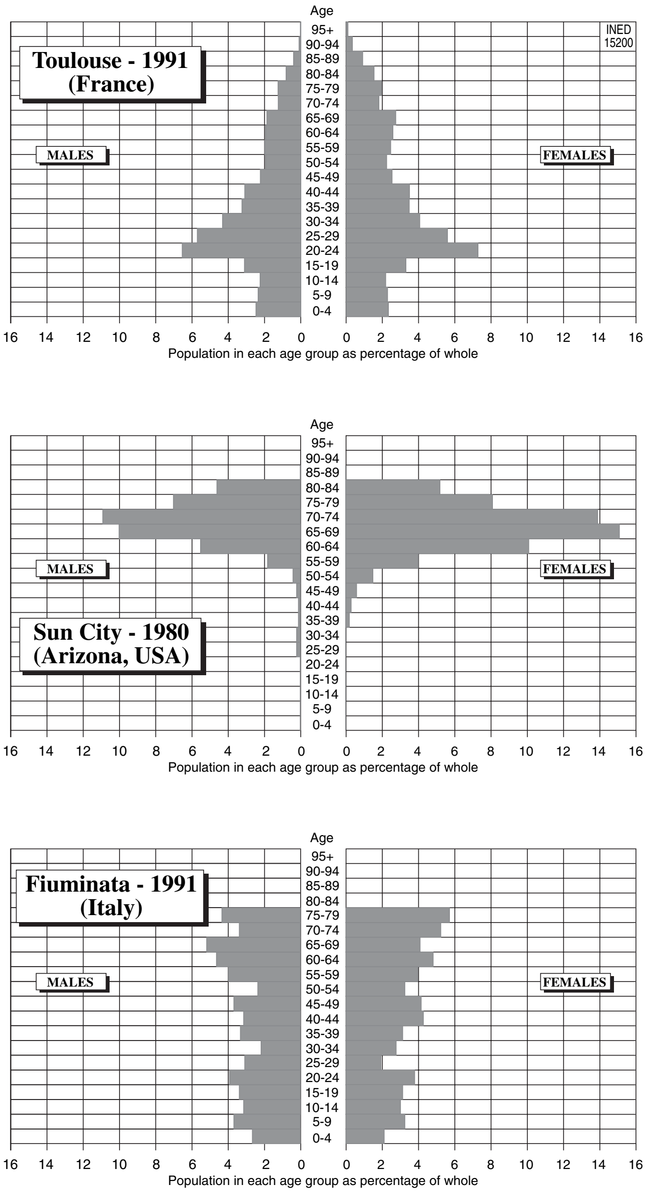

FIGURE 4–11 Population pyramids of Toulouse (France), Sun City (Arizona, US). and Fiuminata (Italy). (Sources: Toulouse: INSEE, 1992; Sun City: taken from Leridon, 1997; Fiuminata: ISTAT, 1995.)

Sun City in the United States, with an almost exclusively pensioner-based economy, which offers the hallucinating image of an inversed population pyramid, floating unanchored without a single inhabitant below the age of 25 (Figure 4–11). Finally, Fiuminata, a small rural town in the Italian Apennines, has been marked by an emigration of adults, which, combined with decades of low fertility, gives the upside-down pattern of a pyramid that is broader towards the top than at the base (Figure 4–11).

c. Three-dimensional Pyramids

It may be of interest to distinguish, within a population pyramid, different categories of population by introducing, together with age and sex, another variable such as economic activity, marital status, nationality, and so forth. Figure 4–12 presents an example: the Italian census population in 1991, broken down by sex, age, and marital status. The distribution of the single, married, divorced, and widowed members of the population within the age–sex groups is thus shown. The pyramid is massively single for those younger than age 20 for men and 17 for women. The married group then rapidly predominates, for both sexes, confining the single to a narrow central band. The divorced occupy an outer fringe between the ages 30 and 60, very small in size because of the low frequency of divorce and the effect of remarriage. From age 50 on, widowhood emerges, with a varying impact on men and women. Among the latter, widows quite rapidly gain ground to become the majority group, whereas among men, widowers remain constantly marginal. This reflects the fact that men die earlier than women. In contrast, in the upper half of the pyramid, there are constantly more married men than married women. This is because men marry women younger than themselves, and more numerous. This imbalance is particularly marked above age 70, when there are three times as many married men as there are married women.

In Figure 4–13, the population pyramid again demonstrates its efficiency for summarizing at a glance how a population is structured according to three variables: here, the research and teaching staff of the Italian Faculty by age, sex, and faculty status. Not only is the gender imbalance striking, it is clear that it is closely associated with age and status. The highest status category (professor) is totally dominated by men, with only a very slight fringe of women, while the lowest status category (researcher) has an important proportion of women. But, for a same status category, women are on average younger than men, which suggests that women have embraced this career more recently than men and that their numbers will in the future draw closer to those of men.

3. The Sex Balance

Because the balance between males and females conditions couple formation and reproductivity, this general presentation given by the population pyramid can usefully be completed by a specific analysis. Indeed, globally, the numbers of males and females are rather well balanced, but in contrast the ratio of men to women varies substantially from age to age.

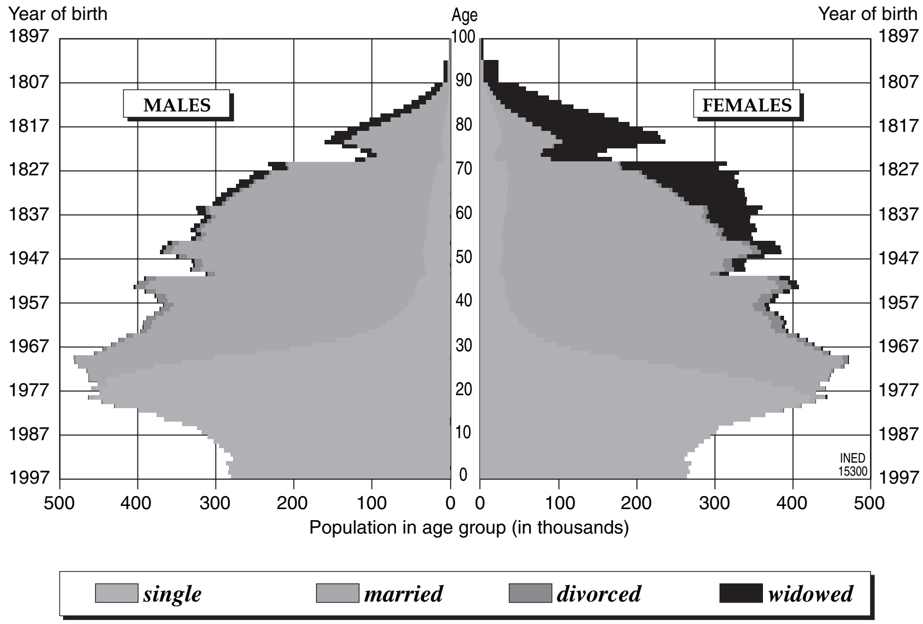

FIGURE 4–12 Population pyramid of Italy, 1991, by marital status. (Source: ISTAT, 1995a.)

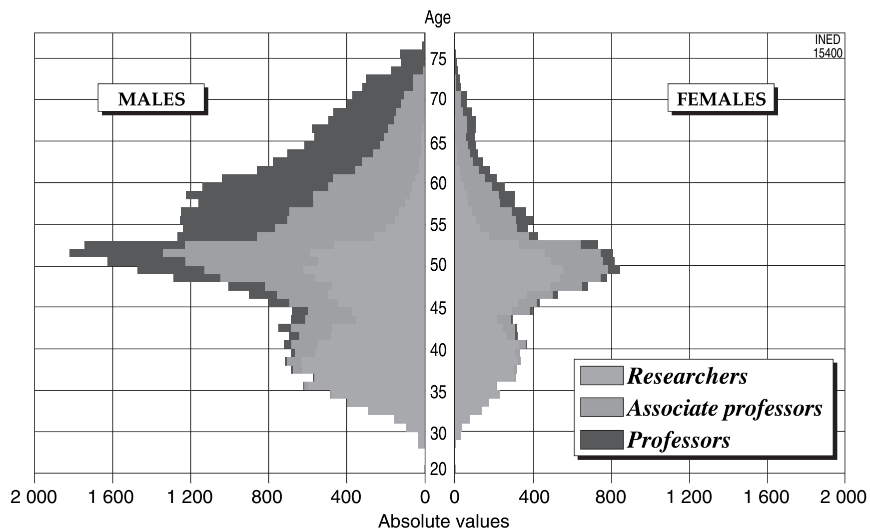

FIGURE 4–13 Population pyramid of the research and teaching staff of the Italian Faculty in 1997, by faculty status. (Derived from data published on the Internet by the Ministero dell'Università e della Ricerca Scientifica e Tecnologica, MURST. Consulted in May 1999.)

a. The Global Balance Between Men and Women

At the national level, in most countries worldwide, the *sex ratio* of the population (the number of males per 100 females) is close to 100 (Figure 4–14). There are, however, some interesting variations. Many industrialized countries (but also others) have values slightly below 100 whereas some southern countries are well above 100. In fact, the global balance between the sexes that is generally observed results (in the absence of substantial migration) from two phenomena that offset each other: Slightly more baby boys are born than baby girls, but they die earlier than the baby girls. If some populations move away from this balance, it is a result of the mortality gap between the sexes has grown or the discriminatory effect of substantial migration flows. For instance, the sex ratio is particularly low in Russia, where excess male mortality is breaking all known records, but it is higher than 100 in India where female mortality was until quite recently higher than male mortality. When Algeria in 1974 is compared with Kuwait in 1980, the sex ratio in

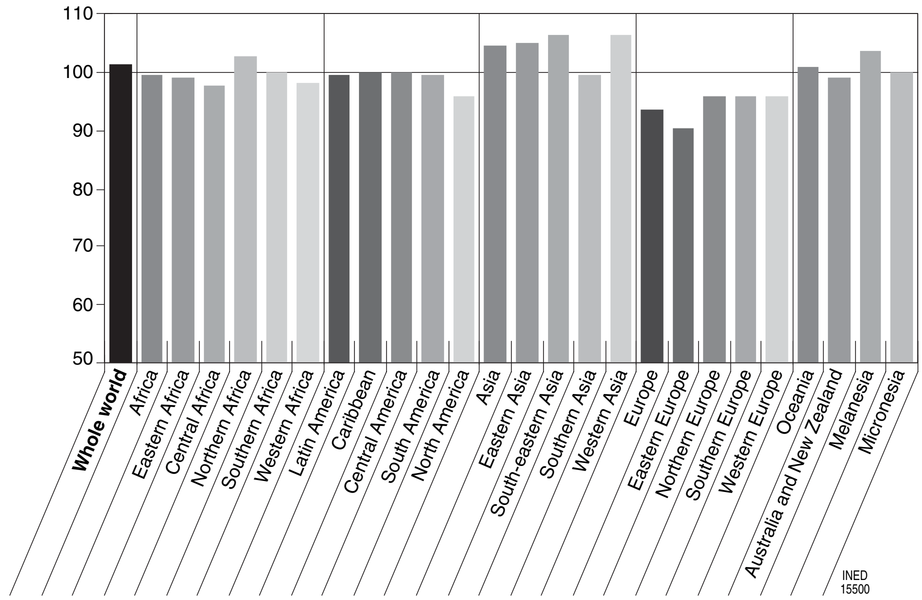

FIGURE 4–14 Distribution of countries by global sex ratio circa 1995. (Source: United Nations, 1997.)

the former is 91 because of the high emigration of males and 134 in the latter owing to high immigration of males.

Naturally, however, the effect of birth, death and migration flows on the balance between the sexes operates differently at the different ages. Accordingly, the population's age structure acts on its sex structure: the more elderly there are in a population, the more the impact of excess male mortality affects the sex structure.

b. Age-specific Sex Ratio

In the absence of migration, the *age-specific sex ratio* (the number of men of a given age to the number of women of same age) follows a classic pattern: around 105 at birth, then with equal balance between men and women at ages 40 to 50, before falling far below 100 at the older ages.

The starting point is the fact that nature produces more baby boys than baby girls. The *sex ratio at birth* (number of male births per 100 female births) is generally very close to 105. This is one of the very rare demographic parameters that is virtually constant. Without any voluntary intervention on the sex of the future offspring (such interventions being limited for the moment),[5] the variations observed around this level of 105 are rare and slight, to the extent that any deviation alerts the expert demographer to the risk of birth registration deficiencies (Vallin, 1973).[6]

This slight headway for boys then dwindles gradually (in the absence of migration) as a result of excess male mortality, which may vary a lot across countries. Figure 4–15 displays the age-specific sex ratios for India and Russia in 1995. The trace of international migration is almost negligible (except for Russia around age 25 years, owing to the recent waves of immigration of young adults, mostly men). Excess male mortality is, on the other hand, much higher in Russia than in India, a country where excess female mortality from childhood to puberty increases the sex

[5] Social preferences for boys or girls (usually for boys) are very strong in some societies, but could until now have little impact on the sex ratio at birth, since sex could not be determined prenatally. The preference for boys has sometimes led to infanticide of baby girls (not only in China), but that affects the ratio of male to female death rates and not the sex ratio at birth. In recent years, however, the development of prenatal scans and amniocentesis has come to permit the prenatal diagnosis of sex, thus opening the door to possible selective abortion. Apparently the latter is beginning to spread in some Asian countries. In certain regions of India and China, the sex ratio at birth in the early 1990s reached values as high as 110 or even 120, and the level increases very significantly with rank of birth (Miller, 1996). At an earlier stage, now we have *in vitro* procreation, the child's sex can theoretically be chosen at time of conception. However, this procedure is rare and statistically negligible.

[6] When registration is incomplete, more baby girls than boys are excluded from the statistics. This is traditionally a case of negligence: it is less important to report the birth of a daughter than of a son. It may also, more seldom, mean some female births have been concealed: in China, for instance, the one-child family policy leads some families to hide the fact they have had a daughter in the hope of having a son later (Miller, 1996).

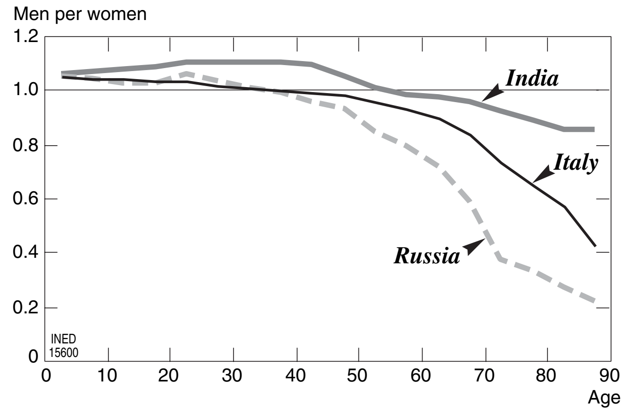

FIGURE 4–15 Age-specific sex ratio in Russia and India in 1995 (Source: United Nations, 1997.)

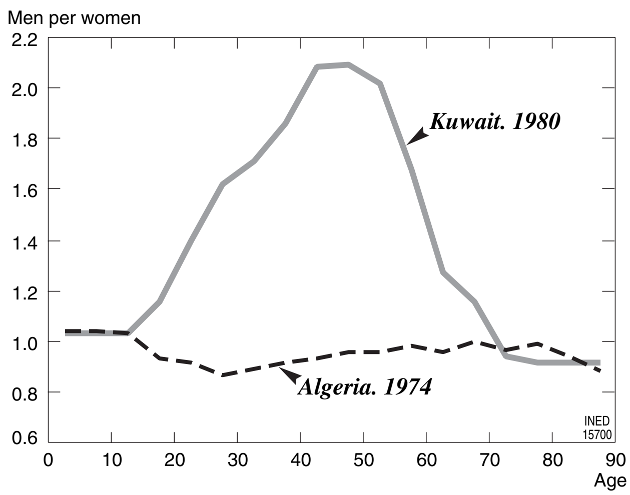

FIGURE 4–16 Age-specific sex ratio in Algeria (1974) and Kuwait (1980). (Source: Algeria: ONS, 1975; Kuwait: CSO, 1995.)

ratio until about the age of 55. In Russia, by contrast, there is excess male mortality at all ages and, leaving aside the anomaly observed at age 25, the sex ratio declines age-wise from birth on, with acceleration after age 50; by the age of 90, there are no more than 20 men for 100 women. We have plotted the curve for Italy in 1995 between these two extreme cases; it is a country with no excess female mortality (unlike India) but with more moderate excess male mortality than in Russia.

Figure 4–16 shows Algeria in 1975 and Kuwait in 1980, two countries whose recent history is marked by migration flows, mostly of men, but in opposite directions. In Algeria, the mass emigration of workers to Europe, France in particular, during the 1960s and 1970s has produced an exceptional deficit of young adult men, whereas in Kuwait, the mass immigration of (often skilled) labor as a consequence of the oil boom has brought the sex ratio to exceptionally high levels at the active ages. Thus, variations in the age-specific sex ratio bring into sharper focus the phenomena that were already clearly detectable on the population pyramid.

Once again, we see to what extent a population's age–sex structure varies as a result of birth, death, and migration trends. Nonetheless, we can also understand the interest of refining the indicators we have used so far (the crude rates) to measure these three factors of population dynamics. Indeed, the variety of the structures means that the crude rates of birth, death, and migration do not measure exactly the phenomena at stake (fertility, age at death, and migration at different ages), but only their combination with the age–sex structure prevailing at a given moment in time.

To go further in the analysis, it is necessary to study fertility, mortality, and migration by sex and age.

II. CRUDE RATES AND AGE-SPECIFIC RATES

Just as the crude death rate is estimated by relating the events occurring in a period to the mean population in that period[7], so the age-specific rates are calculated by relating the events occurring at a given age during the reference period to the mean population of this age during the period.

Like the crude rates, the age-specific rates are generally calculated from annual observations. They can also be calculated on the basis of shorter or longer periods of observation. In this case, to obtain the annual dimension that is universally used for purposes of comparison, the denominator must simply be multiplied by the number of years (or the fraction of a year) that gives the dimension of the reference period.

1. Age-specific Mortality

The *death rate* $m_{(x,t)}$ at age x in year t is obtained by relating the deaths $D_{(x,t)}$ occurring that year among persons of that age to the mean population of same age (generally estimated by the simple average of the

[7] In the preceding chapter, we have seen that a crude rate for all ages can be calculated by relating the number of events to the mean population. For instance, the crude death rate m_t in year t is equal to:

$$m_t = -\log\left(1 - \frac{D_t}{P_t}\right) \cong \frac{D_t}{(P_t + P_{(t+1)})/2}$$

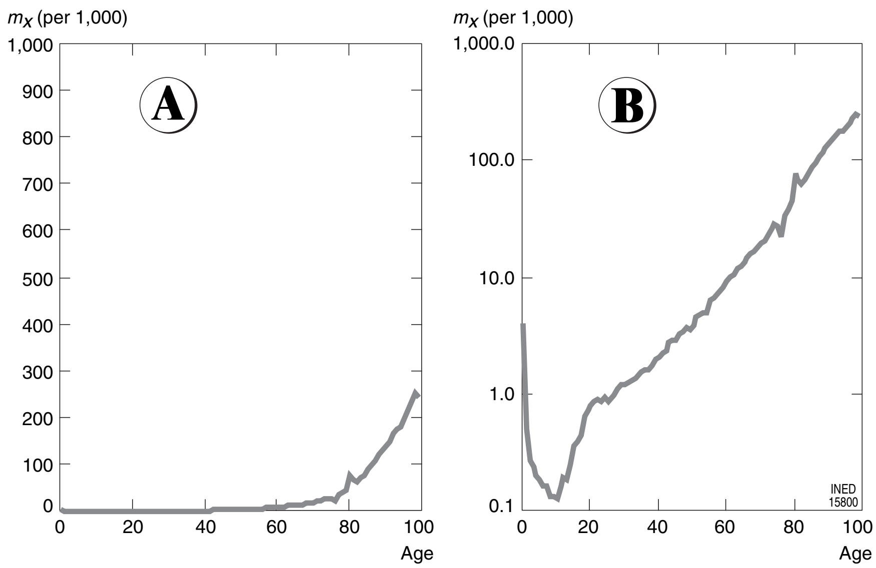

FIGURE 4–17 Age-specific death rates in France, 1995: arithmetic and semilogarithmic representations.

populations $P_{(x,t)}$ and $P_{(x,t+1)}$ on the two 1 January surrounding t)[8]:

$$m_{(x,t)} = \frac{D_{(x,t)}}{(P_{(x,t)} + P_{(x,t+1)})/2}$$

Thus, in France, the *Statistique du mouvement de la population* (Demographic Yearbook) for 1995 informs us that 774 people died that year at the age of 22. According to Institut National de la Statistique et des Etudes Economiques, the population of this age was 861,362 on January 1, 1995 and 808,621 on January 1, 1996. The death rate at age 22 is therefore:

$$m_{22} = \frac{774}{(861,362 + 808,621)/2} = 0.93\text{‰}$$

The rate can be calculated in this way for each individual age or by age groups, in particular when the distribution of deaths (or of population) is known only by age groups:

$$m_{((x,x+a),t)} = \frac{D_{((x,x+a),t)}}{(P_{((x,x+a),t)} + P_{((x,x+a),t+1)})/2}$$

[8] This approximation follows on directly from the preceding footnote:

$$m_{(x,t)} = -\log\left(1 - \frac{D_{(x,t)}}{P_{(x,t)}}\right) \cong \frac{D_{(x,t)}}{(P_{(x,t)} + P_{(x,t+1)})/2}$$

We shall see in Chapter 9 that to estimate mortality by this rate supposes, in addition, either the absence of all competing factors (here, migration) or independence between the competing factor(s) (here, migration) and the studied phenomenon (here, mortality). Finally, it supposes of course that the population is homogeneous (Chapters 9 and 14).

Figure 4–17 illustrates the results for France in 1995. On the left side, with an arithmetic scale, the rates are very low until age 50 to 60 years, then rise rapidly with age, in a near-exponential manner. That explains why, conventionally, age-specific mortality rates are plotted using a log scale (right-side graph): the variations at young ages become more visible and the near-exponential growth at older ages can be verified.

This age-wise mortality increase can be interpreted as the statistical translation of the process of biological aging of the human body. The older one becomes, the more the vital functions become impaired and the greater the risk of dying. The regularity of the age-wise increase in the risk of dying is striking, even if causes other than aging can bring about death. There are two exceptions to this regular progression. One, observed everywhere, concerns the first years of life; the other is around age 20 and is more specific to the example shown here. First, at the youngest ages, mortality begins by diminishing with age, until approximately age of 10. This is the effect of another biologic process: birth and the first days of life are particularly perilous (obstetric trauma, environmental aggressions with which the newborn cannot yet cope, elimination of serious congenital malformations spared by intrauterine mortality, etc.), and these dangers disappear rapidly as the infant ages. At around age 10, this process is essentially completed and the process of biologic aging starts to take over, thus inverting the age-specific mortality trend. Around age 20, however, another exception is observed: a strange hump in the curve that has no biologic explanation, but reflects the excessive importance of traffic accidents in mortality at these ages. Indeed, within the framework imposed by the biologic process, an actual mortality level depends also on social behaviors and on the health system.

2. Age-specific Fertility

The shift from crude birth rate to age-specific rates is more complex. It is obviously not the newborn who must be differentiated by age but the parents, whose propensity to procreate must be measured. To mark this difference, the conventional terminology distinguishes between *fertility*, which is measured by age, and *natality*, which refers to the global frequency of births. Furthermore, fertility depends on three elements: women's reproductive capacity, that of men, and the meeting of these two aptitudes through couple formation, with all three elements depending on age. There are therefore at least three ways to measure a population's fertility, according to whether it is approached from the angle of women, men, or couples. The latter is the most complex approach. It requires knowledge of couple formation and dissolution by duration of union. But couple formation is closely linked to reproductive capacity and it is this (therefore the age of the partners) that first and foremost governs a population's fertility; thus, the idea of approaching fertility via the individual. However, a choice must be made: via men or via women? The convention is to measure women's fertility,[9] for at least two reasons, a theoretical one and a practical one. Biologically, it is the woman and not the man who sets the limits of a population's fertility: a woman generally brings to maturity only one ovum per cycle, when fecunded she then has 9 months of pregnancy, and once the child is born there will be a lapse of time (that may be lengthened if she breast-feeds) before ovulation is resumed. A man emits millions of spermatozoa and is subjected to none of the constraints of pregnancy. In a population, therefore, women's fertility could theoretically reach its biologic maximum with a very small proportion of men. By contrast, it is difficult to imagine how many women would be needed to bring just one man's fertility to a biologic maximum. This argument is theoretical, however, insofar as humans are essentially monogamous. More concretely, maternity is more visible and easier to verify than paternity and its observation is simpler. It is more rare for a birth to be registered as "of mother unknown" than "of father unknown." In a survey, it is easier to enumerate a woman's offspring than a man's, and a man may even have children whose existence is unknown to him.

Having opted for this course of action, the age-specific *fertility rates* $f_{(x,t)}$ can be calculated in the same way as the age-specific death rates, but putting in the denominator only the number of women: at age x in year t, the births $N_{(x,t)}$ to mothers aged x in year t are related to the average of the numbers $F_{(x,t)}$ and $F_{(x,t+1)}$ of women aged x on the first of the two Januarys surrounding t.

$$f_{(x,t)} = \frac{B_{(x,t)}}{(F_{(x,t)} + F_{(x,t+1)})/2}$$

So, in France in 1995, 25,766 children were born to mothers aged 22 and the number of women of this age was 424,430 on January 1, 1995 and 398,774 on January 1, 1996, which gives a fertility rate at age 22 of:

$$f_{22} = \frac{25,766}{(424,430 + 398,774)/2} = 62.6\%$$

This rate can be calculated for each age or age group. It is obviously null before puberty and after the menopause; the usable age span is approximately from age 15 to 50.

Reading the results for France in 1995 (Figure 4–18), the fertility rate is very low before age 18, then increases rapidly, peaking at ages 26 to 27 at a level of 150/1000 before decreasing, more slowly, and becoming almost negligible after age 40. Like the relation of the mortality curve to aging, this curve is closely related to a biologic process: fecundity. Fecundity begins at puberty and ends normally with the menopause, but may also, for a variety of reasons, continue for longer or stop earlier, so that even between ages 15 and 50, the proportion of fecund women is

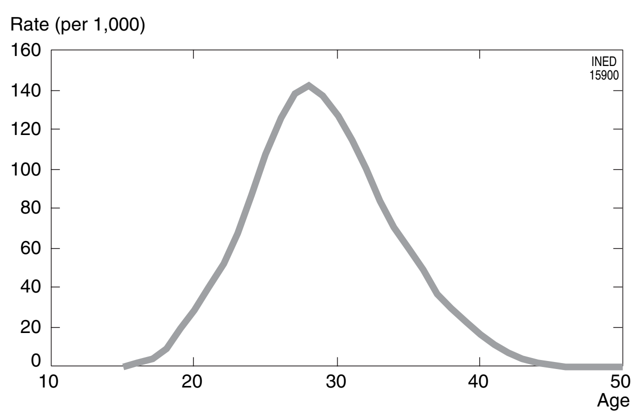

FIGURE 4–18 Age-specific fertility rates in France, 1995.

[9] Men's fertility is sometimes measured, and the results can be quite different, with a notably higher level of male than female fertility, in particular in cases of polygamy and large age gaps between spouses (Brouard, 1977, 1989; Maffioli, 1992; Pison, 1982).

never 100% and varies with age, peaking, once more, at around the age of 25. However, as in the case of mortality, within the limits set by this biologic constraint, fertility is filtered by social rules and individual attitudes, which organize sexual relations (notably through couple formation) and modulate their results.

Even more than for mortality, this fertility curve allows us to perceive to what extent the total number of births observed in a population (and so the crude birth rates) can depend on its age–sex structure. An immigrant population, for instance, can have high fertility but low birth rate, if the immigrants are mostly men. Similarly, when depleted cohorts, such as those born during the war, enter the childbearing ages, the birth rate falls all the more sharply as the fertility curve is concentrated on a small number of ages.

3. Age-specific Migrations

In the same way as for mortality and fertility, it is possible to calculate at each age the rates of *immigration*[10] $i_{(x,t)}$, *emigration* $e_{(x,t)}$ and *net migration* (or *balance of migration*) $nm_{(x,t)}$, by relating the numbers of immigrants $I_{(x,t)}$, emigrants $E_{(x,t)}$ and the net number of migrants ($I_{(x,t)} - E_{(x,t)}$) observed at each age in a given period, to the mean population of same age in the period. Thus, at age x in year t, we have:

$$i_{(x,t)} = \frac{I_{(x,t)}}{(P_{(x,t)} + P_{(x,t+1)})/2},$$

$$e_{(x,t)} = \frac{E_{(x,t)}}{(P_{(x,t)} + P_{(x,t+1)})/2}$$

and

$$nm_{(x,t)} = \frac{I_{(x,t)} - E_{(x,t)}}{(P_{(x,t)} + P_{(x,t+1)})/2}$$

The problem is that the data required to calculate these rates are rarely available. Indeed, few countries routinely record migrations, and even when this is the case, registration is even more rarely complete. In most cases, the data are from retrospective questions asked during a census. Even if they are of good quality, that only gives, for international migration, numbers of arrivals but not of departures. For provinces or regions within a country, however, it is possible to calculate rates of in-migration, out-migration, and net migration by age.

The calculation of these rates will differ from the mortality and fertility rates. The data generally refer to a period of more than year and the rates calculated directly will not be annual rates; the population at end of period is known, but not the population at beginning of period, so the mean population cannot be obtained as above.

Let us take the example of the Italian census of 1991, which contained a question on place of residence 5 years earlier. For a given region—say, Lazio—we therefore have the number of residents in 1991 who were not residents in 1986 (immigrants) and the number of residents in 1986 living elsewhere in 1991 (emigrants). We note here a third problem: among the "immigrants" we have in-migrants from other regions of Italy as well as immigrants from other countries, whereas among the "emigrants" we have only out-migrants to other regions of Italy and not emigrants to other countries, who are obviously not covered by the census. The symmetry between immigration and emigration rates is therefore not perfect. This is acceptable, however, when international emigration is negligible compared to mobility within the country. This is roughly the case for Italy that became a country of immigration in the 1980s.

To calculate the mean population for the denominator, an initial population must be calculated by adding to the census population of each age in 1991 the deaths that have occurred during the five preceding years in each of the corresponding birth cohorts and net migration must be subtracted.

We then obtain rates of immigration, emigration, and net migration by age (here, in fact, we have only 10-year age groups) for the period 1986 to 1991. For instance, at ages 25 to 34, the immigration rate is:

$$i_{(25-34)} = \frac{I_{(25-34)}}{P_{25-34,1991} + (D_g - I_g + E_g)/2}$$

where D_g, I_g and E_g are the numbers of deaths, immigrants, and emigrants since 1986 in the birth cohorts aged 25–34 in 1991. To estimate E_g, of course, international emigration that escapes the census must also be estimated. Using a number of hypotheses that we lack space to develop here, Istituto Nazionale di Statistica has reconstructed the populations by region and age groups in 1986. On the basis of these estimations, having now a population at beginning and end of period, we can proceed as follows:

[10] Leaving aside the conceptual problem raised by the notion of immigration rate, mentioned in the previous chapter, given that immigration is an event that affects individuals who are external to the study population. The immigration rate is in fact a risk of emigrating for individuals external to the population, which cannot be measured because the denominator is unknown. By calculating immigration rates, it is considered that the host population (and not the individuals forming it) is globally subjected to a risk of immigration. The nature of this risk is obviously not the same as the risk of emigration, even if the two are apparently perfectly symmetrical.

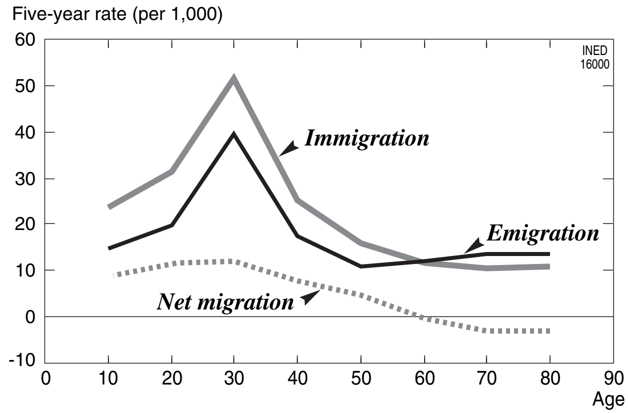

FIGURE 4–19 Age-specific immigration, emigration, and net migration rates for the Italian region of Lazio during the 5 years before the 1991 census.

$$i_{(25-34)} = \frac{I_{(25-34)}}{(P_{25-34,1986} + P_{25-34,1991})/2}$$
$$= \frac{41,817}{(788,721+830,524)/2} = 0.052 = 52\%$$

In the same way:

$$e_{(25-34)} = \frac{32,133}{(788,721+830,524)/2} = 40\%$$

and

$$nm_{(25-34)} = \frac{41,817-32,133}{(788,721+830,524)/2} = 12\%$$

Figure 4–19 shows the variations in these different rates by 10-year age groups. The immigration and emigration curves are similar and classic, peaking sharply around age 30. Net migration on the other hand is biased, as we have mentioned, by the fact that international emigration is not taken into account.

These results, we have said, concern a 5-year observation period. To give them an annual dimension, for comparison with the mortality and fertility rates calculated previously, we can as a first approximation divide them by five.[11]

4. The Relationship Between Crude Rates and Age-specific Rates

The crude rates measure the frequency with which the studied events (deaths, births) occur in a population, but they do not inform us about actual mortality and fertility, which are expressed more accurately by the mortality and fertility functions by age described by the age-specific rates. The crude rate is in fact nothing but a weighted average of the age-specific rates by the proportions of population[12] of each age. So, for the crude death rate d we have:

$$d = \sum_{x=0}^{\omega} m_x p_x \Big/ \sum_{x=0}^{\omega} p_x$$

and for the crude birth rate b:

$$b = \sum_{x=0}^{\omega} f_x p_{f,x} \Big/ \sum_{x=0}^{\omega} p_x$$

where $p_{f,x}$ represent the proportion of women by age and p_x for both sexes by age.

With the same mortality and fertility rates, two populations with different age–sex structures will have different crude death and birth rates. Two examples will amply illustrate the practical importance of this difference between crude rates and age-specific rates.

Let us suppose, for example, that the population of Kenya in 1969, whose population pyramid we have shown in Figure 4–8, had the same mortality as France that year. Using the French age-specific death rates, we calculate the crude death rate that Kenya would have had that year and compare it with the actual French one. To do so, we simply multiply, age by age, the French rates by the Kenyan proportions of population (Table 4–3).

The same mortality gives a crude rate of 11.6/1000 with the French age structure and only 6.9/1000 with the Kenyan age structure. This is obviously explained by the fact that the population of Kenya is much younger than in France, where the high death rates among the elderly concern much larger numbers of the population and weigh more heavily on the crude rate than when these rates are applied to the Kenyan population. We can see how important a population's age structure is for the expression of one of the components of its natural dynamics, mortality.

The same holds, more or less, for fertility, although with a slight difference in that the balance between men and women intervenes more directly and that, with respect to age, it is the childbearing ages that weigh most heavily on the expression of the second component of natural dynamics. Let us apply, for instance, the French age-specific fertility rates in 1980 to the age–sex structure of Algeria in 1974 and China in 1995. With the same fertility rate, we obtain a crude birth rate of 13/1000 in Algeria and 18/1000 in China instead of 15/1000 in France.

[11] By so doing, we suppose that events are distributed equally over the 5-year period. Another hypothesis would be to suppose the annual rates were constant over the 5 years.

[12] We refer here to the average population observed during the considered interval of time (the mid-year population for annual rates).

TABLE 4–3 Comparison of the crude death rate in France in 1969 and the crude death rate Kenya would have had that year with French age-specific death rates

Age	Age-specific rates	Age structure of population		Weight of age-specific rates	
	France, 1969	France	Kenya	France	Kenya
0–4	0.0046	8.45	19.23	0.0004	0.0009

It may seem surprising that the birth rate obtained for Algeria is lower than that in France although the relative proportion of women in the Algerian population is augmented by the mass exodus of male workers (Figure 4–16). In fact, this phenomenon is more than offset by the very large numbers at the base of the population pyramid (Figure 4–10), which, on the contrary, reduce the weight of women of childbearing ages. By contrast, in China, the proportion of women of childbearing ages is swollen by the facts that the younger cohorts are reduced by the recent fertility decline, the cohorts aged 50 to 60 years are reduced by the birth deficits due to the Sino-Japanese and second world wars, and the older cohorts are still very small; this explains why the crude birth rate is higher than in France and far higher than in Algeria. We can see how the exceptional Chinese age structure promotes high birth rates, so that, despite the considerable headway already achieved, the fertility level continues to preoccupy the authorities.

The same relationship naturally exists between the crude rates and the age-specific rates of migration. Given the same propensity to migrate at all ages, the crude rate will depend on the population's age structure.

TABLE 4–4 Comparison of the French crude birth rate in 1980 and the crude birth rates 1974 Algeria and 1995 China would have had given the French age-specific rates

Age	Age-specific rates	Proportion (%) of total population			Weighting of age-specific rates

III. THE RELATIONSHIP BETWEEN AGE-SPECIFIC RATES, AGE STRUCTURE, AND POPULATION GROWTH

We have now seen how the two elements of natural population dynamics (fertility and mortality) affect the age structure and how, reciprocally, the latter affects the translation of population dynamics in terms of crude birth and death rates and, therefore, natural increase. To show this, we have focused on the diversity of particular situations often inherited from specific events. Let us now consider globally the historical transformation of age structures resulting from the revolution of demographic behaviors that began in Europe in the 18th century, and more recently in the rest of the world, and how this structural change has affected population growth.

Starting in the mid 18th century in Europe, a long period of in-depth economic and social transformations led to a decisive mortality decline, among other consequences. In a first stage, this mortality decline created a gap with fertility, which remained unchanged, thereby opening up an era of exceptional population growth. In a second stage, fertility also began to decline and population growth decelerated. The birth rate then drew closer again to the death rate until a quasi-balance was once more struck between the two components of natural increase, this time at a very low level for both. These mortality and fertility declines radically transformed the population pyramid, which, in turn, contributed to translating these declines in terms of population growth.

1. The Historical Transformation of Two Population Pyramids: France and England

This same transformation affected France and England differently. In England, the pattern of change was a classic one, whereas in France where the mortality and fertility declines began early and simultaneously, population growth was modest and the aging of the pyramid occurred sooner (Figure 4–20).

In England[13], between 1750 and 1850, the mortality decline, in the absence of fertility decline, produced an unprecedented population growth and a broadening of the base of the pyramid. The total population soared from 5.8 million to 18 million in the space of a century, whereas the proportion of those younger than 15 years rose from 32.9% to 36.0%. With fertility essentially constant[14], the total population growth was due essentially to the mortality decline, but this also made the population younger, since the gain was in infant mortality and this produced a result comparable to an increase in birth rates. By contrast, during the same 100 years in France, the population growth was moderate, from 25 to 36 million, and the proportion of those younger than 15 years fell from 32% to 27%. The reason is that the fertility decline, begun concomitantly with the mortality decline as early as the mid 18th century, so reduced the birth rates (from 40 to 27 per 1000) that the absolute annual number of births stopped rising and even fell slightly, despite the population growth and an age structure that was increasingly favorable to the proportion of women of childbearing ages. On the other hand, as in England, the mortality decline focused on infant mortality, which to some extent thwarted population aging by slowing down the reduction of the proportion of those younger than 15 years.

Half a century later, with the continued reduction of both fertility and mortality in France, the population has virtually stopped growing (from 36 to 38 million) but the proportion of children has continued to fall (from 27.3% to 25.6%). In England, by contrast, the population has continued to progress rapidly (from 18 to 33 million). However, it is also in the middle of this period that the long-term fertility decline finally emerged in England, more than a century after France, and the pyramid can be seen to start narrowing at the base as the proportion of those younger than 15 years falls from 36% to 32%.

Let us jump forward another 50 years to 1951. We find a total population that has barely increased in France (43 million), a proportion of those younger than 15 years that has continued to shrink (23%), and a very irregular population pyramid. In fact, this situation is the combined result of several factors working in opposite directions. On one side, World War I severely reduced the male cohorts born in 1880 to 1898 and produced a major deficit of births in 1914 to 1918. These same depleted cohorts were then hit by World War II and produced new undersized birth cohorts in 1940 to 1944.

On the other side, after 40 more years of fertility decline, the behavioral changes that emerged during World War II suddenly brought about a rise in birth rates after the Liberation, which by far exceeds a simple catching-up of postponed births, and marks the beginning of a new period of population growth in

[13] For England, we reconstructed the historical population pyramids from unpublished data elaborated for the preparation of *The population history of England 1541–1871* (Wrigley and Schofield, 1981) and kindly communicated by Edward Wrigley.

[14] In fact, it increased during the second half of the 18th century, then fell in the early 19th century, so that the birth rate recovered in 1830 to 1850 the level of 35/1000 it had had in 1750 to 1760 (Vallin, 1994).

France. Without this invigoration of fertility, which suddenly widens the base of the pyramid, the proportion of those younger than 15 years would have fallen below 20% and the French population would have been no more than 40 million. These 40 million would not have been reached without the net migration that was positive almost continuously from the end of the last century (Figure 4–20).[15]

During the same interval, England's population continued its strong growth, from 33 to 44 million, but it was now its turn to enter fully into the phase of population aging as a result of the fertility decline. This evolution is accentuated by the birth deficits in the two world wars (even if the impact of the first is much slighter than in France). Finally, like France, it is marked by the baby boom of the late 1940s, but that is not enough to prevent the proportion of those younger than 15 years falling from 32% to 22%, the same level as in France.

At this stage, especially in France but also in England, the changing shape of the population pyramid had a profound impact on the conditions of expression of mortality and fertility in terms of crude rates and consequently of natural increase. In fact, apart from the fluctuations produced by the aging of the depleted wartime cohorts, these changes do not affect so much the birth rates, insofar as there is a gradual swing between the reduction of the share of young people and the increase of the proportion of elderly, leaving the adult (and childbearing) ages relatively stable. By contrast, regarding mortality, the population aging tends to slow down considerably the reduction of the crude death rate as the age-specific rates decline. So, in 1950 to 1951, the crude death rate in France was 12.8/1000, but with the age structure of 1750, it would be no more than 7.5/1000. The crude birth rate, instead of the observed 19/1000, would be 22, whereas the growth rate, instead of 0.6% would be 1.5%, almost three times more. We can see to what extent change in population structure, under the effect of change in fertility and mortality, modifies in turn the resulting population dynamics.

Since 1950, there have been many further changes in France and England. With slight variations, after the exceptional rejuvenation of the pyramids linked to the baby boom, both countries continue their route of rapid population aging under the dual effect of a resumption of the secular fertility decline and a change in the nature of the mortality decline. Indeed, if fertility remained at the relatively high level of the 1950s until around 1970, it then began a new downward trend, the end of which is difficult to forecast today. Also in the 1970s, a new mortality decline emerged, in which cardiovascular diseases took over from infectious diseases as the focus of the victory over death. The result is an unprecedented mortality decline at older ages, while the progress made in infant mortality, already at very low levels, has stagnated. Previously a factor of rejuvenation, the mortality decline thus becomes per se a factor of population aging.

At the dawn of the 21st century, therefore, France and England, with some 60 million inhabitants each, present similar age structures: already filled out towards the top (20% of 60+ in France in 1997 and 21% in England in 1990) and narrowed at the base (19% of under-15s in both countries), but having for the moment exceptionally high proportions of adults aged 20 to 50 years. The latter presently delay the reduction of birth rates, but this reduction may be all the more severe in the future when the following cohorts, who are much less numerous, reach the childbearing ages; at the same time, the currently exceptional proportions of adults will accelerate the aging of the population as they progress further up the pyramid. Thus, a third factor of demographic aging, added to the specific effects of mortality and fertility change, is already written into the age structure of these two populations.

2. Fifty Years of Change in China

Figure 4–21 illustrates the case of China, whose population pyramid has undergone the same combined effects of interactions between structure and dynamics, as a result of the same kind of evolution, but within a much shorter lapse of time. Indeed, China has covered in a few decades virtually the same path as France in two centuries.

In 1953, the Chinese pyramid was almost exactly triangular above age 8 or 9, as a result of long-term near-constant fertility and mortality, which produced a fairly modest rate of growth. However, the base of the pyramid is very broad owing to the rapid but recent decline of infant mortality, a sign of the considerable health progress made as from the late 1940s.

In 1964, the pyramid above age 10 is in large part simply a moving upward of the pyramid for 1953. We note just a perceptible hollowing for the cohorts born around 1945, who were still children during the Great Leap Forward and suffered especially from the famine in 1960 to 1961. It is this period of crisis that cuts deeply into the pyramid at age 4, most acutely, but also at ages 5, 6, and 3, signing the remarkable deficit of births we have previously discussed (Figure 4–7). The

[15] Apart from the 1930s when the economic crisis reversed the trend.

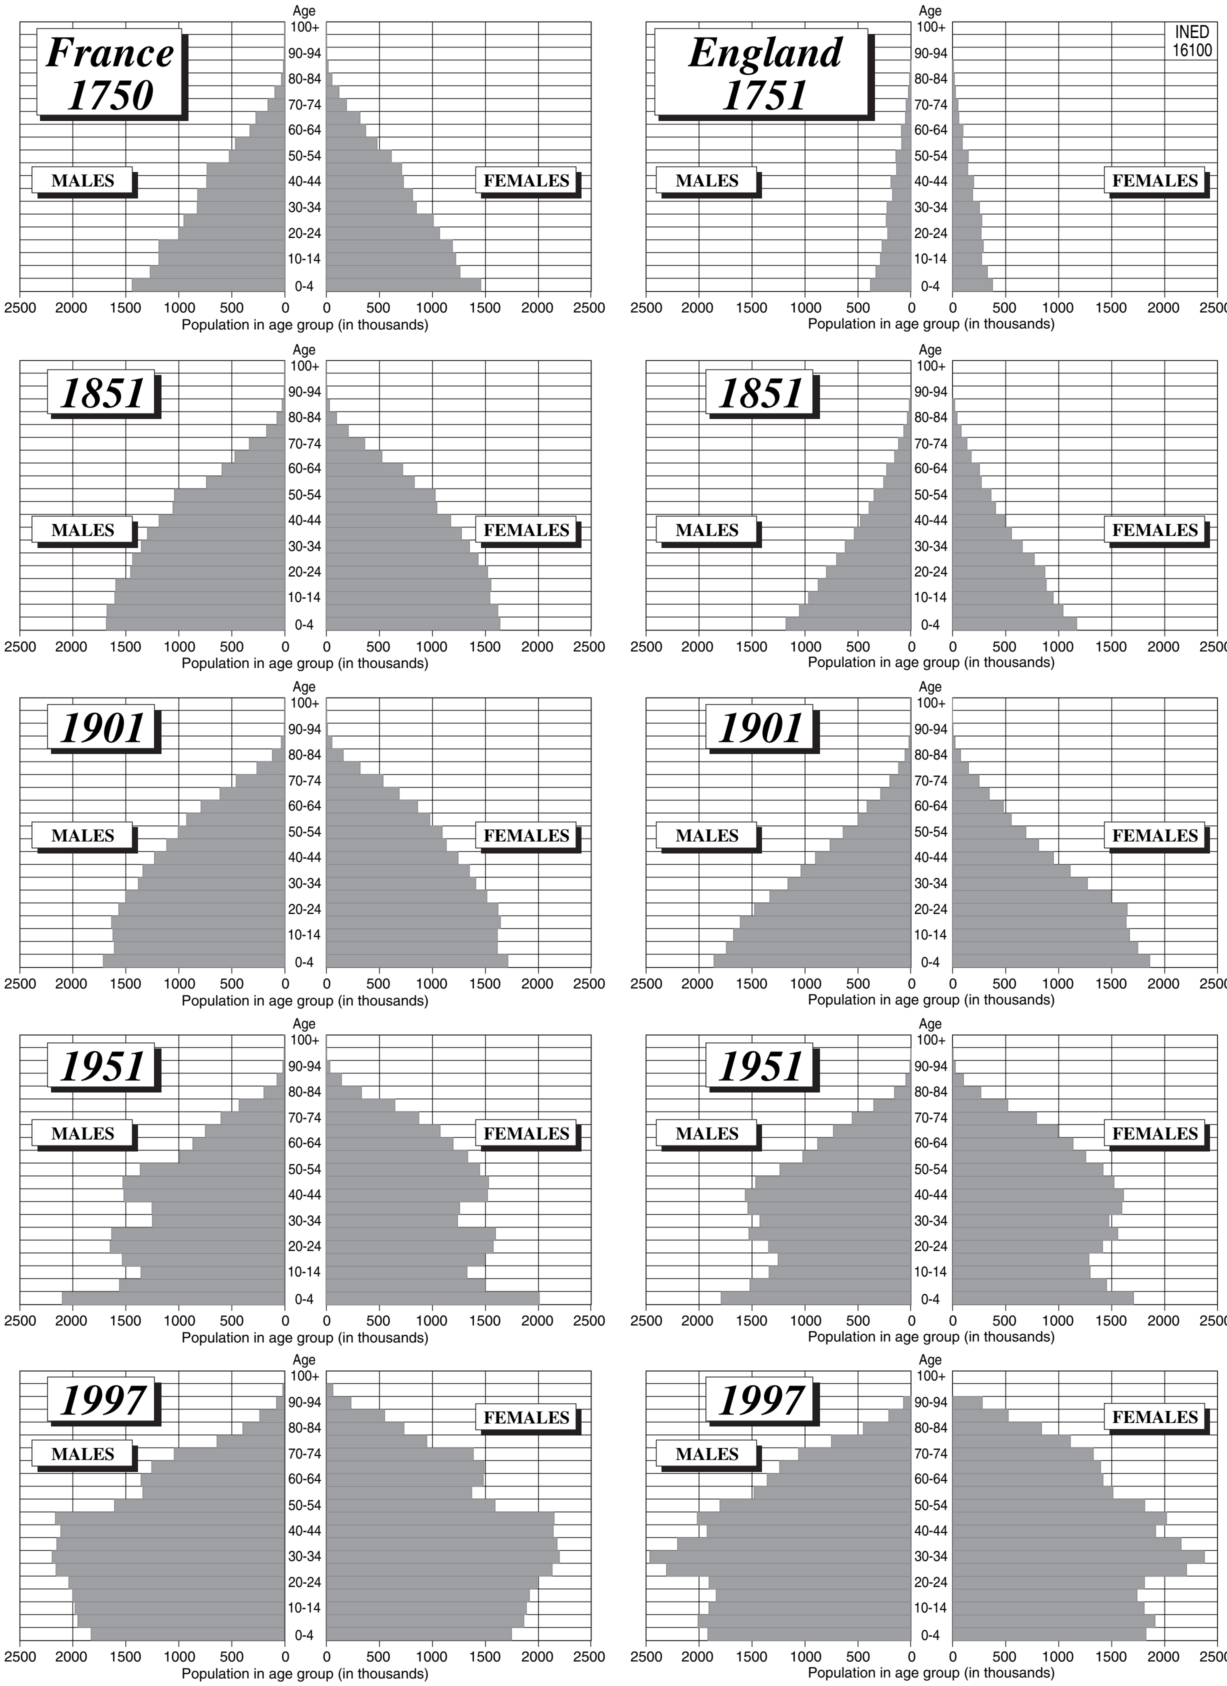

FIGURE 4–20 Evolution of the population pyramids of France and England since 1750.

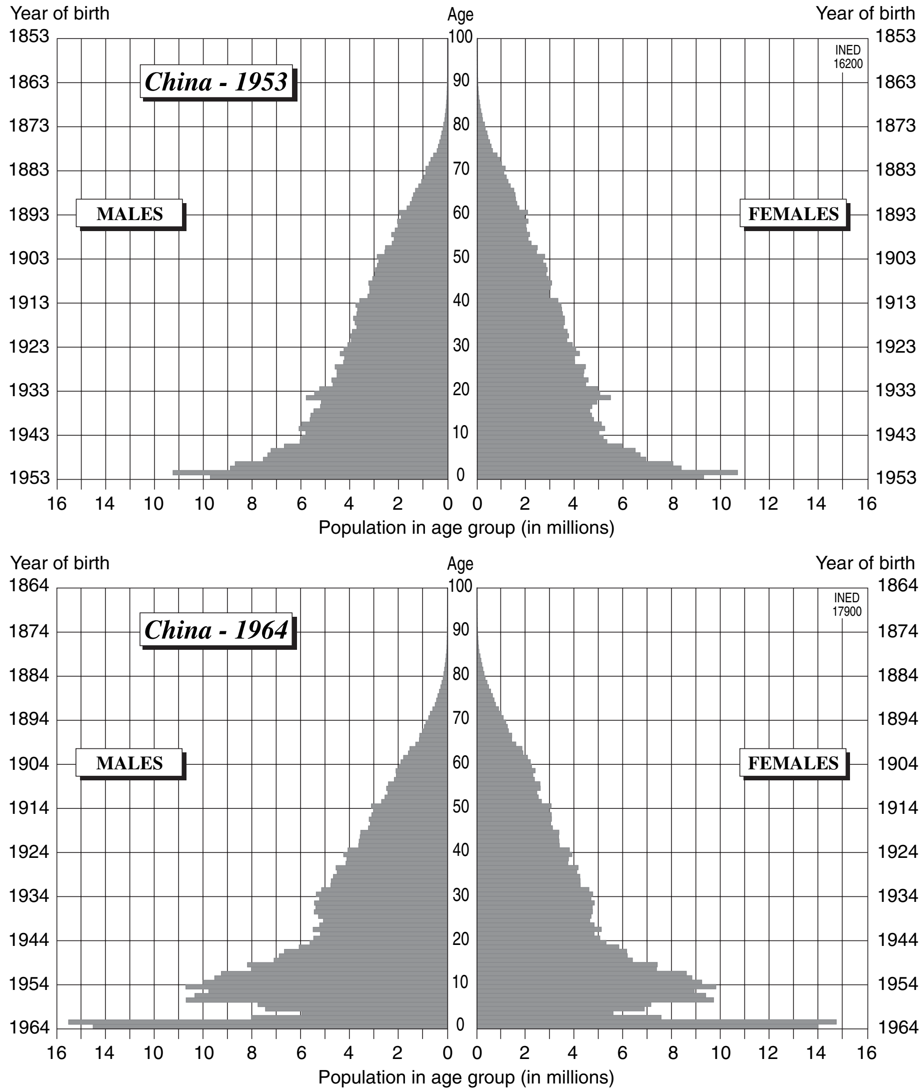

FIGURE 4–21 Evolution of China's population pyramid, 1953–1990.

exceptionally large populations of ages 0 and 1 express the revival of births that then followed this dramatic crisis.

These events can also be traced in the 1982 population pyramid, moved on 18 years from that of 1964. But the base of the pyramid has again changed. After the relatively high fertility of the post–Great Leap Forward years, which produced 10 inflated, although fluctuating, birth cohorts from 1963 to 1973, a new change can be noted. Starting in 1970, the birth control policy became more severe, which downsized the subsequent cohorts. The impact was all the greater as the couples concerned included the depleted cohorts of the Great Leap Forward.

Once again, the population in 1990 bears the marks of these events, some ages higher up, but once again the base of the pyramid is changing. The very large cohorts born after 1962 have now reached the childbearing ages and, as a ripple effect, engender a second baby boom, although a minor one compared to the years 1963 to 1972. Contrary to what was often suggested at the time, the upturn is indeed due more to this structural effect than to a real failure of China's birth control policy. The very base of the pyramid shows, in fact, a reduction of birth rates after 1988 and a new cutback in the size of the last two cohorts.

These interactions between population structure and population dynamics, which we have approached intuitively by examining the historical evolution of a number of population pyramids, will find formal expression in Lotka's equations and in population models (see Chapter 20). Before exploring these, however, we will need to delve further into mortality and fertility analysis (Chapters 11 and 12).

PART

II

THE LONGITUDINAL APPROACH

Description of Demographic Processes in a Birth Cohort

GRAZIELLA CASELLI AND JACQUES VALLIN

So far, the natural and migratory components of population dynamics have been considered through a period analysis of specific situations. Thus, the period risks of individuals of a given age were approached by defining age-specific fertility, mortality, and migration rates. These age-specific risks clearly display between-population variability and between-period variability within the same population. A closer analysis means clarifying, for each component of change, the nature of the relations between these age-specific risks, to combine, then incorporate them in population models, to give a fuller picture of the mechanics of population dynamics.

The most straightforward way to understand what these age-specific rate series mean and how they can be combined is to stay as close as possible to the real-life experiences and events of the individuals who make up the population. Instead of looking at the risk exposure at each age during a single year, we will look at the risk exposure at each age of their lives by a universe of individuals born the same year. This is what demographers call the *cohort approach*, as opposed to the *period approach*, based on an analysis of the risks in a specified period.

Essentially, this is a purely descriptive approach to demographic phenomena, considered discretely. It is an essential first step before moving on to a closer analysis that involves the way they interact. This step obviously rests on two fundamental working assumptions: The population is *internally homogeneous* and the phenomena studied are *independent*. Obviously, these assumptions will almost never be perfectly true at all times, so they must be discarded at a later stage to analyze in more specific detail how these different phenomena *interact* in *heterogeneous populations*.

We first briefly describe an age-specific rate matrix by which to distinguish more precisely between the cohort and period approaches (Chapter 5), and then specify the different time breakdowns usable in demographic analysis (Chapter 6) and methods of accounting for and combining cohort and period approaches (Chapter 7). We will then consider the conceptual differences between different measures of incidence relations—frequencies, rates, and probabilities (Chapter 8)—and look more closely at the assumptions of independence between events and population homogeneity (Chapter 9). We will discuss observation methods specific to the cohort analysis of fertility, mortality, and migration (Chapter 10), preparatory to constructing a cohort mortality table (Chapter 11), defining the various longitudinal fertility measures (Chapter 12) and introducing the cohort analysis of migration (Chapter 13).

Variation Through Time of Age-Specific Rates

GRAZIELLA CASELLI AND JACQUES VALLIN

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

Institut national d'études démographiques (INED), Paris, France

Table 5–1 shows a few elements making it possible to find one's way in the matrix of age-specific death[1] rates observed during two centuries in France. In fact, it is rare to have access to such series of age-specific rates. To calculate them, one needs annual statistics concerning age-specific deaths and age-specific population estimates for January 1 of each year. In France even the age-specific death series is only available from 1899 and INSEE, the French Statistical Institute, has only been publishing regular annual estimates of the population on January 1 of each year since 1950. The death rates used here therefore are based essentially on historical reconstructions.[2]

The type of table shown in Table 5–1 can be read from different angles. Each column gives a series of age-specific death rates calculated for a given calendar year, whereas each row represents the annual variations in age-specific mortality. Therefore, Figure 5–1, which covers 10 annual age-specific death rates in columns, illustrates the evolution, in 20-year intervals over two centuries, of the age-specific curve, whereas Figure 5–2, which covers 10 annual series of rates represented in rows, illustrates the evolution of mortality at the ages of 0, 10, 20, . . ., 80, and 90 years, since 1806. These are two illustrations of the same reality seen, on the one hand, from the angle of transformations that health improvements have imposed on the age-specific structure of mortality and, on the other hand, from the angle of specific changes in causes of death at different ages.

This matrix can however, also be interpreted from a third angle, by following people's biographies from their birth until their death. All that is needed for this is to start from age 0 in a given year, to pass to age 1 of the following year, to age 2 of the year after that, and so on until the limit imposed by the available data. If one starts at age 0 in 1881, for example, one reaches the age of 100 in 1981. In this way we follow, according to age, the mortality that affects approximately[3] all of the individuals born during the same calendar year, which demographers commonly refer to as a *birth cohort*. Thus, Figure 5–3 illustrates the changes in the age-specific mortality structure of birth cohorts, by 20-year birth intervals, since 1806.

The differences between Figures 5–1 and 5–3 illustrate the difference between the period and cohort approaches to mortality. One example of the passage from one to the other is indicated on each of the two figures by points in bold.[4] In Figure 5–1, these points make it possible to follow observations of the 1926 birth cohort. The difference between these two illustrations of the same database is obviously due to the fact that mortality has changed over the centuries with improvements in health status. A given birth cohort

[1] The rates used here have been obtained directly, on the basis of deaths by age and on population estimates by age for the period from 1899 to 1996 (Vallin and Meslé), but indirectly, for the period from 1806 to 1898, on the basis of estimated annual age-specific probabilities of dying from historical reconstructions of complete annual life tables (Meslé and Vallin, 1989). The corresponding definitions and calculation methods are described in subsequent sections.

[2] For the period from 1899 to 1950 (Vallin, 1971) and for the 19th century (Meslé and Vallin, 1989).

[3] We will see in subsequent sections that a birth cohort can only be rigorously followed if special conditions are respected in terms of computation.

[4] Birth cohort 1926 in Figure 5–1 and year 1946 in Figure 5–3.

TABLE 5–1 Elements of a complete matrix of annual age-specific death rates for France from 1806 to 1995 (rates per thousand)

Age	Calendar year												
	1806	1807	1808	. . .	1850	. . .	1900	. . .	1950	. . .	1994	1995	1996
0	188.97	199.18	193.95		145.16		188.78		53.54		5.99	5.00	4.80
1	80.98	84.04	75.82		59.09		34.20		5.28		0.49	0.51	0.45

benefits from health conditions that change as it grows older. If, for example, one compares the mortality of a birth cohort with that of the year of its birth, mortality at the first year of age will of course, be largely shared by both series, but gradually the mortality conditions of the birth cohort will grow further away from those of the year of birth and become closer at the older ages to those of the year at which the birth cohort will die out. On the whole, since the change is a decline in the death rate, conditions at the end of life will be better than those prevailing in the year of birth. However, more temporary differences may appear in the

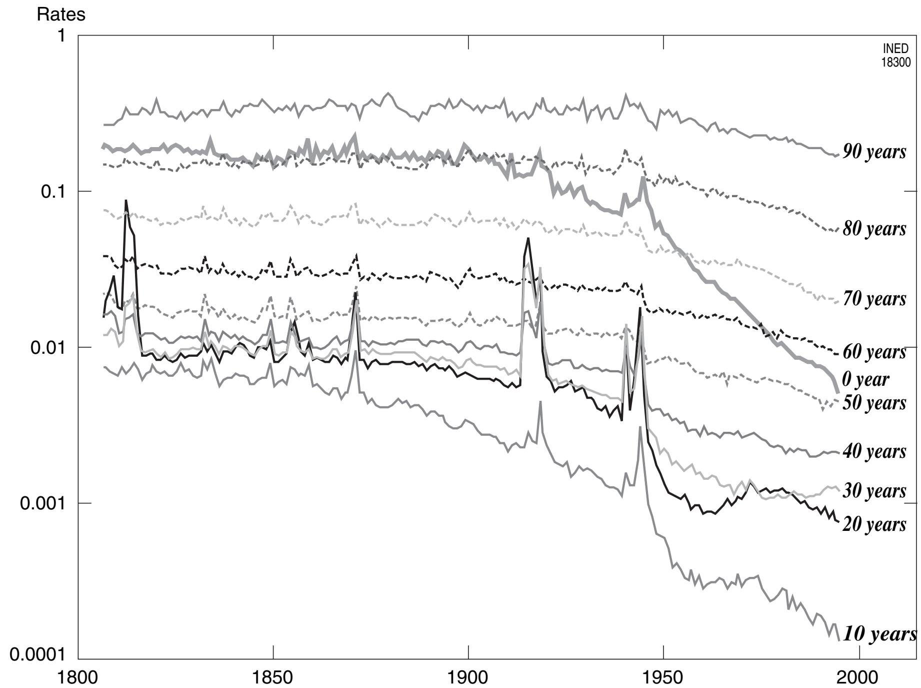

FIGURE 5–2 Annual change (1806–1996) of certain age-specific death rates (0, 10, 20, . . ., 80, 90 years) in France.

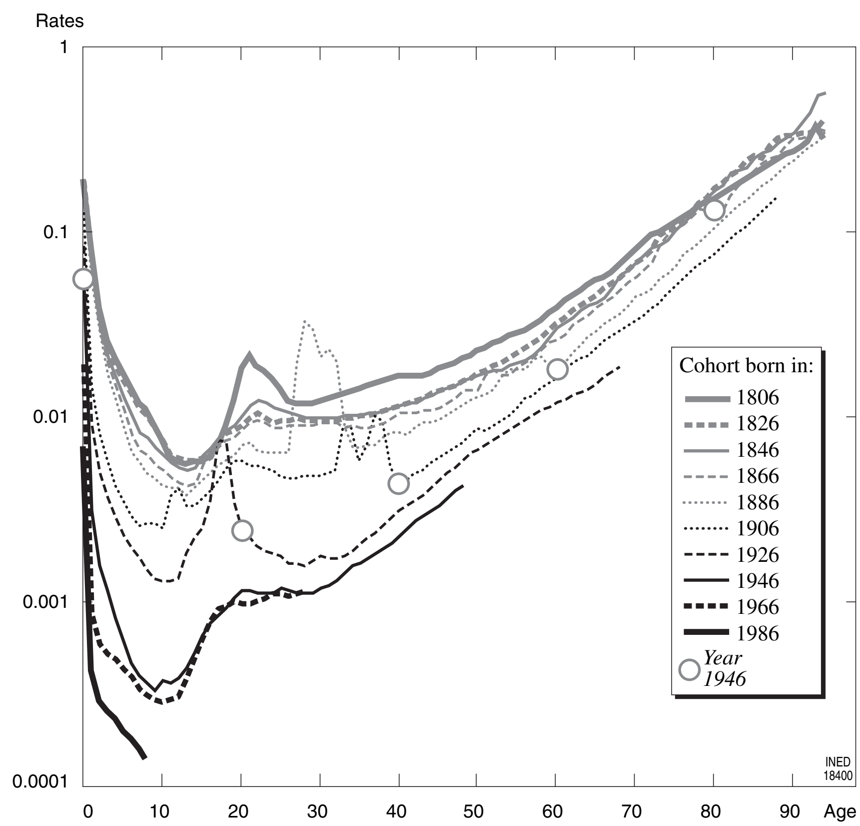

FIGURE 5–3 Age-specific death rates for cohorts born at 20-year intervals from 1806 to 1986 in France.

opposite direction. Figure 5–3, for example, clearly indicates that certain birth cohorts have experienced, because of the two world wars, specific mortality risks at certain ages that make the age-specific mortality curves completely atypical.

It should immediately be pointed out that death rates by year of age and by year of observation calculated by period, such as those in Table 5–1, are not an exact reflection, when assembled diagonally, of the mortality of birth cohorts. In fact, at each age they measure the mortality of a given calendar year, whereas at each age the mortality of a birth cohort must necessarily be spread out over two calendar years. This is what we must now explain by presenting more clearly how demographic events may be located in time and how they should be grouped together in order to measure their frequency.

I. TIME, AGE, COHORT

1. Absolute Time and Relative Time: Dates and Ages (or Durations)

Any demographic event may be situated in time in two ways, according to whether one refers to *absolute time*, as marked out in the official calendar (its *date of occurrence*) or in *relative time*, determined by the time elapsed between the event in question and an initial event directly concerning the individual. If this initial event is the person's birth, this relative time will be the *exact age* the person will have reached when the event studied occurs. But the initial event may, in certain cases, also be of another nature, for example, arrival in the country, starting school, marriage, a first pregnancy, and so forth. We are then dealing with specific concepts of *duration of a state* or of the time elapsed since a given event. It is, in fact, possible to distinguish two types of relative time according to whether the initial event and the event being studied concern the same person:

- Relative time between different events in the life of the same person (length of time between first marriage and birth of the first child, time elapsed between two successive births, time elapsed between one migration and the following migration, etc.);
- Relative time between different events in the lives of different people (time elapsed between the death of a young child and the birth of the following child, time elapsed between the death of a person and that of his/her spouse, etc.).

According to the objective of the analysis, a choice will have to be made between one relative time and another. If, for example, one wishes to measure fertility in marriage without making the distinction of birth order, reference must be made to all the births of the same woman at the time elapsed since marriage. If on the contrary one wishes to analyze independently the occurrences of successive births, for each birth the time elapsed since the previous birth will be used, with reference to the marriage (or first sexual intercourse) only for the first birth. In the same way, one may analyze professional careers either by constantly referring to the time elapsed since entry into employment or by referring for each employment to the time elapsed since obtaining the previous employment.

Last, when combining in the same analysis the impact of several phenomena, for example fertility and migration, one may have to introduce a multidimensional time, associating elapsed time between births and elapsed time between successive migrations.

2. Exact and Complete Age (or Duration)

Time is constantly passing, of course, and events occur selectively, each one at a precise moment, a *date*, if absolute time is concerned, or an *elapsed period of time*

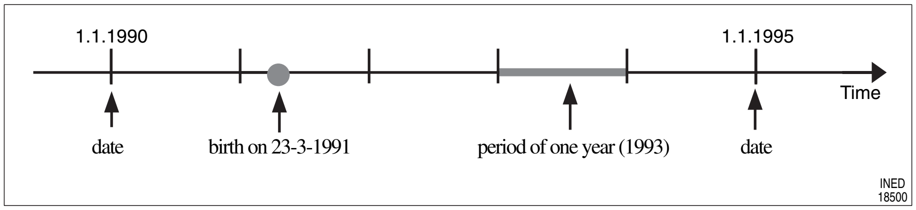

FIGURE 6–1 Absolute time elapsed, date, period, and situation of an event on the basis of the calendar year.

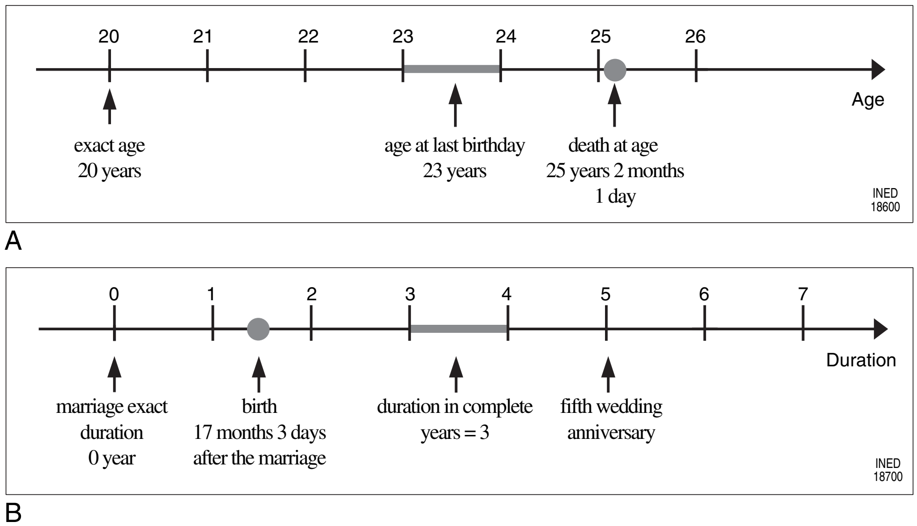

FIGURE 6–2 **A:** Relative time elapsed since the birth: birthday, exact age at the time of the event, and age in complete years. **B:** Relative time elapsed since a given event, for example a wedding: wedding anniversary, exact duration of the marriage at the time of the event and complete duration of the marriage.

(*exact* age, *exact* length of stay, *exact* length of marriage, etc.) if relative time is concerned. But between these events there are discontinuities, and for calculating rates one must bring together those events that occur during the same lapse of time. This is what we have done until now, without any greater degree of precision, by adopting the calendar year as a unit of time, which is the reference generally used in demography. A line representing absolute time in Figure 6–1 localizes the first of January, which marks the beginning of the calendar years, the date of an event (in this case a birth), and a period of one calendar year during which events may be observed. Figure 6–2A situates in the same way, but this time on a line representing age, a number of birthdays, the exact age of an event (in this case a death), and a length of time elapsed between two birthdays, which is usually referred to as *age in complete years* or age at last birthday, whereas Figure 6–2B represents the exact duration of a marriage at the time of the birth of a child as well as different wedding anniversaries and the complete duration of the marriage.

3. Complete Age and Age Reached During the Year

This distinction between exact age and age in complete years may seem naive. However, it is fundamental for the analysis. To be correctly used, a statistic by age (or time elapsed since a previous event) must have been clearly established according to a correct definition of the age (or of the duration) at the time when the data are gathered. When, in a census, a survey or a declaration made to the civil registrar, the age of a person is registered, the way the age of the person is calculated must be agreed upon. This will rarely be the exact age because it would take an unnecessarily long time to detail the age in years, months, days, hours, and so forth, without attaining total accuracy. An approximate solution that is often used consists of obtaining the date of birth as precisely as possible (day, month, year) and to then deduce the age by deducting the difference from the date of registration. If the date of birth is not used, there are possible choices between several age concepts. The age in complete years, the one we defined in the prior section, is customarily fixed at the level reached at the last birthday and remains constant until the following birthday. This must not be confused with the *age reached during the year*[1] (or in period differences), which remains constant during the whole calendar year in terms of the birthday that will be that year. Nor should it be confused with the *individual year of age*. Therefore, on March 31, 1999, a baby born July 1, 1998, will be *aged 0 in complete years* but it will be 1 *year old in the year* and in its first *year of life*. But 6 months later, on September 30, the infant will be aged 1 *complete year*, 1 *year in the year*, and will be in its second *year of life*.

In fact, although saying "I am in my x[th] year of life" is quite common in certain cultures, this notion of age is almost never used in the production of statistical tables. On the other hand, the two other solutions of grouping together exact ages into *age groups* are used and it is essential for the analysis to know which type of age group is concerned: standard *age in complete years* or *age reached during the year*.

4. Birth Cohort and Cohorts in General

From the moment that an event is dated in a precise manner according to the calendar (date) and the age (exact age), a third parameter may be deduced, which sometimes resembles a third dimension of time: the fact of belonging to a *birth cohort*, which is an essential tool in longitudinal analysis in demography.[2] A birth cohort is composed of all the people born during the same calendar year. This notion of cohort can in fact be generalized, as explained in a previous section, to the whole time elapsed since a prior event (migration, marriage, entry into employment, etc.), and reference is thus made to *marriage cohorts* or cohorts in general. For practical reasons until the end of this chapter we will deal essentially with age, but the same approach is valid for any time elapsed since a given event.

II. THE LEXIS DIAGRAM

A little over a century ago, Wilhelm Lexis (1875) proposed a method, which has since become famous, for illustrating demographic events through the use of the dual time dimension (calendar and age) and representing the different useful classifications for analysis, according to age, period, and birth cohort.[3] At the cost of a transformation rendering it even more practical, this mode of representation was popularized at the end of the 1950s among French-speaking demographers, and by Roland Pressat, on the occasion of the publication of the first edition of his manual of demographic analysis (1961).

1. Point-events, Lifelines, and Birth Cohorts

The principle is very simple. It is a Cartesian system in which the first axis measures absolute time (the calendar) and the second, relative time (age). It is then very easy to situate within it any event (birth, marriage, migration, maternity, death, and so forth) according to these two coordinates. By linking the events concerning the same person, a *lifeline* is obtained, which is automatically situated on a parallel to the bisector of the two axes, since age increases at the same pace as time elapses. Figure 6–3, for example, represents the life of a woman born on January 31, 1902 who migrated on March 16, 1916, married on May 22, 1926, gave birth to a child on May 8, 1927, and died on July 7, 1939. At each date of each event, there is a corresponding vertical line that cuts the lifeline at a point situated on a horizontal line indicating the exact age at which this event occurs.[4]

[1] The age reached during the year is the difference between the year of observation and the year of birth. Therefore, during the whole of 1998, a person born in 1956 is 42 years of age reached during the year.

[2] The *birth cohort*, a group of people born in the same year, is indeed a special example of the more general notion of the *cohort* (group of people having experienced the same event during the same unit of time).

[3] There is a brief summary of the origins of this type of representation in an article written by Graziella Caselli and Enzo Lombardo (1990) and in an article by Christophe Vanderschrick (1992). In fact the idea originally came from Georg Knapp (1868, 1869) before being adopted by Karl Becker (1874) and clarified by Wilhelm Lexis (1875), but also and at the same time, by Abraham Verweij (1874), alias Abraham Verwey (1875).

[4] In fact, this definition of what is known as the *Lexis Diagram*, proposed by Roland Pressat, is different from the one developed by its inventor. Wilhelm Lexis followed the lives of people on a vertical to the time line, by tracing *life durations* and not the *lifelines* drawn by Roland Pressat. Thus, he followed, in counter-diagonal lines, *isochrones* (groups of events occurring at the same date) which, in Pressat's diagram, are read vertically. It should be noted that this currently standard presentation of the Lexis diagram is however, not universal. The Anglo-Saxons, who use it much less than French-speaking demographers, sometimes draw an inverted diagram in which the age is presented on the x-axis and time on the y-axis, from the top downwards. The lifelines are therefore descending diagonals. However, Anglo-Saxons also use the presentation proposed by Pressat. Nathan Keyfitz, for example, used the same year the Pressat-type presentation for his *Applied Mathematical Demography* (Keyfitz, 1977b) and the inverted presentation for the revised edition of his *Introduction to the Mathematics of Population* (Keyfitz, 1977a), the first edition of which dated from 1968.

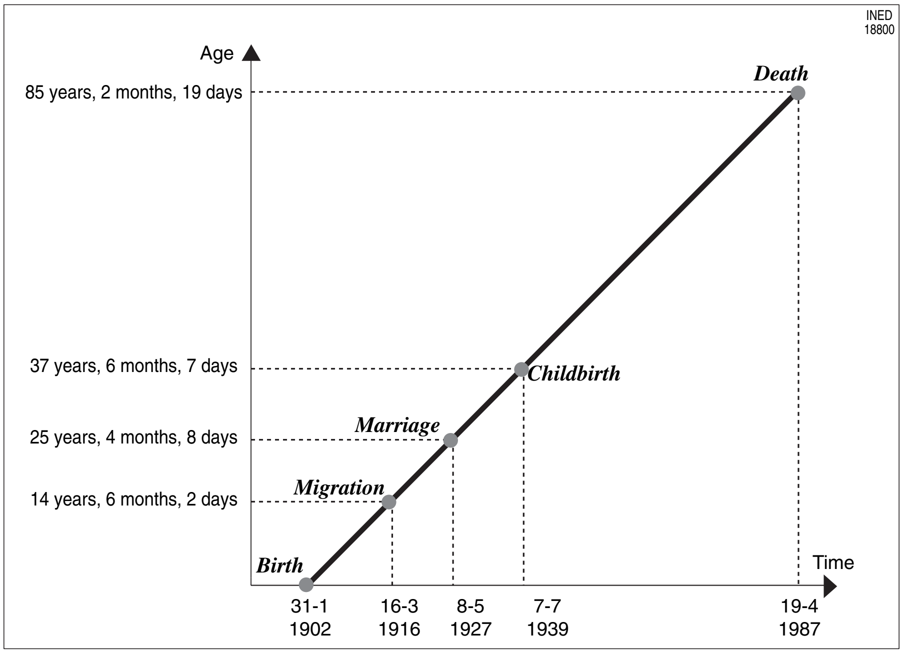

FIGURE 6–3 Representation, on a Lexis diagram of a lifeline, with an event point (migration, marriage) and a terminal death point.

2. Populations and Events

The Lexis diagram makes it possible to make useful classifications for the analysis of events as well as of populations. Concerning populations (Figure 6–4) lifelines may be grouped together in columns of varying thickness according to the time elapsed between the births of the first lifeline from that of the last lifeline. If one groups together the lifelines of people born the same year, framed within diagonals starting January 1 and December 31 of the year in question, one identifies a birth cohort. Our graph represents, therefore, a beginning of a column of lifelines composing birth cohort *C*, born in 1991. The people still living, when the column of lifelines of a same birth cohort cross a vertical line in the diagram, make up the population of this birth cohort at the date corresponding to this vertical line. If the date is January 1, these people are all of the same age in complete years and they make up the population of this age at this date.[5] Thus, *P* represents the population aged 2 on January 1, 1991, composed of people from the birth cohort of 1988 still alive at that date.

Concerning events, the sets of births, occurring by definition at the exact age of 0, obviously always appear as segments on the time axis.[6] Therefore, on Figure 6–4, *B* represents the births of 1993. But all the other events (marriages, migrations, deaths, etc.), occurring at different ages, will be represented in specific surfaces of the Lexis diagram according to the way they have been identified by age and time.[7] Only very special events such as *birthdays* will also be assembled on the segments of lines (parallel to the time line). Therefore, segment *V* in Figure 6–4 illustrates the

[5] In certain statistical publications one may find populations on January 1 and in others, populations on December 31. In fact, there is no difference between a given population on December 31 of one year and the same population on January 1 of the following year. In fact, in the first case the estimate is made at the end of the year, December 31 at midnight, and in the second case it is made at the beginning of the year, January 1 at 0 hour.

[6] At least in this general case of a diagram representing the life of individuals within a population. In such a case births must be represented at age 0. However, these births are in fact the sum of all the *maternity* points that appear, in the course of a year, among women of different ages. These maternity points, as we shall see in the case of fertility analysis (Chapter 12) will be grouped together within surfaces of the Lexis diagram according to the age or the cohort of the mother. The births of a mother will be considered as events whereas all of the births of one year appear here as the initial size of the birth cohort.

[7] Note, however, that the Lexis diagram may be used while replacing the age by the time elapsed since a given event. It is then this reference event, which will be represented by the segments on the time line. Thus, if one studies fertility in marriage and refers to the time elapsed since marriage and not to the mother's age, the lifelines will start with the marriage and will be grouped together in *marriage cohorts*. The marriages of each cohort will occupy a segment of the time line but the maternities (along with any other events such as migration, death, etc.) will be identified among the different surfaces of the Lexis diagram.

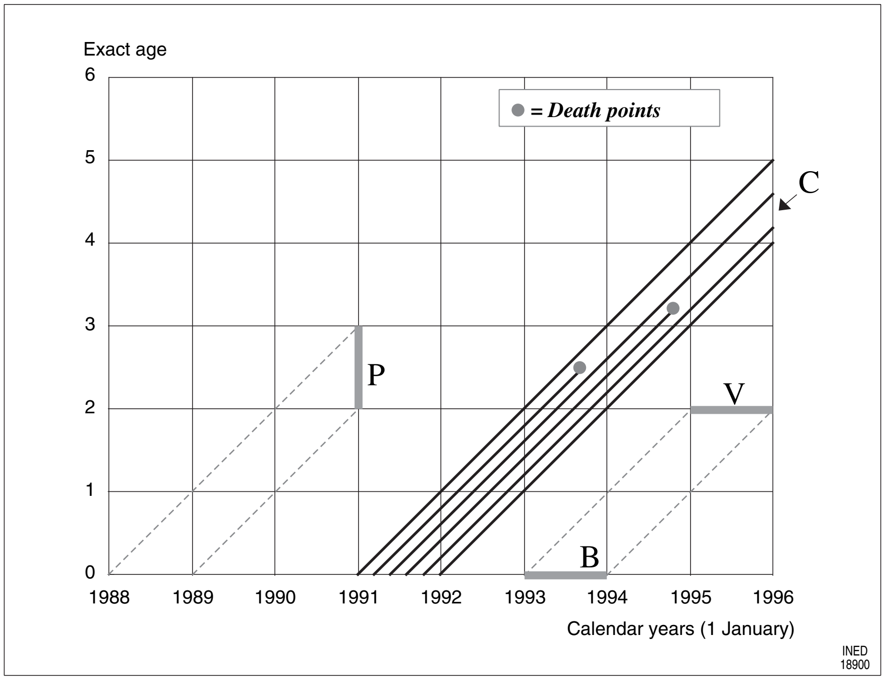

FIGURE 6–4 Lexis grid with the births of 1 year, the population by age, and the column of lifelines of a birth cohort.

second birthday celebrated in 1995 by individuals born in 1993. This number may also be interpreted as being that of the people belonging to the birth cohort of 1993 in the population having the exact age of 2 years.

3. Different Ways to Classify Events by Year of Age

Figure 6–5 illustrates the three standard ways of classifying events according to age, time and birth cohort, which correspond to the three ways that will allow us to locate events classified in the usual statistical publications. Parallelogram E_2 groups together events having occurred during a given year (in this case year A_4) within a given birth cohort (in this case, the cohort born in year A_0). This is how events classified by *calendar year and year of birth* or by *calendar year and age reached during the year* are situated. It becomes immediately apparent that these events occur at the exact age of $x + 4$, but that they do not all occur around the same age in complete years. Some occur before $x + 4$ and others afterward. They therefore concern two age groups in complete years, groups $(x + 3, x + 4)$ and $(x + 4, x + 5)$, without, for that matter, grouping together all the events that may be observed that year in these two age brackets.

On the contrary, parallelogram E_1 groups together events having occurred within the same birth cohort (born in year A_0) at the same age in complete years, the age $(x + 1, x + 2)$. It represents the ages classified by *age and year of birth* or even *age and cohort*. This time it should be noted, however, that they occur before and after a January 1 and are distributed therefore over 2 years (here, years A_1 and A_2).

The third way of classifying events according to age and time consists of grouping by *age and calendar year* or, more precisely, by *age in complete years and calendar year*. This classification corresponds to square E_3 in Figure 6–5. This time, we are indeed dealing with a group of events all occurring at the same age in complete years, the age bracket $(x + 1, x + 2)$, during the same calendar year (here, year A_4). On the other hand, they do not all concern the same birth cohort, since some of them occur among people born in year A_2 and others, the following year, A_3.

Each of these classification methods leads to different perceptions of reality that may seem very similar but that may also, in certain cases, have significant consequences for the analysis. The Lexis diagram makes it possible to avoid sometimes major errors of interpretation.

Otherwise, each one of these three computation methods presents different advantages depending on the type of analysis being made. Only the first method of classification, by calendar year and year of birth, may be used indifferently for either *cross-sectional analysis* (by calendar year) or *longitudinal analysis* (usually by cohort). On the other hand, it presents the

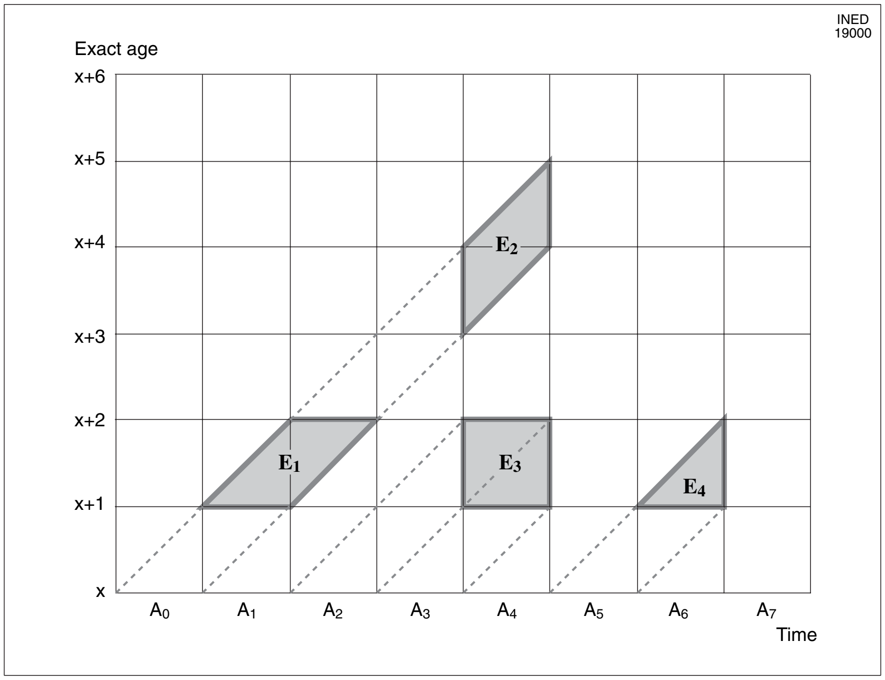

FIGURE 6–5 Representation of events on the Lexis diagram according to different possible annual classification modes.

disadvantage of not clearly identifying the age, because the events are spread out before and after the birthday, whereas age is more naturally perceived as an interval between two birthdays. For cross-sectional analysis, distribution of death by age in complete years and calendar years (the squares of type E_3) is preferred, whereas the ideal for longitudinal analysis is to have deaths distributed according to age in complete years and by cohort (parallelograms of type E_1).

Increasingly, however, current statistics are delivered according to what is customarily called *double classification*, which makes it possible to reconstruct the three cases of the previous figures indifferently. The events of a given calendar year, thus classified *by age and by year of birth* or *by age and by cohort*, then appear in the triangles of the Lexis diagram, such as triangle E_4 in Figure 6–5, which represents the events occurred during the year A_6 in the cohort born in the year A_5 and therefore, with an age in complete years (x + 1, x + 2). By appropriately combining these triangles two by two it is, of course, possible to reconstruct the parallelograms and the square described here.

4. Pluri-annual or Infra-annual Classifications

Conversely, statistics may only provide large classifications, by grouping together ages, calendar years, or cohorts. Here again, the Lexis diagram is very useful for rapid visualization of the type of data one is dealing with. Figure 6–6 provides a few examples. Parallelogram *ABCD*, for example, represents a case of events observed during the same calendar year (year A_5) but classified *by quinquennial groups of birth years* (cohorts relating to the years A_0 to A_4). The individuals concerned have, in the year A_5, exact ages between x and $x + 6$ years, but some events having occurred that year at the ages in complete years of x or x + 5 are excluded, because they either concern the cohort that is too old, relating to A_{-1} or the cohort that is too recent, relating to A_5 (the two triangles next to the extremities of parallelogram *ABCD*).

In the same way, rectangle *EFGH* represents the case of events having occurred in the course of the same calendar year (year A_7) classified by *quinquennial completed age groups*. It is apparent that these events concern not five but six cohorts (those relating to the years A_2 to A_7).

Lastly, parallelogram *FIJK* represents the case of events observed, for example, during a retrospective survey, classified by *quinquennial age groups within the same cohort*. In this case, the observation covers six calendar years (A_8 to A_{13}).

These types of data may also be classified by calendar year within the same cohort (parallelogram *LMNO* in Figure 6–6). The observation within the same birth

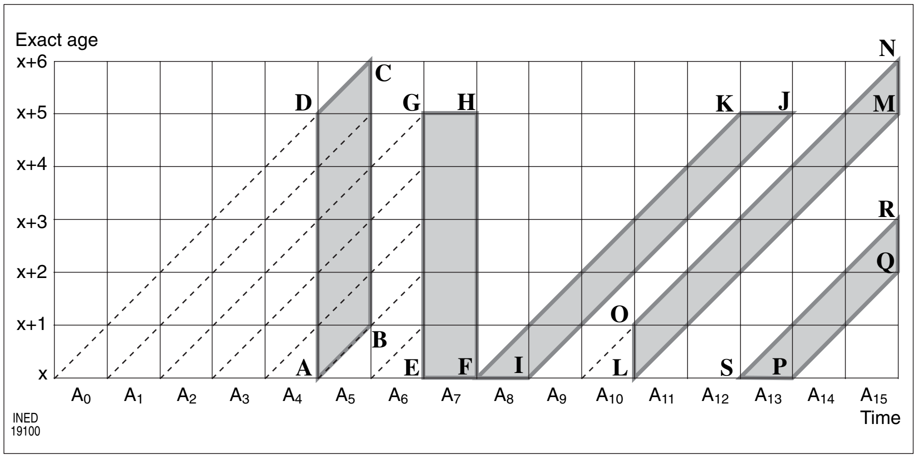

FIGURE 6–6 Representation of events on the Lexis diagram, according to different age groups.

cohort therefore covers five full calendar years but the extreme ages at last birthday are incomplete.

It is even more obvious in this case that the classification of events by calendar year and by quinquennial age group (rectangle *EFGH*) applies perfectly to cross-sectional analysis, whereas classification by quinquennial age groups within the same cohort (parallelogram *FIJK* in Figure 6–6) naturally lends itself to cohort analysis. If one accepts a slight difference in the situation of ages this is also respectively the case for the classification of events in the year by quinquennial groups of cohorts (parallelogram *ABCD*) for cross-sectional analysis, and for events concerning a cohort classified by groups of calendar years (parallelogram *LMNO*), for cohort analysis.

Sometimes classifications of events require changes in criteria. Notably, the observation of data from retrospective surveys, which are usually provided by cohort, find themselves, however, interrupted by the date of the survey and some groups of events are of the same type as that represented in Figure 6–6 by the trapezium *PQRS*, which represents events having occurred in a cohort relating to year A_{13} during the 3 years (A_{13} to A_{15}) before the survey. Here again, we have chosen a favorable, hypothetical case in which the survey took place on January 1.

Finally, data may often be supplied by groups of years of observation. Figure 6–7 situates on the Lexis diagram the three types of classifications in the case of decennial age groups and groups of five cohorts or of five calendar years: *completed age groups and calendar year groups* (rectangle *ABCD*), *intervals of exact age and groups of cohorts* (parallelogram *ABEG*), and *completed age groups and groups of cohorts* (parallelogram *BEFH*).

Of course, in addition to helping to visualize different pluri-annual groups, the Lexis diagram also provides valuable help in illustrating the classification of events according to age and calendar intervals that are smaller than a year. All that needs to be done in such cases is to change the scale. It is possible to work in months, weeks, days, or in any other unit of time adapted to the data being analyzed.

III. ELEMENTS FOR COMPUTING A RATE, ACCORDING TO THE CLASSIFICATION MODE OF EVENTS

1. Rates for a Year of Age

Previously, we defined the rates by age for fertility, mortality, and migrations (Chapter 4). In the case of mortality, for example, we have seen that the rate for year t at age x is equal to:[8]

$$m_{(x,t)} = \frac{D_{(x,t)}}{(P_{(x,t)} + P_{(x,t+1)})/2}$$

In fact, the significance of parameters x and t varies according to the data used for the calculation. The Lexis diagram can be a great help in identifying, according to these variations, the elements that are

[8] It should be noted that this is an approximation based on the hypothesis of a linear change in the size of the population:

$$m_{(x,t)} = -\log\left(1 - \frac{D_{(x,t)}}{P_{(x,t)}}\right) \cong \frac{D_{(x,t)}}{(P_{(x,t)} + P_{(x,t+1)})/2}.$$

We will see in Chapter 9 that the evaluation of mortality with such a rate supposes the absence of any competing phenomena (in this case migration) or independence between the competing phenomena (in this case migration) and the phenomenon studied (in this case mortality). In addition, it supposes that the population is homogeneous (Chapters 9 and 14).

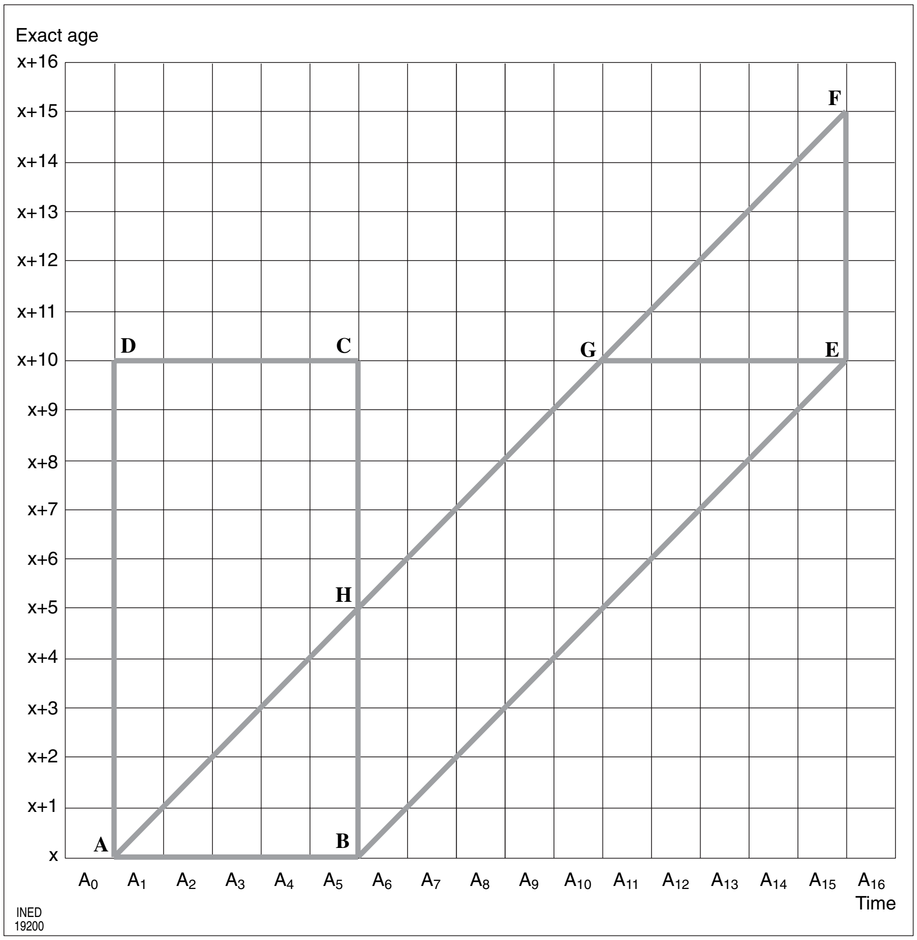

FIGURE 6–7 Representation of events on the Lexis diagram, according to different pluri-annual classification modes.

really needed for calculating rates in the different possible situations (Figure 6–8).

If the deaths are classified by year of age and calendar year (square *ABCD*), deaths having occurred during the year considered t (between January 1 t and $t + 1$) in the age class (x, $x + 1$) will be related to the mean population of age (x, $x + 1$) during the year. It is generally possible to estimate this average by the half sum of the populations observed at the beginning and at the end of the year. A first, most common, rate at age x is thus obtained, which we will call type 1 rate:

$$m'_{(x,t)} = \frac{D^t_{(x,x+1)}}{\left(P^t_{(x,x+1)} + P^{t+1}_{(x,x+1)}\right)/2}$$

These are rates by year of age and calendar year that have been used to construct the second part (1899–1995) of the complete matrix (1806–1995) a few elements of which are given as examples in the beginning of Chapter 5 (Table 5–1). Because of a lack of precise data, the first part (1806–1898) of this matrix has been built indirectly based on an estimate of *probabilities of dying* by age which will be dealt with further on (Chapter 11).

If the deaths are classified by year of birth and calendar year (parallelogram *EFGH* in Figure 6–8), the deaths having occurred during the year considered t in cohort C ($t - x$) reaching the exact age x during this year will be divided by half the sum of populations of age ($x - 1$, x) on January 1 t_3 and of age (x, $x + 1$) on January first t_4. A second rate at age x (type 2) is obtained, which is sometimes referred to as a prospective rate:

$$m''_{(x,t)} = \frac{D^{C(t-x)}_{(x-1,x+1)}}{\left(P^t_{(x-1,x)} + P^{t+1}_{(x,x+1)}\right)/2}$$

When deaths are grouped by age in complete years and year of birth or cohort (parallelogram *IJKL* in Figure 6–8), it is necessary to proceed in the same way as above, to divide the deaths occurred in this birth cohort between the exact ages of x and $x + 1$ by half

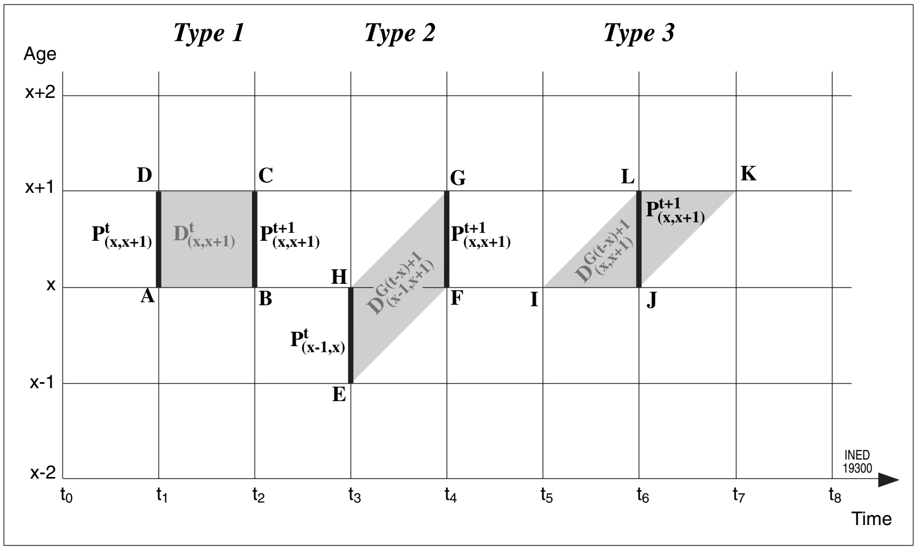

FIGURE 6–8 Representation of the elements required for computing a death rate by age according to the classification mode of the deaths.

the sum of the numbers of individuals of the cohort present at the time of their birthdays x and $x + 1$, but these data do not feature in any of the usual statistics. Because the deaths concerned are distributed more or less equally between the triangle *IJL*, belonging to the year t and the triangle *JKL* belonging to the year $t + 1$, we will take the denominator of the population at complete age $(x, x + 1)$ on January 1 of the year $t + 1$, which is generally a good estimator of the mid-year population. A third rate at age x (type 3) is obtained, which can truly be defined only if one has a double classification of deaths by age and by year of birth:

$$m'''_{(x,t)} = \frac{D^{C(t-x)}_{(x,x+1)}}{P^{t+1}_{(x,x+1)}}$$

2. Differences Among the Three Rate Types

The *double classification* of the deaths of each calendar year by age and by year of birth, which in France for example has been in existence since 1907, will enable us to illustrate our point with an example with figures, demonstrating that in certain cases such subtleties in computations are far from superfluous.

Table 6–1 provides an extract of these French mortality statistics for the years 1993, 1994, and 1995, relating to a number of age groups, accompanied by population estimates at the same ages on January 1st of 1994 and 1995. Figure 6–9 places on the Lexis diagram the elements of this table that are appropriate for computing death rates by age for the year 1994, according to the three usual approaches mentioned previously.

For instance, at the *completed age* of 74, the death rate (type 1, Figure 6–9) is equal to:

$$m'_{74} = \frac{2{,}889 + 4{,}275}{(121{,}312 + 202{,}140)/2} = 0.04430$$

On the other hand, at the age of 74 *reached during the year*, the rate (type 2, Figure 6–8) is equal to:

$$m''_{74} = \frac{4{,}142 + 4{,}275}{(210{,}506 + 202{,}140)/2} = 0.04080$$

But this rate, in fact, concerns an age that is half a year less than the type 1 rate. To make a valid comparison with the previous rate, the average of the type 2 rates at 74 and 75 years has to be made, i.e., from Table 6–1:

$$\overline{m''_{74}} = \frac{m''_{74} + m''_{75}}{2} = \frac{0.04080 + 0.04348}{2} = 0.04214$$

Lastly, the rate computed between the exact ages of 74 and 75 in the cohort celebrating its 74th birthday in 1994 is equal to:

$$m'''_{74}(C_{1920}) = \frac{4{,}275 + 4{,}084}{202{,}140} = 0.04135$$

This result must be compared with the rate of the same type obtained in the previous cohort celebrating its 74th birthday in 1993 and which also crosses the square of the Lexis diagram concerned by the type 1 rate:

$$m'''_{74}(C_{1919}) = \frac{2{,}318 + 2{,}889}{121{,}312} = 0.04292$$

TABLE 6–1 Extract of mortality statistics by age for 1994 and corresponding populations[1] on January 1 of 1994 and 1995

Age (x)	Deaths						Populations		Rates (for 1000) in 1994					
	1993		1994		1995				Type 1	Type 2		Type 3

[1] The population numbers are estimates by INSEE, on each January 1, based on the numbers obtained at the censuses, taking into account births, deaths and migration balance.

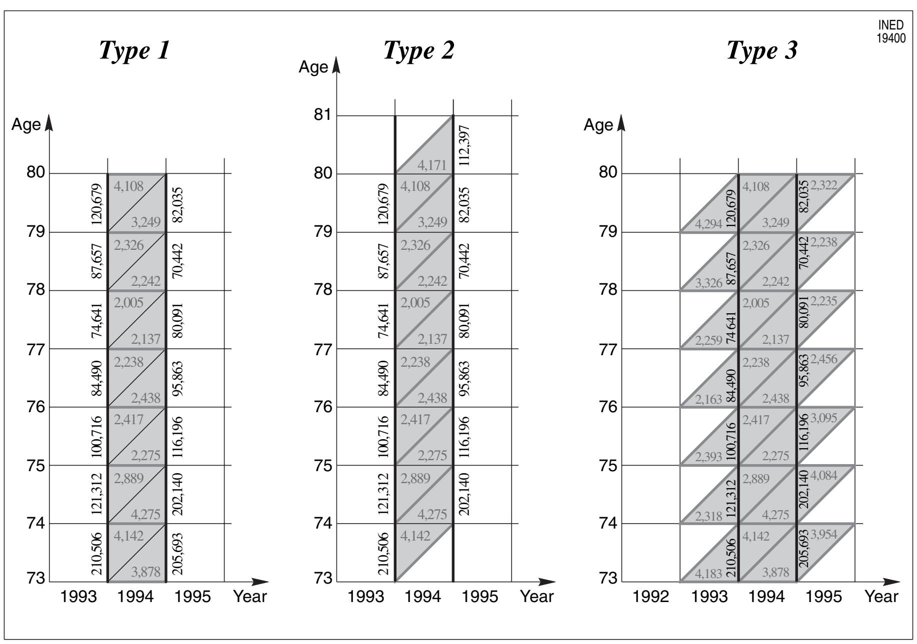

FIGURE 6–9 Elements for computing different types of death rates between the ages of 65 and 85 years in France (men).

For comparing with the previous rates one must, here again, compute the average of these two results to focus the measure on 1994. Thus the rate of 0.04214 is obtained, which is very close to the result obtained with the type 2 rate.

Thus, we now have three death rates established for the same calendar year at the same age but opposing a higher value obtained with the type 1 rate (44/1000) to the two other lower values provided by types 2 and 3, which are much closer to one another (42/1000).

In fact, the differences observed here correspond to an exceptional situation. Indeed most of the time, there is practically no difference between the three types of rates. This supposes, however, that the sizes of the neighboring cohorts that come into the calculation are distributed in a similar manner according to age. In most cases this is fine, and the method used for calculating the rate is of little importance. In the example taken here, the sizes of successive cohorts varies suddenly. In fact, this concerns cohorts born in 1919 and 1920, just after World War I, which, as we know created a sharp rise in births. Therefore, on January 1, 1994, the number of men suddenly declined from 210,506 at age 73 to 121,312 at age 74 (Figure 6–9). The 1919 cohort represents those in the last year in the deficit of births, whereas those born in 1920 belong to the first full cohort after the War. It is this fluctuation that, by suddenly modifying the distribution by age of individuals within cohorts, is at the origin of the discordance observed here between type 1 rates and the others (Figure 6–10).

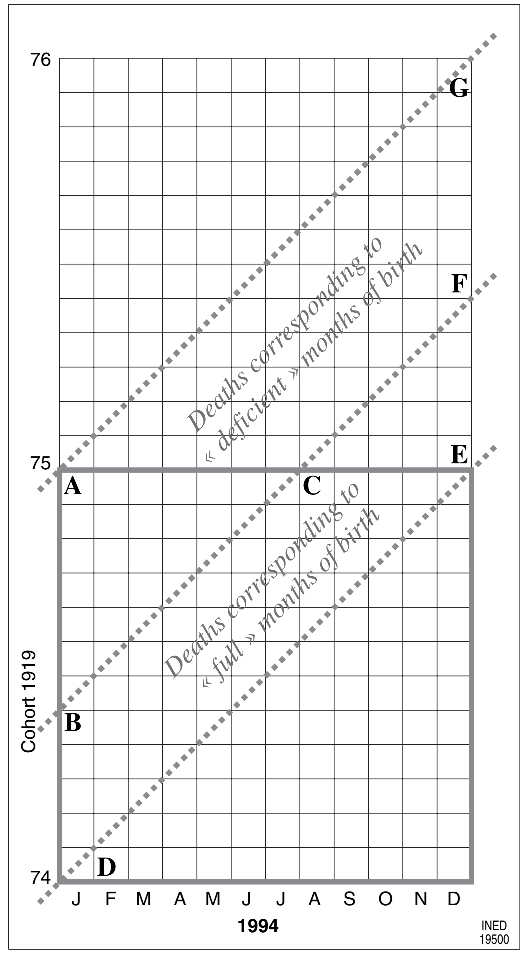

FIGURE 6–10 Representation on the Lexis diagram of two portions of the cohort of 1919, from the months with low birth rates and the months with high birth rates, during the year of 1994.

The sudden change in the number of births that causes the difference in the sizes of the cohorts did not, in fact, happen exactly at the passing of 1919 to 1920 but during 1919, precisely at the end of summer, 9 months after the Armistice and demobilization. Because of this, among the deaths in 1994 that occurred in the 1919 cohort at 74 years of age, some of the deaths correspond to the 8 or 9 first months with a low number of births and others to the 3 or 4 last months with a high number. However, for the first part of this cohort there is less time between January 1, 1994 and the 75th birthday (triangle *ABC* in Figure 6–10) whereas for the second part there is much more time in the same interval (trapezium *BCDE*). Therefore, the number of deaths at that age in this cohort in this year depends more on the people born during the months with a high number of births than on those born in the months with low numbers; divided, as if nothing had happened, by the population size, without any distinction in terms of month of birth, this will overestimate the death rate at that age. Hence the abnormally high level of the death rate at 74 in 1994. Inversely, the same year, at 75, the rate is underestimated because the contribution of the months with a high number of births of the cohort of 1919 to mortality is very short (triangle *CEF* in Figure 6–10) whereas that of the months with low numbers is much longer (trapezium *ACFG*).

The same phenomenon occurs in the opposite direction with the passage of the cohorts born in 1914 (the last full year before the war) and 1915 (first year with a deficit in births), which reached 80 and 79 years of age, respectively, in 1994. This time, it is within the cohort of 1915 that monthly births suddenly declined in the spring. The same causes producing the same effects; therefore, in 1994, one obtains a death rate of type 1, which is abnormally low at 78 and abnormally high at 79.

Type 2 and 3 rates, calculated strictly within the same cohort, are, on the contrary, practically unaffected by this statistical artifact, whether it be before or

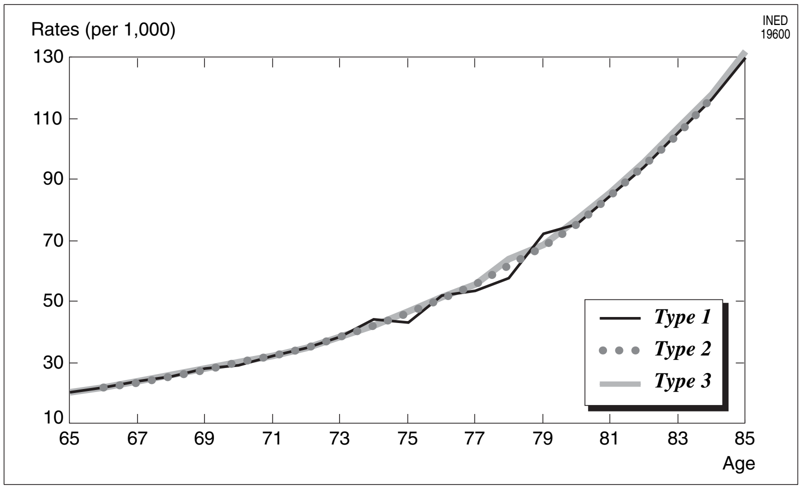

FIGURE 6–11 Death rate by age between 65 and 85 years in France, in 1994, according to method of calculation.

after the average of the two contiguous rates has been obtained to center the result on the same complete age and the same calendar year as the type 1 rate.

In any case, this type of problem only arises when there are strong variations in sizes between contiguous birth cohorts. Figure 6–11 clearly shows that apart from the ages reached by cohorts affected by the war, there is practically no difference between the three types of rates by age.

To account for this problem due to the computation of rates in the Lexis squares, Gérard Calot proposed a weighting method according to the monthly distribution of births forming each cohort. All that is needed is to apply to the deaths in each Lexis triangle a correction factor calculated according to this monthly distribution (Calot, 1984).

3. Rates by Age Groups

In Chapter 4, we discussed the calculation of rates by age groups following the general formula:

$$m_{((x,x+a),t)} = \frac{D_{((x,x+a),t)}}{\left(P_{((x,x+a),t)} + P_{((x,x+a),t+1)}\right)/2}$$

As with the rates by individual year of age, different computation methods are possible according to the way the available data is presented. Figure 6–12 illustrates the data that may be used for computing death rates by age groups according to possible classification modes.

If, for example, deaths are classified by calendar years and quinquennial age groups (rectangle *ABCD* in Figure 6–12), we will divide deaths having occurred between the exact ages x and $x + 5$ by the average of the populations of the same ages on each January 1:

$$m'_{((x,x+5),t)} = \frac{D^{t}_{(x,x+5)}}{\left(P^{t}_{(x,x+5)} + P^{(t+1)}_{(x,x+5)}\right)/2}$$

In the similar case in which the deaths of the calendar year are grouped according to year of birth (parallelogram *EFGH* in Figure 6–12), one obtains:

$$m''_{((x,x+5),t)} = \frac{D^{(t)}_{G(t-(x+5),t-x)}}{\left(P^{t}_{(x,x+5)} + P^{(t+1)}_{(x+1,x+6)}\right)/2}$$

Note that these two types of rates according to age groups are annual rates, because, although they group together the deaths of five age brackets, they relate these deaths to equivalent groups of population size by age. This is true whatever the number of age groups. These rates are directly comparable to the rate by individual year of age mentioned here, the first being obviously similar in nature to type 1 and the second to type 2. To do so, place the rate by age group in relation with the rate by age corresponding to the central age of the age group. Thus, the first quinquennial rate mentioned here will be related to a rate at complete age $x + 2$, or on average at exact age $x + 2.5$. The second will be compared with a rate at exact age $x + 3$. It is, of course, impossible to compute a similar type 3 rate.

On the other hand, if the deaths are classified by birth cohort and group of calendar years, it is possible to obtain in cohorts a type 2 rate and a type 3 rate, of pluri-annual dimension, which will not be directly comparable with any type 1 rate.

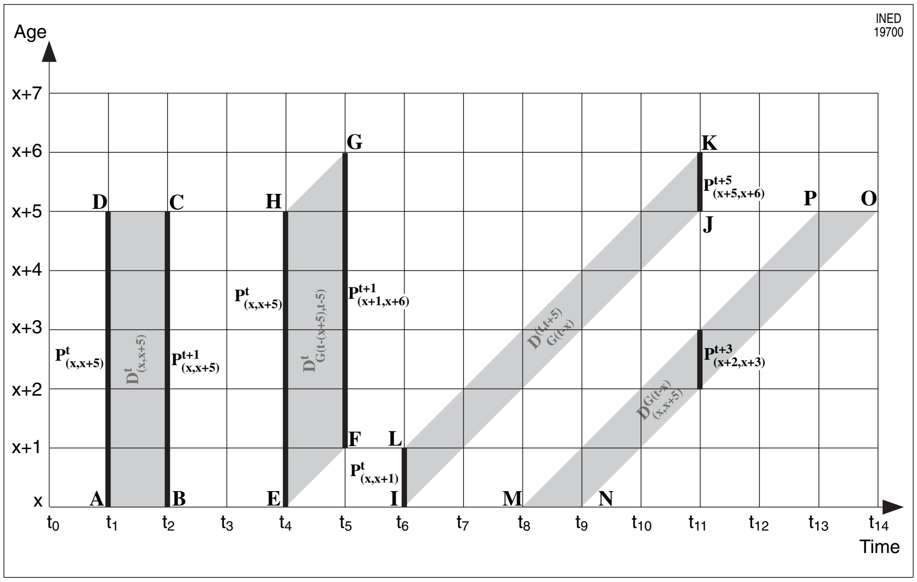

FIGURE 6–12 Representation of the elements needed for the calculation of death rates by age according to how deaths are classified.

If, for example, deaths are classified by birth cohort and groups of five calendar years (parallelogram *IJKL* in Figure 6–12), a type 2 rate can be calculated as follows:

$$m''_{((x,x+5),(t,t+5))} = \frac{D^{(t,t+5)}_{C(t-x)}}{\left(P^{t}_{(x,x+1)} + P^{t+5}_{(x+5,x+6)}\right)/2}$$

In the same way, if the deaths are classified by cohort and quinquennial age intervals (parallelogram *MNOP* in Figure 6–12), one will take as an estimator of the average size of the actual population at the x^{th} and $(x + 5)^{\text{th}}$ birthdays of the cohort born in the year $t - x$, the population aged $(x + 2, x + 3)$ on January 1 of the central year t_{+3}. One then obtains:

$$m'''_{((x,x+5),(t+5))} = \frac{D^{C(t-x)}_{(x,x+5)}}{P^{t+3}_{(x+2,x+3)}}$$

In both of these cases, the rates are no longer on an annual dimension scale since the deaths of five age groups are related to the mean size of a single birth cohort. One may of course obtain this annual dimension by dividing the result by five (or, more generally, by the number of age groups concerned). It is only on such a condition that one may compare these results to those of rates per individual year of age by referring to the central age of the group.

Finally, note that in most cases age groups are identified by ages in complete years rather than by exact ages. Therefore, one notes in all these formulas, x instead of $(x, x + 1)$, $(x, x + 1)$ instead of $(x, x + 2)$, . . ., $(x, x + 4)$, instead of $(x, x + 5)$, and so forth., thus replacing an interval between two extremes of exact ages by a series of ages in complete years.

4. Pluri-annual or Infra-annual Rates

The reader will easily extrapolate to the cases where deaths are classified by age groups as well as by groups of birth cohorts or calendar years. Moreover, we have only used as an example here the most standard cases. In fact, the data available are much more varied, but the principle remains the same: The simple fact of correctly entering on a Lexis diagram a few elements of the death statistics used will certainly facilitate the choice of population to be entered in the denominator of the rates.

5. A Special Case: The Infant Mortality Rate

In addition to the three possible types of rates mentioned so far, mortality at under 1 year of age is very often measured by an *ad hoc* indicator, called *the infant mortality rate*, but which is very different from the rates we have just defined. Instead of relating deaths of less than 1 year to an average population of less than 1 year as indicated above for any age x, these deaths are related to births:

$$mi_{(t)} = \frac{D_{(0,t)}}{B_t}$$

We shall see in Chapter 8 that this "rate," used extremely often, is similar to a *probability* such as we will define later on. Given the title of the chapter, we could not end without evoking its existence.

Institut national d'études démographiques (INED), Paris, France

To examine the evolution of any demographic phenomenon—the structure of a population, or the intensity of the components of its dynamics, such as fertility, mortality, or migration—we need to take at least three dimensions into account: time, age, and the intensity of the phenomenon. This is the case, for example, with the matrix of mortality rates by age and calendar year shown in Table 5–1 of Chapter 5: The matrix provides an indicator of the force of mortality for about 100 age-years and nearly 200 years of observation. This would also be true of a matrix that assembled fertility rates or population size by age for a period of one or two centuries. Unless we could develop three-dimensional graphic media,[1] such matrices would pose the classic problem of how to display a three-dimensional phenomenon on a two-dimensional sheet of paper.

In fact, there are only two solutions: We can try to depict the three dimensions in identical fashion, using perspective-creating devices of the kind first used by Renaissance painters,[2] or we project one of the three dimensions on the plane formed by the two others. Naturally, the second solution is more common. In demography, however, it is used in only two of the three possible ways: Intensity is always chosen as one of the two axes of the projection plane. Indeed, intensity curves (for population size, fertility rates, mortality rates, etc.) are very often shown as a function of age, or of time, by projecting on this Cartesian plane the situation characterizing a specific period or age, respectively. The third dimension is materialized simply by juxtaposing several curves on this projection plane. These two ultraclassic types of projection are illustrated in Figures 5–1 and 5–2 of Chapter 5. In the far less common projections of the third kind, intensity is projected on the plane formed by age and time. Yet it is this third solution, well known to geographers, that undoubtedly offers the best substitute for the impossible "perfect" display of the three dimensions.

[1] A few decades ago, for example, Institut National d'Etudes Démographiques exhibited a three-dimensional volume structure showing the change in the French age pyramid over a century.

[2] Notably Mantegna in the Sala degli Sposi (Bridal Chamber) in Mantua.

I. ATTEMPTS AT THREE-DIMENSIONAL REPRESENTATION

The problem is identical to the one that geographers have faced for centuries in mapping relief. Unless they can produce actual *relief maps*—as cartography institutes are now doing ever more routinely—geographers need to represent, on a plane, a nonplane surface each of whose points is situated in a space defined by three dimensions: longitude, latitude, and altitude. The earliest attempts typically consisted in using *trompe-l'œil* images of hills and mountains to provide an ornamental identification of places mapped in the two dimensions regarded as the most important: longitude and latitude. This practice of pictorial representation later led to stylized graphic devices such as cross-hatching or shading. In fact, however, the standards now required for these devices depend on a more modern invention: *contour lines*. The first demographers made their own attempts to put into perspective the three main dimensions of the phenomena they were studying (see Caselli and Lombardo, 1990).

For example, Luigi Perozzo (1880) used an earlier diagram by Berg (1860) as a model for a perspective representation of the change in the Swedish population that was exhibited at the 1875 Geographic Congress and the 1878 Paris Exhibition. The diagram comprised a line plotting the number of births over more than a century (1750–1875). Above that line, Perozzo placed a perspective view of the age pyramids observed at each census, at 5-year intervals (Figure 7–1).

A few years later, the same author (Perozzo, 1883) published a new chart with a twin perspective view of the probabilities of a man aged *x* marrying a woman aged *y* and the probabilities of a woman aged *x* marrying a man aged *y*. The probabilities were shown as a function of the age of each spouse (Figure 7–2). Each view featured a splendid "witch's hat" illustrating the high concentration of marriages in a small number of spouse–age combinations.

With modern computer technology, this formerly tedious operation has become much easier. It is, for example, commonly used in architecture. However, it is not widely used in demography. The advantage of computer-aided perspective design is the possibility of switching perspective angles instantly, on screen. One can thus take decisions on the final appearance of a construction by examining the various angles from which it can be viewed once it has been built.

Similar attempts have been made by Thomas Pullum (1980), for example, concerning fertility in the United States (Figure 7–3). By presenting the 1920 to 1970 matrix of age-specific fertility rates from different angles, he shows that the visual impression varies considerably with the angle chosen.

This finding effectively pinpoints the major drawback of the stratagem as applied to demography. Unlike the architect, the demographer is not attempting to choose the most handsome structure or variation of age-specific fertility or mortality, but to describe observed reality as faithfully as possible. It may be

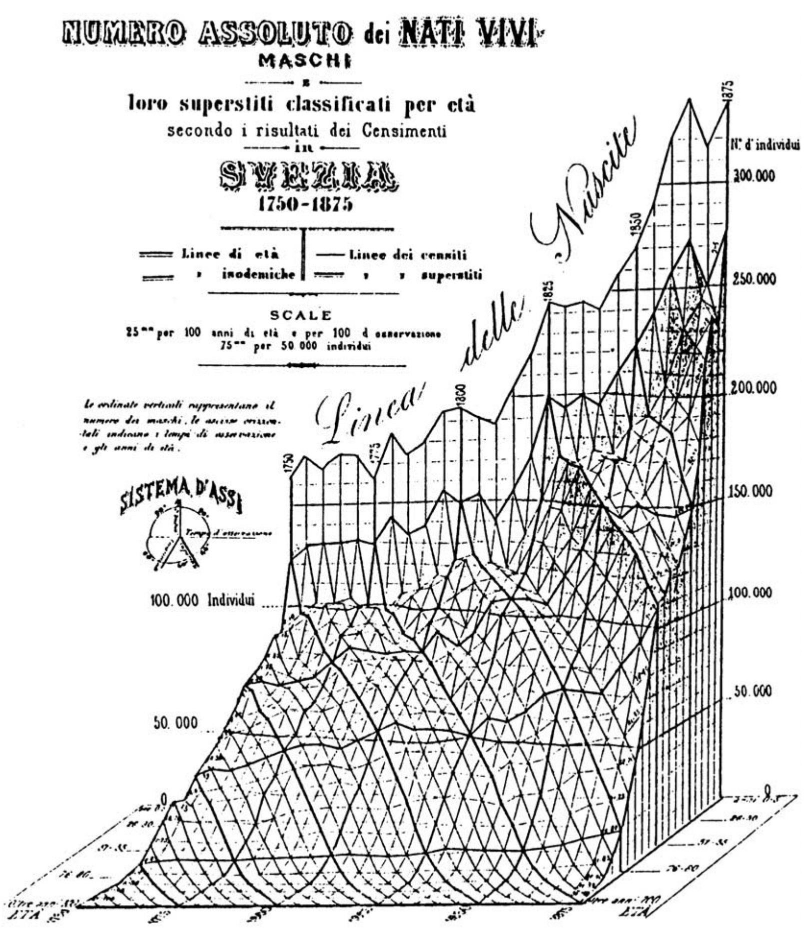

FIGURE 7–1 Perspective view of change in Swedish age pyramid compared with birth curve, by Luigi Perozzo (1880).

useful, for this purpose, to systematically examine on a computer screen all the possible facets of a perspective view, but at the time of publication the demographer must choose which chart to print, and there is no objective reason to pick one angle instead of another.

Figure 7–4 shows the large 1806 to 1995 matrix of French age-specific male mortality, under what we regard as the most expressive angle, in terms of (1) the radical fall in mortality over the long term and (2) the severe disruptions caused by the Napoleonic wars, the Franco-Prussian War of 1870, and the two world wars. However, our deliberate choice to highlight these major historical events promotes the legibility of some aspects to the detriment of others that are, perhaps, no less important. For example, we can very easily track the change in infant mortality, but it is much harder to glimpse mortality at age 60. Likewise, it is fairly easy to distinguish the overall profile of age-specific mortality and its considerable change over two centuries, but we have trouble making out the details of this transformation.

From this dual standpoint, perspective adds nothing to the classic projection on a Cartesian plane in which age or time is plotted against intensity. These two classic approaches—which require a choice between age and time to define the projection plane—are, however, relatively powerless in themselves to depict a fundamental demographic reality: the life of generations. In fact, from this third angle, we need to define age and calendar as the two axes of the projection plane—as Wilhelm Lexis did when designing his diagram (see Chapter 6). Age and calendar thus become the two major references for locating an event in time, just as longitude and latitude are the geographer's two preferred references for locating a spot on the Earth's surface. What we now need to do is to follow the geographers' example and adopt their most rigorous technique for mapping relief: contour lines. This will enable us to visualize the intensity of demographic phenomena on the projection plane.

II. CONTOUR LINES

It is no coincidence that the first demographer to use contour lines, Pierre Delaporte, is also the first to have attempted to plot the mortality of French birth cohorts. The problem to be solved here is the way in which the data are compiled. We know the number of inhabitants in a given year, or the mortality or fertility rate at a given age, or, conversely, the values of these indicators in a given calendar year for a given age. By contrast, we do not know the age or the instant to which the rates 10, 15, 20 . . . per thousand apply, rates that could be used to determine the contour lines. To plot contour lines showing the century-long change in age-specific mortality, we must therefore begin by constructing what Delaporte calls *mortality surfaces* from the available values for age-specific and period mortality rates.

For this construction task, Pierre Delaporte actually made the debatable choice of smoothing as much as possible the variations in age-specific mortality and in

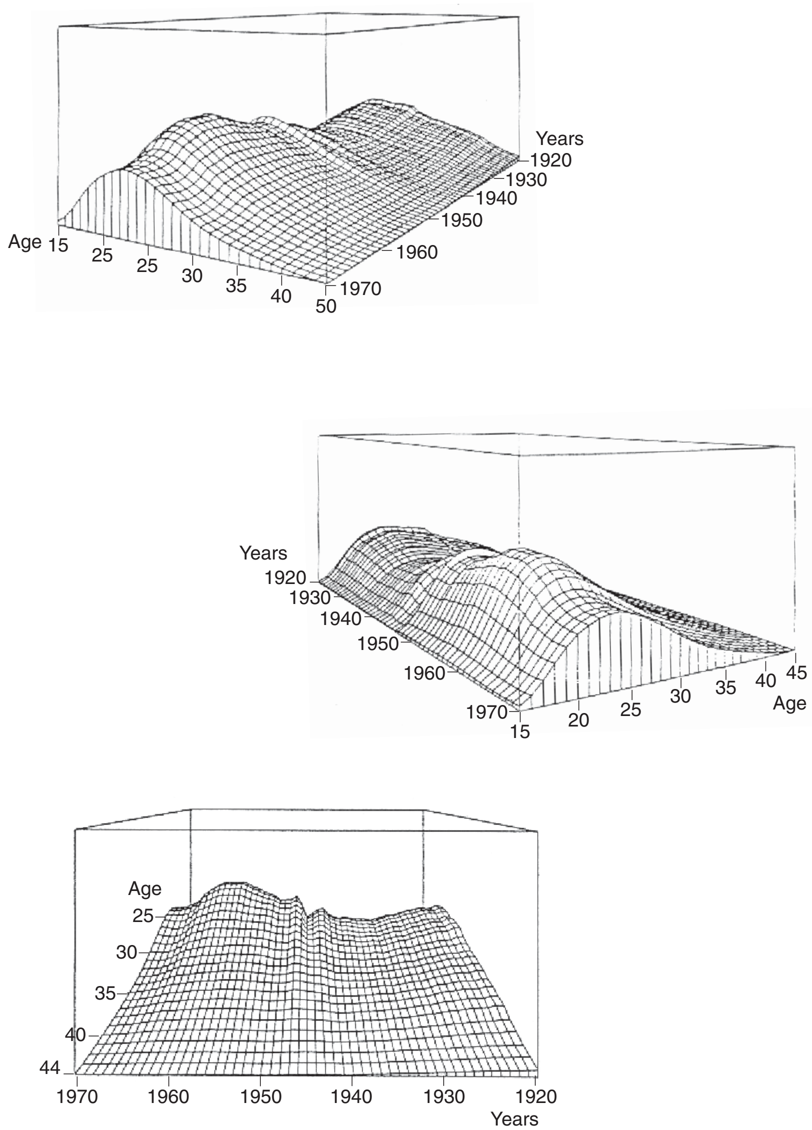

FIGURE 7–3 Alternative perspective views of changes in age-specific fertility of white U.S. females, 1920–1970, prepared by Thomas Pullum (1980).

mortality over time.[3] He therefore gave preference to rates for age groups covering several years, and interpolated between the central ages and the median dates of these rates. After examining different mathematical interpolation models, he opted for simple graphic interpolations. He started, of course, by interpolating the age-specific rates of each period, followed by the change over time of each age-specific rate. This enabled him to determine, for each period, the exact age at which the rate reached a particular, noteworthy

[3] Admittedly, in some cases, smoothing is entirely justified as a way to minimize the effect of observation errors. One can thus readily agree with Pierre Delaporte when he writes, "We have eliminated oscillations from the Demonferrand tables above age 50, for they seem solely due to attraction phenomena for round ages" (p.28). But we can hardly concur with his subsequent comments, "We have used slightly lower rates for the adjustments than the rates of the Bertillon tables between ages 0 and 40, as the deaths in these tables include those of the 1848 Revolution (France registered 973,000 deaths in 1848 compared with 836,000 in 1847), the Crimean War (cholera epidemic and siege of Sebastopol, which reportedly caused the death of 80,000 French), the Italian war, and the occupation of Algeria. France also experienced two cholera epidemics in 1849 and 1854. We classify cholera among the catastrophic events that could usefully be eliminated from the analysis. Having made its first appearance in Europe in 1832, it should not be included in the natural variation of the mortality surface." This deliberate removal of all "bumps" judged to be abnormal is both an illusion (resting on the misguided quest for a "natural" law of evolution) and a serious impediment to the goal pursued (i.e., the study of mortality by cohort). Such cross-sectional smoothing is likely to eliminate phenomena that would be interesting to observe longitudinally.

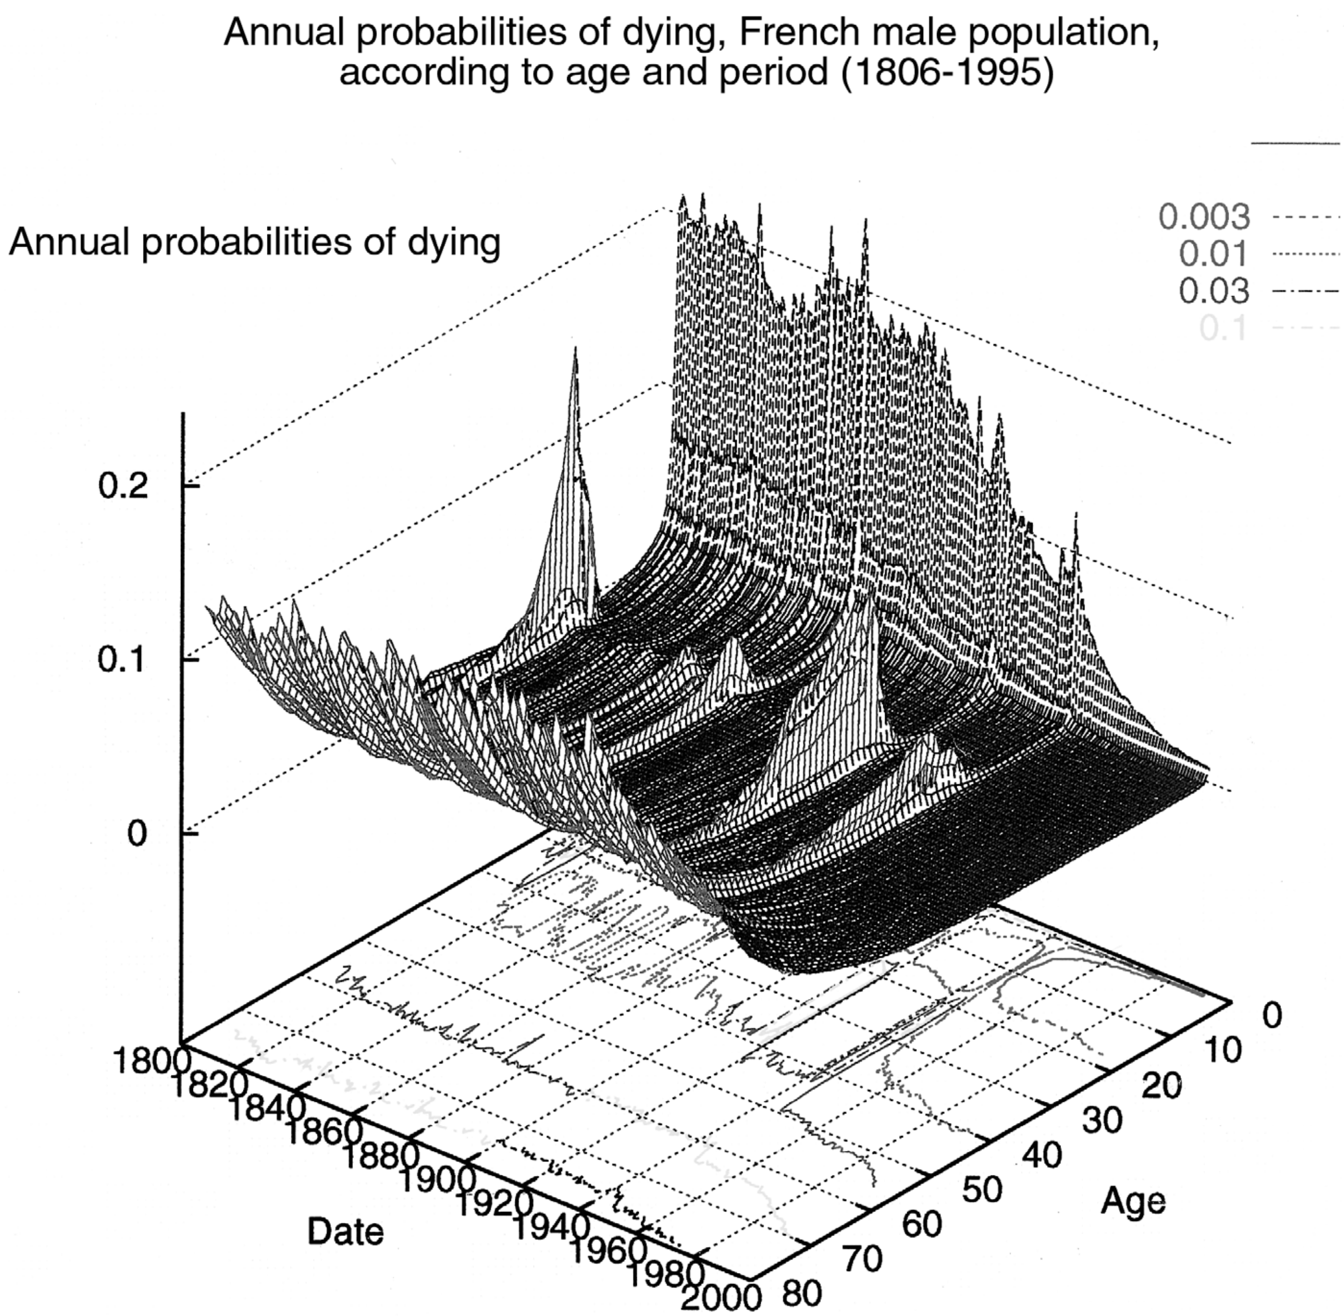

FIGURE 7–4 Perspective view of 1806–1995 matrix of French age-specific male mortality (chart from Nicolas Brouard [1997]). (Figure 7–4 also reproduced in color plate section.)

value, and for each age the exact date at which that same value was reached. From this, he deduced several points of the cross-section of the mortality surface by level. A final smoothing turned the broken lines thus obtained into *adjusted contour lines* (Figure 7–5).

Forty years later, at a time when cohort analysis enjoyed a revival of interest thanks to the rise of APC (age, period, cohort) models[4] (Hobcraft *et al.*, 1982; Caselli and Capocaccia, 1989), James Vaupel, Bradley Gambill, and Anatoli Yashin developed a software program at IIASA[5] that allowed the automatic projec-

tion, on the age/period plane, of a contour-line display of the mortality surface generated by a matrix of age-specific and period rates. The principle is identical to Pierre Delaporte's, but the interpolations needed to locate the exact dates and ages for a given value of the mortality rate are automated (using a linear interpolation of the rates' logs).

Figure 7–6 illustrates the result obtained with the matrix of the probabilities of French males dying in the period of 1806 to 1995.[6] The surfaces are colored to show the mortality levels to which they correspond. This graphic display enables us to read the change over time in the age-specific risks of death and the age-related variations of those risks. Following the horizontal lines, we can see the mortality rate for a given age decrease with the color shift. Likewise, along the vertical lines, the color shifts give us the variation in age-specific mortality for a given observation year. The combination of these two variations causes the blue zone of the lowest mortality rates to gradually widen over time: in the 19th century, it was narrowly confined to adolescent ages; in the 20th century, it widened rapidly to embrace all ages between 1 and 40 by the 1990s. The chart also vividly illustrates the war-related crises of excess male mortality, from the Napoleonic wars to the Franco-Prussian war of 1870 and the two world wars. The crises are shown by vertical bars whose colors contrast with those displayed by the same ages in the surrounding years. We can also read this type of chart diagonally to follow the individual histories of selected birth cohorts. French male mortality is not deeply marked by generation effects.

By contrast, Italian male mortality offers a good example of generation effects. Figure 7–7 uses the same method to display the matrix of Italian male probabilities of dying for the period of 1887 to 1992. Some birth cohorts stand out by forming diagonal lines of distinctive colors. They notably include two groups of cohorts: children born during World War I, and individuals aged 10 to 15 years during that war.

In conclusion, to broaden the range of examples, we have used the contour-line method in Figure 7–8 to plot the change in the age distribution of the French male population over a century, from 1899 to 1996. The

[6] In Chapters 8 and 11, we elaborate on the definition of probabilities of dying and their differences with the rates used until now. In the present context, probabilities and rates can be used interchangeably.

cohort effects are trivial, since it is obvious that the current population sizes depend directly, at any given moment, on the number of births at the origin of each generation.

Rates, Frequencies, and Probabilities

GUILLAUME WUNSCH

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Up to now, various types of rates have been computed by dividing the number of events by an average population, without taking account of the differences in substance between births, deaths, and migrations, nor the types of situations one encounters when computing these rates. The purpose of this chapter is therefore to distinguish between the different types of events and rates when evaluating the incidence of a particular demographic phenomenon such as fertility or mortality.

I. TYPES OF EVENTS AND POPULATION STATES

1. Repeatable and Nonrepeatable Events

Death is a unique event, in all the meanings of the word, whereas most women and men experience giving birth or fathering more than one child. Many people also migrate several times during their lives. Death is therefore a *nonrepeatable* (or nonrecurrent) event whereas birth and migration are *repeatable* (or recurrent) events, in the sense that individuals can experience these events several times during their lifetime. Repeatable events can however be made nonrepeatable if one gives them a *rank order*. Births can thus be ordered according to rank one (first birth), rank two (second birth), and so forth. In a similar way, one can distinguish the first migration from the second, and so on. Death always has rank one! One simple way to describe a demographic phenomenon is then to classify events according to their rank order, as in a table of births by rank. In a low-fertility country, most births are located in the rank one and two categories; in high-fertility countries, numerous births occur at higher ranks too. Birth certificates should therefore always include the order of the birth in the lifetime of the person, mother, or father.[1]

Even though birth is a repeatable event, it must be stressed that each birth is nevertheless a unique individual experience. Giving birth to one's first daughter Sally is a different life experience from giving birth to one's fourth child Billy. The reasons people do or do not have a first child can therefore be quite different from those explaining why couples have had a fourth child or not. The same holds true for migration: Migrating as a child depends on causes other than migrating as a young adult or after retirement. Once again, although migration is a repeatable event, each move is a unique experience based on a specific set of circumstances, such as marriage, change of occupation, need of a nursing home, and so forth. A detailed analysis of migration has to take these various reasons into account. Death is nonrepeatable, but the process leading to death might entail a series of repeatable issues, such as a succession of illnesses. Once again, each sequence should be considered separately from each other, in a life course perspective.

2. Ranks and States

One can establish a one-to-one correspondence between the ranks of the events one experiences and

[1] The two are not necessarily the same, due to polygamy or to multiple marriages in one's past.

the states one is in. In the case of death, one obviously moves from the state of being alive to the state of deceased. To give another example, first marriage changes the state of the female or male from single to married. In the field of fertility, having a first child modifies the *parity* of the woman concerned: she has moved from parity zero to parity one. If she has a second child, she will move on to parity two, and so on. Parity k is therefore the state one is in when one has had k children during one's past life. A childless woman or man is thus of parity 0. Note that as one moves from parity k to parity $k + 1$, the number of persons involved usually decreases, as not all individuals of parity k will have a child of rank $k + 1$. People of parity $k + 1$ are therefore a subset of those of parity k. Counting either nonrepeatable events or changes of states lead both therefore to the same numerical result. Similarly, estimating the probability of having a fourth child, for those exposed to risk, is equal to determining the probability of moving from parity three to parity four. As one produces a table on births by rank order based on the vital registration system, it is also useful to draw up a table of women by age according to parity, based on data from a census or a survey. Once again, in a low-fertility country, most women at the end of their reproductive period will be of low parities, while in a high-fertility country a large proportion of women will be in the higher parity groups.

3. Absorbing and Transient States

The state of deceased is an *absorbing* state, in the terminology of Markov chains: once entered, it is never left. On the other hand, parity three and parity four are states that *communicate* with each other: One may move from parity three to parity four, and then on possibly to parity five or more, although backward transition (from four to three or five to four) is impossible. In this case, there is only a one-way transition between parity state three and parity state four. In other situations, such as in the study of health and morbidity, one can observe on the contrary two-way transitions between *transient* states, moving from the state of good health to the state of being ill, and then back again to the state of good health if one recovers from the disease. Explaining demographic trends implies describing as a first step these changes between successive states. *Multistate* demographic models follow individuals from one state to the other and compute the probabilities of going out, coming back, or staying in each state during a specified period (see e.g., Halli and Rao, 1992, Section 2.5). The data one deals with should therefore distinguish the order of the events concerned and the corresponding states one is in.

4. Possible and Fatal Events

Not only does death differ from migration or maternity because it is nonrepeatable, but contrary to the other two events it is also *fatal*. Although a woman may spend her whole life without bearing a child, or a person may never cross the borders of his or her country, no human being can escape the fact that he or she will eventually die. This difference will obviously be reflected in the measures of final *intensity* (i.e., the *quantum* or number of events per person) of the phenomenon. At the scale of one's lifetime, the intensity of mortality is always 100%, meaning one death per person. On the contrary, in the fields of fertility and migration, these measures can take values other than one, such as bearing two children over one's lifetime or experiencing five migrations or changes of residence between birth and death.

5. Censoring

An event such as death or international out-migration excludes those who experience it from observation. The observation is *censored*, as one says, by death or by migration. On the contrary, having a birth does not exclude the female from observation; it changes her parity state, as we have seen, but we can still follow her after the child is born. Internal migration does not censor the data either, if the person can be followed in the country from one place of residence to the other thanks, for example, to a population register. Once again, internal migration changes the characteristics of the person (from a one-time migrant to a two-time migrant for example) but he or she can still be followed in the country one is dealing with. Data on fertility can therefore be obtained by a retrospective survey, for those who have not experienced international out-migration or death; the same is true for internal migration or for morbidity. In all these cases, the person who is interviewed should adequately recall his or her past life[2] and produce the information required on the number of births, migrations, or illnesses he or she has experienced. On the contrary, due to censoring, international out-migration and especially death cannot be observed by retrospective interviews. These people are therefore lost to follow-up, and a major question is to what extent those who have died or migrated out of the country differ from those who have survived and

[2] As cognitive abilities decrease with age, the quality of retrospective data often deteriorates at older ages, even excluding extreme cases of, e.g., persons affected with Alzheimer disease. Errors are more important for certain types of information than for others, depending on the type of memory involved.

stayed. This important issue will be discussed in Chapter 9.

II. REPEATABLE EVENTS: RATES AND FREQUENCIES

Consider a retrospective cohort study where women, interviewed at the end of their reproductive period (e.g., 55 years of age), are asked how many live births they have had during their lifetime. Let F_{55} stand for the number of women interviewed. If B_x represents the number of births occurring in this cohort of women at completed age x, then B_x/F_{55} is the relative number of births at age x per woman. This ratio is called the *age-specific fertility "rate"*[3] or more rarely the *age-specific fertility frequency* at age x. The sum Σ_x (B_x/F_{55}) over all x yields the average number of children[4] born during the reproductive period (i.e., a measure of the *intensity or quantum* of fertility). The denominator F_{55} concerns all women, having had or not a child during their lifetime.

As only survivors (to death and migration) can be interviewed at the end of the reproductive period, the measure of fertility quantum described above is net of the effects of mortality and migration. Furthermore, if mortality and migration do not select women with higher or lower fertility than those who survive until the end of their reproductive period, this measure of quantum is identical to that which would have been obtained if there had been no mortality nor migration at all during the reproductive period, except for larger confidence intervals due to the smaller number of cases involved. If censoring such as death or migration does, on the contrary, select women with different fertility levels, then the measures obtained by retrospective questions do not yield the same result as in the absence of censoring. In this case, birth, death, or migration are not *independent* from each other due to known or unknown common causes. For example, if the population is *heterogeneous* such that women of lower socioeconomic status have higher fertility and also a higher chance of dying than low fertility women of higher social status, censoring will select women with potentially higher fertility and progressively lead to a cohort of survivors of lower fertility (see Chapter 21). Social status is here a *common cause* of both fertility and mortality, and the two phenomena are therefore not independent. In this case, fertility measures will differ in the presence or in the absence of censoring.

Suppose now that births by age of mother are recorded each year by the vital registration system, giving for the same cohort births B'_x at completed age x. If F_x stands for the number of women surviving (to death and to migration) at that age, the ratio B'_x/F_x will be equal to the ratio B_x/F_{55} if women surviving until age 55 are not a selected group with respect to their fertility. Once again, women with higher fertility might be exposed to higher risks of dying or of migrating; in this case, B_x/F_{55} would actually be lower than B'_x/F_x due to the selection effect, as F_x also includes here women with higher fertility who will die or migrate eventually before reaching age 55. Once again if there is no selection (i.e., if there is *independence* between fertility on the one hand and mortality and migration on the other hand), the age-specific fertility "rate" or frequency B'_x/F_x will be equal to B_x/F_{55} at each age x, and therefore one can also characterize the average intensity or quantum of fertility by the sum of frequencies or "rates" $\Sigma\, B'_x/F_x$.

In practice, the denominator F_x is more or less equal to $F_{x+0.5}$ at exact age x + 0.5, if births are recorded by completed age x (see Chapter 6). The fertility "rate" can then be written $B'_x/F_{x+0.5;}$ the extension to intervals x to x + n is immediate, as the "rate" or frequency is then more or less equal to ${}_nB'_x/F_{x+n/2}$. Once again, the average number of children born for this cohort of women is obtained by summing the number of "rates" or frequencies by age intervals x to $x + n$ over all x. If the fertility "rate" is computed on a period basis for a particular year, by dividing the number of births ${}_nB'_x$ recorded during the year between exact ages x to $x + n$, by the mid-year population ${}_nF_x$ aged x to $x + n$, then the period rate should be multiplied by the age interval n for comparison with its cohort equivalent, as ${}_nF_x \cong {}_nF_{x+n/2}$ under the hypothesis of identical cohort fertility "rates." As an alternative, one can consider that the denominator of the "rate" is $1/n^{\text{th}}$ of the *person-years* lived in the age range x to $x + n$, i.e. roughly ${}_nF_x/n$.

Examples can be found in most demographic textbooks (such as Pressat, 1983; Preston, Heuveline, and Guillot, 2001; or Wunsch and Termote, 1978). As an illustration, the Belgian female cohort born in 1959 has given birth to 7494 children during the year 1990, subdivided into 3841 births at completed age 30 and 3653 at completed age 31. The corresponding mid-year estimated female population is 78,663. The age-specific fertility "rate" or frequency is thus 7494/78,663 = 0.09527 at exact age 31 on average. Similarly, if the data on births and on population numbers are available each year, one can compute the fertility "rate" at each

[3] In French, it is called *taux de fécondité* or sometimes *naisssances réduites* in Louis Henry's terminology. As the term *rate* has various meanings in demography, the term is put here between inverted commas in view of distinguishing it from the *exposure rate* which will be defined further on.

[4] In demography, fertility is usually restricted to *live births* only.

age during the whole reproductive period for birth cohort 1959. The sum of these rates will be equal to the average number of children born per woman of this cohort in the absence of mortality and migration, if the latter do not select women with lower or higher fertility than those females who remain in the population.

III. NONREPEATABLE EVENTS, PROBABILITIES, AND OCCURRENCE/EXPOSURE RATES

The approach developed in the previous section applies to all *repeatable and nonrepeatable events*, but only for those demographic processes such as fertility or nuptiality (see Chapter 25) that do not exclude the population from observation. In the case of *nonrepeatable* events, such as births by birth order, the same procedure can be used (see Chapter 12 for an example). Once again, to obtain measures of fertility by birth order net of the effects of censoring by death or migration, independence between fertility and the censoring phenomena is required although in reality, selection effects do occur due to the heterogeneity of the population. In particular, as we are now dealing with nonrepeatable effects—there should be no difference in mortality and migration between women of different parities, at the same age. This assumption has been called the condition of *continuity* in the demographic literature (Henry, 1972, Chapter 4). If this condition does not hold, as for example in the case where having a child increases one's risk of death, censoring will once again select women with higher fertility and the actual data will not reflect what would have been the quantum of fertility in the absence of censoring. These conditions of independence and of continuity will be more thoroughly discussed in Chapter 9.

This methodology cannot be used in the field of mortality because mortality excludes people from observation; it is therefore impossible to collect mortality data by retrospective surveys[5] as "dead men tell no tales." As "rates" or frequencies (as defined above) cannot be used in this situation, the analysis of mortality in the absence of migration is based instead on the *probabilities* of dying by age estimated in the absence of censoring by migration. The same approach can in fact be applied to all nonrepeatable events, such as births or emigrations by rank order.

[5] One can however obtain indirect estimations of mortality at retrospective surveys by obtaining e.g. data from mothers on the proportion of their children dead or by asking the household head how many deaths have occurred in the household during a given period. These indirect methods are used when vital registration does not exist or is of poor quality (see Volume 4).

1. Nonrepeatable Events and Probabilities

Suppose that the exact times of death are known and that deaths are registered per day. This is the case if the death certificate registers the time of death by day, month, and year; for example, it is known that Mr. George Brown has died on February 21, 1998. If a cohort is followed day by day, it is possible to compute the risks of dying for this cohort during each day j by the method developed by E. L. Kaplan and P. Meier;[6] (see e.g., Estève *et al*. 1993, Chapter 4, for an application). The probability of dying in the absence of migration, during day j, is taken equal to $q_j = D_j/P_j$, where D_j represents the number of deaths which have occurred during day j and P_j stands for the population exposed to risk at the beginning of the day, for example those having survived to death *and* out-migration during their lifetime until day j. If E_j out-migrants are observed during the same period j, one supposes that all D_j deaths have occurred before the E_j migrations; the population P_j exposed to death is therefore not affected by the occurrence of E_j. The population P_{j+1} exposed to the risk of dying during the next day $j + 1$ will then be equal to $P_j - D_j - E_j$, and $q_{j+1} = D_{j+1}/P_{j+1}$.

The only assumption the method requires is that death occurs during each period before its competitor, migration in this case. The method also easily takes care of immigration. If I_j immigrants are observed during day j, one assumes once again that they occur after deaths D_j. The formula for q_j therefore remains the same. The population exposed to risk at time $j + 1$ then becomes equal to $P_j - D_j - E_j + I_j$. Having computed the daily probabilities of dying q_j in the absence of migration, it is easy to derive the yearly probability of dying q_t during year t, in the absence of migration, using the multiplicative property of probabilities of survival. One has

$$q_t = 1 - \Pi_j(1 - q_j)$$

for j varying from the first day of the year (day 1) to the last day of the year (day 365); as usual, Π_j is the symbol of multiplication over j.

Aalen (1978; see also Courgeau and Lelièvre, 1992) has generalized this approach to take account of dependent risks in multiple decrement models. His approach is based on martingale counting process theory, leading to a multiplicative intensity model. An advantage of this model is that the changes in the risk set can depend quite arbitrarily on past, though not on

[6] Kaplan and Meier (1958). Assuming that deaths occurring during an *i*th time interval are considered as a binomial variable, E.L. Kaplan and P. Meier propose that each death occupy an interval by itself. See e.g. Harris and Albert (1991) for further reading, including confidence bands for the Kaplan-Meier survival curves.

future, failures. The Aalen estimator is a cumulative hazard rate, the values of which can be plotted and compared between multiple samples. The theory also allows the construction of confidence bands for the empirical cumulative intensities.

The *Kaplan-Meier* method is recommended as long as the units of time remain short; ideally, the estimator should be computed for each death separately when it occurs, except if several deaths happen at the same time. In practice, one depends upon the unit of time adopted in the data set (e.g., the hour or the day). If deaths are recorded per year, the estimator $q_t = D_t/P_t$ would not be adequate, as the assumption that competing events all occur after all deaths have been observed becomes less and less plausible as the unit of time increases. If out-migration had not occurred, the number of deaths during year t would have been greater than the number D_t actually observed, as some of the would-be migrants would have died during the year. Let K_t stand for this unknown number. The probability of dying in the absence of migration would then be

$$q_t = \frac{(D_t + K_t)}{P_t}$$

The numerator takes account of the number of deaths D_t actually observed, and the number K_t one would have observed in addition if there had been no migration. The problem is then estimating K_t. If all potential out-migrants die during the period, $K_t = E_t$; if all survive, $K_t = 0$. The probability would therefore be at the most $(D_t + E_t)/P_t$ and at the least $(D_t)/P_t$. The real situation is somewhere in-between.

Let Q_t $(0 \le Q_t \le 1)$ stand for the probability of dying of the potential migrants. Assuming rather arbitrarily that they would have been subjected to half the risk during the period, if they have left the country more or less uniformly over the period on average,[7] the probability in the absence of migration is then

$$q_t = \frac{(D_t + 0.5E_tQ_t)}{P_t}$$

Q_t is unknown and can be less than, equal to, or greater than q_t, depending on the fact that out-migrants are healthier than others, similar to the nonmovers, or in a less good condition. In the absence of information on the difference between Q_t and q_t, one usually takes $Q_t = q_t$ under the rather strong assumption that migrants are a perfect random sample of the population and therefore do not differ on average from those who remain. This is equivalent to assuming that death and migration are *independent* events (i.e., that there are no common causes or causal links between mortality and migration). Mortality and migration would in this case be two independent competing risks for the survivors (to death, to migration) at the beginning of the time interval considered. Under this assumption, the probability of dying is then estimated by what is sometimes called the approximate *Berkson formula* for the probability of dying, which is frequently used in the construction of life tables (see Chapter 11):

$$q_t = \frac{(D_t + 0.5E_tq_t)}{P_t}$$

or:

$$q_t = \frac{D_t}{P_t - 0.5E_t}$$

In the case of immigration, the formula simply becomes:

$$q_t = \frac{D_t}{P_t - 0.5E_t + 0.5I_t}$$

For example, having recourse once again to the Belgian data for the 1959 female birth cohort observed during the year 1990, one knows that 44 deaths have occurred in this cohort during the year. There have also been 789 immigrations and 615 emigrations of females during the same period at this age. The population of the cohort exposed to risk at the beginning of the period is 78,599. Without correction for migration, the probability of dying would therefore be equal to:

$$q_{1990} = \frac{44}{78{,}599} = 0.00055980 \cong 0.6 \text{ per thousand}$$

The *Berkson* formula for the corrected probability is in this case equal to:

$$q_{1990} = \frac{44}{78{,}599 - 0.5 \times 615 + 0.5 \times 789}$$
$$= 0.00055918 \cong 0.6 \text{ per thousand}$$

The correction is not significant in this example, but this is not always the case in practice. Having computed the probabilities of dying at all ages for this cohort, one can set up a cohort *life table* as discussed in Chapter 11. Cohort mortality studies are usually restricted to segments of people's lives, such as between, for example, 55 and 75 years of age if one is particularly interested in the mortality experience of this age group.[8]

[7] A mathematically more precise demonstration is given e.g. in Pressat (1995, p. 83–88).

[8] This would be the case for example if the study focuses on particular diseases of older ages, such as ischemic heart disease or cancer.

It must be stressed that the probability of dying at each age is in fact an average measure applied to all the members of the cohort surviving until that duration. If the population is *heterogeneous* with regard to mortality, and this will be the usual case, persons with a higher probability of dying will on average experience death earlier than those with a lower risk of dying. As age increases, the population of survivors will proportionately be composed more and more of individuals with lower risks, as the others have dropped out of observation due to death. For example, in the developing countries, it is well known that measles kills the weakest children, especially those with malnutrition. In this case, the survivors would consist of the strongest children having a lower average probability of dying. In this example, there could however be another selection effect. Survivors could possibly consist of weakened children through the detrimental effect of measles on the state of nutrition. The latter children would therefore have a probability of dying greater during the following months than the one the population would have experienced if it had not been exposed to measles, as observed in the Kasongo for example.

In each actual situation, one should thus be aware of possible selection effects and try to point them out. Attempts have been made to correct the impact of unobserved heterogeneity assuming subgroups with different risks among the population (see Chapter 21). Results are however sensitive to the choice of the mixture model. A good solution is trying to find out the causes of the underlying heterogeneity, in view of delimiting more homogeneous subgroups, as pointed out a long time ago by, for example, Henry in demography, MacMahon and Pugh in epidemiology, or Salmon in the philosophy of science. Better still, if the data are available, one can take account of individual life histories and apply the techniques of event-history analysis to this data set. Finally, one can put together individual data and contextual variables in a multilevel model, thus avoiding in the analysis both the atomistic and the ecological fallacies (Courgeau, 2004).

Probabilities may also be computed in the field of fertility for example, if one is dealing with births by rank order (see Chapter 12). Over very small periods of time however, such as t to $t + \delta$, one can nevertheless evaluate the probability for a woman to give birth in the interval $t; t + \delta$ regardless of birth order, assuming that the occurrence of birth at the micro level is generated by an underlying Poisson process or better still by a Yule or a Polya process (Chiang, 1968); the result will remain between 0 and 1. The probability that an event occurs during the time interval $(t, t + \delta)$ can be written $\lambda\delta + o(\delta)$ where $o(\delta)$ represents the probability that more than one event occurs in $(t, t + \delta)$. The notation $o(\delta)$ stands for any function of δ, which tends to 0 faster than δ. Different assumptions concerning λ yield different models of fertility.

2. Occurrence/Exposure Rates

In the case of *nonrepeatable* events, one may also compute *rates* of exposure in addition to or instead of *probabilities.* For example, with mortality rates instead of dividing the number of deaths observed during a period by the initial population of survivors exposed to risk, possibly corrected for competing events such as migration, take the ratio of the number of deaths (occurrences) to the exposure time or *person-years* of exposure observed during the period. Using the same symbols as before, the number of person-years of exposure during year t is equal to:

$$P_{t+1} + 0.5\ D_t + 0.5\ E_t - 0.5\ I_t$$

One assumes that deaths D_t, in- and out-migrations I_t, and E_t all occur on average at the middle of the year as, for example, in the case of an uniform distribution of events over the year or a linear survivorship function over the interval. Survivors P_{t+1} at exact age $t + 1$ have obviously lived 1 whole year[9] between t and $t + 1$, while those experiencing death or migration have been exposed on average one half-year. The *occurrence/exposure rate* or *central rate* of death is then equal to

$$r_t = \frac{D_t}{P_{t+1} + 0.5D_t + 0.5E_t - 0.5I_t}$$

or

$$r_t = \frac{D_t}{0.5(P_t + P_{t+1})}$$

The last formula is obtained by replacing P_{t+1} in the denominator of the rate by its equivalent $P_t - D_t - E_t + I_t$, yielding the average of P_t and P_{t+1} assuming an uniform distribution of events over the interval. The formula is easily extended to a period of n years, from t to $t + n$:

$${}_n r_t = \frac{{}_n D_t}{0.5 \cdot n \cdot (P_t + P_{t+n})}$$

${}_nD_t$ representing the number of deaths during the n-year period. For example, the Belgian data on mortality would yield a rate of

[9] Except those who have immigrated, on average at mid period, during the year; this is the reason why 0.5 I_t are subtracted from the sum.

$$r_{1990} = \frac{44}{0.5(78,599 + 78,729)}$$
$$= 0.00055934 \cong 0.6 \text{ per thousand}$$

the numerator being the number of deaths observed in the 1959 female birth cohort during the year 1990, and the denominator being the female population surviving at mid-period, an estimate of the person-years of exposure to risk during the time-period.

As for probabilities over discrete intervals, occurrence/exposure rates can be computed for all nonrepeatable events such as death, birth by rank, migration by order, and so forth. The denominator is always the *person-time* of exposure to risk by those who have not experienced censoring either by the event studied (e.g., death) or the competing events (e.g., migration).

Rates have the advantage over probabilities that they do not depend upon the length of the time interval considered. For example, one may not compare the probability of dying between 20 and 21 years of age with that between 20 and 25, as the longer the interval the more deaths there will be. These probabilities cannot be put, for example, on the same graph. On the contrary, one may compare the occurrence/exposure rates between these two age groups, as rates are expressed per person and per unit of time. Rates do not depend therefore on the length of the interval. To give another example in the field of infant mortality, one may not compare the neonatal probability of dying to the postneonatal probability, as the former covers the first month of life and the latter the last 11 months of the year. The time interval of the latter is thus 11 times that of the former. One may however compare the neonatal infant mortality rate[10] to the postneonatal rate.

3. Frequencies and Rates

One should distinguish between two types of fertility or emigration *rates*. In the case of fertility for example, one rate is equal to the age-specific fertility "rate" or frequency obtained by dividing births (all birth orders or by birth order) by the population surviving to competing events (death and migration), while the other rate is an age-specific occurrence/exposure rate obtained by dividing the number of births by order by the population which has neither experienced the event studied (birth of a certain order) nor the competing events (death and migration). As we will see in Chapter 14, the latter type of rate is much to be preferred to the former. The terminology actually used in the literature can be confusing, as pointed out in footnote 10. In French, one usually distinguishes between frequencies ("reduced events" or "second category rates"), occurrence/exposure rates ("first category rates"), and probabilities ("quotients"). In English, the terminology actually used is not always that clear, the term *rate* often being used in the sense of a probability, of an exposure rate, or of a frequency as defined above! The terms *central rate* and *occurrence/exposure rate* are synonyms.

4. Relations Between Probabilities and Occurrence/Exposure Rates

As seen above, probabilities and exposure rates are quite similar indicators, but they differ radically from frequencies (as defined previously). Probabilities and rates both apply to nonrepeatable events. The numerators of the two are identical, but they differ in their denominator. In the case of probabilities, the denominator is the population exposed at the beginning of the interval, while in the case of rates it is equal to the person-years of exposure. The latter denominator can be approximated by the average population exposed at the beginning and end of the year, assuming a linear survivorship function, if the time interval is 1 year. It is therefore easy to transform rates into probabilities and vice versa. A general relation would be:

$$_nq_t = 2n\ _nr_t / (2 + 2(1 - {_na_t})n\ _nr_t)$$

where n is the age interval t to $t + n$ and $_n\mathrm{a}_t$ is the fraction of time spent alive in the age interval t to $t + n$ by those who die during this interval (Chiang, 1968). If deaths are uniformly distributed over the age interval, for example, if the survivorship function is linear, $_n\mathrm{a}_t = 0.5$ yielding the formulas described below. Assuming a uniform distribution of events over the year, one thus obtains:

$$q_t = \frac{2r_t}{2 + r_t}$$

To demonstrate, replace the rate r_t by its value given above $D_t\ /\ (P_{t+1} + 0.5\ D_t + 0.5\ E_t - 0.5\ I_t)$; one obtains the probability $q_t = D_t / (P_{t+1} + D_t + 0.5\ E_t - 0.5\ I_t)$. Replacing P_{t+1} by its value $P_t - D_t - E_t + I_t$ yields $q_t = D_t / (P_t - 0.5\ E_t + 0.5\ I_t)$, which is in fact the approximate *Berkson* formula obtained above for the net probability of dying. The formula can easily be extended to n-year intervals:

$$_nq_t = \frac{2n \cdot {_nr_t}}{2 + n \cdot {_nr_t}}$$

[10] In current practice, the term *infant mortality rate* is often used for *infant mortality probability*, an unfortunate linguistic confusion between rate (probability) and rate (exposure rate)!

The inverse relationship can also be obtained:

$$ {}_n r_t = \frac{2\,{}_n q_t}{n(2 - {}_n q_t)} $$

These formulas can also be adapted to take into account the possible nonuniform distribution of events over the interval, if one knows this distribution. For example, an exponential survivorship function would yield:

$$ {}_n q_t = 1 - e^{-n \cdot {}_n r_t} $$

For example, if the Belgian male occurrence/exposure death rate in the 80 to 85 age group is 0.12420, the corresponding probability of dying will be

$$ {}_5 q_{80} = \frac{2 \times 5 \times 0.1242}{2 + 5 \times 0.1242} = 0.47386 $$

supposing a linear survivorship function, and

$$ {}_5 q_{80} = 1 - e^{-5 \cdot 0.1242} = 0.46259 $$

assuming an exponential one. The difference is not totally negligible as, at that age, mortality is relatively high and the form of the survivorship function in this 5-year age interval must be taken into account.

IV. SINGLE AND MULTIPLE DECREMENT

Up to now, probabilities of dying for example have been corrected to obtain a measure of the probability of dying *net* of migration, in what is called the *single decrement* approach. One wishes to know in this case the probability of dying in the absence of other censoring events. In the actual world, the population is affected by both events, death and migration, and this has to be taken into account in population projections. In this case, one may wish to compute in a *multiple decrement* approach a *gross* probability of dying and a *gross* probability of emigrating with no correction for competing risks. One would then have, respectively:

$$ \kappa_t = \frac{D_t}{P_t} \quad \text{and} \quad \varepsilon_t = \frac{E_t}{P_t} $$

the probability of attrition by both death and out-migration being in this case:

$$ s_t = \frac{D_t + E_t}{P_t} = \kappa_t + \varepsilon_t $$

which is equal to the sum of the gross probabilities. Gross probabilities are therefore additive, which would not be the case with net probabilities as it is now shown. Let q_t and e_t stand respectively for the *net* probabilities of dying and out-migration obtained by the Berkson formula:

$$ q_t = \frac{D_t}{P_t - 0.5E_t} \quad \text{and} \quad e_t = \frac{E_t}{P_t - 0.5D_t} $$

In this case, out-migration is competing for censoring with death and vice-versa. It is easy to check that the probability of exit by either death or out-migration is not equal here to the sum of q_t and e_t. However, the probability of neither dying nor emigrating is equal to the product of their complements, if the probabilities are independent. The global probability of attrition due to death and migration, in the *single decrement* approach, is therefore equal to:

$$ s_t = 1 - (1 - q_t)(1 - e_t) = q_t + e_t - q_t e_t $$

For example, if the male *net* probability of dying in the 80 to 85 age group is 0.46259, as obtained above, and the net probability of out-migrating from the area of residence is 0.18926, the total probability of exit due to both mortality or out-migration would be:

$$ {}_5 s_{80} = 0.46259 + 0.18926 - 0.46259 \times 0.18926 = 0.56430 $$

If they were *gross* probabilities, one would have instead:

$$ {}_5 s_{80} = 0.46259 + 0.18926 = 0.65185 $$

As the difference can be significant, as one sees from this example, it is important to know if the probabilities one is using are gross or net; not all authors explain how they have computed the probabilities they have obtained, and the results can therefore be misleading in comparative studies.

The single decrement approach based on net probabilities is often used when one is interested in one particular event, such as death in the absence of migration or, to give another example, death from ischemic heart disease in the absence of all other causes of death. On the other hand, the multiple decrement approach based on gross probabilities is adopted when one is examining the multiple causes of exit, such as in the case of the various causes of death. Examples and further discussion can be found in Preston *et al*. (1972, 2001). Note that computing gross probabilities requires no assumption, whereas establishing net probabilities usually assumes the independence between these probabilities. Without making any assumption on the relationship between risks, one may therefore compute gross probabilities of internal migration after marriage or vice versa, on the basis of survey data, as long as one does not raise the question of what these risks would have been in the absence of mortality and international migration.

V. THE FORCE OF ATTRITION

In the previous sections, it has been stated that demographic measures can be estimated for very small intervals of time. However, the advantage of greater precision is compensated by the disadvantage of dealing with small numbers of events and individuals. As the time interval becomes smaller, one reaches at the limit what is called the *force* or the *instantaneous rate* already developed in Chapter 3 for the crude rate. This section therefore develops briefly the concept of *force*, which is used in the actuarial literature and in mathematical demography, mortality being taken here as an example. Consider once again the number of survivors P_x at exact age x, and suppose there is no migration. The force of mortality is then defined as:

$$\mu_x = \lim_{\Delta x \to 0} \frac{P_x - P_{x+\Delta_x}}{\Delta_x P_x} \quad \text{for} \quad \Delta_x \geq 0,$$

or:

$$\mu_x = -\frac{\mathrm{d}P_x}{P_x \mathrm{d}x}$$

The minus sign is due to the fact that the survivorship function P_x decreases as x increases; its derivative is therefore negative. As the force of occurrence must be positive, one must multiply the derivative by – 1. One notices that, in fact, the force of mortality is an instantaneous death *rate*, with deaths as the numerator and person-time as the denominator. The discrete death rate centered on age x, as presented before, is therefore usually a very good approximation of the force of mortality at age x. The above expression μ_x is also equal to

$$\mu_x = -\frac{\mathrm{d}(\ln P_x)}{\mathrm{d}x}$$

where *ln* stands for the natural logarithm.

Inversely, one can obtain P_x by integration. Writing $\mathrm{d}(\ln P_x) = -\mu_x \mathrm{d}x$ integration gives

$$\ln P_x = -\int \mu(a)\mathrm{d}a + c$$

where c represents an integration constant. The former expression is equal to

$$P_x = c^* e^{-\int \mu(a)\mathrm{d}a} \quad \text{with} \quad \ln c^* = c$$

As the number of survivors at duration x depends upon the forces of death from 0 to x, one writes:

$$P_x = c^* e^{-\int_0^x \mu(a)\mathrm{d}a}$$

For $x = 0$, $P_0 = c^*$ so that finally

$$P_x = P_0 e^{-\int_0^x \mu(a)\mathrm{d}a}$$

The discrete probability of dying can then be obtained by the complement of the probability of survival over the interval, for example:

$$q_x = 1 - \frac{P_{x+1}}{P_x} = 1 - e^{\int_x^{x+1} \mu(a)\mathrm{d}a}$$

Applications can be found in Keyfitz (1977). This approach will be discussed again in the context of the life table (Chapter 11).

Competing Risks, Independence, and Continuity

GUILLAUME WUNSCH

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

As seen in Chapter 8, measures of the components of population change must address the problem of censoring and of competing risks. Censoring occurs when the observation is truncated and the persons are lost to follow-up. For example, in a prospective study on mortality, where survivors are followed up over a period of several years, censoring might occur as a result of out-migration. To give another example, in the field of fertility, in a study on the use-effectiveness of a new contraceptive, where users are followed up for several months, censoring might happen due to death or out-migration, but also because of withdrawing from the survey to switch to another contraceptive method or because they wish to conceive. These exits from follow-up disturb the observation, but they also hamper, for example, the evaluation of the use-effectiveness of the new contraceptive if censoring or loss to follow-up selects persons with higher or lower use-effectiveness than those who remain in the study. Similarly, in the study of mortality, out-migrants might have risks of dying different from those who do not move; probabilities of dying drawn from the study do not therefore reflect the actual risks in the total population. As this heterogeneity of risks seems likely, between those who stay in the study and those who do not, the question is what would have been the result if there had been no censoring effects (i.e., no disturbances or competing risks)?

I. THE CONDITION OF INDEPENDENCE

The first problem concerns the measurement of the risk over a specific time interval in the absence of other causes of exit. As seen in Chapter 8, if individual exact times of occurrence are available, the *Kaplan-Meier* estimator of this probability is highly recommended, because it does not assume any particular relationship between risks. This is also the case of the *Aalen* estimator (Courgeau and Lelièvre, 1992, Chapter 4). The only assumption concerns the occurrence of more than one event during the interval; in that case, one assumes that the event of interest (e.g., death) happens before its competitor (e.g., migration). If individual times of occurrence are not available, such as when deaths and migrations are recorded by 1-year intervals, formulas have been developed under the assumption that the *forces* of mortality and migration, or the events themselves, vary over the interval in a specific way, and that the risks are independent in the sense that, for example, the probability of dying is not influenced by the presence of migration. If competing *forces* are assumed to be proportional over the interval, one obtains the so-called *Elveback formula* for the net probability of dying, whereas if deaths and migrations at each age are considered to be proportional over the interval, one obtains the *Berkson formula* of which an approximation was given in Chapter 8. The reader is referred to Le Bras and

Artzrouni (1980) for a thorough discussion of these two approaches, and to Chiang (1968) for a general discussion of competing risks theory.

As an example, suppose that survivors at ages x and $x + 1$ are equal to P_x and P_{x+1}, and that D_x deaths and E_x emigrations occur during the interval x to $x + 1$. One has $P_{x+1} = P_x - D_x - E_x$. The *Elveback* formula would estimate the probability by taking:

$$q_x = 1 - \left(\frac{P_{x+1}}{P_x}\right)^{\frac{D_x}{D_x+E_x}}$$

while the more common *approximate Berkson* formula would lead, as seen in Chapter 8, to:

$$q_x = \frac{D_x}{P_x - 0.5E_x}$$

In practice, both formulas give close results, especially if the *exact Berkson* or *Schwartz and Lazar* (1961) formula is used instead of its approximation:

$$q_x = \left[1 + 0.5\left(\frac{D_x}{P_x} - \frac{E_x}{P_x}\right)\right] - \sqrt{\left[1 + 0.5\left(\frac{D_x}{P_x} - \frac{E_x}{P_x}\right)\right]^2 - 2\frac{D_x}{P_x}}$$

For example, if for a cohort of males aged 75 in completed years (i.e., between exact ages 75 and 76 years) one observes 4732 deaths, 3294 out-migrations, and 78,231 survivors at exact age 75, the *Elveback formula* would give the following result:

$$q_{75} = 1 - \left(\frac{70,205}{78,231}\right)^{\frac{4732}{4732+3294}} = 0.06183$$

The *approximate Berkson formula* would lead to:

$$q_{75} = \frac{4,732}{78,231 - 0.5 \times 3,294} = 0.06179$$

Finally, the *Schwartz and Lazar* or *exact Berkson formula* would yield:

$$q_{75} = \left[1 + 0.5\left(\frac{4,732}{78,231} - \frac{3,294}{78,231}\right)\right] - \sqrt{\left[1 + 0.5\left(\frac{4,732}{78,231} - \frac{3,294}{78,231}\right)\right]^2 - 2\frac{3,294}{78,231}} = 0.06183$$

One sees that the *Elveback* and *Schwartz and Lazar* formulas give in this case identical results, while the *approximate Berkson* formula yields a lower estimate. There are no major reasons for choosing one or the other estimate, except on the basis of the underlying models and therefore of one's assumptions relating to the two competing risks. The *approximate Berkson formula* is simple and easily takes immigration into account;[1] it could therefore be preferred for these reasons.

As a second problem, consider the condition of *independence*, which is at the basis of the methods developed in the preceding section. For example,[2] are death and migration independent events? Although mutually exclusive, these events might be dependent. For example, migration might select healthier persons than those staying in the country of origin, leading to biased probabilities of dying in this country, in the sense that if no migration had occurred probabilities of dying would have been lower than those actually computed. Usually, and in the absence of contrary evidence, the event of interest and its competitor(s) are considered independent from each other, but this is only a stopgap. In the presence of information on possible common causes of competing events, one's approach should control for the common factor(s) (see e.g., S. Prati, 1995). Oftentimes, lack of suitable data will leave these factors uncontrolled. Assuming the absence of selection effects, as one does under the independence assumption, is not satisfactory in this case; procedures requiring independence should then be considered only as a model of the underlying process, meaning here a simplified representation of the true but unknown situation.

Some demographers have tried to waive the condition of independence by incorporating some form of dependency between competing risks (for an overview, see J. Duchêne, 2002). Without outside information this solution is inadequate, as it has been shown[3] that to each competing risks model with dependent risks, one may associate another model with independent risks, which is observationally equivalent in the sense that data will never be able to distinguish between the two models. The best way out is therefore to obtain more knowledge on the possible common causes of competing events.[4] Confounders can then be controlled as seen above, if one has collected the necessary data. If data on individual life courses are available, this set can be analyzed using event-history techniques taking into account each individual life course, under the assumption that one's past conditions determine one's present situation. Data, analysis, and synthesis or explanation, cannot be dissociated in practice, as all scientists know.

[1] The Schwartz and Lazar formula can lead to aberrant results in the case of immigration.

[2] A more detailed discussion is given in Chapter 44, on dependencies between causes of death.

[3] For a recent demonstration, see Mouchart and Rolin, 2002, theorem 4.2.

[4] See for example Kalbfleisch and Prentice, 1980, Chapter 7.

II. THE CONDITION OF CONTINUITY

In the field of fertility, it was seen in Chapter 8 that two conditions were to be satisfied in order to use rates or frequencies, the condition of *independence* and the condition of *continuity* in Louis Henry's terms. In that case, frequencies or rates could be used instead of probabilities, the advantage being that rates require less data than probabilities because only the population surviving the disturbances (death, migration) is concerned, whereas probabilities also require information on the population that has not (yet) experienced the event under study (e.g., the move from parity 3 to parity 4). However, the advantage of using rates is minimized by the supplementary condition of continuity, which must be satisfied in this case. Both approaches require that the condition of independence be satisfied. Independence is probably not guaranteed in most cases, and the same is probably true for continuity too.

From a causal perspective (see G. Wunsch, 1988), two events A and B are *causally independent* if there are on the one hand no *common causes* to both such that C causes A and B, and on the other hand if there is no *causal relationship* between A and B such that A causes B or B causes A. The *independence* assumption in demography covers the first part of the requirement, while the *continuity* assumption addresses the second part. The absence of common causes is needed for all measures, rates, probabilities, and frequencies, except if one can control for all of the common causes—a doubtful exercise indeed. Some form of unknown selection probably operates in most cases, and the independence model stands as a significant simplification of reality in this case. *Continuity*, on the other hand, supposes no causal relation between competing processes, such as fertility changing one's probability of survival. If this happens, relating births by order to the total population escaping disturbances does not lead to the true ratio in the absence of disturbances, as the parity distribution would not be the same in both cases. For example, females without children would have a higher chance of surviving than females with children, if fertility lowers one's probability of survival. As fertility rates and probabilities take parity into account, continuity is not required in this case.

As stressed in Chapter 8, the problem of dependent or independent risks arises when people are lost to follow-up and one wishes to know, in this case, what would have been the risk in the absence of censoring. If there is no censoring (i.e., if all persons remain in observation), there is no major reason to adopt this viewpoint. One can study whether marriage influences occupation and internal migration, or vice versa, without having to assume independence between these factors. On the contrary, if marriage does influence occupational status, there is by definition in this case a causal dependence between both factors, as marriage is then a cause of occupational change. Assuming independence in this situation would be absurd! The same is true in the case of nonmarital cohabitation and marriage, as the duration of cohabitation increases, most likely, the probability of marriage. Once again, there is a causal dependency here between the length of cohabitation and marriage, and the hypothesis of independence would be incorrect.

To conclude, one may say that the usual measures demographers use, probabilities, rates, or frequencies, require *causal independence* between competing events, if one wants to answer the "what" question of the single decrement approach: what would have been the rate-probability-frequency in the absence of censoring and competing events? The condition of causal independence is most probably not satisfied in practice, and the measures one obtains using the traditional formulas should therefore be considered with some degree of skepticism. One's efforts should then be geared to testing the independence assumption by checking if the variables considered are associated by common causes or causal links. This implies in practice moving from description to explanation, and having recourse to more powerful methods based on statistical analysis, such as covariance structure modeling, multistate transition modeling, or event-history analysis if individual data are available. The ideal is probably measuring all links between the variables one is interested in, both known . . . and unknown. In this situation, there would be no need anymore to assume independence and continuity! This ideal can probably never be attained,[5] but it is good scientific practice to try to reach it over and over again.

CHAPTER

10

The Longitudinal Approach

GUILLAUME WUNSCH

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

As pointed out several times in the previous chapters, there are two different temporal ways to look at data in demography. One determines the characteristics of a population and its behaviors relating to fertility, mortality, and migration at a particular point in time, and possibly compare these characteristics from year to year. This approach is known as a *cross-sectional* or *synchronic study*, also called a *period* observation and analysis.[1] This type of study can therefore be considered as a *photograph* of the population, or of a sample of the population, at point of time *t* or at several points of time. The second way to look at data entails following up people who have had, for example, a heart attack (myocardial infarction), determine their probability of dying each year, and compute the average span of time between their infarct and their eventual death. We can also relate each individual's survival or death, at a specific duration elapsed since his or her heart attack, to his or her age, gender, way of life, and other possible explanatory factors. This approach is known as a *longitudinal study*.[2] As we will see in this chapter, from the viewpoint of data collection, longitudinal observations can be conducted prospectively or retrospectively.

During the last decades, the longitudinal approach has become a major means of study, due to the search for explanations and causal factors or determinants. In this case, one must indeed time-order the succession of events, as causes must always precede effects in time.

As longitudinal analysis is required for the understanding of the internal dynamics of demographic phenomena (i.e., their intensity and tempo), we have preferred to develop the method here, although its usefulness will be made much clearer in Section II and subsequent volumes.

I. INDIVIDUAL AND COHORT DATA[3]

Longitudinal analysis implies following the units of observation or cases over time, to study their changes of states in temporal succession and the durations of the interval between two successive transitions. For example, in the case of fertility, one may be interested in knowing what proportion of women move from parity zero to parity one, from parity one to parity two, and so forth, and in computing the average waiting times between these changes of states. *Time* is therefore a key issue in longitudinal research. One must adequately define the duration of the study (e.g., a study of female fertility should follow women from menar-

[1] Strictly speaking, a period study refers to the incidence of events occurring during a specified period of time in the area considered, such as deaths occurring during the year 2004 in Belgium. A cross-sectional study, such as the estimation of the point-prevalence of disability in the Belgian population, refers on the other hand to a specific point in time (e.g., June 30, 2004). A cross-sectional (synonym: synchronic) study shows the characteristics of people surviving at that time, and the latter may differ however from those who died before the study.

[2] The terms *longitudinal*, *follow-up*, *life course*, *prospective* and *cohort* are often used as synonyms. In this section, longitudinal is more general than prospective (synonym: follow-up) and cohort.

[3] This section is partly based on a chapter by G. Wunsch (1993).

che to menopause), decide on the right unit of time for the study (a time unit of 1 year is too long if one is interested in seasonal variations), and time order correctly the succession of events if we are involved in causal analysis (causes always precede effects in time).

From the viewpoint of data collection, longitudinal observations can be conducted prospectively or retrospectively. *Prospective longitudinal research* implies following the cases forward in time, according to the *arrow of time* as philosophers say. This is the procedure adopted for patients having suffered a heart attack for example; their survival or death is assessed from medical records, registration data, or multiround surveys.[4] A significant advantage of a prospective study, contrary to a retrospective one, is that the characteristics of those who drop out from observation are known for those variables that have been recorded.[5] One can therefore determine if censoring selects individuals with different characteristics than those who remain in the study. Moreover, prospective studies are not affected by recall bias as in the case of retrospective or case-control studies. Prospective longitudinal studies have several drawbacks, however. They are very expensive to carry out, are subject to attrition or loss to follow-up, and require large initial populations if events are rare.[6] Due to sorting (selection) effects, the group probably becomes more and more biased as time passes: People who drop out of the study are often different from those who remain. Once again, heterogeneity of risks among individuals has to be taken into account.

If the phenomenon studied does not exclude individuals from observation, a much cheaper and easier way of conducting a longitudinal research is through *retrospective observation* (also called a *retrospective panel design*). For example, in fertility research, females who have reached the end of their reproductive period are questioned on their past fertility experience. Reproductive histories taking account the number of live births and the date of each birth, among others, can therefore be constructed for each woman interviewed at the end of her reproductive life. However, retrospective longitudinal research is influenced by recall lapses (some events may be forgotten), inadequate recollection of time patterns (dates are often poorly remembered), selective recall (the respondent interprets the relationship between events), and changes through time in the social representation of events (such as abortion or cohabitation). Finally, retrospective analysis may suffer from biased group composition; for example, females with higher fertility may have had higher risks of dying before their menopause and will therefore not be correctly represented in the survey. Moreover, retrospective analysis is inadequate (as noted previously) for phenomena leading to population exclusion, such as death or emigration: Unfortunately, we cannot interview the deceased on their cause of death! For a good discussion of the respective advantages and disadvantages of retrospective and prospective analysis, see Henry (1959).

In longitudinal research, prospective designs (also called *follow-up studies* or *prospective panel designs*) follow the *same* individuals forward in time. Individual *life courses* or trajectories, such as one's reproductive career for example, can then be constructed for all cases that are followed over time. However, as we have seen, this research design will lead to sample attrition or loss to follow-up. Another approach, which avoids this problem to a large extent, is to collect longitudinal data on *nonidentical but comparable* individuals (or cases) over time, as in a *repeated cross-sectional design.* In the latter approach, probability samples are drawn from the same population and the characteristics of the cases are compared from sample to sample. Samples of the same or similar sizes can be compared, but individual life courses cannot be constructed, as the same individuals are not observed over time (see e.g., Jones, 1996, Chapter 6) and therefore techniques such as event–history analysis cannot be used. In this approach, comparisons are therefore possible on the aggregate level, but not on the individual level. The same situation arises if we have recourse to anonymous vital registration data.

Up to now, cases have been followed either forward or backward in time (i.e., prospectively or retrospectively), but the entry of the cases into observation did not refer to a particular time period; furthermore, one did not take into account the periods of time (month, year) during which the observations were made. For example, all patients having a heart attack (the onset of the process studied, called the *event origin*[7] were followed, regardless of the date of their heart attack. This date was not taken into consideration, as the duration since the onset of the process was the only time variable deemed to be of interest. The patient's *age* at onset was obviously considered, but the patients could be grouped together according to their age at onset, whatever their year of birth. In this design, aging is the prime temporal variable, and no particular considera-

[4] Also called *panel surveys* in the social sciences.

[5] The two groups (those who drop out and those who remain in the study) may differ on unrecorded variables.

[6] In this situation, *case-control* studies are probably preferable as they are much cheaper and easier to carry out (see Gray, 1988). For a thorough discussion of the case-control approach, see Bernard and Lapointe (1991).

[7] The term was coined by Henry (1959).

tion is given either to the year of birth of the patient or to the periods (calendar months or years) of observation. The duration elapsed since the heart attack is therefore an indicator or proxy for biologic aging, given the chronologic age of the patient at onset. One could replace age, in these circumstances, by a series of biologic indicators that would reflect the aging process itself.

Consider now the situation where we suspect that the environmental conditions of the times we live in may have an impact on heart disease, due for example to the incidence of more stressful events.[8] We may then take the succession of *calendar years* as a proxy for the changes in environmental conditions (e.g., marital conditions, political conditions, socioeconomic conditions, etc.) over time. History, as represented by the succession of calendar years, would then be our temporal variable in this case, if we neglect the *duration* component. In this situation, one could compute the time series of deaths occurring after a heart attack, whatever the age of the patients, and study the association[9] between this time series and one or several time series of environmental indicators, such as income per capita or the percentage of unemployed.

Finally, suppose that a new anticoagulant drug has an impact on tertiary prevention if delivered in the days after a heart attack. Some of the patients in the sample have had their infarct at a time when the drug was still unknown. Others, on the other hand, were born later and therefore had the opportunity to receive the drug.[10] In this case, another temporal variable—the year of birth of the patient—must be taken into account: For a given age at onset, some patients were born too long ago to receive the drug and others on the contrary benefited from the discovery. The *birth cohort* can be taken in this case as the temporal factor of interest; it is in fact a proxy for a dummy variable (such as 0 and 1) indicating if one has or has not taken the drug.[11]

Since the seminal work of Whelpton (1954), Henry (1959, 1966a and b), and Ryder (1965), the cohort approach has become a common way of structuring demographic data. As Ryder (1965, p. 845) has stressed, members of a birth cohort share "a common historical location" as they have lived through similar experiences. Therefore, in Ryder's terms, "each cohort has a distinctive composition and character reflecting the circumstances of its unique origination and history; [. . .] the community of date equips each cohort with its own expanse of time, its own style, and its own truth." For example, wars or epidemics may leave a negative imprint on the future health of individuals who have experienced these hardships at a similar age, or unfavorable health conditions early in life might leave the strongest alive and lead to reduced cohort mortality later in life. These and other possible cohort effects are discussed in Hobcraft *et al.* (1982). Cohort effects seem to be less common in the field of fertility, where period effects predominate (Bhrolchain, 1993). Therefore, as Calot (1993) has pointed out, even if the cohort approach might seem more natural than the period approach, in the sense that one is following a group of individuals according to the *arrow of time*, this does not mean that cohorts are necessarily a better temporal frame of reference than periods. The choice between a period or cohort approach thus depends on the phenomenon one is studying and on the questions raised.

Consider now the risk of dying at a certain age x. This risk is age dependent, as mortality varies greatly according to age-related biologic factors. It is also period dependent, as the conditions of the period, in the social, economic, and public health fields for instance, have an impact on mortality. It is finally cohort dependent, as the similar history of the members of the cohorts in such matters as vaccination, availability of medicinal drugs, smoking habits, and so forth have an impact on their eventual mortality. One can therefore consider that this risk of dying is subjected to *age effects*, *period effects*, *and cohort effects*, and we might then wish to try to disentangle these effects. In a causal perspective, this means incorporating the various underlying causes into an explanatory mechanism or theory and then applying a suitable causal model such as covariance structure analysis.[12] Statistical problems can crop up however in *APC (age-period-cohort) models* if we want to use age, period, and cohort as proxies of the latent unknown causes, as the three variables are not linearly independent: Knowing two of these variables yields the third by simple addition or subtraction (see Chapter 18).

Generally speaking, cohort analysis refers to what was called above a repeated cross-sectional design, in the sense that the experience of a *group* of persons—and not individual trajectories—is followed through time. As Ryder (1965) has noted, "the cohort record, as macro-biography, is the aggregate analogue of the individual life history." This is typically the case when

[8] Such as the collapse of the Soviet Union and its impact on the quality of life and health of the Russian population.

[9] Such as the Granger co-integration method.

[10] The same holds for the introduction of techniques such as coronarography.

[11] Care must be taken however to distinguish between *actual* (or real) cohorts and *synthetic* (hypothetical or fictitious) cohorts, which rely solely on the data of a period.

[12] Such as LISREL or Mplus.

data are provided by a vital registration system: Individual records are usually not available because the data are grouped over individuals and time, but one may study, for example, the nuptiality or mortality of birth cohorts over time if marriages or deaths are classified each year by age and year of birth. French-speaking demographers therefore make the useful distinction between *données continues* (aggregate longitudinal data) and *données suivies* (individual longitudinal data); see for instance Henry (1959).

If *individual* longitudinal data are available from a survey or a register (such as a cancer register), for example, it is always possible to group the data by cohort according to a specific event origin, for example by birth cohort. Computation is made easier in this case but we lose the valuable information on individual differences *within* the cohort, that is on *intracohort heterogeneity*. The converse is obviously not possible: If one has only aggregate data, it is impossible to break the latter down into individual life courses. Greater effort should therefore be made to collect individual histories (life courses) rather than aggregate cohort data; this point was already stressed more than 40 years ago by Louis Henry (1959). It is thus strongly recommended to use the full information on individual life histories, instead of aggregating the data by cohort, and to apply *event history analysis* (such as the Cox hazard models) to the data on individual trajectories. This is possible thanks to the availability of adequate computer software. Cohorts can be distinguished in this approach by including in the statistical model the year of birth (or the calendar period defining the cohort) among the individual explanatory variables, similarly to such categoric variables as race or place of birth. One could also conduct the analysis at a double level, that of the individual and that of the cohort. *Multilevel* statistical methods (see Chapter 24) can be used for this purpose (Snijders and Bosker, 1999).

II. THE LONGITUDINAL APPROACH: DESCRIPTIVE MEASURES

1. Fertility

In the field of *fertility*, longitudinal data for individuals are very often collected by surveys[13] incorporating retrospective questions on the number of *children born alive* and on the date of birth of the children or the age of the mother or father at birth of the child. Most surveys collect data for women, although male

TABLE 10–1 Number and proportion of women according to parity

Indicator	Parity					
	0	1	2	3	. . . *i*	*k*
No. women	P_0	P_1	P_2	P_3	P_i	P_k
Proportion of women:	p_0	p_1	p_2	p_3	p_i	P_k

fertility can be studied, too. As the number of children depends, among others, on the age of the woman, young women usually having borne fewer children than older women because of a shorter length of exposure time, fertility measures are usually computed for women of the same age. If one takes women aged 50 and over for example, *completed fertility* or *ultimate family size* is obtained in the sense that these women have terminated their fertility history. The *quantum* or *intensity* of fertility for each female in this group is simply the total number of children born during her reproductive life, while her *tempo* of fertility is the succession of ages at which she has given birth to these children. Moreover, the difference between dates of birth of two successive children yields the length of the *birth interval* between these two events. If a woman has borne no child during her reproductive lifetime, she is defined as infertile. *Infertility* can be either due to biologic reasons (it is then called *infecundity* or *sterility*) or to the couple's decision to avoid childbearing (see the chapters in Section II on the biologic and social determinants of fertility, including Chapter 34 by Henri Leridon). A fecund woman is therefore not necessarily fertile,[14] but all fertile women were fecund at least until the time of their last child.

Some simple summary measures of the quantum (or intensity) and tempo of fertility can now be computed. A more detailed presentation and an example are given later on in this volume, in Chapter 12. A first descriptive measure is the distribution of the population of females according to the number of children they have borne. Write P_i for the number of women having borne *i* children during their life. One can then draw Table 10–1, *k* being the maximum number of children born.

Women having had *i* children during their lives are said to be of total *parity i*. To bear *i* children during their lifetime, they have had children of respectively birth *order*[15] 1, 2, . . . *i*. Each proportion p_i is simply obtained by taking the ratio $P_i/\Sigma_i P_i$. *The average number*

[13] Censuses can collect information on fertility using retrospective questions.

[14] Be careful! The French term for *fertility* is *fécondité*, and for *fecundity* it is *fertilité*. This confusion is unfortunate and must be kept in mind when reading papers in French.

[15] Multiple births are given different birth orders.

of children born, a measure of average intensity often used in fertility research, is then equal to

$$\Sigma_i iP_i/\Sigma_i P_i \text{ or } \Sigma_i ip_i, \text{ as } \Sigma_i p_i = 1,$$

with the sum extending from 0 to k. The number p_0 is equal to the proportion of infertile or childless women, as defined above in this section. One can also compute the variance or the standard deviation of the fertility distribution—measures of *dispersion* of total parity around the mean. Other descriptive measures such as the median fertility and quartile deviation can also be obtained.

One can also compute an *average age at childbearing*, a summary measure of the tempo of fertility, by taking the average of all ages of mothers at birth of their children.[16] Similarly, one can compute the average age of mothers at the birth of order one, of order two, and so forth. Once again, measures of dispersion around the mean may be computed. One may also compute the *probability* for females of a given age x to bear a child during a certain period, for example 1 year between ages x and $x + 1$, yielding a schedule of fertility probabilities by age. Other tempo measures can be obtained by taking the average of the *birth* intervals[17] between birth orders one and two, between birth orders two and three, and so forth. These measures and others are developed in Chapter 12, where examples are given of the various measures of quantum and tempo of fertility.

Up to now, all women past their childbearing age have been considered. Similar measures can be computed for women who are still in their reproductive period, once again controlling for their age. For example, consider females age 30. One can compute for this group the average number of children born up to this age and the average age at childbearing, keeping in mind that the data are *censored* by the date of the survey (i.e., these women can still have other children in the future after age 30). Birth intervals can also be computed between births of successive orders. As the data are censored, *open birth intervals* might however be closed in the future if another birth occurs. As intervals *straddling* the survey date are on average longer (for the same birth orders) than those intervals that are already closed, care must be taken if average birth intervals are computed in this way. These and other problems related to censored data are examined in Chapter 12.

For the open age group 50+, it must be stressed that fertility measures are usually not computed for the whole group, even if the survey or census addresses women of all ages.[18] As fertility has most probably varied in the past, it makes sense to take account of the various ages (i.e., of the various *birth cohorts*) involved. For example, one may consider separately all women aged 50 to 55, 55 to 60, and so forth, and compute for each of these age groups the descriptive measures developed above. For example, if the survey is held at the end of year 1995, fertility measures could be computed separately for women born in 1941 to 1945, in 1936 to 1940, and so on. The choice of the age interval depends on on the precision with which one wants to study past fertility and on the number of females in the sample. If few women are involved, the data must be grouped together to reduce random *noise*.

At high ages, e.g., above 80, the number of women is usually very low and these women might be selected[19] for their higher (or lower) fertility. For example, women having many children are more exposed to maternal mortality. In this case, women surviving at the time of the interview will have had, on average, a lower fertility at a given age than those who have died. Migration can also be a selection factor: If women with low parities tend to migrate (i.e., leave the country) more than women of higher parities, the sample will be biased in favor of the latter. In general, if the phenomenon studied is not *independent* of the processes that exclude individuals from observation, retrospective questions will lead to biased response, as only those *surviving* these processes (mortality, out-migration) will be interviewed. In the case of fertility, it is therefore possibly preferable to avoid dealing with the higher age groups and to restrict the analysis to women younger than 70 years. The rational choice of a cut-off age must consider the factors discussed previously.

Age is obviously not the only factor having an impact on fertility. The probability for a woman of giving birth during a certain period, a year for example, is dependent on other factors such as the number of previous births, her marital or partnership status, her economic condition (activity, household income), use or nonuse of contraception, her values and those of her partner, and so forth. More and more surveys therefore include questions on the current and past conditions and behaviors of the spouses or partners. In this case, fertility can be analyzed by taking account of the women in each of the various categories

[16] If data are aggregated by age, one can determine at each age x during the reproductive period the *age-specific fertility rate* (ASFR) at age x by dividing the number of births at that age by the average number of women of the same age. This yields a fertility schedule of *rates* by age of mother; see Chapter 12.

[17] Usually excluding multiple births in this case.

[18] Very often, fertility surveys only consider females aged 15 to 50 or 55. In this case, past trends in completed fertility cannot be observed.

[19] As usual, the term *selection* is not used here in its Darwinian meaning.

considered. For example, the probability of giving birth at age 30 can be computed for women who are married and economically active, who already have two children, who are practicing Roman Catholics, and so forth. The population of females is in this case classified into the various possible categories taking into account the variables at hand, and fertility measures of quantum and tempo can be computed for each of these categories and compared between categories. As usual in data analysis, *intragroup* variance can be compared to *intergroup* variance, and the relevance of the various categories can thus be assessed. This is possible because individual data are used rather than just group means.

As the cells in the multidimensional table resulting from this decomposition often contain only a small number of women and results are therefore subjected to a lot of random noise, another procedure is to have recourse to statistical methods of *event history analysis.* In this case, the probability of transition from one parity state to another is related to the various determinants of fertility (or covariates) as contained in the interview questionnaire, by way of some specific statistical function. Following the path-breaking work of Cox, it is now possible to estimate the impact of these determinants using exponential statistical models with time-dependent covariates. These covariates can be quantitative or qualitative, and computer programs (such as TDA, Transition Data Analysis) can estimate the parameters of the regression equation. Blossfeld and Rohwer (1995) present a good overview of this approach.

Up to now, only individual data on fertility have been considered. The advantage of this approach is that one has information on the individual's fertility behavior during her lifetime and on the possible determinants of this behavior drawn from retrospective surveys concerning the individual and, in some cases, the context or environment in which she has lived. Data on fertility are also recorded in all the developed countries by the *vital registration system.* Usually these data are aggregated and made available in tables or on magnetic or optical support. Longitudinal fertility measures can be computed from this source too, keeping in mind however that individual data are usually not available, for privacy reasons, and few data on the characteristics of the individual and a fortiori on the possible determinants of fertility are collected in the vital registration system. Chapter 12 discusses this type of data and shows how longitudinal summary measures of quantum and tempo of fertility can nevertheless be computed for aggregates such as birth cohorts.

The situation is drastically improved if data from the vital registration system are linked to the census data through a *personal identification number.* In this case, the characteristics of the individual are known, at least those recorded on the census form. Individual census forms can also be linked from one census to another, yielding individual life histories *sampled* at each census time. The problem however is the temporal *sampling* frequency: intercensal intervals are usually long (around 10 years) and, therefore, changes that may have occurred during the intercensal periods remain unknown. Nevertheless, the information thus obtained can be treated as longitudinal individual data, even if the actual names of the individuals remain unknown for privacy reasons.[20] The approaches developed previously for individual data can be used in this case.

2. Mortality

Longitudinal individual data in *mortality* research can be provided by *prospective surveys.* The intensity of mortality being always equal to one (everybody dies!), mortality research focuses instead on the tempo of mortality (i.e., on the age at which one dies). The average of ages at death is called the *expectation of life at birth* for the persons concerned (see Chapter 11). The variance of ages at death can easily be obtained from the individual ages at death. Aggregating individual experiences, *probabilities* of dying can also be computed by age and sex, to obtain the age- and sex-specific mortality schedules. Medical *causes of death* are also examined, and studied over time in a longitudinal perspective (see Volume 2). Finally, the characteristics of the deceased can be used to explain their age and cause of death, using various types of regression techniques (see e.g., Kahn and Sempos, 1989).

Contrary to fertility research, *retrospective* questions are not very useful in the field of mortality: The dead do not adequately answer the questionnaire! Relatives of the deceased person can however be asked retrospective questions, and this approach is used in *case-control studies*, for example. However, information thus obtained, even from persons close to the deceased, are often not very reliable.[21] For example, few widows know the actual occupation (or income) of their former husband or his sexual behavior if he has died from venereal disease! However, retrospective data on child

[20] Who is interested in the name of the person anyway? Good research and privacy are therefore compatible if each individual can be followed through time thanks to a personal code or identification number.

[21] Even a question on deaths occurring in the household during the past 12 months does not yield very good information, as surveys conducted in the developing countries have shown.

mortality have been collected in many surveys in the developing countries, such as the World Fertility Survey (WFS) and the Demographic and Health Survey (DHS) by asking the mother questions on the survival or death of her children and their age at or date of death (see the chapter on data collection in Volume 4, Chapter 121). Questions on the survival of siblings are also asked to evaluate adult mortality.

In demography, no large *prospective survey* on mortality has ever been carried out, contrary to the field of epidemiology. This source requires large samples and the cost is indeed enormous. Prospective surveys are also hampered by *loss to follow-up* by people eventually dropping out of the survey and therefore reducing the sample size and possibly biasing its composition, as those who drop out do not necessarily have the same characteristics as those who remain in the sample. Longitudinal research with individual data in mortality can be based on the *record linkage* of census and vital registration data. For example, in the case of Norway, a longitudinal study (Wunsch *et al*.,1996) has been conducted on males and females who were followed from one census to the next since 1960. The fact of dying or surviving at each age has been related to the present and past characteristics of the persons deceased or alive using logit regression techniques—these characteristics being derived from the individual census forms.

Contrary to prospective surveys, very large samples or even the whole population can thus be followed. On the other hand, only the characteristics recorded at census are available, although the situation can be further improved if the individual data provided by other registers (e.g., cancer or cardiovascular registers) or other sources (social security, for example) are also linked to the census and vital registration data. The use of the same personal identification number in all these sources makes linkage at least theoretically possible. Record linkage is slowly becoming one of the major sources of individual longitudinal mortality research in developed countries. The method requires an excellent information system and a good coverage; thus, it is not suitable for developing countries. However, even in developed countries, the method has been criticized by those who want to protect individual privacy, although the use of personal codes (no names and addresses) essentially guarantees the confidentiality of information.

If record linkage is not available, one must resort to aggregate mortality data provided by the vital registration system. In this case, longitudinal research can only be performed on aggregates. Mortality rates or probabilities can be computed by age and sex and birth cohort. Cohort age- and sex-specific mortality schedules can therefore be derived, and *cohort life tables*[22] can be set up (see Chapter 11). Intercohort differences in the timing of death and possibly in the medical causes of death can then be observed longitudinally, but intracohort differences are unknown as individual data are not available. Furthermore, care must be taken to achieve comparable definitions of medical cause of death over time if the latter are used (see Vallin and Meslé, 1988).

3. Migration

Finally, in *migration* research (see Chapters 13 and 22), longitudinal analysis can also rely on *retrospective* surveys for all types of mobility except international emigration; in the latter case, the emigrants have left the country and cannot be interviewed. Otherwise, the approach is quite similar to that used in fertility studies. One can ask the persons sampled when they have moved during their lifetime, where they came from, and where they went. Measures of intensity (number of moves) and of tempo (age at migration) can be obtained. Furthermore, the interval between moves can be computed, and the geographical trajectory assessed, as migration involves *time* and *space.* One can moreover collect background information on possible determinants of migration, and relate these possible determinants to the moves. For example, Courgeau and Lelièvre (1992) have used data from a triple biographic survey on migration, occupation, and family to study the interrelations between these factors. They have also developed statistical methods and computer programs to analyze this type of data set.[23] In fact this type of data can be modelled by parametric, semiparametric, and nonparametric *event history models*, according to the applicable assumptions. More methods and computer programs are being developed in this area, and individual longitudinal data analysis should take advantage of this relatively recent methodology. Individual data on migration can also be obtained by longitudinal prospective studies, although these are rare in this field.

If individual data on migration are not available, longitudinal cohort data can be analyzed in countries, such as Belgium, that have a *population register* incorporating a registration of changes of residence. This register can yield individual data if each person in the register can be followed over life by his/her personal identification number. Compared with retrospective surveys, however, the population register includes few

[22] For an example, see Mamelund and Borgan (1996).
[23] Courgeau and Lelièvre (1992).

covariates that can be used to explain the quantum and tempo of migration. However, the register covers the whole population and takes account of all migration flows occurring in the country during any period of time. Ideally, one should have both a population register for measuring flows and retrospective surveys for explanatory studies, possibly linking the two sources together. One could also link the population register data on moves to the characteristics of the movers obtained from the census forms, if both sources are linked. The advantage here is that both sources cover the whole population.

In all longitudinal studies discussed in previous sections, whatever the method, the main advantage is to locate events in *time*. The temporal sequence of events can indicate possible causal patterns, because causes always have to precede effects in time for reasons which will not be discussed here (Wunsch, 1988). For example, the probability of marriage for males having started their occupational career in agriculture is much higher after leaving agriculture; on the other hand, their change of activity is not dependent on their marital status (Courgeau and Lelièvre, 1992). The temporal order of the two events (leaving agriculture and marriage) is therefore highly important if one wants to explain the interrelation between the two events. To give another example, one observes that female activity and fertility are correlated, women with more children being less active than women with few children. This might be due to the fact that women with few or no children have more opportunities to look for jobs or to the fact that women who work want fewer children. A single-round survey giving only the *prevalence* of women according to parity and activity cannot discriminate between these two plausible explanations. One needs again the life history of women to determine the temporal order of the two variables. One might then see that a woman decides not to work once she has had a child or that her occupation leads to postponement of childbearing. In fact, the same woman can experience the two situations at different stages of her life.

In the field of longitudinal mortality research, as Duchêne and Wunsch have initially suggested (Caselli *et al*., 1989; Duchêne and Wunsch, 1991; Salhi *et al*., 1995), there are advantages in taking account of the order of events and the type of states one has experienced during one's lifetime, a state being defined by the various characteristics of an individual at a point in time, and finally of the time spent in each state. Such a *state–time–order transition model* could be used in other fields. Once again, individual longitudinal data are required in this case. Longitudinal individual data enable one to distinguish the time order of events and eliminate incorrect explanations. This cannot be achieved with cross-sectional or longitudinal aggregate data. Good demographic data collection and analysis should thus address individual life histories even if there is a price to pay; prospective or retrospective studies are required, and record linkage should be achieved.

Finally, longitudinal research can move beyond the individual and consider what happens to the individual's family, environment, and so forth. A family or a household is difficult to follow over time, but other procedures are being developed to link the individual to the group, such as using the concept of *contact circle* or having recourse to multilevel modelling (Lelièvre *et al*., 1998; Courgeau and Baccaïni, 1998; see also Chapter 24). The behavior of an individual also depends on the context in which he or she lives, and demographic explanations must take these multilevel strategies increasingly into account.

Cohort Life Table

JACQUES VALLIN AND GRAZIELLA CASELLI

Institut national d'études démographiques (INED), Paris, France

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

As death is a *nonrenewable event* at the individual level, mortality can be directly subjected to the probabilistic risk measurement defined earlier (Chapter 8). This approach will enable us to follow, from its birth, the gradual extinction of a cohort whose initial population is reduced by death from one age to the next, until its total disappearance. Indeed, as long as humans have not discovered the secret of immortality, this total disappearance is inevitable. In demography, death is termed a *fatal event*. Probabilistic analysis thus has a simpler aim when applied to mortality than in its general applications: Here, we do not have to measure *final intensity*, which necessarily equals unity. It is sufficient to measure the *tempo*, in other words, the age at death, absent any competing risks. That is the purpose of life-table construction.

In this chapter, therefore, we will begin by spelling out the various practical alternatives for determining the age-specific *probabilities of dying* in a cohort. Next, we construct the life table, describing its main functions and their interrelationships. In the final section, we discuss the difficulties involved in computing mortality at the oldest ages and in closing the table, as well as the special treatment customarily reserved for infant mortality.

I. CALCULATING A COHORT'S PROBABILITIES OF DYING

Monitoring a birth cohort directly up to its complete extinction is no easy task. Imagine taking a sample of births observed in a given year and documenting the children's survival, year after year, until the last one dies . . . 100 or 120 years later! No demographer could, of course, survive such an endeavor. And any attempts to base a health care policy on such a long-term approach would very likely be soon discouraged. The notion is not, however, totally ridiculous. In fact, it underlies several intensive studies on selected populations that lack any reliable civil registration system. In these regions, demographers have set up *population observatories* to monitor, for the longest possible period, the population of a very specific geographic area starting from an initial census and from each year's new births.[1] The data gathered can at least be used to begin series of cohort-specific probabilities of dying, even if the probabilities are confined to the life interval between the initial births and the most recent observations. This method is thus chiefly of use for analyzing childhood mortality. To compute the probabilities directly would require two conditions, both of them highly improbable: Either the observed population must not lose any of its members through emigration, or a supplementary survey must be carried out to track the emigrants in their new localities. In theory, the data collected in such population laboratories should also allow the compilation of partial probability series for the cohorts born before the initial census (and hence an analysis of adult mortality) on the basis of the population enumerated at each age. There are several problems, however. First, the series would be cut off

[1] For more details, see Chapters 121 and 124 in Volume 4 of this Treatise (see also Das Gupta *et al.*, 1997).

or censored at both ends: before the initial census and after the most recent observation. Second, as a rule, the series are undermined by the unreliability of information on age in these populations without civil records; hence the risk of incorrectly identifying the series' starting-points.

Some retrospective surveys could also yield suitable data for the direct computation of cohort-specific probabilities of dying.[2] One particularly relevant source is the surveys aimed at reconstructing the complete maternity history of women. These surveys must collect, with sufficient accuracy, the two vital items of information on child survival: date of birth and date of death. Maternity surveys have been conducted in many countries in recent decades, not only in the developed countries to study the determinants of fertility, but also—and even most commonly—in a growing number of developing countries, for which this type of survey is often the only reliable way to measure fertility and infant and child mortality (before even analyzing their causes). Two large-scale international data-gathering operations have been carried out for these purposes: the World Fertility Survey (WFS) in the 1970s by the International Statistical Institute (ISI),[3] and the Demographic and Health Survey (DHS) by Macro International Inc. from the 1980s onward.[4] Again, this type of observation confines the analysis to child mortality. It also has two weak spots. First—and, no doubt, most important—the data gathered depend on the quality of responses by the women surveyed. Respondents may fail to mention certain events, either through forgetfulness or to avoid painful memories. In either case, this can have a major impact on infant and child mortality statistics, as neither the births nor the deaths will be declared. Second, even if these events are actually mentioned, there may be much imprecision about the dates of their occurrence, which will considerably impede the analysis. In addition to this critical data collection problem, there is a methodologic issue. Naturally such surveys can only serve to explore mortality among the offspring of women still alive and present in the survey locality at the time of the survey. We therefore assume that the mortality of the children of these women does not differ from that of the children of the women whom the survey was unable to cover, either because they too were deceased, or because they had left the locality where they resided at the time of the preparation of the sampling frame from which the surveyed sample was drawn. In other words, it is assumed—in all likelihood, wrongly—that there is no link between the children's mortality and their mothers' mortality or migration. Yet, this serious theoretical problem is less important than the observation problem.

In any event, it is wishful thinking to hope we can ever construct a complete series of probabilities of dying that would provide a full record of a cohort's mortality from its birth to its extinction, from data directly gathered on a longitudinal base. The task is practically beyond the reach of population laboratories and strictly excluded from the field of retrospective surveys on women's maternity history. Ultimately, the only way to arrive at such a result is to use the current statistics compiled from civil records and population censuses, in countries where these information sources—in particular, civil registration—have been properly maintained for at least a century.

1. Starting a Series of Cohort-specific Probabilities of Dying from a Retrospective Survey

The data gathered from retrospective surveys on the maternity history of a sample of women theoretically provide—subject to the reservations mentioned previously—an ideal starting point for calculating the cohort-specific probabilities of dying. However, the data gathered must be processed to the necessary level of detail, which is seldom the case.

Let us take, for example, the Egyptian DHS survey of 1992 (El-Zanaty *et al*., 1993). As in all DHS surveys, module 2 of the questionnaire, *reproduction*, asks each woman to provide a complete list of the children to whom she has given birth; for each child, she is asked to indicate the sex, month, and year of birth; survival at time of survey; and, if the child has died, age at death. Using such information, we can obviously group the children together by birth year and, for each cohort thus constructed, obtain the number of deaths occurring in the cohort at successive ages, regardless of whether the children have left the mother's residence or not. For these children, we are operating strictly within the framework of a closed population (i.e., without migration). The annual probability of dying at age x, ${}_1q_x$, can be obtained directly by dividing the D_x deaths observed at the age reached during the year x to the B births of the cohort minus the deaths occurring up to the exact age x:

[2] See Dominique Tabutin's Chapter 121 in Volume 4.

[3] Between 1973 and 1981, 44 national surveys were carried out under the World Fertility Survey program: 13 in Africa, 16 in Asia/Pacific, 14 in Latin America, and one in Europe (ISI, 1986; Cleland and Scott, 1987).

[4] From 1986 to now June, 2002, 153 surveys were carried out in 68 countries under the Demographic and Health Survey program: six in Central Asia, 32 in Latin America and the Caribbean, 25 in South/Southeast Asia, 20 in North Africa/West Asia/Europe, and 70 in Sub-Saharan Africa (http://www.measuredhs.com).

$$_{1}q_{x}=\frac{D_{x}}{B-D_{(0,x)}}$$

Unfortunately, the data from this type of survey are rarely processed with the necessary level of detail. In particular, none of the reports published on DHS data supplies the table that would allow a computation of these annual probabilities. In fact, these reports only give the total deaths observed between birth and the survey date for each birth cohort. For Egypt, for example, we have the following table (Table 11–1), whose elements are plotted on a Lexis diagram in Figure 11–1.

TABLE 11–1 Births and deaths by cohort, from 1992 Egyptian demographic and health survey

Year of birth	Births	Death before survey date	Survivors at time of survey
1992	1,511	51	1,459
1991	1,707	120	1,587
1990	1,694	125	1,568
1989	1,774	149	1,626
1988	1,964	158	1,806
1987	1,884	152	1,732
1986	2,008	244	1,763
1985	1,751	239	1,512
1984	1,766	248	1,518
1983	1,902	265	1,637
1988–1992	8,649	603	8,046
1983–1987	9,312	1,149	8,163
1978–1982	8,376	1,288	7,088
1973–1977	6,070	1,240	4,830
before 1973	5,802	1,521	4,281
Total	38,209	5,801	32,408

Note: This table, reproduced from the original as published, includes a few minor discrepancies between certain sums and the summed elements.

Source: El Zanaty Fatma H., Sayed Hussein, Zaky Hassan H., and Way Ann A., 1993. *Egypt Demographic and Health Survey 1992*. Cairo, National Population Council and Calverton, Macro International Inc., 317 p.

As the survey was conducted in November 1992, 1992 is a year of incomplete observation, which is why the number of births (1511) is considerably smaller than those of preceding years. Likewise, the Lexis trapezoids containing the deaths are missing a month on the right. That is not the main problem, however. The missing element is the distribution by years of age (by Lexis parallelograms) within each trapezoid. To obtain the distribution would require a supplementary processing of the survey.

The authors of the report have avoided doing so, preferring to compute probabilities of dying by period (and not by cohort): We will comment on these later when discussing cross-sectional analysis and the use of the fictitious cohort as a device (Chapter 14).

Reprocessing the basic data of the Egyptian survey,[5] we obtain the following age distribution of deaths occurring among the 6070 children born in the 5-year period from 1973 to 1977 (Table 11–2). By grouping births in 5-year periods, we reduce the stochastic effect inherent in small numbers; by examining this group of years of birth—which is fairly remote from the survey date—we can track the mortality of these children over a 15-year period.

The probabilities are very simple to calculate in these conditions. To obtain the annual probability at age 0, $_{1}q_{0}$, we divide the deaths observed between 0 and 1 years of age (first line of second column of Table 11–2) by births (first line of third column).

$$_{1}q_{0}=\frac{D_{(0,1)}}{B}=\frac{796}{6,070}=0.13114$$

We then subtract the deaths at less than 1 year from births to obtain the number of cohort survivors at the first birthday (second line of third column); we divide the deaths between ages 1 and 2 by that survivor figure to obtain the annual probability of dying, $_{1}q_{1}$, at age 1, and so on, until the bottom of the table.

$$_{1}q_{1}=\frac{D_{(1,2)}}{B-D_{(0,1)}}=\frac{207}{6,070-796}=0.03925$$

These probabilities are annual in age terms, which is why, by convention, the index 1 is placed to the left of the symbol q. However, the probabilities represent the average mortality of a 5-year group of birth cohorts.

We can also determine probabilities with different age dimensions. For example, to measure the mortality of children older than 1 year, it is common to calculate the probability $_{4}q_{1}$, between 1 and 5 years, and the probability $_{5}q_{5}$, between 5 and 10 years:

$$_{4}q_{1}=\frac{D_{(1,5)}}{B-D_{(0,1)}}=\frac{375}{6,070-796}=0.07110$$

and

$$_{5}q_{5}=\frac{D_{(5,10)}}{B-D_{(0,5)}}=\frac{45}{6,070-796-375}=0.00919$$

The procedure is simple, but the main drawback is that it is confined to a very narrow portion of the life of the cohorts studied.

[5] We thank Zaia Bedidi for having carried out this special processing of the Egyptian DHS data.

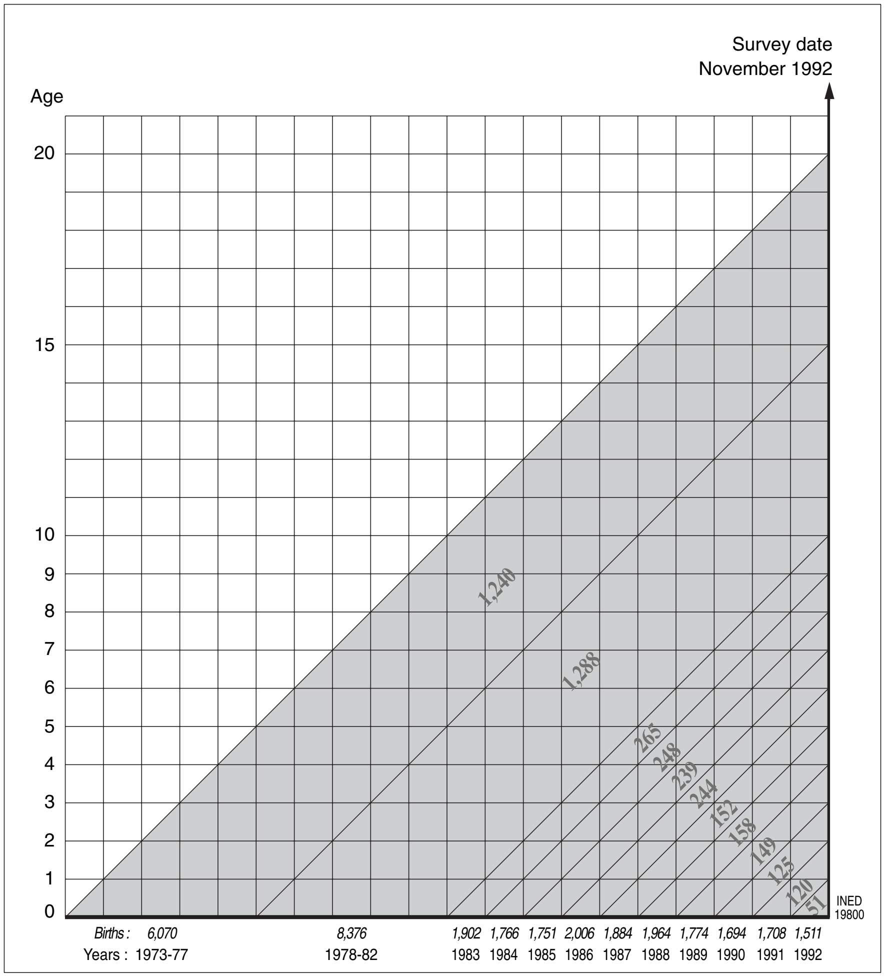

FIGURE 11–1 Representation on a Lexis diagram of child-survival data published in 1992 Egyptian Demographic and Health Survey report.

2. Calculating a Complete Series of Cohort-specific Probabilities of Dying from Current Statistics

To extend this calculation to all ages of life, we must use the long data series available in certain countries, with a sufficiently long tradition of current civil registration statistics and censuses. Let us go back to the French data from which we computed the series of age-specific proportions from 1806 to 1995, used in Chapters 5 and 6 and updated to 1997 (Vallin and Meslé, 2001). This data set is actually divided into two subsets, 1806 to 1898 and 1899 to 1995. For the second—thanks to the data published periodically by INSEE (the French national statistical institute) since World War II and a reconstruction of series for earlier years (Vallin, 1973)—we now have complete annual series of births, population by year of age on January 1, and deaths by year of age and year of birth (the basic triangles of the Lexis diagram). For the first subset, which covers the 19th century, the series are a historical reconstruction from far less detailed data that led to the estimation of annual series of probabilities of dying by year of age (Meslé and Vallin, 1989).

The second data subset (1899–1995) offers an example of favorable conditions for the construction of complete series of cohort-specific probabilities of dying from current statistics. As we shall see, it is possible to calculate these probabilities by making acceptable hypotheses on migrations and their relations with mortality.

a. Classic Probability, Between Two Birthdays

Let B_t be the births occurring in year t, $P_{t,(x,x+1)}$ the population of age $(x, x+1)$ on January 1, t, $D^i_{t,(x,x+1)}$ the deaths in year t at age $(x, x+1)$ in cohort i, and $D^{i-1}_{t,(x,x+1)}$ the deaths occurring in the same year t at

TABLE 11–2 Age distribution of deaths occurring among children born in 1973–1977 according to 1992 Egyptian demographic and health survey and calculation of probabilities of dying

Exact age x	Deaths between ages x and $x+1$	Remaining population at age x	Probability of dying between ages x and $x+1$
0	796	6070	0.1311
1	207	5274	0.0392
2	96	5067	0.0189
3	52	4971	0.0105
4	20	4919	0.0041
5	11	4899	0.0022
6	16	4888	0.0033
7	8	4872	0.0016
8	7	4864	0.0014
9	3	4857	0.0006
10	3	4854	0.0006
11	3	4851	0.0006
12	4	4848	0.0008
13	1	4844	0.0002
14	4	4843	0.0008
15		4839	

the same age $(x, x+1)$ in the preceding cohort $(i-1)$.

With no Migration

Let us start with the B_t births of cohort i born in year t. Absent any migrations, the probability of dying at age 0 would be equal to:

$$ {}_1q_0 = \frac{D^i_{t,(0,1)} + D^i_{(t+1),(0,1)}}{B_t} = \frac{D^i_{(t,t+1),(0,1)}}{B_t} $$

where i is the cohort born in year t. More simply, if we abandon the indexing by calendar year, which is redundant with the indexing by cohort:

$$ {}_1q_0 = \frac{D^i_{0,1}}{B^i} $$

Then, subtracting from the births the deaths occurring in the cohort before age 1, we would obtain the denominator by which to divide the deaths occurring in the same cohort between ages 1 and 2 to determine the probability of dying at age 1:

$$ {}_1q_1 = \frac{D^i_{1,2}}{B^i - D^i_{0,1}} $$

And finally, by generalizing, we could determine the probability of dying at any age $x > 0$:

$$ {}_1q_x = \frac{D^i_{x,x+1}}{B^i - \sum_1^x D^i_{x-1,x}} = \frac{D^i_{x,x+1}}{B^i - D^i_{0,x}} $$

With Migrations: Problems and Solutions

However, like most real populations, the French population is not *closed*. It experiences inflows and outflows due to migration. The application of the formulas above in this section would bias the mortality calculation for two reasons: (1) deaths of immigrants, who do not belong to the initial birth cohort whose mortality we seek to measure, are included in the deaths that form the numerator of the probabilities; (2) deaths of emigrants, who, unlike immigrants, do belong to the initial cohort studied, are not counted. If we use the general formula given for x, this bias worsens with age because the greater the distance from the birth year, the wider the interval disturbed by migrations. To analyze populations open to migrations, we must therefore introduce a correction into the initial formulas.

For simplicity's sake, let us consider the net migration (immigrants minus emigrants) and use $M^i_{x,x+1}$ to denote this balance for cohort i at age $(x, x+1)$. We now need to subtract the deaths of these net immigrants from the deaths forming the numerator. Unfortunately, there are no statistics available on the subject. We must therefore resort to a *first hypothesis*. Let us admit, again for the sake of simplicity, that the mortality of migrants is identical—at least in a first approximation—to that of the entire population studied. We can then estimate the number of deaths to be subtracted from the numerator by assigning to net immigrants the probability of dying that we are seeking to determine. However, there is a second practical problem: The migration inflows and outflows are spread over time between the two birthdays concerned. If they had all occurred at the exact age x, we would obviously have had to assume that all the net migrants were exposed to the risk of dying in the population studied for the entire duration of age $(x, x+1)$, and the deaths to be subtracted from the numerator for age $(x, x+1)$ would be estimated by $(M^i_{x,x+1} \cdot {}_1q_x)$. Conversely, if they had all occurred at the exact age $(x+1)$, none should be subtracted. In most cases, it is fairly safe to assume that, on average, these movements occur midway on the time line, and we can thus subtract the average of the two quantities—for example, $(0.5 \cdot M^i_{x,x+1} \cdot {}_1q_x)$, from the numerator. Combining this *second hypothesis* with the first, we can write the probability of dying at age 0 as follows:

$$ {}_1q_0 = \frac{D^i_{0,1} - 0.5 \cdot M^i_{0,1} \cdot {}_1q_0}{B^i} = \frac{D^i_{0,1}}{B^i + 0.5 \cdot M^i_{0,1}} $$

and, more generally, for the other ages x:

$$ {}_1q_x = \frac{D^i_{x,x+1}}{B^i - (D^i_{0,x} - M^i_{0,x}) + 0.5 \cdot M^i_{x,x+1}} $$

Calculation without Migration Data

The third problem is that France keeps no reliable record of migration movements comparable to its civil registration of births and deaths, so we do not know the $M^i_{x,x+1}$ values. On the other hand, France does publish estimates of the population by year of age on January 1 of each year. We can therefore attempt to estimate the population at birthday x from this far more recent information rather than from the initial number of births. Let $M^i_{t,(x,x+1)}$ be net immigrants of year t at age (x, $x + 1$) in cohort i (first triangle of Lexis diagram) and $M^i_{(t+1),(x,x+1)}$ the net immigrants of the following year (t + 1) at the same age (x, $x + 1$) in the same cohort i (second Lexis triangle). We can replace the previous formula by:

$$ {}_1q_x = \frac{D^i_{x,x+1}}{P^i_{t,(x,x+1)} + D^i_{t,(x,x+1)} - M^i_{t,(x,x+1)} + 0.5 \cdot M^i_{x,x+1}} $$

In theory, this equation assumes an even more detailed knowledge of migrations because it refers to a dual classification of migrations by age and year of birth. In fact, however, it shows that we can calculate the probabilities by eliminating all explicit references to migrations. For this, we need only accept a *third hypothesis*, which is simple and in most cases close to reality—namely, that the number of net immigrants in a cohort at a given age is evenly distributed between the two triangles of the Lexis diagram concerned. This gives:

$$ M^i_{t,(x,x+1)} = 0.5 \cdot M^i_{x,x+1} $$

and, in final form:

$$ {}_1q_x = \frac{D^i_{x,x+1}}{P^i_{t,(x,x+1)} + D^i_{t,(x,x+1)}} $$

We can therefore easily disregard the migration issue if we have annual statistics for (1) deaths by year of age and year of birth and (2) populations by age on January 1. However, we must bear in mind that the estimates of population by year of age at January 1 taken here for granted rely on intercensal reconstructions. These, in turn, assume, if not full data on migration flows (rarely available), at least an estimate of intercensal flows and a model for determining their annual distribution (see Chapter 13).

More concretely, let us go back to the example taken from the French data set and used in Table 6–1 of Chapter 6 to compute the male mortality rate at age 74 in 1994. Let us now determine the probability of dying of the 1920 cohort, which turned 74 in 1994. Obviously, we need to use the items required for calculating type 3 rates, as in Chapter 6. Figure 11–2 plots their positions on the Lexis diagram (parallelogram *ABCD*).

The probability is equal to:

$$ {}_1q_{74} = \frac{D^{1920}_{74,75}}{P^{1920}_{1995,(74,75)} + D^{1920}_{(1994),(74,75)}} = \frac{4,275 + 4,084}{202,140 + 4,275} = 0.04050 $$

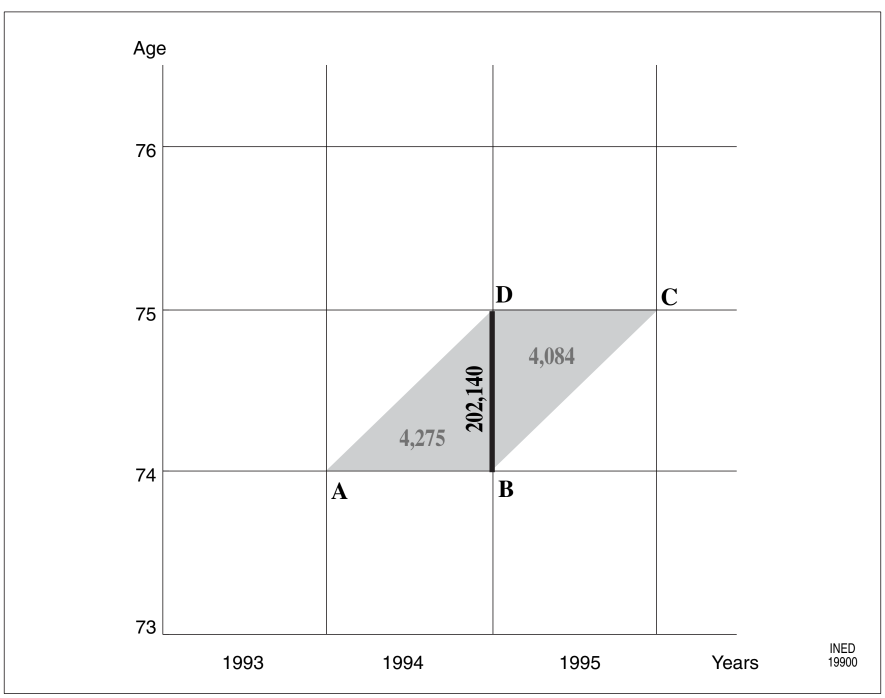

FIGURE 11–2 Representation on a Lexis diagram of items needed to compute probability of dying at age 74 for 1920 French male cohort.

where the year shown in the index corresponds to January 1 of that year.

Rates and Probabilities

It will be recalled that the type 3 mortality rate, computed with these same data in Chapter 6, was 0.04135. The difference is small. This is generally the case as long as we are dealing with relatively low death risks.

However, by definition, the difference between the rate and the probability increases with the degree of risk.[6] We can see this in summary form in Table 11–3, which compares the theoretical results that we would obtain in a closed population and a uniform distribution of deaths between two birthdays. The difference is minimal when the probability is below 10/1000. But it rises very quickly. If the probability reaches 100/1000, the rate is 5% higher than the probability. For a probability of 500/1000, the rate exceeds the probability by one third; at the top end of the scale, whereas the probability cannot—by definition—exceed unity, the rate peaks at twice that value.

In a population such as the French, the age-specific probability of dying rarely reaches values high enough to diverge substantially from the rates determined with the same data. In the male cohort born in 1899, however, we note sizable differences for infant mortality and for mortality at the oldest ages (Figure 11–3). In this cohort, the probability of dying before age 1 is 185/1000, and the rate exceeds the probability by nearly 15%. The difference stays below 3% until

[6] Using the rate-to-probability conversion formula given in Chapter 8, we effectively obtain:

$$_nq = \frac{n \cdot {}_nm}{1+\frac{n}{2}\cdot {}_nm}$$

in other words:

$$\frac{_nm}{_nq} = \frac{_nm}{n \cdot {}_nm}\cdot\left(1+\frac{n}{2}\cdot {}_nm\right) = \frac{1+\frac{n}{2}\cdot {}_nm}{n} = \frac{1}{n}+\frac{_nm}{2}$$

and, in the end, if $n = 1$:

$$\frac{m}{q} = 1+\frac{m}{2}$$

TABLE 11–3 Theoretical comparison between rates and probabilities

Deaths	Initial population	Final population	Probability	Rate	Ratio
1	100,000	99,999	0.000010	0.000010	1.000005
10	100,000	99,990	0.000100	0.000100	1.000050
100	100,000	99,900	0.001000	0.001001	1.000500
1,000	100,000	99,000	0.010000	0.010050	1.005025
10,000	100,000	90,000	0.100000	0.105263	1.052632
30,000	100,000	70,000	0.300000	0.352941	1.176471
50,000	100,000	50,000	0.500000	0.666667	1.333333
70,000	100,000	30,000	0.700000	1.076923	1.538462
90,000	100,000	10,000	0.900000	1.636364	1.818182
100,000	100,000	0	1.000000	2.000000	2.000000

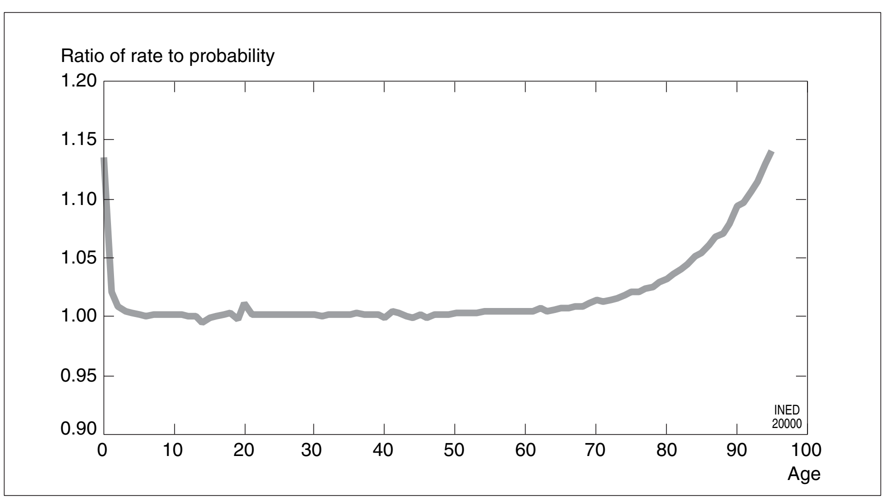

FIGURE 11–3 Ratio of type 3 rate to age-specific probability of dying in French male cohort born in 1899.

approximately age 80 (and, at most ages, is much smaller); but it increases very swiftly beyond age 80 and, toward age 90, returns to the level observed at under age 1. However, when actual data are used, the definitional difference is not the only reason why the rate differs from the probability.

Let us compare the result obtained above to the value that we would have obtained by applying to the age-74 rate the conversion formula given in Chapter 8 for determining the probability:

$$_{1}q_{74} = \frac{2 \cdot {}_{1}m_{74}}{2 + {}_{1}m_{74}} = \frac{2 \cdot 0.04135}{2 + 0.04135} = 0.04051$$

The difference is admittedly minimal, but it does exist. The reason is that the formula supposes a uniform distribution of deaths between two birthdays. In the present case, we are close to this hypothesis, which is not always the case. The best example of the problem is given by infant mortality.

In this same 1899 cohort, the probability of dying at age 0 is 185/1000 and the rate is 215/1000; applying the formula above, we would have found a probability of 194/1000—an overestimation of 5% (Table 11–4).

The discrepancy is obviously due to the fact that 75% of infant deaths are concentrated in the first triangle of the Lexis diagram, versus only 25% in the second triangle. Let us imagine that the total deaths at under age 1 were evenly distributed between the two Lexis triangles. The probability would have been 194/1000, with no change in the rate, and the application of the formula would have yielded the same result (last line of Table 11–4).

Again, we find a fairly large discrepancy between the probability and its estimate based on the rate at age 1, since the imbalance between the two Lexis triangles is still significant at that age. The error is 0.5%. At subsequent ages, however, this type of error becomes negligible (under 2/1000). In fact, it varies either way, no doubt because of the annual mortality fluctuations.

However, infant mortality is the exception that confirms the rule: At most other ages, the deaths are just about evenly distributed between the two Lexis triangles, and we can, without risk of serious error, estimate the probability from the rate using this classic formula if the rate is computed with the same data used to determine the probability.

b. *Other Approaches to Annual Probability*

The data needed to perform the calculations discussed here are not often available, however. Few countries have—as France does—long annual series of deaths by age and year of birth, and systematic estimates of the population by age at January 1. Other approaches to cohort-specific probabilities of dying are possible. The two most important are discussed in the following subsections.

Projective Probabilities

Some countries publish their current annual statistics of death by age reached in the calendar year. In Chapter 6 we defined a type 2 rate that corresponds to this type of classification. One can also calculate a probability of the same kind, generally called a *projective probability*, as it is perfectly suited to the needs of population projections. Let us take up our example of male French mortality at 74. The necessary data are illustrated in Figure 11–4 (parallelogram *ABCD*).

In this case, if there were no migrations, the population exposed to the risk would be, quite simply, the population aged 74 (in complete years) on January 1,

TABLE 11–4 Comparison between rates and probabilities at young ages in 1899 male cohort

Age	Death		Population on Jan. 1 of second year	Rate	Probability		Ratio
	1st year D1	2nd year D2	P	t	Computed q	Estimated from rate q'	q'/q
With the deaths observed in each of the two Lexis triangles							
0	59,716	19,433	369,000	0.2145	0.1846	0.1937	1.0493
1	6,760	3,003	340,200	0.0287	0.0281	0.0283	1.0054
2	1,880	2,919	334,900	0.0143	0.0142	0.0142	0.9985
3	1,821	1,782	332,700	0.0108	0.0108	0.0108	1.0001
Assuming deaths evenly distributed between the two Lexis triangles							
0	39574,5	39574,5	369,000	0.2145	0.1937	0.1937	1.0000

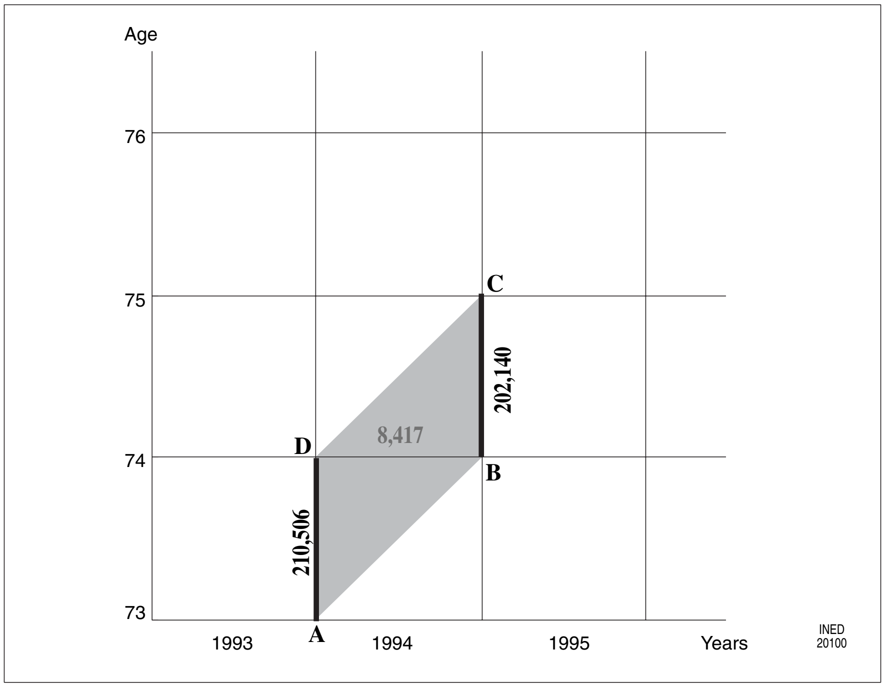

FIGURE 11–4 Data needed to determine the projective probability of dying at age 74 (France, males).

1994. But, as before, we need to factor in migrations. By analogy with the previous computation, it will be easily understood that this can be achieved by using as the denominator the cohort's average population on January 1, 1994, and January 1, 1995, to which we add half of the deaths in the parallelogram:

$$ {}_1q_{74} = \frac{D^{1920}_{1994,(73,75)}}{0.5\cdot\left(P^{1920}_{(73,74)}+P^{1920}_{(74,75)}\right)+0.5\cdot D^{1920}_{1994,(73,75)}} $$

$$ = \frac{8,417}{0.5\cdot(210,506+202,140)+0.5\cdot 8,417} = 0.03998 $$

If we compare this projective probability with the type 2 rate computed in Chapter 6, we find, unsurprisingly, a difference on the same order of magnitude as the one we found with the classic probability: the figures are 0.0400 for the projective probability versus 0.0408 for the type 2 rate.

Moreover, between the projective probability and the classic probability, we find a difference comparable to the one between the type 2 and type 3 rates: They are separated by roughly a half-year of age. The projective probability at 74 years (0.0400) is slightly below the classic probability at the same age (0.0405) because it is centered on the exact age of 74 whereas the classic probability is centered on 74.5 years.

It is fairly easy to shift from one probability to the other using interpolation (linear or, better yet, logarithmic) between two ages, as long as we remain in age brackets where mortality varies steadily with age. This is generally the case, except for mortality at very young ages.

Infant mortality poses a special problem here. The method for computing the projective probability disregards the first Lexis triangle. For this first triangle, we need to determine a probability that is neither classic nor projective, since it measures the risk of dying between birth and the following January 1. Chapter 14 shows that it may be useful to generalize the calculation of *partial probabilities* of this type. In the present case, however, the partial probability is something of an intruder in a series of probabilities by year of age—because, on average, it covers only a half-year of age. To estimate the classic probability at 0 year from the projective probabilities, we must use age-0 weights based on observations made in similar populations for which dual classifications of deaths by age and year of birth are available.

Indirect Calculation Based on Rates in the Squares of the Lexis Diagram

If the current annual statistics list deaths only by age in complete years, we cannot directly calculate any probability of dying. Thus, we must be content with estimating the deaths from the type 1 age-specific rates computed in the Lexis squares as described in

Chapter 6. However, we will never obtain a cohort-specific measure, since two contiguous cohorts cross each Lexis square. To find a measure that best approximates a classic probability for a given age, we must average the rates of two consecutive years in which the cohort studied reaches that age. For example, the probability of dying at age 74 for the 1920 cohort will be estimated from the type-1 rates at age 74 of the years 1994 and 1995, respectively, 0.0443 and 0.0418. As the average of the two rates is 0.0431, the rate-to-probability conversion formula gives us a probability of 0.0422.

This figure is much higher than the one obtained with the direct computation (0.0405): the probability is overestimated by more than 4%. This is the same problem already encountered in our comparison between the three types of age-specific rates: The disturbances produced by World War I in the timing of births of the 1919 cohort entail an overestimation of the type 1 rate at 74 years in 1994, and this impacts on the average of the two rates used here (Chapter 6)—a totally atypical situation. In most cases, the estimation of the classic probabilities is entirely acceptable, subject to the reservations voiced earlier concerning the uniformity of the age-specific distribution. However, we have deliberately returned to this example, to remind the reader that it has no universal value.

Likewise, we can estimate the projective probability at age x from the average of the type 1 rates of the two ages in complete years situated on either side of age x. Both rates, this time, belong to the same calendar year and, in our example of mortality at age 74 for the 1920 French male cohort, the result is not affected by the problem mentioned above. However, we find an overestimation of 1.5% by comparison with the direct method, which is due to the nonlinear variation of age-specific mortality.

Table 11–5 summarizes the results obtained using these different approaches for estimating the 1920 French male cohort's probabilities of dying at age 74.

II. CONSTRUCTION AND MAIN FUNCTIONS OF THE TABLE

Using age-specific probabilities of dying, we can (1) provide a complete description of the mortality process experienced by a cohort until its final extinction, (2) track the gradual reduction of its initial population from one age to the next, (3) determine the distribution by age at death of that initial population, and (4) calculate the average number of years lived by the individuals in the cohort (i.e., their *life expectancy*). For all these purposes, we need only construct the *life table*. Later, however, we will see that the life table can also be entered by means of a continuous computation, using mortality rates directly as estimators of the *force of mortality*.

1. Constructing the Table from the Probabilities of Dying

Let us begin with the series of age-specific probabilities of dying, ${}_1q_x$, for a given cohort. We set an arbitrary initial number of births (known as the life table *radix*): As a rule, the number is a power of 10 to facilitate the computations and the presentation of comparable results. We then construct the cohort's life table, using a series of iterations.

Let l_0 be the life table radix. We start by computing $d_{0.1}$, the number of deaths between ages 0 and 1:

$$d_{0,1} = l_0 \cdot {}_1q_0$$

Subtracting these deaths at under age 1 from the initial population, we obtain the number l_1 of survivors of the table at the first birthday:

$$l_1 = l_0 - d_{0,1}$$

Next, we apply the probability of dying at age 1 to these survivors to obtain the deaths in the table between ages 1 and 2:

TABLE 11–5 Classic and projective probabilities of dying at 74 for 1920 French male cohort, using different approaches

Calculation method	Classic probability		Projective probability	
	Result	Error, %	Result	Error, %
Direct calculation	0.04050		0.03998	
Estimation using type 3 rate	0.04051	0.02		
Estimation using type 2 rate			0.03998	0.00
Estimation using average of projective probabilities	0.04158	2.67		
Estimation using average of type 1 rates	0.04216	4.10	0.04058	1.50

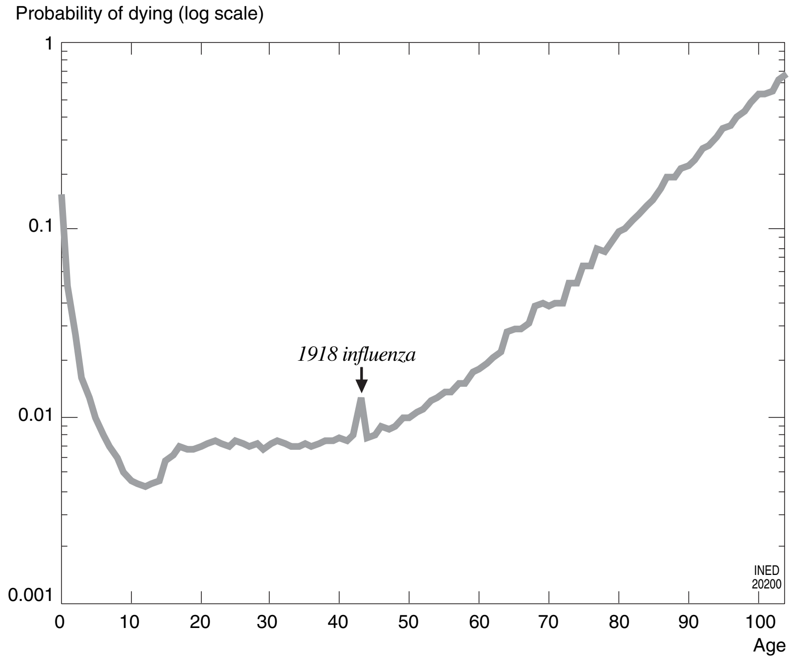

FIGURE 11–5 Age-specific probabilities of dying for the French female cohort born in 1875.

$$d_{1,2} = l_1 \cdot {}_1q_1$$

and so on, until the complete extinction of the initial population, under the effect of a final probability that is theoretically equal to unity:

$$d_{\omega-1,\omega} = l_{\omega-1} \cdot {}_1q_{\omega-1}$$

while:

$$l_\omega = l_{\omega-1} - d_{\omega-1,\omega} = 0$$

Figures 11–5, 11–6, and 11–7 illustrate the values of these three basic life-table functions for the French female cohort born in 1875.[7] The table is provided in the appendix.

In this cohort, the probability of dying starts from a very high level, with a value of about 150/1000 between birth and the first birthday. It bottoms out toward 10 to 15 years before surging at about 16 to 17 years to a level where it remains until approximately age 40. At all these ages, advances in health suffice to offset the loss of vitality due to aging. However, at age 50 and up, the age effect outweighs the health-progress effect, and the probability rises almost exponentially with age (Figure 11–5).

This general profile of the mortality curve results from a compromise between two deep-seated trends: the change in the risk of death with age and the change in health conditions over time. The profile also displays traces of specific events experienced by the cohort. Actually, the only significant accident experienced by this female cohort was due to the 1918 influenza pandemic. World War I, by contrast, caused no major disturbance. The cohort was 39 years old in 1914 and 42 years old in 1917. The mortality of women of those ages was barely affected, contrary to that of men, who—even at those ages—paid a heavy tribute to the war. On the other hand, the mortality curve of the 1875 female cohort is mildly disturbed by World War II. The second conflict, far more than the first, caused a general deterioration in health conditions, affecting both men and women, and the elderly as much as persons of combat age.

The survival curve (Figure 11–6) masks these dips and peaks in the probability of dying. However, it vividly illustrates the two major phenomena that presided over the cohort's extinction: (1) the very high infant mortality, which, right from the start, deprived the cohort of a large section of its initial population, and (2) the rising risk of death beyond age 50, which hastened the reduction in the cohort size.

The distribution of deaths by age is overwhelmingly dominated by the heavy infant mortality, which, of course, was experienced by the cohort at its largest size (Figure 11–7). All subsequent experiences seem marginal by contrast. When the risk of dying reaches new peaks after age 50, it applies to a very small group of survivors, and the second death distribution peak

[7] We choose this cohort because it is that of Jeanne Calment, who broke all known human longevity records when she died on August 4, 1997, at the age of 122 and a half (Allard *et al.*, 1998).

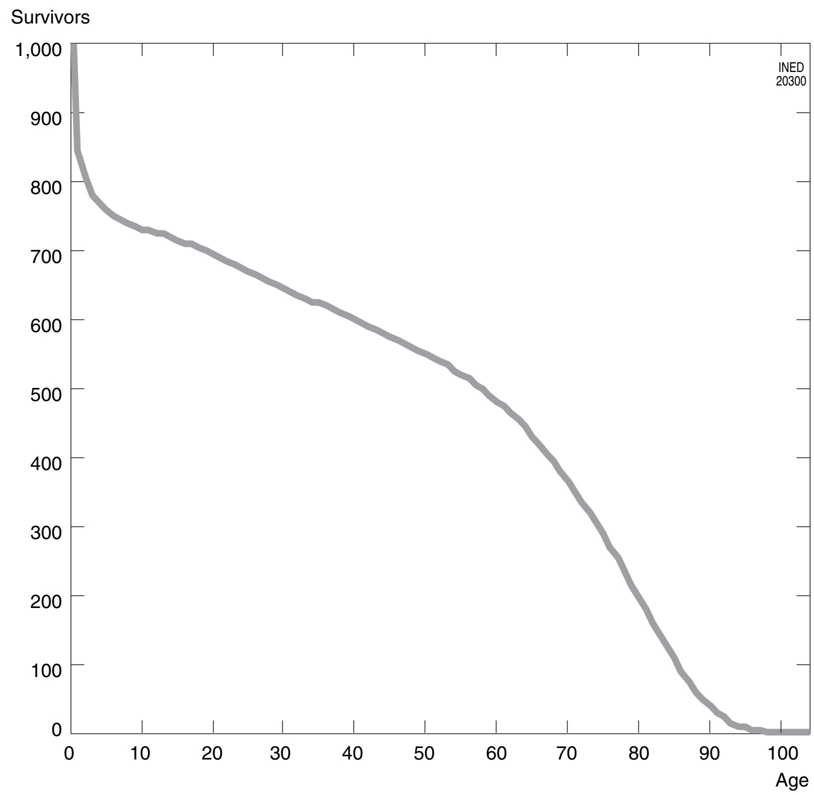

FIGURE 11–6 Survivors of the life table of the French female cohort born in 1875.

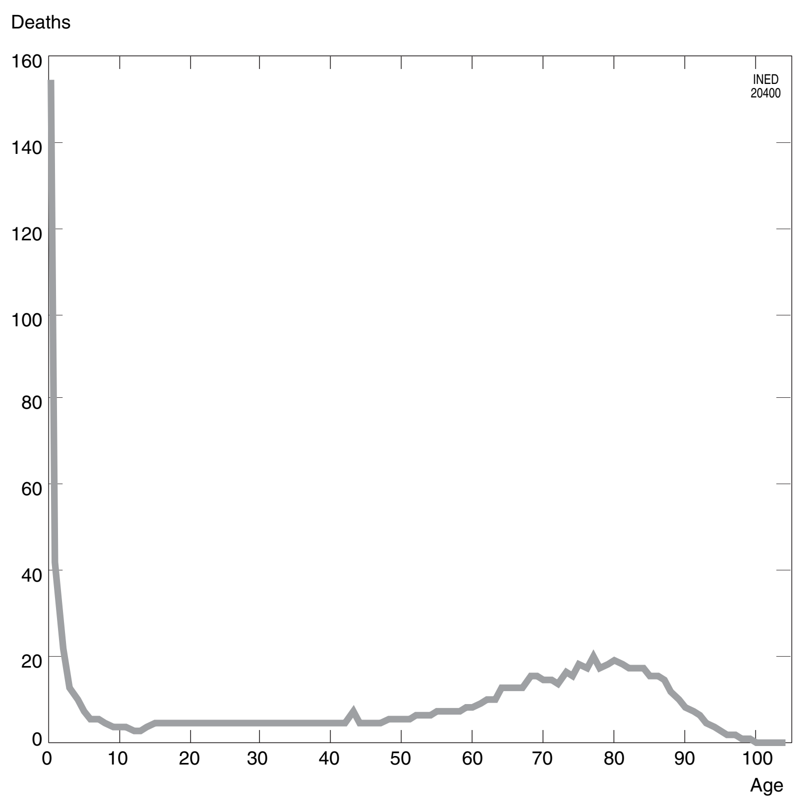

FIGURE 11–7 Life table deaths of the French female cohort born in 1875.

observed at 75 to 80 years or so is very modest in comparison. The impact of the Spanish influenza of 1918, while visible, is far more subdued here than on the probability curve.

When measured on an annual basis, these three main variables of the table can be combined to arrive at multiannual dimensions. The deaths are additive:

$$d_{x,x+a} = \sum_{x}^{x+a-1} d_{x,x+1}$$

The probabilities of survival are combined indirectly, via the probabilities of survival between two successive birthdays:

$$p_{x,x+a} = 1 - {}_aq_x = \prod_{x}^{x+a} {}_1p_x = \prod_{x}^{x+a} (1 - {}_1q_x) = 1_{x+a} / 1_x$$

and

$$l_{x+a} = l_x \cdot p_{x,x+a}$$

2. Entering the Life Table via Deaths, in a Closed Population

Constructing a cohort life table from probabilities is the only possible approach when using current annual data on a real population that experiences migration flows and changing health conditions. In the very infrequent case where we would use longitudinal observation data on a closed population, we could, of course, simply express the age distribution of actual deaths as a ratio of a power of 10 and equate it with the deaths in the table:

$$d_{(x,x+1)} = \frac{D_{(x,x+1)}}{B} \cdot l_0$$

For example, in the case of the 1992 Egyptian survey, if l_0 = 10000, the deaths in the table can be immediately deduced from the actual deaths (Table 11–6). From this, we can readily deduce the two other functions of the table, taking its radix as our starting point:

$$ {}_1q_0 = \frac{d_{0,1}}{l_0}$$

then, again:

$$l_1 = l_0 - d_{0,1}$$

and so on.

In this type of situation, as we lack the necessary perspective, we cannot expect to observe the complete distribution of deaths by age. We do know, however, that all the individuals of the cohort must die and we can deduce the expected deaths beyond the last age observed by subtracting the sum of actual deaths from the number of births. The table will remain incomplete, but we will at least be able to define its beginning.

TABLE 11–6 Actual deaths and deaths in table for children in 1992 Egyptian demographic and health survey born in 1973–1977

Exact age x	Actual deaths $D_{(x,x+1)}$	Deaths in table $d_{(x,x+1)}$
Births	**6,070**	**10,000**

10	3	5
11	3	5
12	4	7
13	1	2
14	4	7
From 15 to ω	4,839	7,972

In all other cases, the age distribution of deaths in the table must not be confused with that of actual deaths. More accurately, the deaths series in the table is the key result expected of any analysis of mortality. Indeed, it is the series that gives us the description of the only variation factor in mortality: its *tempo*.

3. Life Expectancy

The tempo of deaths in the table is, in particular, the factor that enables us to summarize a cohort's mortality by determining its *life expectancy at birth*. Whether deduced directly from a longitudinal observation or constructed from probabilities, the tables' death series gives us the distribution of the individuals composing the cohort by age at death, and we can use the data to obtain their average life span (their life expectancy at birth) by calculating the average of their ages at death. Typically, to compute this average, we assume a uniform distribution of deaths between two birthdays. We therefore consider that the deaths of age (x, x + 1) occur at age (x + 0.5). The life expectancy e_0 at birth is thus equal to:

$$e_0 = \frac{\sum_{0}^{\omega-1} (x+0.5) \cdot d_{x,x+1}}{\sum_{0}^{\omega-1} d_{x,x+1}}$$

But, as $d_{(x,x+1)} = l_x - l_{x-1}$, we can also write this in simpler form:

$$e_0 = 0.5 + \frac{\sum_{1}^{\omega} l_x}{l_0}$$

More generally, we can calculate life expectancy at any age *x:*

$$e_x = \frac{\sum_{j=x}^{\omega-1} (j - x + 0.5) \cdot d_{j,j+1}}{\sum_{j=x}^{\omega-1} d_{j,j+1}} = 0.5 + \frac{\sum_{j=x+1}^{\omega} l_j}{l_x}$$

If mortality were constant with age or rose continuously with age, life expectancy would obviously decrease in a very steady pattern with age. In fact, in the 1875 French female cohort, life expectancy starts by rising at young ages (Figure 11–8). Infant mortality is so high that, by the sheer fact of having survived, infant girls still alive at age 1 have 7.5 years more life expectancy than the total cohort at birth. Mortality remains high enough at ages 1 and 2 to keep life expectancy on an upward trend until age 3, when it is 10 years longer than life expectancy at birth. It is only beyond age 3 that life expectancy moves onto a steady downward path.

Without actually undermining what we have just said about the 1875 cohort, this life-expectancy computation calls for two comments.

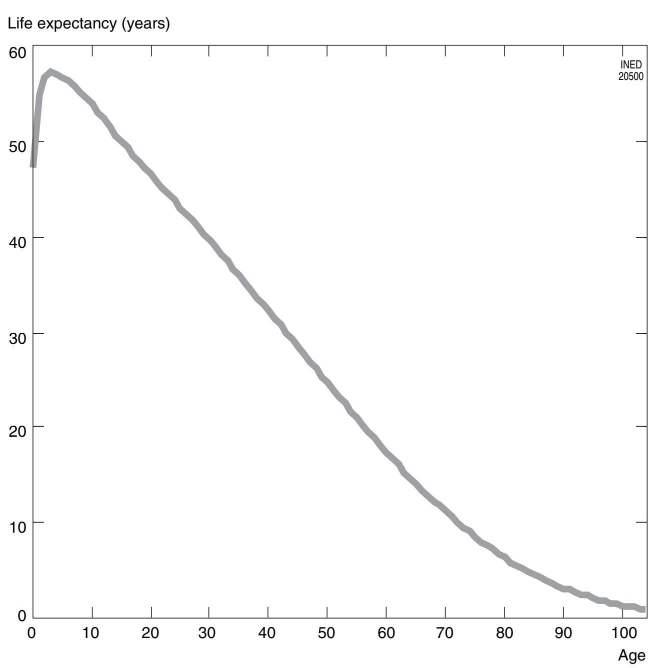

FIGURE 11–8 Age-specific life expectancy in French female cohort born in 1875.

First, if the actual distribution of deaths between two birthdays is indeed very close to the equidistribution hypothesis at nearly all ages, this profile—as we have already seen—does not apply to the start of life. The life expectancy calculation would be more accurate if we could determine probabilities by month of age for the earliest ages, especially when infant mortality is very high. Absent the necessary data, we can also apply a different weighting for the initial ages, based on empirical observations of populations with similar mortality levels. This refinement in the measure is, however, seldom used. The most common approach is to assume equidistribution at all ages of the table.

Moreover, the life expectancies computed in this manner are, in reality, no more than estimates (to a partial extent). The actual current statistical data used in the standard computation of probabilities of dying are no longer reliable after a certain age. This makes it impossible to pursue the calculation until the cohort's total extinction, especially when we are dealing precisely with the cohort whose last death, that of Jeanne Calment, occurred at age 122—long after the penultimate death. Concretely, the probabilities used here are reliable only until an age *k*—in this case, around 85 or 90 years (Vallin and Meslé, 2001). Pending the discussion in the section entitled "The Oldest-Ages Problem and Table Closure," which addresses the specific solutions for estimating with greater precision the probabilities of dying at the very oldest ages, we must make do with an incomplete table; to determine life expectancy, we must close off the table arbitrarily by estimating life expectancy at age *k* as realistically as possible. For any age *x* younger than *k*, we obtain:

$$e_x = \frac{\left(\sum_{j=x}^{k} (j - x + 0.5) \cdot d_{j,j+1}\right) + (k - x + e_k) \sum_{j=k}^{\omega-1} d_{j,j+1}}{\sum_{j=x}^{\omega-1} d_{j,j+1}}$$

$$= 0.5 + \frac{l_k(e_k - 0.5) + \sum_{j=x+1}^{k} l_j}{l_x}$$

In consequence, the life expectancy at birth of Jeanne Calment's cohort is 47.2 years, if we take 4.48 years as the life expectancy at 85.[8] The arbitrary closure of the table at age *k* has almost no effect on the result (as we shall see in greater detail in Chapter 14). By contrast, the closer *x* gets to *k*, the more life expectancy at age *x* depends on the cutoff point.

[8] This estimate of life expectancy at 85 years is actually derived here from an extrapolation of probabilities of dying at the oldest ages.

We can also use the table's arbitrary closure to obtain an estimate of life expectancy at birth in a retrospective longitudinal observation cut off at the survey date. For this purpose, we combine the start of the life table actually observed with a life expectancy taken from a *standard table* (see Josianne Duchêne's Chapter 128 on this topic in Volume 4) adjusted to the situation for the age at which the information gathered stops. In the case of the Egyptian survey given as an example at the start of this chapter, we could have taken into account the mortality of the cohort's first 15 years of life and closed the table with a life expectancy at age 15 of 46 years—which, according to the standard tables of Coale and Demeny (1983), is consistent with the actual level of infant and child mortality.[9] The estimated life expectancy of these Egyptian cohorts would be 48.9 years at birth and 58.3 years at age 1. This method is all the more approximate as the final age of observation is young and infant mortality is low. In the Egyptian case, we can clearly see that with nearly 80% of survivors at age 15, most of the mortality is experienced after age 15; the method's value is all the more limited as no one knows how the Egyptian health situation will evolve as the cohort studied grows older. The procedure may, however, be useful in contexts where infant mortality is very high—which are also, typically, the contexts where we know nothing about adult mortality.

III. FROM THE DISCRETE TO THE CONTINUOUS: ENTERING THE TABLE VIA THE FORCE OF MORTALITY

The life table functions described here in discrete mode can also be treated in a continuous mode. To enter the table in continuous mode, we must first specify the relationships between probability, rate, and force of mortality. For this, we need to introduce a new function into the table: the *number of years lived in an age interval*.

1. Number of Years Lived in an Age Interval or "Person-years"

Starting with the functions already defined in discrete mode, and in particular the l_x series, we can—by postulating a uniform distribution of deaths between two birthdays—compute the number ${}_1L_x$ of years lived in an age interval $(x, x + 1)$ as the half-sum of the survivors at the two birthdays on either side:

$${}_1L_x = \frac{l_x + l_{x+1}}{2}$$

The number is also (1) the number of *person-years* exposed to the risk of mortality at this age in the cohort and (2) the number of persons in the cohort who have reached the complete age $(x, x + 1)$ on January 1 of the xth year after their birth. The death rate at age x is thus equal, in the life table, to:

$${}_1\overline{m}_x = \frac{d_{(x,x+1)}}{{}_1L_x}$$

This ${}_1\overline{m}_x$ rate computed in the life table is slightly different from the ${}_1m_x$ rate calculated from the actual data insofar as the first is based, by definition, on the equidistribution of deaths in the age interval—a situation never fully attained in reality. In fact, as long as mortality decreases with age (until approximately 10 years), ${}_1m_x > {}_1\overline{m}_x$, and, later, ${}_1m_x < {}_1\overline{m}_x$ (Keyfitz, 1977).

To shift from the discrete to the continuous, we must look at what happens to the rate ${}_1\overline{m}_x$ in the table in an infinitesimal age interval. For this purpose, we need to define in continuous terms the sum of years lived in the age interval $(x, x + 1)$. If $l(a)da$ is the time lived by the cohort between ages a and $a + da$, ${}_1L_x$ can be written:

$${}_1L_x = \int_x^{x+1} l(a)da$$

This integral defining ${}_1L_x$ measures the area located between the l_x curve, the lines of equations $a = x$ and $a = x + 1$, and the x-axis (Figure 11–9).

2. The Force of Mortality and Its Relationship with the Death Rate

The *force of mortality* at age x is the limit value of the death rate of the table ${}_n\overline{m}_x$ when n tends toward 0:

$$\mu_x = \lim_{n \to 0} {}_n\overline{m}_x = \lim_{n \to 0} \frac{{}_nd_x}{{}_nL_x}$$

Taking the earlier expression of ${}_1L_x$, we find the equation already mentioned in Chapter 8:

$$\mu_x = \lim_{n \to 0} \frac{l_x - l_{x+n}}{\int_x^{x+n} l(a)da} = \frac{-1}{l_x} \cdot \frac{\partial l_x}{\partial x}$$

In other words, after solving this differential equation:

$$\mu_x = -\frac{\partial l_x / \partial x}{l_x}$$

[9] As it happens, it is the western model that best matches the structure of infant and child mortality measured by the 1992 Egyptian Demographic and Health Survey; the level observed is slightly below the male level 13 of the model, which gives a life expectancy of 45.5 years at age 15.

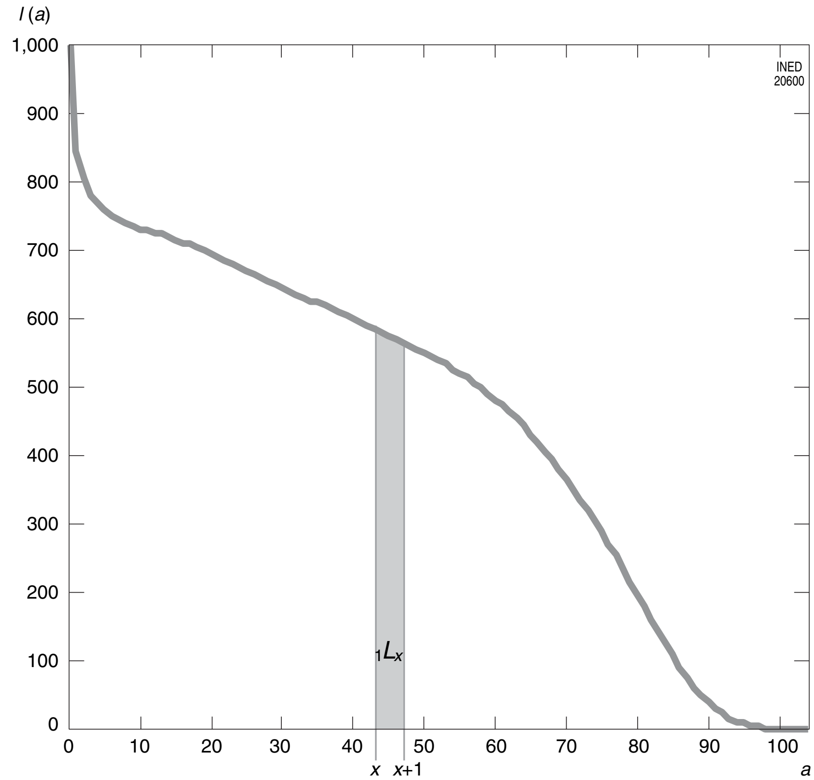

FIGURE 11–9 Area defined by ${}_1L_x$ in the life table of the French female cohort born in 1875.

or

$$\mu_x = \frac{-\partial(\ln l_x)}{\partial x}$$

Within an age interval, the force of mortality measures the mortality at each instant (i.e., the age-specific *instantaneous mortality* rate). For example, μ_{x+n} is the instantaneous rate for each age between x and $x + n$, where n varies between 0 and 1. In a way, this rate can be regarded as a sort of average of all the instantaneous rates of the interval. That is why the rate of the table, generally called the *central death rate*, is a good estimator of the force of mortality at mid interval:

$$\mu_{x+0.5} \cong {}_1\overline{m}_x$$

Concretely, as we have seen, we calculate the death rate, ${}_1m_x$, as the ratio of actual deaths in a given age interval to the number of person-years exposed to the risk, estimated by the half-sum of the actual cohort population at either end of the interval. Pollard (1973) has shown that, if one uses annual age groups, ${}_1m_x$, is equally a good estimator of the force of mortality $\mu_{x+0.5}$:

$$\mu_{x+0.5} \cong {}_1m_x$$

Thatcher *et al.* (1998) have shown that the error committed by equating the force of mortality with the actual rate depends on the relationship between the force of mortality and age. If the relationship were constant over the entire age interval, the error would be null. However, even when the force of mortality grows exponentially with age, the error remains modest as long as we use a one-year age interval: in the real universe studied by the authors, the error never exceeds 0.8%.

3. Force of Mortality and Probability of Dying

If we revisit the survival function, we can also study the relationship between the force of mortality and the probability of dying (i.e., the probability of dying defined in discrete terms).

Integrating $\mu_x = -[\partial l_x/\partial x]/l_x$, we obtain the analytical expression of S_x:

$$l_x = l_0 \exp\left[-\int_0^x \mu(a)da\right]$$

If $l_0 = 1$, l_x is equal to the probability ${}_xp_0$ of survival from birth to age x:

$${}_xp_0 = \exp\left[-\int_0^x \mu(a)da\right]$$

and the probability of dying in the same interval, the probability ${}_xq_0$, is equal to:

$$ {}_xq_0 = 1 - \exp\left[-\int_0^x \mu(a)da\right] $$

Last, the conditional probability ${}_1q_x$ of dying before age $x + 1$ when reaching age x is equal to:

$$ {}_1q_x = 1 - \exp\left[-\int_x^{x+1} \mu(a)da\right] $$

As an age interval comprises an infinity of discrete ages, the force of mortality at the discrete mid-interval age (x, $x + 1$) is regarded, for the sake of convenience, as equal to the probability of dying in the discrete computation mode:

$$ {}_1q_x \cong 1 - \exp[-\mu_{x+0.5}] $$

This relationship shows that, when the force of mortality $\mu_{x+0.5}$ tends toward infinity, ${}_1q_x$ tends toward 1. At the same time, the rate of the table, ${}_1\overline{m}_x$, tends toward 2, since ${}_1\overline{m}_x = 2{}_1q_x/(2-{}_1q_x)$.

Thus, the force of mortality can be proxied by:

$$ \mu_{x+0.5} \cong -\ln(1 - {}_1q_x) $$

When the age interval is 1 year, this approximation is even better than the one provided by the rate. If the force of mortality is constant, the error is obviously null. If it rises exponentially with age, Thatcher *et al.* (1998) have shown that the error can hardly exceed 0.04%.

4. Another Look at the Relationship Between Rate ${}_1m_x$ and probability ${}_1q_x$

Combining the relationships above, we obtain:

$$ \mu_{x+0.5} \cong {}_1m_x $$

$$ \mu_{x+0.5} \cong -\ln(1 - {}_1q_x) $$

$$ {}_1q_x \cong 1 - \exp[-\mu_{x+0.5}] $$

We can therefore write:

$$ {}_1m_x \cong -\ln(1 - {}_1q_x) $$

and

$$ {}_1q_x \cong 1 - \exp[-{}_1m_x] $$

Taken together, these relationships show that, if we define the year of age as our unit, we can generally use the rate, the probability, or the force of mortality interchangeably. But, whatever the length of the age interval, these equations also make it possible, when one of the indicators is known, to determine the other two.

5. Life Expectancy in Continuous Terms

Generalizing the definition given at the start of this section for the number of years lived in a 1-year age interval, ${}_1L_x$, we can integrate $l(a)da$ from age x to the extreme age ω to obtain the total number of years lived beyond age x:

$$ {}_{\omega-x}L_x = T_x = \int_x^{\omega} l(a)da $$

Dividing this total by the number of survivors at age x, we obtain life expectancy at age x:

$$ e_x = \frac{T_x}{l_x} = \frac{\int_x^{\omega} l(a)da}{l_x} $$

Life expectancy at birth is, of course, equal to:

$$ e_0 = \frac{T_0}{l_0} = \frac{\int_0^{\omega} l(a)da}{l_0} $$

IV. THE OLDEST-AGES PROBLEM AND TABLE CLOSURE

In determining the probabilities of dying at the oldest ages, we come up against two very different problems. In most cases, as explained in the second section of this chapter, this obliges demographers to interrupt the table construction at a given age and to arbitrarily assign it the most plausible life expectancy possible in order to close the table.

The first problem is that the empirical data on the oldest ages are often of poor quality. The ages of the very elderly are subject to reporting errors. One of the most classic error factors is the prestige surrounding the elderly, which sometimes encourages the reporting person to exaggerate. In countries where civil registration is recent or does not function well, this type of error can impair death statistics as well as population counts to a sometimes-phenomenal degree. For example, legends have emerged on the presence of supercentenarians in Georgia (in the Caucasus) or certain Andean valleys (Allard, 1991). In countries with a long tradition of comprehensive birth records, the risk is relatively low for death registrations, which are usually based on official documents. However, the risk does persist in censuses: These generally rely on respondents' declarations, which are not systematically checked. Such errors break the strict consistency between numerator and denominator needed to calculate probabilities from current statistics. The French data taken here as an example visibly suffer from this restriction. Above a certain age, the probabilities determined by empirical methods display an erratic profile that contrasts sharply with their smoother upward path at earlier ages (Figure 11–10).

As we can see, the empirical computation ceases to be reliable at approximately age 85 for most of the older cohorts shown here. However, we also note that the quality of the data improves over time and varies from one sex to the other. In the most recent female cohorts (1880, 1890, and 1900), the increase in probabilities with age remains steady until almost age 100 (up to the end of the observations available for the 1900 cohort). That is still the case for the 1890 and 1900 male cohorts but not for the 1880 cohort, whose probabilities are visibly incorrect beyond age 90. Moreover, the fluctuations at the oldest ages observed in the older cohorts are far wider among men than among women.

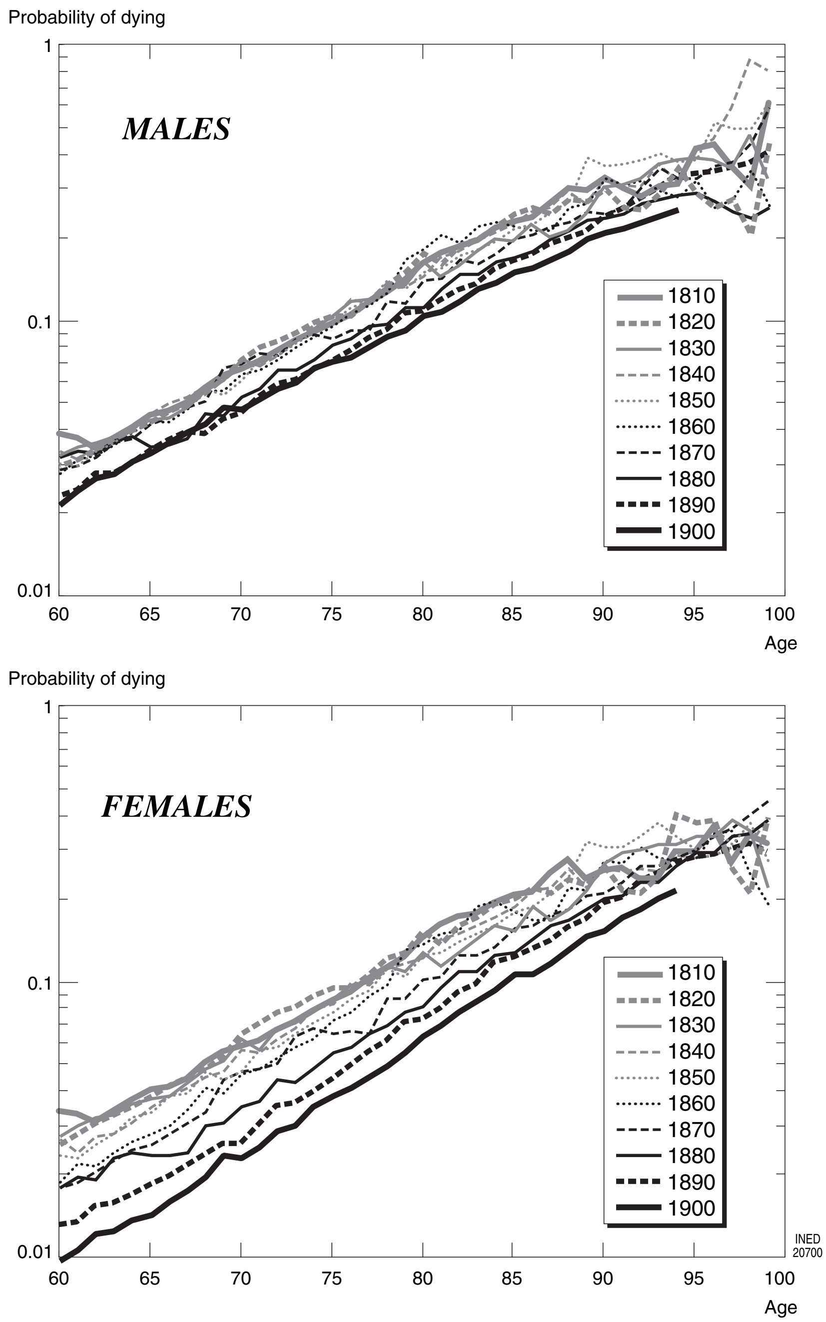

FIGURE 11–10 Probability of dying older than 60 years in French cohorts born between 1810 and 1900, in 10-year intervals, by sex.

This sex difference, however, is probably not due to a difference in data quality; it has more to do with the second problem posed by the measure of mortality among the very elderly.

This second problem is of an entirely different nature. The greater the decrease in cohort with age, the smaller the number of observations on which the computation rests. At the very oldest ages, numbers inevitably become so small that the probability calculation loses the value it derives from the law of large numbers at other ages. This phenomenon naturally occurs earlier among men than among women, who are far more numerous at the oldest ages, owing to male excess mortality.

When we estimate the age-related change in mortality in this manner, the randomness factor outweighs the theoretical risk that we are seeking to measure.

The problem becomes most acute when the cohort is reduced to a handful of survivors. Indeed, even at the very high mortality levels for these ages, chance may have it that no survivor dies in a full year of observation. The French female cohort born in 1875 offers the best illustration, since Jeanne Calment[10] died at age 122, in 1997, 5 years after the penultimate death in the cohort, which occurred in 1992, at age 117; the three previous deaths in the cohort occurred at the ages of 116 (in 1991), 114 (in 1989), and 109 (in 1984).[11]

The best way to definitively solve the first problem would be, of course, to improve data collection conditions to dispel any uncertainty over the measurement of the age of the elderly, in particular in censuses. The surge in the number of the very old, and the socioeconomic problems this entails, explains the growing interest in the extreme age category. France made a special effort to verify the ages of the over-90s in the 1990 census, and one can hope that such campaigns will intensify in most countries. Another solution is to perform specific surveys to measure the mortality of the very elderly, such as the survey on centenarians conducted in France by the IPSEN Foundation (Allard *et al.* 1996). This is also the goal of the program that has been under way for the several years at the University of Odense and the Max Planck Institute of Demographic Research, which aims to gather the largest possible set of reliable data on mortality at the oldest ages (Kannisto, 1994, 1996). However, these efforts clearly cannot solve the problem of the quality of old data—which are indispensable for constructing cohort life tables—and leave unsolved the issue of randomness due to small numbers.

On the first point, a special approach to old-age mortality proposed by Vincent (1951) provides a partial remedy to this difficulty: it is known as the *extinct cohorts* method. Concerning the second problem, in the wake of Gompertz (1825), several authors have suggested methods for extrapolating age-specific mortality that allow an estimation of mortality at ages when it is no longer observable.

1. The Extinct-Cohort Method

Since the age of the oldest individuals is less accurately identified by censuses when they are still alive than by the civil records at the time of their death, is there a way to measure their mortality using only the age information recorded when they die?

As seen earlier, in the absence of migration, we could construct a cohort life table simply by taking the number of births and deducting the deaths recorded at each successive age. There would be no need to refer to population data. However, the method is totally unsuitable for a population that experiences migration flows.

Vincent's (1951) ingenious method rests on the notion that a procedure inconceivable to perform from births is probably not impossible to carry out from deaths, beyond a certain age. Vincent argued that at the uppermost ages, at least at the national level, migration is so limited that it becomes entirely marginal relative to mortality, which is very high.

Accordingly, starting with the death of the cohort's last survivor, we can determine the number of survivors at any age x, by successively combining the deaths observed at the preceding ages:

$$l_x = \sum_{x}^{\omega-1} d_{x,x+1}$$

In this case, the survivors l_x and the deaths $d_{(x,\,x+1)}$ are exactly, by hypothesis, those of the sought-for life table. Constructed in this manner, however, the table has an indeterminate radix. To link this end-of-table to the table computed using the classic method for the younger ages, we must (1) reduce the total population in the death series thus calculated to the number of survivors at the age when the conventional calculation stopped or (2) go back to the probabilities and complete the series of classic probabilities by adding the probabilities determined by means of the extinct-cohort method for the oldest ages.

If we return to the example of the Jeanne Calment cohort, born in 1875, and apply the extinct-cohort

[10] Jeanne Calment was born in Arles (France) on February 21, 1875, at 7 AM. and died, also in Arles, on August 4, 1997, at the age of 122 and a half (Allard *et al.*, 1994, 1998).

[11] If, however, the ages at death reported to the civil registrar for these persons are correct. While Jeanne Calment's age at death has been thoroughly checked (Allard *et al.*, 1994, 1998), the same cannot be said for the earlier deaths in her cohort (Meslé *et al.*, 2000).

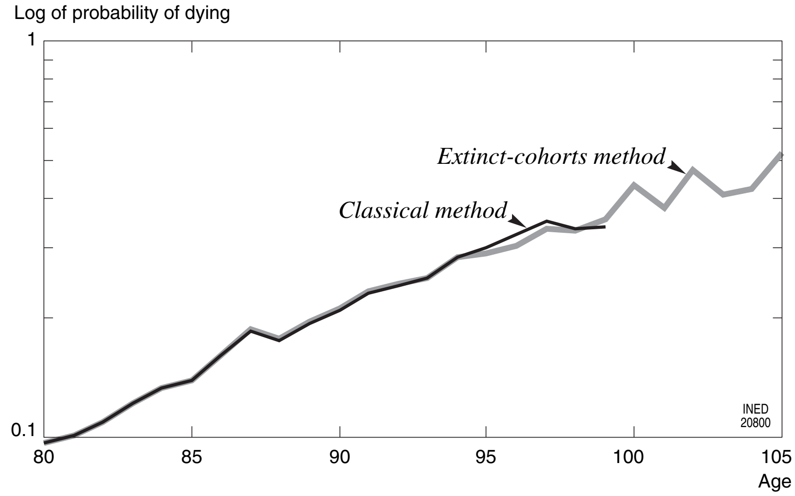

FIGURE 11–11 Comparison of classic probabilities of dying and probabilities given by the extinct-cohort method, beyond age 80 (France, 1875 cohort).

method to measure its mortality beyond age 85, its life expectancy at 85 is 4.7 years. Had we used the probabilities calculated with the classic method until age 100[12] (with a life expectancy of 1.5 years at that age), we would have found 4.5 years. The difference, therefore, is not very great at age 85, but the probability series beyond that age is very different and, the older the age, the more the life expectancy given by the classic method depends on the arbitrary value chosen to close the incomplete table (Figure 11–11).

2. Extrapolation Methods

Although the extinct-cohort method provides a partial solution to the problem of age-reporting errors in censuses, it is obviously powerless to deal with the problem of small numbers. It is difficult to accept the notion that, in the French female cohort born in 1875, the mortality reflecting the cohort's health condition was 0 from ages 117 to 122, then jumped to 100% at age 122 because Jeanne Calment remained the sole survivor for 5 years. What would we have observed if, at age 110, the cohort comprised not merely four women (Jeanne Calment and the three others who would live beyond 110) but 1000 or 100,000? The question is all the more sensitive as it raises issues about the ultimate age of life.

A number of authors have tried to model the observed part of the mortality curve to extrapolate it to the ages where it is no longer measurable, either because of poor data quality or owing to the random effect of small numbers. Although their priority has been to estimate mortality, these authors have also had to address the extreme-age issue, if only implicitly.

a. From DeMoivre to Gompertz

Back in 1725, Abraham DeMoivre sought to answer this question by formulating the hypothesis that the number of persons alive at a given age is proportional to the number of years between that age and the extreme age of life:

$$l_x = l_0\left(1 - \frac{x}{\omega}\right)$$

from which it appears that the force of mortality is equal to:

$$\mu_x = \frac{1}{\omega - x}$$

The hypothesis of a linear change in l_x with age was indeed fairly consistent with what was known about mortality at the time, particularly from Halley's table (1693). Today, of course, the assumption seems quite naive. Most of all, however, DeMoivre's formula implied that the issue of the limit age of life had been settled beforehand. The age of 86 suggested by DeMoivre is obviously well below what we may reasonably imagine today.

A century later, Benjamin Gompertz (1825)—relying on an admittedly far greater abundance of data—made the far more realistic proposal that the force of mortality μ_x should be deemed to follow an exponential function of age:

[12] Unfortunately, we cannot use the same method to determine probabilities of dying after age 100 because the population estimates by age at January 1 do not distinguish the number of individuals by age beyond 100.

$$\mu_x = Bc^x$$

where B and c are constants (curve [1] of Figure 11–12). Benjamin Gompertz saw in this mathematical model a description of "two generally coexisting causes; the one, chance, without previous disposition to death or deterioration; the other, a deterioration, or an increased inability to withstand destruction" (Gompertz, 1825; p. 517).

This formulation requires no preconceived notion on the limit age of life—hence the statement by Smith and Keyfitz (1977) that "Gompertz is as much remembered for having reasoned well: his Law is a better description of the upper ages than DeMoivre's hypothesis that populations collapse towards a specific age limit." In fact, however, Benjamin Gompertz was assuming that there is no age limit to life. Once the constants B and c have been set on the basis of the analysis of empirical data, the extrapolated values of the force of mortality can increase without limit; μ_x can tend toward infinity, at the same time as x, whereas the probability of dying ${}_1q_x$ will merely tend toward 1, without ever actually reaching it. Provided that the population is large enough, these assumptions theoretically allow for the survival of at least a few individuals beyond any limit. Contrary to what Vincent (1951) had conjectured when trying to determine the uppermost age from Gompertz's law, the refusal to set an arbitrary age limit is tantamount to denying the existence of a limit.

Nonetheless, Gompertz's formula enables us to extend the actual values of the life table with extrapolated values up to the age we want; typically, this is the age at which the real population studied contains few or no survivors. In these conditions, the method used to close the table matters little, as it will only affect the description of the mortality of those rare survivors.

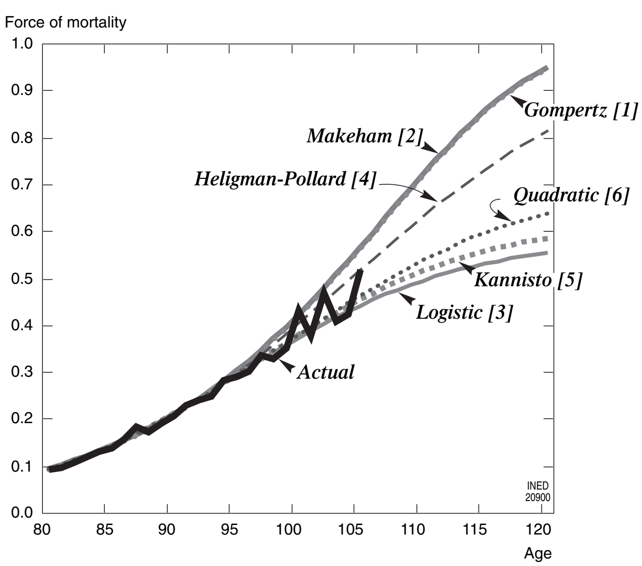

FIGURE 11–12 Comparison of actual probabilities of dying and probabilities obtained with various models, beyond age 80 (France, 1875 cohort).

b. From Exponential Functions to Logistic Functions

After Gompertz, a number of authors tried to improve the fit between the mortality-curve adjustment formula and the underlying philosophy. Although the exponential growth of mortality with age reflects the degeneration process, one must accommodate the fact that some causes of death are not directly linked to the process. Makeham (1860, 1867) held that some causes of death are independent of age and suggested extrapolating the force of mortality at the upper ages using a Gompertz law modified as follows (Figure 11–12):

$$\mu_x = A + Bc^x$$

where parameter A represents the risk of dying for age-unrelated causes (Thatcher *et al.*, 1998).

The hypothesis of age-unrelated causes of death is altogether questionable, but it is true that the adjustment of the mortality curve by means of the Gompertz formula has to contend with the fact that not all the causes of death vary identically with age, and that some most definitely do not follow an exponential path. That is why Jean Bourgeois-Pichat (1952), in constructing his "limit biological life table," confined his use of Gompertz's law to extrapolating the mortality of the causes that he deemed *endogenous*. Although Bourgeois-Pichat's approach was later taken up by Bernard Benjamin (1982), many authors have tried to refine the Gompertz model for all-causes mortality. In so doing, they have simply added parameters to the basic formula to take into account particular nonexponential factors in the observed-mortality curve (Duchêne, 1980). Other authors have investigated alternative adjustment models.

In the 1930s, Perks (1932) used empirical data to show that the μ_x values of a life table can be fitted very well to a logistic function of the form:

$$\mu_x = c + \frac{ae^{bx}}{1 + \alpha e^{bx}}$$

where a, b, c, and α are constants (Figure 11–12). In fact, when α is equal to 0, the form is identical to the Makeham function. That is why, at the ages when α is small (generally until 80–85 years or so), Makeham's law and Gompertz's law both provide wholly acceptable fits (Figure 11–12).

In the late 1950s, the path opened by Perks was followed again by Beard (1963, 1971) with the so-called Gamma-Makeham model. This was later reworked by James Vaupel *et al.* (1979) to establish a *frailty* model. Other authors, as well, drew inspiration from Perks, confirming the relevance of the Gamma-Makeham model in describing mortality at the oldest ages (Le Bras, 1976; Gavrilov and Gavrilova, 1991; Yashin and Iachine, 1995, 1997).

In their attempt to describe mortality at all ages, Heligman and Pollard (1980) put forward a new exponential model with eight parameters:

$$\frac{q_x}{p_x} = A^{(x+B)^c} + D \cdot \exp\left(-E(\ln x - \ln F)^2\right) + GH^x$$

where the last term is explicitly designed to describe the mortality at over 50 years (Figure 11–12). The authors assume that, beyond age 50, mortality obeys the following relationship:

$$\frac{q_x}{p_x} = GH^x$$

where, of course,

$$p_x = 1 - q_x$$

while G and H are constants: G is the basic, aging-related mortality; H is its growth rate with age.

The relationship can also be written:

$$q_x = \frac{ae^{bx}}{1+ae^{bx}}$$

This is equivalent to admitting that, from age 50 up, the probability of dying follows a logistic function, with values ranging between 0 and 1:

$$Logit(q_x) = \ln(a) + bx$$

In the 1990s, Väino Kannisto *et al.* (1994) showed that—in countries with reliable data—the age-related growth of the force of mortality slows from 75 to 80 years onward. At those ages, its shape becomes very similar to a logistic curve. These authors, as well, proposed a function of the type:

$$\mu_x = \frac{ae^{bx}}{1+ae^{bx}}$$

which can also be written:

$$Logit(\mu_x) = \ln(a) + bx$$

(Figure 11–12).

Another interesting proposal was made by Coale and Kisker (1990) to describe mortality between ages 85 and 110. Their model is of the form:

$$\ln(\mu_x) = a + bx + cx^2$$

where c is negative. This is known, in the literature, as the *quadratic model* (Figure 11–12).

To assess the capacity of these different models to fit the data actually observed, we have applied them to the mortality of the French female cohort of 1875 determined with the extinct-cohort method (Figure 11–11). The best fit is obtained with the logistic models.

For a long time, demographers have noted that the growth rate of the force of mortality decreases at the oldest ages. In addition, the slowing was attributed to the degradation of data quality at those ages. However, with the improvement in data and the rapid rise in the number of elderly due to greater life expectancy, it is increasingly being noticed that mortality ceases to follow the Gompertz model beyond a certain age (Horiuchi and Coale, 1990; Kannisto, 1994; Thatcher *et al.*, 1998; Wilmoth and Horiuchi, 1998). An initial explanation of this phenomenon may be found in the differences in frailty between individuals of the same cohort (Vaupel and Yashin, 1985; Vaupel and Carey, 1993).[13] The fall in the growth rate of mortality with age would, on this assumption, be due to a change in the cohort structure by frailty level. Each subset with the same frailty effectively follows a Gompertz distribution, whose level is specific to its degree of vulnerability. However, as the most vulnerable subsets are eliminated sooner, the rate of increase of the overall mortality risk slows. A second possible explanation is that the health improvements among the very elderly actually benefit the hardiest individuals rather than the weakest. Here, it is not the composition of the population by degree of frailty that changes, but rather the difference in mortality between frailty groups that widens.

If we held to the first explanation, this deviation from the Gompertz law at the upper ages might not be incompatible with an immutable theoretical extreme age at death. By contrast, with the second explanation, the hypothesis of the fixed limit age becomes much harder to defend.

An analysis of these dynamic relations between heterogeneity and mortality at the oldest ages in the French population (Barbi *et al.*, 2003) has shown that, in reality, both processes are at work.

Figure 11–13 shows that for French women, from the oldest to the most recent cohorts, the slowdown in age-related mortality growth observed for the total population (μ) is due to two concurrent processes: (1) a homogenization of the cohort group in terms of indi-

[13] See also Chapter 21, by James Vaupel and Anatoli Yashin.

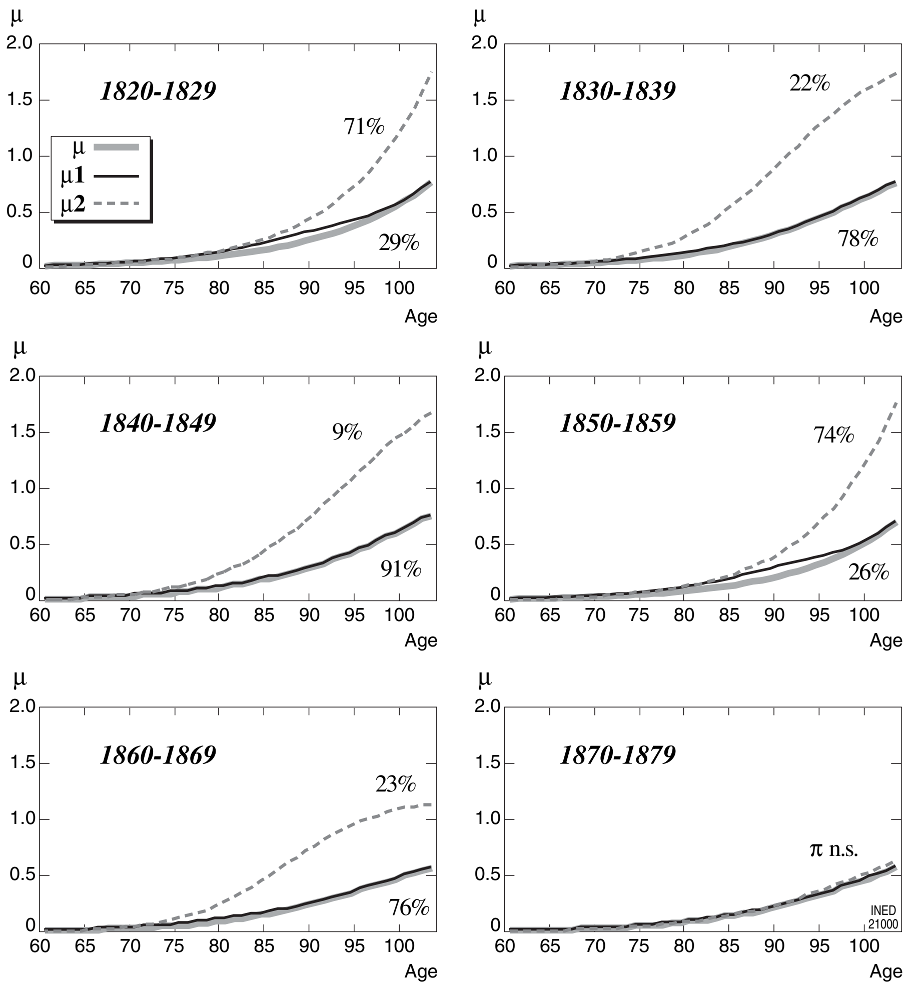

FIGURE 11–13 Estimation of the force of mortality for two subsets of individuals with different frailty (μ_1 for the frailest and μ_2 for the hardiest) and for the entire population (μ) in the six groups of French female cohorts. (Source: Barbi *et al.*, 2003.)

vidual frailty (the mortality of the frailest being much higher, their proportion in the cohort falls very rapidly with age) and (2) a slowdown in age-related mortality growth, among the frailest (μ_1) and the hardiest (μ_2) alike.

V. THE SPECIAL CASE OF INFANT MORTALITY

Although mortality at the oldest ages poses theoretical problems that are hard to solve, mortality at young ages also deserves special attention (but for historical and practical reasons rather than theoretical ones). The issue here is not so much to find a remedy to a still-unsolved problem but to avoid confusing the various indicators that have been enshrined in standard usage for practical reasons.

Owing to the preeminence of child mortality in the overall mortality of human populations, and to its enduring major importance in some populations even today, it was soon realized that child-mortality analysis should take precedence over all other investigations of mortality as a tool for conducting health policy. Numerous studies in historical demography have shown that until the mid-18th century in western Europe and even until the early 20th century in several countries of central/eastern Europe (Vallin, 1989, 1991), nearly half the members of a newborn cohort died before age 5 and almost 30% before their first birthday. Today, no population experiences such a massive loss in peacetime, but in some developing countries, particularly in rural areas, we can still observe losses in excess of 10% before age 1 and of almost 20% before age 5. In such situations, child mortality carries an extremely heavy weight in cohort life expectancy. Thus, we can understand why it has been tracked for so long, even in the absence of any resources for a sophisticated measurement of mortality.

In fact, the earliest current statistics on death distinguished deaths at under 1 year of age from total deaths. Even today, in many situations where only rough mortality statistics are available, the figures almost always show at least the total of deaths at all ages and the number of deaths of infants less than a year old.

The *infant mortality rate* is the simplest mortality indicator that one can calculate, after the crude death rate—and sometimes even ahead of it. However, the indicator designated by that standard term is neither a rate nor a probability according to any one of the several definitions discussed in this chapter. In reality, it is the ratio of deaths at under age 1 observed in the course of a calendar year to the number of births in that same year:

$$m_i = \frac{D_{0,1}}{B}$$

It is not a rate, as it does not express the ratio of deaths to an average population exposed to the risk. Nor is it a probability since (apart from the migration issue explored earlier) we can easily see in Figure 11–14, which plots the computation elements on a Lexis diagram, that only a portion of the deaths constituting the numerator occurred among children born during the year studied.

In the example of Figure 11–14, which concerns French male mortality in 1920, the infant mortality rate works out at:

$$m_i = \frac{35,433 + 13,692}{432,036} = 113.7/1000$$

whereas the age-0 mortality rate calculated in the Lexis square comes to:

$$m_0 = \frac{35,433 + 13,692}{(234,700 + 396,000)/2} = 155.8/1000$$

and the average of the two cohorts' probabilities of dying at age 0 contributing to the deaths used to compute the infant mortality rate is:

$$m_0 = \frac{26,417 + 35,433 + 13,692 + 14,925}{(260,455 + 432,036)} = 130.6/1000$$

The infant mortality rate is well below the death rate at age 0 (113.7/1000 versus 155.8/1000). This is quite normal insofar as the same number of deaths is divided in the first case by the number of births, and in the second by an average population of children aged under one year—who, all other things being equal, have already experienced part of the infant mortality. This initial differentiation factor is the same as the one that separates an age-specific rate from a probability.

Again, however, we can clearly see in this example that there is a great difference between the infant mortality rate and the average of the two classic probabilities at age 0 (113.7/1000 thousand instead of 130.6/1000). This is mainly due to the sharp fluctuation in the number of births linked to the end of World War II.

To obtain the exact measure of a true probability of dying, which would reflect the deaths composing the numerator of the infant mortality rate, we should (1)

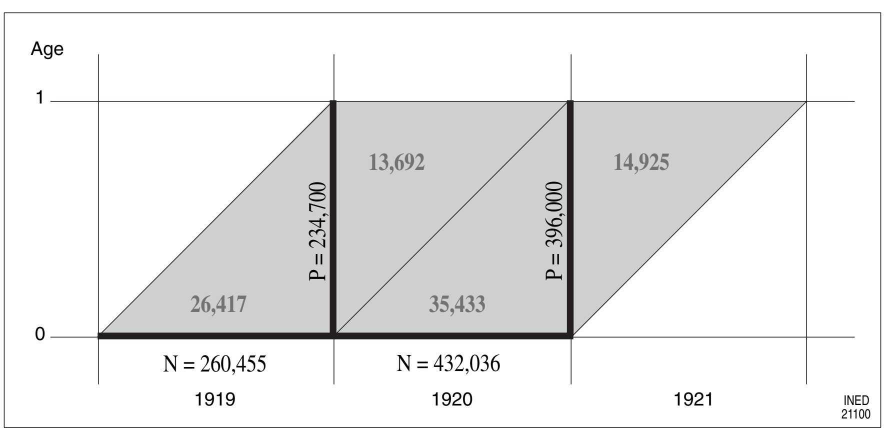

FIGURE 11–14 Lexis diagram locating the data that can be used for different measures of infant mortality (France, males, 1920). Note: To allow for the change in the territory covered by the statistic, the 209,185 births and 21,217 deaths at under age 1 of the 1919 cohort registered in 1919 have been weighted by the ratio 234,700 : 188,500 (population under age 1 on January 1, 1920, for the two territorial definitions).

compute the ratio of the deaths in the first Lexis triangle to 1920 births only and (2) determine the ratio of deaths in the second triangle to 1919 births:

$$m'_i = \frac{13,692}{260,455} + \frac{35,433}{432,036} = 134.6 / 1000$$

There remains a small difference between this adjusted infant mortality rate and the average of the two classic probabilities, owing to the fact that infant mortality varies from year to year. To obtain a measure from classic probabilities centered on 1920, we use three observation years. If mortality were constant, these two measures would be strictly identical.

However, to perform this type of correction—which transforms an infant mortality rate into a true probability of dying (if we disregard the migration issue)—we need the breakdown by cohort of deaths at under age 1 observed during the year. Such figures are seldom available. That is why demographers sometimes weight infant mortality rate by births; for this purpose, they refer to a standard distribution of deaths at under age 1 between the Lexis triangles corresponding to the mortality level of the population studied. For an infant mortality in the range of 100 to 150 per thousand, the ratio ranges between two thirds and one third. In the previous case, we would therefore have estimated a weighted infant mortality rate, which can be equated with a classic probability as follows:

$$m'_i = \frac{(35,433 + 13,692)}{432,036 \cdot 0.67 + 260,455 \cdot 0.33} = 130.9 / 1000.$$

This result is indeed close to the 134.6 computed with the true distribution.

Once again, however, we have taken a fairly uncommon example of a sharp fluctuation in the number of births to highlight the measurement differences tied to the differences in the definition of the various possible indicators of infant mortality.

In summary, the conventional infant mortality rate is never equivalent to a true death rate at age 0. On the other hand, the conventional rate is strictly comparable to the classic probability of dying at age 0 if the number of births is constant and if mortality does not vary in the course of the 3 years centered on the rate measurement. In other words, if the real fluctuations in births and deaths are small, the conventional rate can be equated with the probability; if the birth fluctuations are significant, we can equate the two after weighting the infant mortality rate by the number of births concerned.

Apart from these issues linked to the definition of commonly used indicators, let us note in conclusion that the measurement of infant mortality is sometimes impeded by problems of defining life and death. Registered deaths are registered precisely by virtue of the legal definition that makes it possible to distinguish between *live births* and *stillbirths*. This definition differs from country to country. Some statistical institutes try—with varying degrees of success—to compile additional information to identify, among the stillborn, those who actually *lived* without being able to attain the legal status of live births: these are known as *false stillbirths*. Such attempts are broadly consistent with the universal definition proposed by the World Health Organization (WHO).[14] To analyze infant mortality with precision, we need to investigate the definition that actually matches the statistical tables used. In France, for example, INSEE (the national statistical institute) has published a special statistical series on the stillborn that distinguished between the true, the false, and the undetermined stillborn. Since 1975, the Institute has simply incorporated the false stillbirths into the birth statistics as well as the death statistics—a decision that does not, however, ensure total consistency with the WHO definition.

Cohort Analysis of Fertility

GUILLAUME WUNSCH

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

I. ANALYZING COHORT FERTILITY FROM RETROSPECTIVE DATA

Chapter 8 showed that measures of the quantum and tempo of fertility in a birth cohort[1] could be obtained either by a retrospective or a prospective observation using fertility frequencies (*age-specific fertility rates* [ASFR]), if the condition of *causal independence* (as defined in Chapter 9) between fertility and the censoring phenomena (mortality, migration) is satisfied. This condition is usually assumed, as previously discussed, when one raises the question of what would have been the quantum and tempo of fertility if there had been no mortality or migration affecting the cohort. This chapter will deal mainly with *retrospective* fertility data, although the *prospective* approach will also be considered.

1. Average Number of Children Born

As pointed out in Chapter 8, suppose that at a survey women are interviewed at the end of their childbearing period, say at age 55, on the number of live-born children they have had during their lifetime and on their age at childbearing (i.e., on their *birth history* or their *maternity history*[2]). Let F_{55} stand for the number of women interviewed and B_x for the number of births occurring at completed age x in this cohort of women. Then, the ratio $f_x = B_x/F_{55}$ represents the age-specific fertility *rate* or frequency at age x for those women interviewed at the end of their childbearing period.

The sum of these *rates* over all x, from puberty to menopause, will yield the average number of children born or average family size at the end of the childbearing period. This *cohort total fertility (TF) rate* (TFR), or *completed fertility rate* (CFR) as it is sometimes called, characterizes the intensity or quantum of fertility and can be written:

$$TF = \sum_{x=15}^{54} \frac{B_x}{F_{55}}$$

Two measures of the *tempo* of fertility can also be obtained from these data (i.e., the average age at childbearing $\bar{x}$ and the corresponding variance v). The mean age at childbearing is simply the weighted average of ages at birth, the weights being the ASFRs at each age:

$$\bar{x} = \frac{\sum x.B_x}{\sum B_x} \text{ or } \bar{x} = \frac{\sum x \frac{B_x}{F_{55}}}{\sum \frac{B_x}{F_{55}}} = \frac{\sum x f_x}{\sum f_x}$$

The variance of age is similarly obtained by the expression:

$$v = \frac{\sum (x-\bar{x})^2 .B_x}{\sum B_x} \text{ or } v = \frac{\sum (x-\bar{x})^2 \cdot \frac{B_x}{F_{55}}}{\sum \frac{B_x}{F_{55}}} = \frac{\sum (x-\bar{x})^2 f_x}{\sum f_x}$$

all sums covering the whole reproductive period.

[1] A cohort viewpoint is adopted here, although, as noted in Chapter 10, one must always remember the critique that has been addressed to cohort studies (Bhrolcháin, 1992; Bongaarts and Feeney, 1998) before embarking on a cohort approach instead of on a period approach.

[2] *Maternity* histories are broader than *birth* histories, as the former collect data on all pregnancies and not only on live births.

If one is only interested in the sole behavior of the subcohort interviewed at the end of the reproductive period, whatever the possible selection effects it has incurred by mortality and migration, it is not necessary to assume independence between fertility and mortality and migration, as this condition is then without purpose. To give other examples, one may examine whether cohabitation is followed by marriage or if change of residence occurs before or after marriage, without assuming independence between the various factors (Courgeau and Lelièvre, 1994). In both of these cases, individuals are not lost to follow-up as when censoring occurs; they only change their characteristics or states. On the contrary, when individuals are lost to follow-up, one should consider whether these individuals differ from those who remain under observation (i.e., if selection effects operate or not on the process one is studying).[3] This is the case when people are lost from observation through mortality or international migration or—in a prospective survey—if they are not followed anymore for various reasons, such as survey dropout. Any withdrawal from observation can bias the results of the study through selection effects (see e.g., Alderson, 1983, Chapter 6).

Consider for example the *Fertility and Family Surveys* (FFS) conducted in Europe under the auspices of the Population Activities Unit of the United Nations Economic Commission for Europe since the late 1980s (Nikander, 1998; Schoenmaeckers and Lodewijckx, 1999). The purpose of these sample surveys is to document various aspects of partnership and reproductive behavior among a sample of women in reproductive ages. The analysis is focused here on the survivors, and not on those who have died or migrated,[4] although *nonresponse* may severely bias the results (Frankfort-Nachmias and Nachmias, 1996, Chapter 8). Contrary to the vital registration system, surveys collect much more information on the characteristics of the females concerned; moreover, these facts are available individually and not as aggregates as in the case of vital statistics. If the latter are still useful for monitoring period trends in fertility, by age or marriage duration for example, they are not of much help for studying the factors that have led to fertility changes, as the amount of information vital statistics contain is minimum. Furthermore, as cohabitation has become common during the last decades in the developed countries, vital statistics are not suited for this situation either, as only the legal marital status of the individual is recorded. Thus, sample surveys have become the main source of data for fertility analysis, both in developed and in less-developed countries.

As stated in a report of the FFS (Macura and Klijzing, 1997; p. 3):

> thus far changes in partnership and reproductive behavior have mostly been documented using data from population census, vital registration and/or population registers. As the depth and breadth of these data vary a great deal across countries, the composite picture they can provide is at best patchy. Moreover, these data are often incapable of shedding light on the more subtle aspects of partnership behavior, such as the onset of sexual relationship, the use of modern contraception, and living apart together, to mention just a few. Also, these data often preclude an in-depth analysis of interactions, such as those between school attendance and work on the one hand, and union formation and childbearing, on the other.

The following sections will therefore deal mainly with *retrospective* fertility survey data, and more particularly with the single-round survey,[5] although the link with the approach using vital statistics will be identified when necessary. Both of these data sources are actually useful in practice. As noted above, and as Handcock *et al*. (2000) among others have pointed out, survey data contain more detail with respect to demographic events and the characteristics of the individuals who do or do not experience these events. On the other hand, registration data are collected for all events in the population. This eliminates sampling error and sample-selection bias. Registration data are also less affected by reporting biases than retrospectively collected data. Moreover, vital statistics enable year-to-year monitoring of fertility trends, for which surveys are less well equipped.

2. Fertility by Birth Order

Suppose a sample of women is interviewed at the end of their reproductive period. If the date of birth of each of their children born alive[6] is recorded, and most usually it is, the *birth history* (marital and extramarital) of each woman is recorded. Knowing the date of each birth and therefore the age of the mother at the birth of her children, one may easily compute the arithmetic average of ages, giving the average age at childbear-

[3] This problem cannot be solved by methods alone, including more sophisticated approaches such as survival analysis; one needs information on the causal relations between the variables concerned and between these and possible common causes.

[4] Although one probably assumes implicitly that the sample interviewed at age 50 represents the past experience of the whole population.

[5] Other types of surveys exist, but they are less common in demography (Tabutin, Chapter 121 in Volume 4; Cleland, 1996).

[6] In demography, fertility is usually restricted to *live births* only. Surveys also often collect data on late fetal deaths, although the quality of these data is probably poorer than that for live births. For the study of fetal mortality, see Chapter 32 by Gourbin in Section 2.

ing for this group of women. As seen above, the average number of births per woman[7] or average family size at the end of the reproductive period, also called total fertility rate (TFR) or completed fertility rate (CFR), is simply the total number of live births declared at a postreproductive age divided by the total number of women at that age, including those women who have never had a child (i.e., the infertile[8] women of ultimate parity 0). As one also knows the birth order of each child, age-specific fertility rates $f_x(k)$ may be computed at age x for each birth order k, yielding the average number $TF(k)$ of births of order k per woman:

$$TF(k) = \sum_x f_x(k)$$

One can also compute the average age at childbearing of birth order k, and the variance of ages around the mean as a measure of dispersion.

Note also that the average number of births of all orders is simply the sum of the average number of births of each order:

$$TF = TF(1) + TF(2) + \ldots + TF(k) + \ldots$$

or

$$TF = \sum_k \sum_x f_x(k)$$

As computers prefer crunching numbers rather than years, months, and days, one usually transforms dates expressed in months and years into *century-months* as follows. Take January 1900 as month 1. March 1950 is therefore equal to 50 years times 12 months plus 3 months (i.e., month 603 in the new system). With this recoding of dates, it is easy to compute the interval between two events. For example, if a woman was born during the month of February 1930 (code 362) and had her first child in July 1951 (code 619), her *age at first birth* is then equal to 619 − 362 = 257 months (i.e., 21 years and 5 months). One can compute the same interval for all women having had at least one birth. The arithmetic average gives the mean length of time between birth of the mother and birth of her first child[9] (i.e., the average age at first birth). A similar code can be developed for years, months, and days. In this case, one must however take into account the different number of days per month as well as the leap years.

One may do the same computation for intervals between births of order k and births of order $k + 1$, giving the average *birth interval*[10] between k and $k + 1$, another measure of the tempo of fertility. As birth intervals depend upon the total number of children born,[11] birth intervals should be compared only among women having the same ultimate family size. Changes in birth intervals are useful indicators of changes not only of the timing of births but also in the quantum of fertility; in high-fertility countries, if fertility decreases birth intervals are usually extended. In low-fertility countries, one may nevertheless observe significant changes in the timing of births, such as the postponement of the first birth, without major changes in the total number of children born (Granström, 1997).

Suppose now that these women aged 50 to 55 years, for example, are classified at the survey according to their achieved family size, w being the maximum number of children born:

Parity	0	1	2	. . .	k	. . .	w
No. women	F_0	F_1	F_2	. . .	F_k	. . .	F_w

Tables like these on family size are often available for censuses too, even those held a long time ago, where a question on the total number of children born has been asked. This distribution can also be combined with year of marriage, age at marriage, and duration of marriage (Anderson, 1998). As stated before, the average family size is then:

$$TF = \frac{\sum_0^{\omega} kF_k}{\sum_0^{\omega} F_k}.$$

Furthermore, the proportion p_k of women having borne exactly k children during their lifetime is:

$$p_k = \frac{F_k}{\sum_0^{\omega} F_k}.$$

The probability a_k of moving from parity k to parity $k + 1$, called the *parity progression ratio*,[12] can then be obtained as follows. Let $TF(1)$, $TF(2)$, . . . $TF(k)$, . . . represent as before the average number of births of order 1, 2, . . . k per woman at the end of

[7] *Descendance moyenne*, in French.

[8] Remember that the term *fertile* is translated by *féconde* in French, whereas *fecund* is translated by *fertile*! With confusions such as these, one understands why the British and the French have quarreled in the past!

[9] Called *intervalle proto-génésique* in French.

[10] *Intervalle intergénésique* in French. Because of the skewed distribution of interval lengths, caused by a small number of very long intervals, the *median* is a better measure than the *mean* (Newell, 1988).

[11] Intervals have to be short to have more than 12 children over one's lifetime!

[12] In French, *probabilitéé d'agrandissement des familles*.

their reproductive period, i.e. the proportion of women having had at least 1, 2, . . . k children. One then has:

$$a_0 = TF(1)$$

$$a_1 = TF(2)/TF(1)$$

$$a_2 = TF(3)/TF(2)$$

$$\ldots$$

$$a_k = TF(k+1)/TF(k)$$

$$\ldots$$

One obtains:

$p_0 = 1 - TF(1)$ and $TF(1) = 1 - p_0$

$p_1 = TF(1) - TF(2)$ and $TF(2) = TF(1) - p_1$ or $1 - p_0 - p_1$

$p_2 = TF(2) - TF(3)$ and $TF(3) = TF(2) - p_2$ or $1 - p_0 - p_1 - p_2$

$$\ldots$$

$p_k = TF(k) - TF(k+1)$ and $TF(k) = 1 - p_0 - p_1 - p_2 - \ldots - p_{k-1}$

$$\ldots$$

The *parity progression ratios* will therefore be equal to:

$a_0 = TF(1) = 1 - p_0$,
$a_1 = TF(2)/TF(1) = (1 - p_0 - p_1)/(1 - p_0)$,
$a_2 = TF(3)/TF(2) = (1 - p_0 - p_1 - p_2)/(1 - p_0 - p_1), \ldots$

$$a_k = TF(k+1)/TF(k) = (1 - p_0 - p_1 - p_2 - \ldots - p_k)/(1 - p_0 - p_1 - p_2 - \ldots - p_{k-1})$$

$$\ldots$$

These parity progression ratios state the *ex post facto* frequency of passing from parity k to parity $k+1$ for the birth cohort considered.

Alternatively, knowing the parity progression ratios, it is easy to derive the average number of births of order k per woman. From the above relations, one has:

$$TF(1) = a_0$$

$$TF(2) = a_1\, TF(1) = a_1 a_0$$

$$\ldots$$

$$TF(k+1) = a_k\, TF(k) = a_k a_{k-1} a_{k-2} \ldots a_1 a_0$$

The average number of children of all birth orders being $TF = \Sigma_k\, TF(k)$ one has:

$$TF = a_0 + a_0 a_1 + a_0 a_1 a_2 + \ldots + \prod_{j=0}^{k-1} a_j + \ldots$$

Birth history data obtained from sample surveys are not exempt from problems. First, as the condition of independence is probably not fulfilled, it is not recommended to interview women at very old ages to reconstruct the fertility history of their birth cohort. The subcohort of women surviving at the time of the survey might be a selected group with respect to fertility, if there is an association between fertility on one hand and mortality and international migration on the other hand. In this case, the results from the survey will not adequately stand for the experience of the whole cohort, including those women who have died or migrated before the interview. Another problem with fertility surveys, as with all surveys, is the sampling error. For example, for a sample of 5000 women, the sampling error for an age-specific fertility *rate* (1 year of age and 1 calendar year) is around 20% to 25% (Verma, 1982; Little, 1982). Survey data are therefore often aggregated into 5-year age groupings per calendar year or five calendar years per single year of age, or both.

If the sample is restricted to women aged 15 to 50, as is often the case, another problem arises when one derives period data from the sample; this is often done in countries where the vital registration system is defective. The further one goes backward in time from the survey date, the more data are missing at older ages. This is due to a censoring effect: as the cutting point of the sample has been fixed at, for example, 50 years of age, and as period analysis requires data from older and older cohorts as one goes back in time, one increasingly underevaluates period fertility as one moves away from the survey date.[13] In that case, fertility at higher ages has to be extrapolated, if one wishes to evaluate period fertility covering all reproductive ages. Another solution is to compare period fertility up to a certain age x only ($x < 50$). For example, one could compare period fertility until age 35 during the 15-year period preceding the time of the survey. In this case, no extrapolation is required but one loses the information for the cohorts aged 35 and over at the time of the survey.

Another censoring effect hampers fertility comparisons by cohort because the date of the survey serves as a cutting point for longitudinal observations. It would therefore be completely inappropriate to compare achieved family size or parity between two or more cohorts at the time of the survey, as their ages may significantly differ. One must thus compare

[13] Evaluating period data from a retrospective survey is useful in developing countries lacking a good vital registration system. To improve period estimates, data can be combined if one has conducted several comparable surveys over time.

fertility of the birth cohorts at the same age, even if this results in loss of valuable information for the older cohorts. One could also extrapolate the incomplete fertility of birth cohorts into the future for comparative purposes, but this solution cannot be recommended.

There are still other problems. If the survey is restricted to married women aged 15 to 50, in this case as Ryder (1982) has pointed out, marriage has always preceded the survey. Therefore, at young ages, say 15 to 20 years at the time of the survey, one selects women who have married young. As the latter usually have a higher achieved fertility than those who marry later, the parity for women aged 15 to 20 at survey time therefore overestimates the fertility of the birth cohort. The problem does not arise at older ages; for example, the fertility of women aged 40 to 45 takes account of all ages at first marriage. Note also that if the survey is restricted to married or ever-married women, it is not possible to derive age-specific fertility *rates* from the survey, as these require as a denominator the total population ever married and single. Finally, fertility surveys can be affected by several types of errors, particularly in the developing countries: errors due to poor reporting of date of birth or age of woman (see Chapters 4 and 10), errors relating to the total number of children born and to their date of birth, and so forth. Data must be verified and perhaps corrected before use (Brass, 1980; Srinivasan, 1980; Preston *et al*., 2001).

3. An Example Based on Moroccan Data

This example is based on original individual survey data obtained by the Demographic and Health Surveys (DHS) conducted in Morocco in 1987 and 1992.[14] The 1987 sample survey focuses on ever-married women aged 15 to 50. Marital status is known at the time of the survey only, although one also knows the number of marriages per woman and the date of her first marriage. Birth history data are collected for all ever-married women. The 1992 data are similar except that the population is composed of ever-married women and of spinsters. Birth history data are collected, however, only for the ever-married. Extra-marital fertility is very low in Morocco; thus, restricting the fertility data only to ever-married women is therefore justified.[15]

Figure 12–1 presents on a *Lexis diagram* (see Chapter 6) the retrospective fertility data for all birth orders by 5-year birth cohorts, 5-year age groups (y-axis), and 5-year periods before the survey (x-axis), taken from the 1987 Moroccan survey. As usual in Lexis diagrams, the time unit (in this case, 5 years) is identical on the x- and y-axes. The number of females interviewed are shown on the y-axis for each age group or cohort. The *average number of children born* per woman (or quantum of fertility) at the end of the reproductive period, taken here as the age group[16] 45 to 50, is simply the sum of all births in the cohort divided by the number of women interviewed (i.e., $TF = (346 + 964 + \ldots + 631 + 224)/759 = 7.4$ children per ever-married woman on average). The same result is obtained by summing the *age-specific fertility rates*:

$$TF = \frac{346}{759} + \frac{964}{759} + \ldots + \frac{631}{759} + \frac{224}{759} = 7.4$$

These rates are usually expressed on an annual basis, obtained by dividing the above ratios by 5 (see below this section). The quantum of fertility is then obtained by summing these average annual *rates* and multiplying the result by 5.

One similarly obtains the average family size, or incomplete average fertility, for those women of younger ages that have not yet reached the end of their reproductive period at the time of the survey (Table 12–1).

The data are censored *on the right* by the date of the survey[17]; these average numbers of children born may not be compared from one cohort to another because these women have not yet all reached the end of their childbearing period.

One can easily derive from the data the average age at childbearing, for those women aged 45 to 49 at survey time, assuming that in each age group births are delivered at mid period:

$$\bar{x} = \frac{15 \times 346 + 20 \times 964 + \ldots + 40 \times 631 + 45 \times 224}{346 + 964 + \ldots + 631 + 224}$$
$$= 28.88 \text{ years}$$

This measure may not be computed for the younger age groups, as these women are still in their childbearing ages.

For the oldest birth cohorts, aged 45–49 in completed years[18] at the time of the survey, who have

[14] "Enquête nationale sur la planification familiale, la fécondité, et la santéde la population du Maroc" (1987) and "Enquête nationale sur la population et la santé" (1992).

[15] This would not be the case, for example, in sub-Saharan Africa.

[16] Some women in this age group have probably not achieved their ultimate family size; as the cutoff age is 50, this underestimation is unavoidable. An ultimate age group of 50 to 55 would have been better in this respect.

[17] They are also censored *at the top* because the cutoff age is 50. *Period* fertility cannot therefore be reconstructed from this sort of data, as more and more data are missing as one goes backward in time.

[18] Forty-five to 50 in exact years.

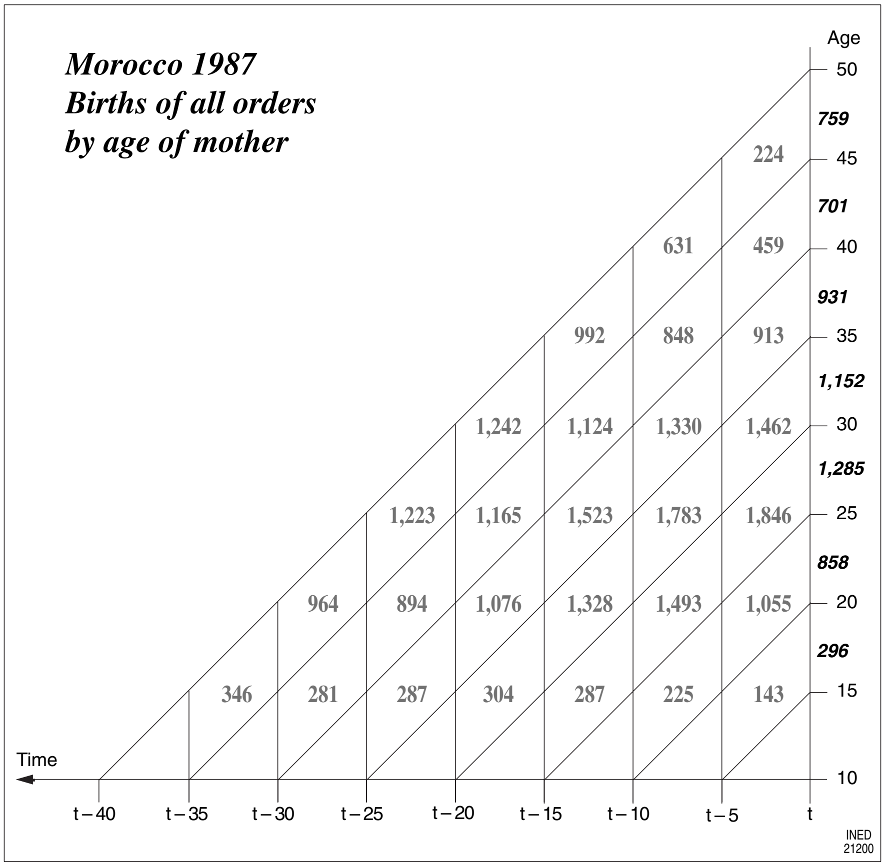

FIGURE 12–1 *Lexis diagram* representation of women and births by 5-year birth cohorts or 5-year age groups (vertical axis) and 5-year periods (horizontal axis), Moroccan Fertility Survey of 1987 (*t* indicates the time of interview, variable from one woman to another). (Source: DHS, Morocco, 1987)

TABLE 12–1 Incomplete average fertility (Morocco, 1987)

Age group (completed y)	Incomplete average fertility
40–44	6.81
35–39	5.51
30–34	4.23
25–29	2.82
20–24	1.49
15–19	0.48

essentially completed their childbearing period, one may compute an annual age-specific fertility rate for each 5-year age group by dividing by 5 the age-specific fertility rates obtained previously (Table 12–2). One knows that, in a country such as Morocco, there remain very few spinsters at that age; one may therefore equate the number of ever-married women to the total number of women whatever their marital status.[19]

[19] Age-specific fertility *rates* or frequencies are ratios of births by age of mother to the number of females of *all* marital statuses, not only those ever-married.

TABLE 12–2 Age-specific fertility rates by 5-year age groups for cohorts aged 45–49 years at time of survey (Morocco, 1987)

Average age of age group, y	Age-specific fertility rate
15	0.0912
20	0.2540
25	0.3223
30	0.3273
35	0.2614
40	0.1663
45	0.0590

On the contrary, one may not compute similar age-specific fertility rates for the younger cohorts, as the younger these are, the greater the difference between the number of ever-married women and the number of women of all marital statuses will be.

Adding up the age-specific fertility rates for the cohort aged 45 to 49 at survey, and multiplying the result by 5, yields the average family size for these women at the end of their reproductive period (i.e., 7.4

TABLE 12–3 Average number of children by birth order (Morocco, 1987)

Birth order	Average number
1	0.94
2	0.92
3	0.90
4	0.84
5	0.79
6 and +	3.03

4	27.08
5	29.10
6 and +	34.76

children per ever-married woman). One may once again obtain from these rates the average age at childbearing (i.e., 28.88 years).

Similar tables and Lexis diagrams (not shown for reasons of space) can be obtained for births by birth order. Considering an open category of six children or more, one obtains (Table 12–3) for the cohort aged 45 to 49 at the time of the survey, the average number of children born by birth order, at the end of the childbearing period.

If one adds up these order-specific averages (i.e., 0.94 + 0.92 + . . . + 0.79 + 3.03), one obtains once again 7.4, the average number of children born (all birth orders) per ever-married woman.

One can also obtain the order-specific average ages at childbearing[20] (Table 12–4) by weighting the mid-interval exact age by the number of births (or the fertility rate) at each age.

One sees that as the birth order increases, the average number of children per woman falls while the average age at childbearing increases, a rather obvious fact. These average ages are obtained assuming that over each interval of time, births are centered on the exact age at the mid of the age group. This is a rather large assumption: for example, the average age at birth of the first child, obtained from the individual data, is actually equal to 20.0 years instead of 20.75 as calculated from the aggregate data. Average durations should therefore always be obtained from the individual birth histories themselves, when they are available, rather than from the aggregated data.

Going back to the average number of children by birth order (Table 12–3), one sees that 94% of the women[21] have had at least one child, and 92% at least two children; thus 94% − 92% = 2% have had only one child during their lifetime. These women are of parity one (or achieved family size) at the end of their childbearing period. The probability of moving from one child (at least) to two children (at least), also called the *parity progression ratio*, is therefore:

$$a_1 = 0.92/0.94 = 0.979$$

Similarly, 92% − 90% = 2% have had only two children (parity two), yielding a parity progression ratio of 90%/92% = 0.978. One thus obtains the distribution of women by parity, and the parity progression ratios for each birth order (the open category 6+ not included). The average number of children of birth order one (i.e., 0.94), can also be considered as the parity progression ratio from 0 to 1 child (at least). The complement 1 − 0.94 = 0.06 is equal to the proportion of women of parity zero, which is the proportion of infertile ever-married women at the end of their childbearing period. In the case of Morocco at that time, this proportion should be close to the percentage of sterile women as voluntary infertility was low (see Chapter 33).

One may also compute the age-specific fertility rates by birth order for the oldest age group (Table 12–5). Multiplied by five, the sum of these rates yields once again the average number of children by birth order already shown in Table 12–3.

Figure 12–2 illustrates these results for the first five birth orders. One observes that the fertility schedule shifts to the right on the graph as birth order increases because a birth of order n can only occur after a birth of order $n - 1$, as already seen from the average ages at childbearing by order in Table 12–4. One also observes that fertility decreases with birth order but in the case of Morocco at that time, still remains high for order five. Indeed, as shown in Table 12–5, fertility above rank five (i.e., 6+) leads to an average of 3.03 children to complete the total family size of 7.41 children per woman.

[20] It is also possible to obtain from these order-specific average ages the average childbearing age for all birth orders (Wunsch and Termote, 1978).

[21] The average number of children of order k is equal to the proportion of women having had at least k children.

TABLE 12–5 Fertility rates by 5-year age groups and birth order for cohorts aged 45–49 years at time of survey (Morocco, 1987)

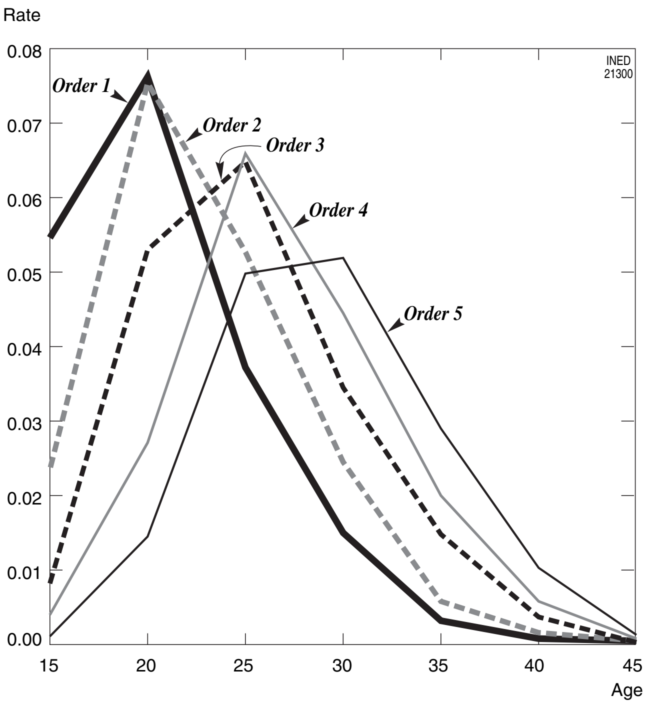

FIGURE 12–2 Fertility rates by age group and birth order. (Source: Morocco, 1987 DHS survey.)

To conclude this example, one can compare the 1987 survey data to those drawn from the 1992 survey. Comparisons are restricted to fertility of all birth orders, for lack of space. Figure 12–3 presents the data from 1992 similar to that shown in Figure 12–1. The number of ever- and never-married women (spinsters) are put on the *y*-axis (*ns* and *s*, respectively). One sees that as age increases, the number of spinsters (*s*) falls sharply; at higher ages, most women are ever-married.

Comparisons between 1987 and 1992 are restricted to ever-married women, for whom the data have been collected in both surveys. For the cohort aged 45 to 49 years in 1992, the ultimate family size (computed as before) is equal to 7.09 births per ever-married woman, while the average age at childbearing is 28.40 years. One observes a fall in family size from one survey to the other, from 7.41 to 7.09, and a slight reduction in the average age at childbearing (from 28.88 to 28.40), although statistical tests should be performed to determine if the differences are significant. Table 12–6 compares the complete or incomplete family sizes controlling for age at survey, between the 1987 and 1992 samples. Except for the first age group (15–19 years), one observes a decrease in the average number of children born in all the other age groups.

From the 1992 data, one may also compute the age-specific fertility rates by dividing in each age group the number of births by the total number of women, ever-married or not. One further divides these ratios by five to obtain rates per annum (Figure 12–4). Results are presented graphically in Figure 12–5. Although fertility is still incomplete in most cohorts, one observes a significant decline in fertility rates as one moves from the older cohorts to the more recent ones, indicating a fall in achieved family size and also most probably an increasing age at childbearing. One may also compare these results to the fertility rates previously obtained for the 45- to 49-year-old cohort in 1987.

If one had only compared the fertility schedules for those women aged 45 to 49 years at survey in 1992 and 1987, one would have noted only a very small and negligible decrease in fertility (Figure 12–6). Actually, from the 1992 data, this very recent decrease in fertility was only experienced by the younger birth cohorts.

Summing the fertility rates and multiplying by five, one obtains the average number of children born up to

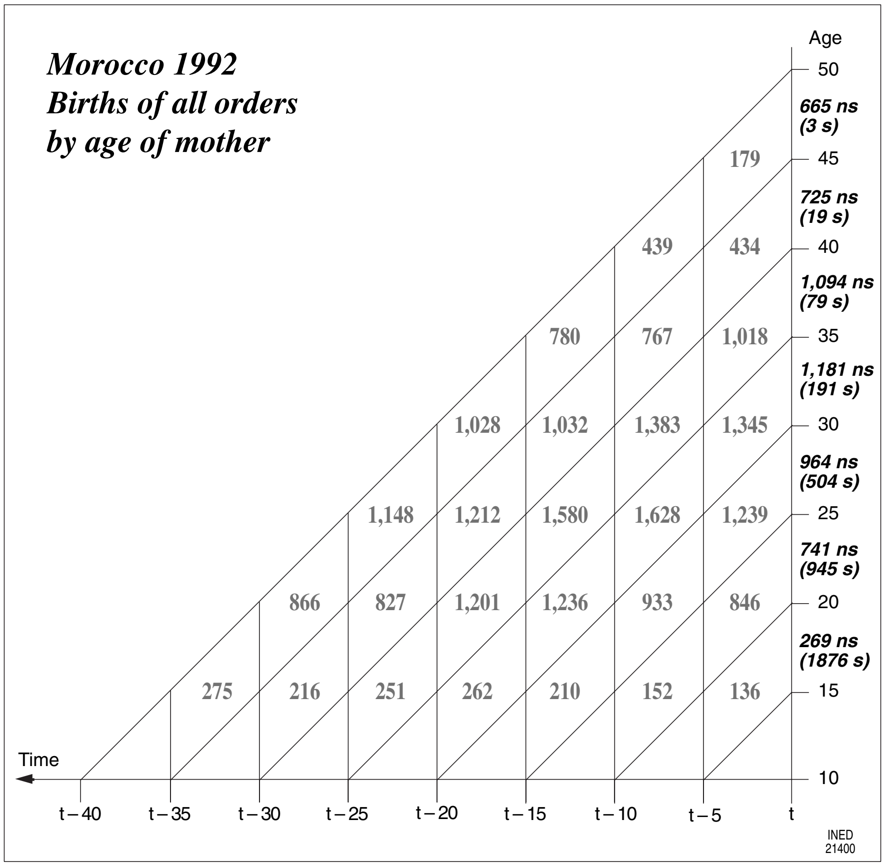

FIGURE 12–3 *Lexis diagram* representation of women and births by 5-year birth cohorts or 5-year age groups (vertical axis) and 5-year periods (horizontal axis), Moroccan Fertility Survey of 1992 (*t* indicates the time of interview, variable from one woman to another). (Source: DHS, Morocco, 1992)

a certain age. For example, one may compute this number at age 30 to 34 years for the various women interviewed in 1992 and older than 30 (Table 12–7). Once again, one sees the fall in fertility from the older to the younger cohorts.

Indicators computed from individual birth histories show an increase, from 20.00 to 20.21 years of age, in the average age at first birth for women aged 45 to 49 years in 1987 and 1992. This average age even reaches 21.08 for those women aged 30 to 34 years in 1992, considering that these women have more or less completed their fertility of birth order one at that age.

One may also compute from individual birth histories the proportion of women still infertile at ages 20 to 24, for those women aged respectively 20 to 24, 30 to 34, and 45 to 49 years at the time of the 1992 survey, 23.6%, 22.7%, and 20.8%, respectively. This confirms the fact, already noted, that the younger cohorts in Morocco are having their children later than the older ones.

II. COHORT FERTILITY FROM VITAL REGISTRATION DATA

Suppose now, for a given birth cohort, that births by age of mother are recorded by the vital (civil) registration system, and that the number of women by age in this birth cohort are estimated for each January 1.[22] As seen in Chapter 8, one may then compute age-specific fertility *rates* by dividing the number of births B_x borne by women of this given birth cohort at age x by the mid-period number of females F_x in this cohort still alive and present at that age. The fertility rates f_x at ages x, taken as the ratios B_x/F_x, will be equal to the rates obtained in retrospective analysis if women interviewed at the end of their reproductive period are not selected for their fertility.

Once again, the average family size will be obtained by summing the age-specific fertility rates over the

[22] These estimates are usually based on past census results.

[a] Age reached during the year. (Source: INSEE)

whole reproductive period, and the average age at childbearing can be computed by weighting each age at birth by the fertility rate at that age. One may also have recourse to births classified by age groups. Examples are given in demographic textbooks (see for example, Pressat, 1983; Wunsch and Termote, 1978).

For example, the Belgian birth cohort born in 1959 has given birth to 7494 children during the year 1990, 3841 births at completed age 30 and 3653 at completed age 31. The mid-period female population (on June 30, 1990) is estimated to be 78,663. The fertility rate at that age is then equal to 7494/78,663 = 0.09527 at exact age 31 on average. Similarly, if data on births and number of females are available each year (and this is not the case with the data published in Belgium), one may compute the fertility rates at each age for the whole reproductive period, for the cohort born in 1959. The sum of these rates over the reproductive life span will give the average number of births per woman in the absence of mortality and migration, if the latter have not selected women with higher or lower fertility than those remaining in the population.

Table 12–8 and Figure 12–7 present the fertility rates by age for the French birth cohort born in 1931, according to each year of observation from 1946 to 1981. The sum of these age-specific fertility rates, from ages 15 to 50, yields the completed family size for this birth cohort (i.e., 2611.3 births per 1000 females or 2.6 births per woman). The average age at childbearing is obtained as usual, by weighting the ages by the corresponding age-specific fertility rates:

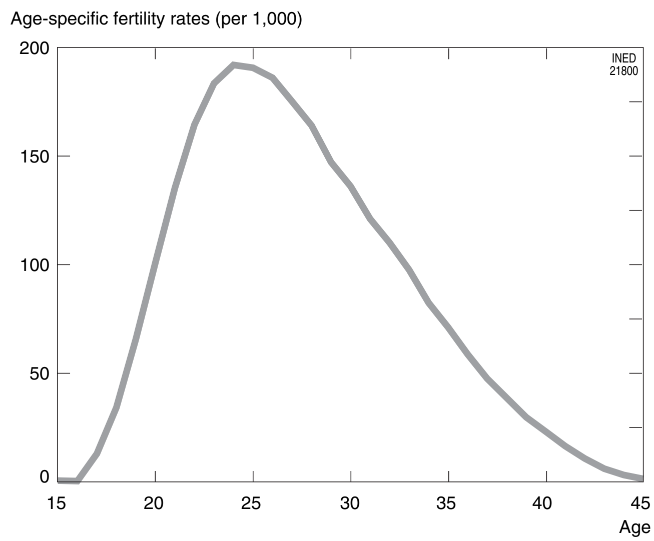

FIGURE 12–7 Age-specific fertility rates of French females born in 1931.

$$15 \times 0.6 + 16 \times 0.4 + \ldots + 49 \times 0.1 + 50 \times 0.1$$

and by dividing the result by the sum of the rates, yielding:

71,628.1/2,611.3 = 27.43 years

In this approach, the fertility rates can also be computed by birth order, say $f_x(k)$ for birth order k, data drawn from the birth certificates being taken as numerator and female population estimates as denominator. The sum over x of these fertility rates by order $\Sigma_x f_x(k)$ is equal to the average family size by order: $TF(1)$, $TF(2)$, . . . Once again one has

$$TF(\text{all orders}) = TF(1) + TF(2) + \ldots + TF(k) \ldots$$

and as shown previously the parity progression ratios can be obtained from these average numbers of children by order:

$$a_0 = TF(1)/1$$

$$a_1 = TF(2)/TF(1)$$

$$a_2 = TF(3)/TF(2)$$

$$\ldots$$

$$a_k = TF(k+1)/TF(k)$$

$$\ldots$$

The average ages at childbearing for births of all orders or by birth order are once again obtained by the weighted average of ages at childbearing, for example, for all orders:

$$\bar{x} = \frac{\sum_x x f_x}{\sum_x f_x}$$

and by order:

$$\bar{x}(1) = \frac{\sum_x x f_x(1)}{\sum_x f_x(1)}, \bar{x}(2) = \frac{\sum_x x f_x(2)}{\sum_x f_x(2)} \ldots . \bar{x}(k) = \frac{\sum_x x f_x(k)}{\sum_x f_x(k)}$$

If births by age are made available between *exact* ages 15 and 16, *exact* ages 16 and 17, . . . and so forth, the values of x will be the exact ages 15.5, 16.5, and so forth. If births are available between *completed* ages 15 and 16, *completed* ages 16 and 17, and so forth, the values of x will be 16, 17, . . . , and so forth in exact ages. Finally, other measures of the tempo of fertility can be computed, such as the variance of ages for all birth orders or by birth order.

III. FERTILITY BY MARRIAGE COHORTS

In many populations, fertility is mainly the fact of married couples, whatever the type of *marriage* (civil, religious, common law, etc.). This issue will be dealt with again in Section 2 in this volume, devoted to the determinants of fertility.[23] In addition to age, it is then useful to classify the retrospective survey data according to duration of marriage, as the latter is a proxy for the number of children born. Taking sufficiently high marriage duration, say 20 or 25 years of marriage, one can then compute the average number of children (all orders and by order[24]) per marriage as a measure of the quantum of marital fertility, and the average duration of marriage at childbearing as a measure of its tempo. One can also compute the average interval between marriage and first birth and the average intervals between successive births for this marriage cohort. If marriage-duration—specific fertility *rates* (frequencies) can be derived from vital statistics,[25] similar measures of average family size by marriage cohort and of average duration of marriage at childbearing can also be obtained in a prospective cohort approach. In both prospective and retrospective approaches, parity progression ratios by marriage cohort can also be computed. One may also compute the incomplete family sizes at lower durations of marriage. The approach is quite similar to that adopted in the previous section, marriage duration being taken into account instead of age.

The Moroccan survey data on births by ever-married women, considered previously, can be cross-classified according to *marriage duration* and *period* for those women in their first marriage at the time of the surveys. Considering that few women give birth to a child after 20 to 25 years of first marriage duration, one obtains an ultimate family size per first married woman of 7.05 in 1987 and 6.84 in 1992, and an average duration of first marriage at birth of the children of 10.02 and 9.48 years, following the same methods of calculation as those described for the birth cohorts. One can also compute the family size at shorter marriage durations for the cohorts interviewed in 1987 and 1992. The results are presented in Table 12–9. One observes once again, this time by marriage cohort, the fall in fertility already seen from the data by birth cohorts.

However, the elimination of age in favor of marriage duration alone does raise some problems. First, among the number of marriages observed after, for example, 25 years' duration, some were concluded at

[23] See in particular, Chapters 25 and 26 on family formation and dissolution, Chapter 28 on the determinants of marriage formation, and Chapter 29 on marital and extramarital fertility.

[24] Birth orders are defined here within marriage.

[25] This requires that births within marriage be registered according to the date of (last) marriage. Usually, the population of the marriage cohort surviving death and migration is not known, and the initial number of marriages is used instead as the denominator of the marriage-duration–specific fertility *rate* (frequency).

TABLE 12–9 Average number of children by marriage duration (Morocco, 1987 and 1992)

Marriage duration at survey	Survey	
	1987	1992
0–4	0.86	0.80
5–9	2.63	2.42
10–14	4.19	4.05
15–19	5.73	5.34
20–24	7.05	6.84

postreproductive ages, especially if remarriages are taken into account. As these marriages do not contribute to fertility, they should be excluded from the data set. Second, the average number of children at duration 25 is biased due to overrepresentation of women who have married at young ages, because these women have a greater chance of still being alive after 25 years of marriage than those who have married at older ages due to the decrease in the probability of survival with increasing age. A woman married at 15 years of age and having a marriage duration of 25 years is more likely to survive than a woman married at 33 and having the same duration of marriage, especially if mortality is high.

The bias is nevertheless easily corrected as follows. Having computed the average family sizes at 25 years' marriage duration TF_x for women marrying at various ages x, the corrected average number of children for the whole marriage cohort is obtained by the weighted average:

$$TF = \frac{\sum F_x TF_x}{\sum F_x}$$

where F_x represents the number of females marrying at age x derived from the vital statistics data at the time of marriage (i.e., 25 years ago), if these data are available. Finally, if the fertility survey restricts the interviews to married women of fertile ages only (from 15 to 50 for example), women of 25 years of marriage duration have all married before age 25, as the sample is confined to women currently aged under 50. Once again, women marrying young are therefore overrepresented due to the sampling procedure this time.

It is therefore necessary to take both age and duration of marriage into account to avoid some of these biases. One then computes the average number of children for females married at age x and having a marriage duration of y, interviewed at age $x + y$. One can also calculate for these subcohorts the average duration of marriage at childbearing and therefore their age at childbearing and the various parity progression ratios for these subcohorts. In temporal or spatial comparisons, this approach has the advantage of showing differences in the *marriage-mix* (i.e., the variations in the proportions of females marrying at specific ages). Another useful measure of the tempo of fertility is the age at *last confinement* in the subcohorts of marriages according to age at marriage; this age usually decreases when fertility starts falling in a high-fertility population. Once again, censoring hampers the analysis however, due to the cutoff survey date, as in the case of birth cohorts. These issues and others will be examined in Chapter 29 devoted to fertility in and outside marriage.

Cohabitation

As discussed in Section 1, nonmarital cohabitation has become more common in the developed countries, and data by marriage duration cannot take this factor into account. In addition, birth of children to cohabitating couples is becoming more common. It is useful, as an indicator of this trend, to compute the ratio of extramarital births as a percentage of all live births for the various birth cohorts considered in a survey. If questions on cohabitation and its duration have been asked in a survey or a census, one may tabulate births according to the partnership status of respondents at the time of the survey (e.g., marriage, consensual union, not in any partnership) and analyze fertility according to duration of cohabitation. It must be remembered, however, that consensual unions tend to break up easily. The full partnership history of the respondent must be obtained to ensure a good description of the fertility history of each person not limited to the partnership status at the time of the survey. For a thorough discussion of the definition and measure of cohabitation, see Toulemon (1996) and Chapter 29.

IV. FERTILITY BY PARITY COHORTS

Parity cohorts are defined by the fact that all women of the cohort have reached a specific parity during the same interval of time. For example, parity cohort 4 of 1960 represents the cohort of women who have borne their fourth child during the year 1960. In general, parity cohort k of 1960 relates to the number of women reaching parity k during the year. By definition, parity cohort 0 of 1960 is taken either as the number of women born or marrying during this year (i.e., the birth or marriage cohort of 1960). Birth histories can therefore be tabulated according to the time of occurrence of births of order k. Consider all those women who have had their first, second, third, . . . kth . . . birth in 1960 (i.e., the parity $k[k \geq 1]$) cohorts of 1960. If the survey is held in 1998, all these women are of postreproductive ages. Among those women who have had k births in 1960, some will have a birth of order $k + 1$ (or more) after that period, and others will have no more children. Let F_{k+1} and F_k stand for these two groups of women. Then the ratio $a_k = F_{k+1}/(F_k + F_{k+1})$ represents the quantum of fertility (in this case the *parity progression ratio*) for this parity cohort (i.e., the proportion of women having another child). The parity progression ratio a_0 for those born or married in 1960 (parity cohort 0) represents the proportion having at least one child. The complement to unity $1 - a_0$ is therefore equal to the proportion of childless females in this cohort (i.e., the percentage of infertile [although not necessarily infecund[26]] women).

For each of these parity cohorts, one can also compute the average time elapsed between births of order k and $k + 1$. For this sole purpose, one usually restricts the analysis to *fertile pregnancies* (i.e., pregnancies ending in one or more live births). This avoids having to deal with near-zero length intervals in the case of multiple births: The latter are coded one fertile pregnancy for the calculation of the interval. This measure of the tempo of fertility of the parity cohorts is equal to the birth interval between birth orders k and $k + 1$ for the parity cohort k of 1960. One can then compare the quantum and tempo of fertility of parity cohorts k for different years, say cohort 1960 compared to cohort 1955, meaning the differences in parity progression ratios a_k and in birth intervals k to $k + 1$.

Once again, birth intervals should be compared for women of the same ultimate fertility at the end of their reproductive period. As high-parity women usually have shorter birth intervals than lower parity females, birth intervals should be compared only for women of the same parity (e.g., the same ultimate family size). If one does not observe this rule, birth intervals seem to decrease with the order of birth, in high-fertility populations, which is not the case in fact. Indeed, the last birth intervals are usually longer than the others, for women of the same ultimate parity, due to decreasing fecundity with age. This erroneous conclusion stems from the fact that birth intervals of higher order are obviously computed for high-parity women only (i.e., families with short overall birth intervals). Another problem arises when computing the average interval between marriage and first birth. This interval is often influenced by the impact of premarital conception. In the absence of information on premarital conception, an approximate solution is to retain only those births born after 8 or 9 months of marriage.

The same sort of measures can also be obtained in a *prospective* cohort approach if births $B(k)$ of order k are registered each year by duration elapsed since the previous birth of order $k - 1$. Birth order may refer to all births borne by a woman during her lifetime or to births born in the current marriage only (first marriage or remarriage). The first option is better because it takes into account the full fertility history of the woman. In comparative studies, care must be taken to ensure that the same definition of birth order is used in all comparisons. For births of order $k = 1$, birth order 0 will be defined once again as the event-origin of the birth or marriage cohort of women, according to that observed. If this registration is available from vital statistics, and such is the case in several countries where the birth certificate contains the necessary questions, it is possible to study longitudinal cohort fertility trends by birth order, according to the interval elapsed since the preceding birth. Let $B(k)_i$ represent the number of live births of order k recorded during a year D at average duration i elapsed since birth $B(k - 1)$ borne by women during year A. The number of births $B(k - 1)$ born during year A corresponds to the number of women reaching parity $k - 1$ during year A, (i.e., to the parity cohort $k - 1$ of year A).

The *birth-interval–specific fertility rate* (frequency) computed for this parity cohort at average duration i is then obtained by dividing the number of births $B(k)_i$ observed at this duration by the number of survivors of the parity cohort. The number of survivors being usually unknown, except possibly for countries with a population register, one divides the number of births of order k by the *initial* population of the parity cohort, equal in this case to the number of births $B(k - 1)$ born during year A, due to the correspondence between order of birth and parity of mother. In general, one therefore computes the ratio:

$$f(k)_i = B(k)_i / B(k - 1)$$

This approximate frequency usually underestimates the true frequency, as the initial population number taken as denominator is generally greater than the actual but unknown population of survivors. Taking the sum of fertility frequencies (parity-specific fertility *rates*) $\Sigma_i f(k)_i$ leads to the average quantum of fertility in this parity cohort, that is to the average number of births of order k per woman of parity $k - 1$. This sum is therefore equal to the *parity progression ratio* for each particular parity cohort (i.e., the frequency of moving from parity $k - 1$ to parity k). This measure will be

[26] An *infertile* woman (i.e. having no children) is not necessarily *sterile*. See Chapters 30 and 33 on the biologic factors of fertility.

[a] or parity, from the mother's viewpoint. (Source: Ryder, 1982)

denoted by the usual symbol a_{k-1}. As to the average duration:

$$\frac{\sum_i i \cdot f(k)_i}{\sum_i f(k)_i}$$

it represents the *average birth interval* in the parity cohort between births of orders $k - 1$ and k. Finally, as with all rates (frequencies), partial intensities of fertility $\sum_{i=0}^{i} f(k)_i$ may also be computed for segmented parity cohorts, indicating the cumulated fertility up to a certain time interval j elapsed since birth of order $k - 1$.

V. FERTILITY BY AGE, MARRIAGE DURATION, AND BIRTH INTERVAL

A thorough analysis of fertility should take account of age, time elapsed since last birth, and marriage duration. However, when using survey data on ever-married women aged 15 to 50 years at time of survey, Ryder (1982) has argued convincingly to drop marriage duration from the analysis, as marriage duration is mainly a proxy of achieved parity, and therefore code the birth cohort, the period of occurrence of marriage (*parity 0*), and the period of occurrence of each birth. Consider for example women aged 45 to 50 at the time of a survey. Number the 5-year age groups 15 to 20, 20 to 25, and so forth in this birth cohort from 0 to 6, and do the same for the calendar periods before the survey. With this recoding, one has age group 15 to 20 equals 0, age group 20 to 25 equals 1, and so forth. Moreover, the 5 years before the survey receive the period code 0, the previous 5 years the period code 1, and so forth. One can then produce a table giving the classification of births by order, for birth cohort number 6 (i.e., women aged 45 to 50), according to the duration in period difference elapsed since the previous birth, marriage[27] being taken as parity 0.

Table 12–10, derived from Ryder (1982), presents illustrative survey data for parity 0 (marriage) and parity 1; similar tables can be drawn for higher parities. One sees that birth cohort $c = 6$ is composed in this example of 954 married women. Of these, 200 married

[27] If one considers instead all women whatever their marital status, birth time of the mother can be taken as parity 0. The first birth interval between order 0 and order 1 is therefore equal to mother's age at first birth.

during period 6, 608 during period 5, and so forth. For the 200 women married during period 6, 62 have given birth to their first child during the same period, 120 during period 5, and 18 during period 4. Similarly, among the 608 women married during period 5, 162 gave birth to their first child during period 5, 358 during period 4, and 58 during period 3, and so on. Therefore, in this birth cohort, one observes 62 first births during period 6, 282 during period 5, and so forth. These figures are then taken as the number of women reaching parity 1 during period 6, and giving birth to their second child during period 6 (20 births), during period 5 (34 births), during period 4 (5 births), and so on.

From this table, one can compute the parity progression ratios. For a_0, one has for the whole cohort

$$a_0 = 895/954 = 0.938$$

However, a_0 varies according to age at marriage, as one can see by computing this parity progression ratio in the various subgroups classified according to the time of their marriage. The following parity progression ratios are obtained:

$$a_0(6) = 200/200 = 1.000$$

$$a_0(5) = 578/608 = 0.951$$

$$a_0(4) = 87/96 = 0.906$$

$$a_0(3) = 21/29 = 0.724$$

$$a_0(2) = 7/13 = 0.538$$

$$a_0(1) = 2/6 = 0.333$$

$$a_0(0) = 0/2 = 0.000$$

One notices that, as age at marriage increases, the parity progression ratios decrease. A similar calculation can be made for a_1. The overall parity progression ratio is equal to

$$a_1 = 747/895 = 0.835$$

and the values for the subgroups are equal to

$$a_1(6) = 59/62 = 0.952$$

$$a_1(5) = 254/282 = 0.901$$

$$\ldots$$

$$a_1(0) = 0/2 = 0.000$$

Once again, fertility decreases as the age at which parity 1 is attained increases. The small numbers involved in this case, influences results, and statistical tests should be made in comparative studies. Nevertheless, the trend in the parity progression ratios is quite obvious.

One may also calculate tempo measures from the data in Table 12–10. For parity 0, for example, the first child is born in all subgroups according to age at marriage at the modal duration one in period difference. In this case, the result is, however, not very interesting, as the 5-year period is so large that the measure is meaningless. One should compute instead the average birth interval from the individual data on the basis of the exact dates of marriage and first birth. The same can be said for the birth intervals 1 to 2, 2 to 3, and so forth.

Other measures of the quantum of fertility can also be computed, such as the *parity progression probabilities* by duration. Going back to Table 12–10 for parity $k = 0$, one sees that out of the 200 women married during period 6, 62 had their first birth during the same period. The probability of giving birth to a first child during duration 0, in period difference, is thus $b_0(1) = 62/200 = 0.310$. At duration 1 in period difference, the probability will be $b_1(1) = 120/(200 - 62) = 0.870$, and at duration 2 (i.e., 6 – 4) one has $b_2(1) = 18/(200 - 120 - 62) = 1.000$. One observes that in the present case

$$a_0 = 1 - (1 - b_0(1))(1 - b_1(1))(1 - b_2(1)) = 1.000$$

Parity progression *probabilities* can therefore be computed at each duration elapsed since the previous birth, with parity 0 being in this example the date of marriage, for all the values of k and j (i.e., for all parities k and periods j of occurrence of birth order k). The parity progression *ratio* is then equal to the complement to one of the products of the complements of the parity progression *probabilities.*

If the sample is small, one may group together all the women (whatever their birth cohort) having a child of order k during a specific period i into a parity cohort without reference to age, as was also the case with vital statistics data. One loses the information on age but one gains in having greater group sizes. Once again, care must be taken to avoid inadequate comparisons. As there is censoring due to the survey date, the fertility of the parity cohorts constituted during periods 3 and 2, for example, may only be compared until duration 2 in completed duration, at the time of the survey. As in the previous situation where age was also taken into account, one may compute parity progression probabilities $b_i(k + 1)$ of reaching parity $k + 1$ at duration i elapsed since the birth of order k. Because birth intervals greater than 10 years are relatively rare, Rodriguez and Hobcraft (1980; see also Brass, 1996) have proposed to use the *partial quantum* after 5 years (or 60 months) as a measure of the fertility of the parity cohort due to the high degree of association between this partial quantum and the complete parity progression ratio. If parity progression probabilities have been computed over a 10-year period, one has

$$a_k \cong 1 - \Pi_i(1 - b_i(k + 1))$$

for i varying from 0 to 9 in completed years. The partial quantum after 5 years (noted B_{60} by Rodriguez and Hobcraft, 1980) would then be equal to $1 - \Pi_i(1 - b_i(k + 1))$, with $i = 0$ to $i = 4$.

In this approach, one mixes age and marriage durations in each parity cohort. Fertility differences between two cohorts of parity k could therefore be due only to differences in the age or marital composition of the parity cohorts. It is probable, however, that this bias is relatively small, especially if births of order $k + 1$ are borne from women having the same age. Computation of parity-specific fertility may also be made for subgroups specific for various explanatory variables, such as education, occupation, and so forth. However, if multiple classifications are used, the size of the subgroups will become very small and the fertility indices will tend to behave erratically. Event-history analysis such as the Cox-type methods (see Chapter 23) applied to the individual data, should here be preferred.

Open and Closed Birth Intervals

When dates of birth are given, it is easy to compute birth intervals by birth order, commonly designated by the order of birth that terminates the interval (Hinde, 1998). For example, the first birth interval is the segment of time between marriage and first birth. Some demographers number the interval instead by the order of birth that opens the interval (Newell, 1988). The first birth interval would, in this case, be the time between the first and second births. It should be stressed that birth intervals may only be calculated for all *closed* intervals (i.e., those terminated by a live birth). In interview data, one may also take account at reproductive ages, of *open* intervals censored by the date of the interview. It can be shown that open intervals straddling the survey date, which will eventually be closed, are on the average longer than those that have been closed before this date (Henry, 1972). One cannot therefore estimate from these sole open intervals the average closed interval. Furthermore, the average of the sole closed intervals for women who have not yet achieved their total family size will underestimate the true overall length of the interval. One must also take into account the fact that some of the women with an open interval will never close this interval, as they will not proceed to having another birth. In this respect, when using open intervals, it is therefore useful to control for age and parity, as these influence the length of the interval. More generally, one may wish to determine the effect of different factors, such as the use of contraception or the level of education, on the probability of closing the interval (i.e., of moving to the next parity). Proportional hazard models, or other forms of event-history analysis, can be used for this purpose (Hinde, 1998).

Finally, the last closed interval and the open interval have sometimes been used as measures of period fertility, in view of examining the impact of birth control on recent fertility trends in less developed countries (Srinivasan, 1980). It is interesting to note that at a particular point in time, the distribution of women according to the length of the open birth interval is similar to a population age structure, except that in the latter case all *open* intervals (ages) will eventually be closed by death. This is not the case in a birth interval structure, as some of the females will never close the interval (i.e., move on to a higher parity). Nevertheless, the similarity between the age and the birth interval structures has been used by several demographers, including Henry, Pressat, Feeney, and Ross, to compare open and closed birth intervals. If fertility is stationary, it can be shown furthermore that the average of all intervals *closing during a specified period* before the survey is equal to the average overall interval. This result is similar to the fact that if mortality is stationary, the average age at death of those individuals dying during the past year is equal to the expectation of life at birth (Leridon and Toulemon, 1997).

Cohort Approach to External Migration Flows

GRAZIELLA CASELLI AND JACQUES VALLIN

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

Institut national d'études démographiques (INED), Paris, France

For a birth cohort, emigration represents an outflow from the cohort. By contrast, immigration is an event of external origin that, by definition, cannot be included in a cohort approach in the strict sense, as it is determined by the behavior of a group of individuals who do not belong to the initial population (Santini, 1992). There is only one situation in which immigration can be regarded as an event that effectively concerns the entire cohort: this is when the study focuses on the internal migrations of a closed population (i.e., without external migrations), where emigration and immigration are simply each other's opposites (immigration to one region consisting of emigration from the other regions). But that is not our purpose here, because at this point we want to examine the role of migration in the overall dynamics of a population.

In classic analysis, however, immigration is regarded as a birth of sorts, with the individual entering the population studied at an age x different from zero; likewise, emigration is, in practice, equated with an early death, since the individual leaves the population studied. Instead of being strictly defined as a set of persons born in the same year in the same territory, the cohort becomes a set of persons born in the same year and living, at the age of observation, in the same territory. On these definitions, the construction of migration indicators becomes far simpler (admittedly, owing to the very special nature of immigration, this expedient is entirely debatable). Even more so than the previously formulated hypotheses on the independence of phenomena (for example, mortality and migration, or fertility, mortality, and migration), the hypothesis of an event that is totally exogenous but just as independent of the structure and dynamics of the initial population lacks credibility. How can one postulate the neutrality of the initial context or the population's unrestricted capacity to export migrants? We should also add that, in practice, because of the shortage of available data, we must often make do with an analysis of net migration, which ignores these issues altogether.

The gathering of information on external migration flows and their characteristics is indeed, almost always, the first and biggest problem. As already discussed in Chapter 4, few countries maintain population registers; even when a register does exist—as in Italy—it is not uncommon for large numbers of migrations to go unrecorded. The problem is particularly acute for immigration, as a large share of inflows occur clandestinely, and legal immigrants sometimes represent only a marginal share of the real total.

Just as a population's natural dynamics depend on the balance between births and deaths, so the migration dynamics are shaped by the difference between inflows and outflows. Obviously, we must be careful to record the direction in which the flows occur (i.e., to subtract departures and add arrivals). We will begin by adopting this method to measure the propensities to emigrate and the propensities to welcome immigrants that can influence the population's dynamics.

But this is not the most interesting approach for the study of mobility itself. What is actually more important is to measure the total intensity of flows in either direction in the course of each individual path. While this approach to migration is not directly applicable to the analysis of population dynamics, we believe it is essential to provide a broad outline here. This will enable us to refer to the approach in the chapters on mobility factors at the end of this volume (Chapters 22 and 23) and—more significantly—in Volume 2 on the determinants of migration.

As a first step, however, let us briefly describe the available data.

I. THE DATA CONSTRAINT

The data situations may be radically different and seldom ideal, and each may require a different approach. Let us rehearse the main possibilities before reviewing the existing methods.

1. Population Registers

As emphasized in the Introduction, the cohort approach can be fully developed when the quality of the population registers available is sufficient to provide a nearly complete record of individual movements and their characteristics. If the system has been operating for a long time, this type of registration enables us to follow each individual's complete sequence of inflows and outflows, from birth or from his or her first entry into the geographic area. If at a given moment in his or her life (for example, when looking for work), a person decides to emigrate, he or she will be deleted from his or her cohort population. If the person returns later (for example to work in the country again or to retire there), he or she will be added to the total again after having been enumerated as an immigrant. This roundtrip can obviously be repeated several times in a lifetime, giving rise to a sequence of multiple migrations. Obviously, other individuals from other geographic areas, but born in the same year as the cohort studied, may swell the ranks of that cohort.

Such information—alas seldom available—makes it possible to construct migration rates or probabilities of migrating for each birth cohort. The indicators may cover either all migrations observed in the cohort, or inflows and outflows separately. In any event, of course, we can only examine the frequency of movements observed relative to the size of the cohort studied. The indicator will be of debatable significance in the case of inflows, because the denominator will consist of a population that is not the source of the events (unless we are dealing with the return of an individual born in the geographic area). However, although immigration is an exogenous event for the population of arrival, it does constitute a fundamental element in the dynamics of any open population. Like emigration or mortality, it contributes to the change in the cohort's size as it ages.

The information gathered from the population registers not only lends itself easily to a classic analysis of flows. It can also provide a sometimes-abundant database for analyzing the interactions between demographic phenomena as well as the determinants of these phenomena, through the succession of the events that form individual histories such as marriage, divorce, widowhood, parenthood, and working career. This usefulness will be illustrated again in later chapters (particularly Chapters 23 and 24) discussing interactions between demographic phenomena and their determinants.

2. Prospective and Retrospective Surveys

We can try to offset the lack of comprehensive current statistics by performing selective sample surveys. There are two possibilities: *follow-up* (or *prospective*) surveys and *retrospective* surveys. Follow-up surveys are based on a sample of individuals taken at birth or at a given age, initially observed at a given date, then monitored by means of successive interviews at regular intervals. With such a sample, however, we can track departures only; by definition, arrivals do not form part of the initial cohort. If, instead of a sample of individuals, we have selected a sample of geographic areas, we can add new entrants to the initial cohort as they arrive, provided that they have experienced the cohort's constitutive event (e.g., birth, for a birth cohort) at the same date as the initial population. This approach, whose principle is fairly similar to that of a population register, has been used in several studies of countries without registers and subject to large departure flows.

As a rule, prospective surveys are conducted over a limited period of time only. In that case, the information gathered is confined to specific life segments between the time of sample selection and the final interview. Another drawback of follow-up surveys is that outflows followed by a return between two interviews may go unobserved.

The second alternative is a *retrospective* survey in which a sample of individuals is interviewed about its past migrations. By choosing a cohort that has reached a reasonably old age at the time of the survey, we can obtain a fairly long-term picture of the cohort's life. Again, however, we are faced with a series of problems that are not readily solved. The first is that retrospective surveys cannot tell us about departures, unless they have been followed by a return in the meantime (admittedly, arrivals are far easier to measure than in prospective surveys, as retrospective surveys can only cover individuals present at the end of the chosen time frame). Second, because of the length of the retrospective observation period, neglecting hypotheses on independence between phenomena and on population homogeneity (Chapter 9) may create serious difficulties. We assume that the persons who could not be interviewed because they have died or emigrated would have had the same migration behavior as those present at the time of the survey (independence hypothesis). We also assume that the outflows from the observation field do not alter the average status of the remaining population (homogeneity hypothesis). Although tolerable over short periods, such hypotheses may well become unacceptable over so long a period. Moreover, the information gathered in these surveys depends largely on respondents' cooperation and memory, and is often vulnerable to major observation errors.

Yet, despite all these shortcomings, the retrospective survey is generally preferred to a prospective survey because it is much cheaper, far quicker to perform, and capable of producing results immediately—as against the many years required by the prospective method.

Many retrospective surveys have been carried out in recent decades, and they have served as a basis for the main methodologic developments in the cohort analysis of migrations (Courgeau 1973, 1980, 1984, 1985a, 1985b, and 1988; Piché *et al*., 1984; Piché, 1990; Riandey, 1988; Bottai, 1990). Among the most innovative studies are the developments in the analysis of individual biographies (Courgeau and Lelièvre, 1989), discussed in Chapter 23.

3. Contribution of Censuses

Many censuses include a few questions on migrations. The three most typical items of information collected are place of birth, place of residence at a given date prior to the census, and date of last migration. With these items, we can reconstruct at least a portion of a cohort's migration history. Naturally, at the overall national level, the census questions only allow a tracking of arrivals. However, if the population studied is that of a particular region, we will also capture emigrants through the results obtained in all the other regions. The place-of-birth question gives us a record of only one migration per individual, with no guarantee of identifying all those who have migrated at least once in their lives, since some may have returned to their birthplaces after a stay elsewhere. If the question is supplemented by others on place of residence at one or more precensus dates, the information will be somewhat fuller, but will inevitably remain very incomplete. In any event, we are still faced with the above-mentioned risks inherent in retrospective surveys. The risk of observation error, in particular, is great because the census is a comprehensive operation carried out quickly and cheaply.

4. Intercensal Net Migration

Censuses, combined with civil-registration data, offer another possibility: the reconstruction of intercensal net migration. If we know the population by year of birth (or, failing that, by age) in two successive censuses, and if we have annual statistics of births and deaths by year of birth (or, failing that, by age), we can deduce the overall net migration for each cohort in the intercensal period. This approach, of course, will give us a very limited view of migrations, since it is only a balance: inflows and outflows cannot be measured separately. Yet, for countries that lack population registers, this is practically the only way to estimate net external migration—so much so that it features prominently in most demographic-analysis manuals.

If we do not have an annual breakdown of deaths by year of birth (or age), we can obtain an approximate result by means of a fairly cumbersome procedure based on life tables showing the presumed mortality of the cohorts studied. This procedure is emphasized in many manuals of demographic analysis (Wunsch and Termote, 1978; Livi Bacci, 1981).

II. AGE-SPECIFIC INFLOW AND OUTFLOW RATES

If we have a systematic record of migrations at our disposal and if the system is sufficiently reliable, we can monitor a cohort using the same approach as in the study of mortality and fertility: if we have figures for the cohort's size and the migration inflows and outflows each year, we can compute immigration and emigration rates.

Like maternity, migration is a renewable event. The same person can migrate several times. However, when analyzing migration dynamics, we must count inflows and outflows separately. Now a single individual cannot leave a second time unless he or she has returned (i.e., unless he or she has made an initial entry), and the ranking of movements in one direction depends entirely on the ranking of movements in the other. As we cannot amalgamate inflows and outflows here, we will save the opportunities for analysis offered by ranking for the overall study of intracohort mobility (Chapter 22). For the moment, we confine our analysis to migration regardless of rank.

As with fertility and mortality, the usable rates are the type 3 rates (Lexis parallelograms between birthdays) if we have a breakdown of migrations by age and year of birth or the type 2 rates (prospective parallelograms) if the statistics are given by year of birth and year of observation (see Chapter 6 and subsequent

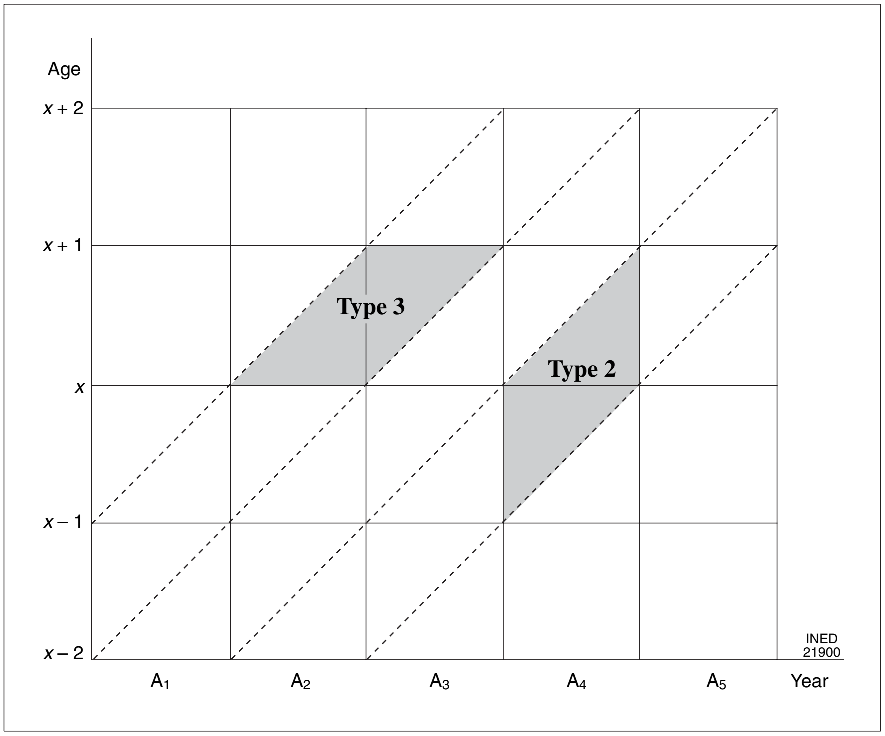

FIGURE 13–1 Representation on a Lexis diagram of the elements needed to compute an age-specific emigration or immigration rate in a cohort.

chapters for different types of rate). But, as in the study of mortality, if we use the type 2 rates, we will have to solve the special problem posed by the first year of age, which straddles an initial Lexis triangle and the first prospective parallelogram (Figure 13–1).

Let D_x^i, I_x^i, and E_x^i be the deaths, inflows, and outflows for cohort i at age x, and P_x^i the number of cohort individuals aged x. The type 3 rate of emigration e_x^i between the exact ages x and $x + 1$ is equal to:

$$e_x^i = \frac{E_x^i}{P_x^i + \frac{1}{2}(D_x^i - I_x^i + E_x^i)} = \frac{E_x^i}{0.5(P_x^i + P_{x+1}^i)}$$

With broader age groups, of n years, the rate is equal to:

$${}_ne_x^i = \frac{E_{x,x+n}^i}{0.5(P_{x,x+n}^i + P_{(x+1),(x+n+1)}^i)}$$

In most cases, however, we calculate type 2 rates. Let $E_{x,x+1}^i$ be the outflows from cohort i at age $(x,x + 1)$ in year t and $P_{x,t}^i$ the number of cohort individuals of age x on January 1 of year t. The emigration rate e_x^i is equal to:

$$e_x^i = \frac{E_{x,x+1}^i}{0.5(P_{(x-1),t}^i + P_{x,t}^i)}$$

Subject to all the reservations expressed earlier on such rates, we can also compute age-specific immigration rates i_x^i in the same manner.

We will accordingly obtain complete series of age-specific emigration or immigration rates for a cohort. We can sum these rates to obtain a synthetic indicator of propensities to depart (EF) and to arrive (IF). ("EF" and "IF" stand for emigration flow and immigration flow, respectively.)

$$EF^i = \sum_{x=0}^{\omega} e_x^i \text{ and } IF^i = \sum_{x=0}^{\omega} i_x^i$$

Again, using an age-group approach, we obtain:

$$EF^i = n \cdot \sum_{x=0}^{\omega} {}_ne_x^i \text{ and } IF^i = n \cdot \sum_{x=0}^{\omega} {}_ni_x^i$$

Of course the difference between the immigration rate and emigration rate at each age gives a net migration rate, and we can also sum these rates to obtain a summary measure of net migration.

Lastly, we can determine a weighted mean age at emigration and mean age at immigration:[1]

[1] Reminder: this formula applies to type 3 rates. If we are dealing with type 2 rates, we will have:

$$\bar{x}^i(e) = \frac{0.25 \cdot e_0^i \sum_{x=0}^{\omega} x \cdot e_x^i}{\sum_{x=0}^{\omega} e_x^i}$$

$$\overline{x}^i(e) = \frac{\sum_{x=0}^{\omega}(x+0.5)e_x^i}{\sum_{x=0}^{\omega} e_x^i} \text{ and } \overline{x}^i(i) = \frac{\sum_{x=0}^{\omega}(x+0.5)i_x^i}{\sum_{x=0}^{\omega} i_x^i}$$

III. ESTIMATING NET MIGRATION: A ROBUST APPROACH DESPITE ITS LIMITS

Absent fuller data on migration flows, we can attempt to estimate the *cohort-specific net migration between two successive censuses*. Two procedures are possible, depending on whether we are working directly with statistics on deaths by age and year of birth or using life tables.

1. Estimation of Overall Net Migration

a. Using Deaths by Year of Birth

If we have the current statistics on death by year of observation and year of birth for the entire intercensal period, we can obtain the cohort-specific net external migration by subtracting cohort deaths from the intercensal net migration (or from the difference between births and the sizes of the corresponding cohorts in the following census), for each cohort.

Obviously the cohort(s) studied must be fully identified. The ideal solution would be for censuses to take place on January 1, which would allow a perfect congruence between death statistics and populations by age, but this is hardly ever the case. If the two censuses have not been carried out at the start of the year but have taken place at the same time of year, we can at least be sure of exactly identifying the same cohort from one census to the other.

In the latter case, however, the 12-month period of births that defines a cohort is not bounded by two January 1sts, but by the two census dates.

Let us consider two censuses performed at an interval of exactly n years, the first in $t1$ and the second in $t2$ (Figure 13–2). Let $P^i_{x,t1}$ be the size of cohort i aged x in the first census, $P^i_{x+n,t2}$ the size of the same cohort at age $x + n$ in the second census, and $D^i_{(x,x+n),(t1,t2)}$ the sum of deaths of cohort i registered during the intercensal period. The cohort's net migration is equal to:

$$NM^i_{x,x+n} = P^i_{x,t1} - P^i_{x+n,t2} + D^i_{(x,x+n),(t1,t2)}$$

If we are studying a cohort born after the first census, we must proceed identically starting with births. Let B^j_t be the births of a cohort j born in one of the intercensal years t, $P^j_{x,t2}$ the size of the same cohort aged x at the date of the second census, and $D^j_{(0,x),(t,t2)}$ the cohort deaths between birth and the second census. The net migration for each of these cohorts is equal to:

$$NM^{j}_{0,x} = B^j_t - P^j_{x,t2} + D^j_{(0,x),(t,t2)}$$

We can also perform the computation for conventional cohorts (i.e., individuals born in the same calendar year). In that case, however, the complete ages at the time of census are not the ages between exact birthdays but the ages between exact ages not expressed as round numbers.

For example, the size of the Italian male cohort born in 1941 was estimated at 354,892 in the October 24, 1971, census[2] (at an age ranging between 29.8 and 30.8 exact years), then at 351,357 in the October 25, 1981, census. Between the two dates, the civil statistics recorded 5391 male deaths for the same 1941 cohort.[3] The intercensal net external migration for the 1941 cohort is therefore equal to:

$$NM^{1941}_{(C1971,C1981)} = 351{,}357 - 354{,}892 + 5{,}391 = 1{,}856$$

Similarly, the 1976 cohort, born after the first census, comprised 390,149 male births, whereas its population enumerated in 1981 totaled 397,603 males, and 10,410 deaths were recorded for the cohort between birth and the 1981 census. The cohort's net external migration between birth and the 1981 census is therefore equal to:

$$NM^{1976}_{(1976,C1981)} = 390{,}149 - 397{,}603 + 10{,}410 = 2{,}956$$

In reality, this net-migration estimate is by default, as the deaths registered in the intercensal period include the deaths of immigrants occurring after they entered Italian territory. By subtracting all these deaths, we underestimate the number of entries. However, because we do not know the number of immigrants, we cannot perform the necessary adjustment with this method.

b. Using Two Life Tables

Even in countries with full statistics, the classification of deaths by year of birth and calendar year is not always available, and the procedure for estimating net migration described in the previous section is rarely followed. A more commonly used alternative is the survival ratio method, which consists in estimating the deaths between two censuses by applying to each

[2] Value adjusted for census error (Caselli *et al.*, 1989).

[3] This result is obviously not published as such in the current statistics. It was kindly provided by ISTAT (the Italian statistical institute), which obtained it by comparing dates of birth and dates of death.

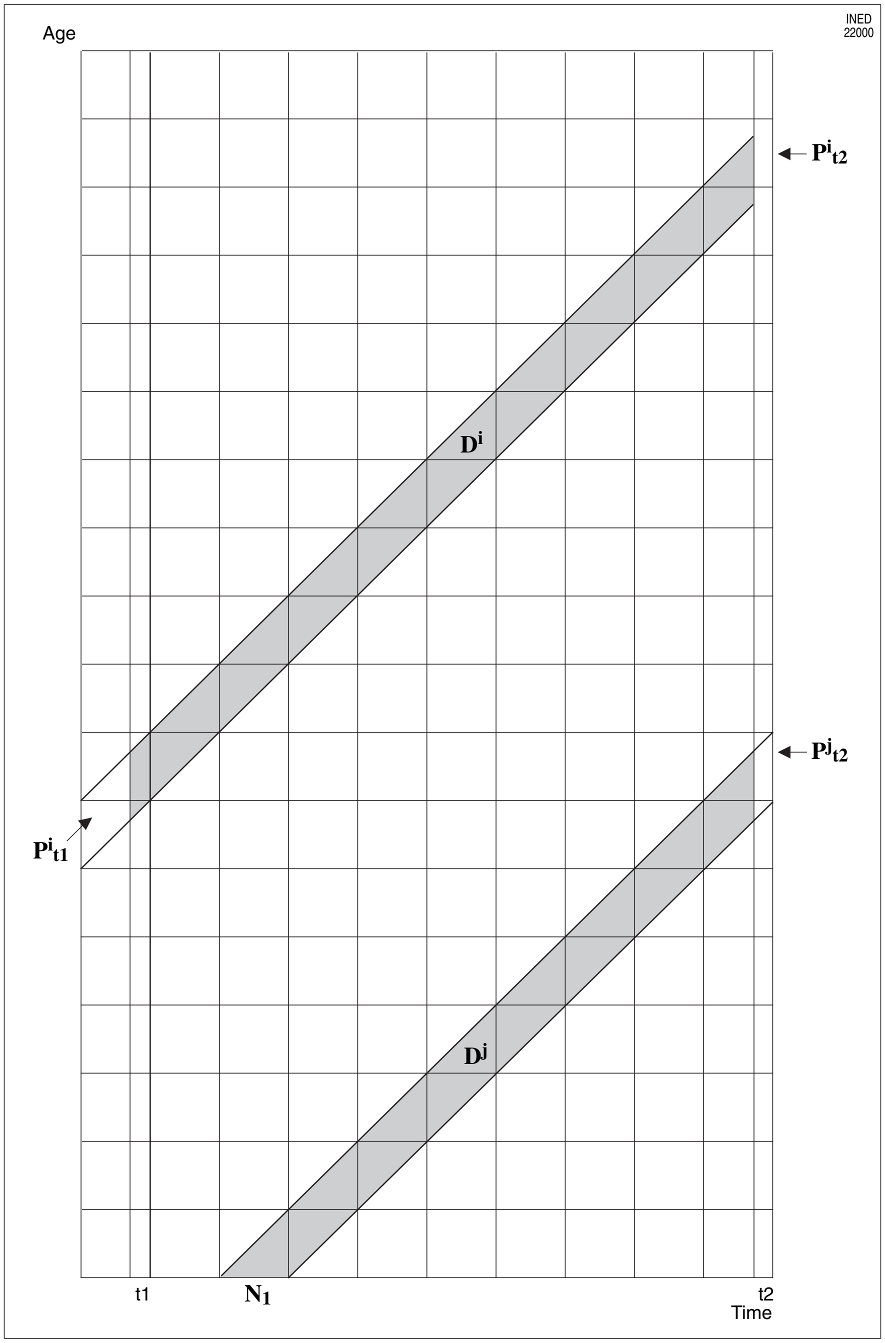

FIGURE 13–2 Position on Lexis diagram of elements needed to estimate a cohort's net migration between two censuses.

cohort the probabilities of dying derived from a suitably chosen series of life tables:

$$NM^i_{x,x+n} = P^i_{(x,x+n),t2} - [P^i_{x,t1} - P^i_{x,t1} \cdot q^i_{x,x+n}]$$

where $q^i_{x,x+n}$ is cohort i's probability of dying between age x in $t1$ and age $x + n$ in $t2$. However, because the aim is to determine a population expected in the second census with no migration to compare it with the enumerated population, we can rewrite the formula more simply (method I) as:

$$NM^i_{x,x+n} = P^i_{(x,x+n),t2} - P^i_{x,t1} \cdot p^i_{x,x+n}$$

where the product included in the second member of the equation represents the expected population, $p^i_{x,x+n}$ being cohort i's probability of survival from one census to the next. The latter value is, of course, a prospective probability of the $L_{x+n,t2}/L_{x,t1}$ type, generally calculated from two life tables constructed for the periods surrounding either census. Naturally, for each cohort *j* born between the two censuses, the period of exposure to the risk of dying is shorter than *n* and the probability of survival is of the $L_{x,t2}/l_0$ type.

However, this method not only suffers from all the drawbacks of the previous one but raises additional problems as well. First, the relevance of the period life tables used to estimate the mortality of the cohorts studied is open to question. Second, if we apply the probability of survival to the initial population, we are applying it *ipso facto* to emigrants beyond the duration of their stay in the geographic area. Conversely, it is true that we ignore the mortality of immigrants since their entry, but, even if the inflows and outflows were broadly of equal magnitude, the problem would be only partially overcome, since the entry and outflow dates are not necessarily equivalent. In reality, the hypothesis underlying this method is that all migration flows occur just before the second census.

According to this method, the intercensal net migration of the Italian male 1941 cohort is estimated at:

$$NM^{1941}_{1971,1981} = 351{,}357 - 354{,}892 \cdot 0.98711 = 1{,}040$$

and that of the cohort born in 1976 is:

$$NM^{1976}_{1976,1981} = 390{,}149 - 397{,}603 \cdot 0.97437 = 3{,}179$$

Following a less commonly used approach, we can work backward from the second census to estimate a cohort size in the preceding census on the assumption of no migration (method II):

$$NM^{i}_{x,x+n} = \left(P^{i}_{(x,x+n),t2} \cdot \frac{1}{P^{i}_{x,x+n}} \right) - P^{i}_{x,t1}$$

However, we will then encounter the same problem in reverse, because we have implicitly assumed that all the migrations occurred just after the first census.

The end result, however, is barely different. For the male 1941 cohort, we obtain:

$$NM^{1941}_{1971,1981} = \left(351,357 \cdot \frac{1}{0.98711} \right) - 354,892 = 1,053$$

and for the male 1976 cohort:

$$NM^{1976}_{1976,1981} = \left(390,149 \cdot \frac{1}{0.97437} \right) - 397,603 = 2,809$$

As Courgeau (1988) has shown, either approach allows us to estimate the net number of migrants, but not the number of net migrations. To estimate the latter, we need to make additional assumptions on the distribution of migration flows (inflows and outflows) within the intercensal interval. The estimation of deaths is hindered by lack of information on the time distribution of migration flows. Several authors (Wunsch, 1969; Dionne, 1970; Courgeau, 1988) propose an identical solution to reduce the estimation error by introducing an estimation of migrants' deaths into the net-migration calculation. Because the distribution of migration flows between the two censuses is unknown, these authors assume an equidistribution of net migration during the period. On the further assumption that mortality (at least at adult ages) rises gradually with age, they attach more weight to the mortality of the second half of the intercensal interval than to the first. Let q_{I} and q_{II} be the probabilities of dying for these two half-intervals. We apply to the migrants of the first half-interval the probability of dying $0.5q_{\text{I}}$, and to the survivors among them the probability q_{II}; to the migrants of the second half-interval, we apply the probability $0.5q_{\text{II}}$. The total number of migrants' deaths accordingly comes to:

$$0.5\left(\frac{NM^{i}_{x,x+n}}{2} \right) q_I + \left[\frac{NM^{i}_{x,x+n}}{2} - 0.5 \frac{NM^{i}_{x,x+n}}{2} q_I \right] q_{II} + 0.5\left[\frac{NM^{i}_{x,x+n}}{2} \right] q_{II}$$

or

$$\frac{NM^{i}_{x,x+n}}{2} [0.5q_I + 0.5q_{II} + (1 - 0.5q_I) q_{II}]$$

In this manner, at the price of some further hypotheses (Wunsch and Termote, 1978; Courgeau, 1988), we can obtain a correction factor $\dfrac{1}{1 - 0.5q^{i}_{x,x+n}}$ to estimate net migrations as follows (method III):

$$NM^{i}_{x,x+n} = [P^{i}_{(x,x+n),t2} - P^{i}_{x,t1} + q^{i}_{x,x+n} P^{i}_{x,t1}] \cdot \left[\frac{1}{1 - 0.5q^{i}_{x,x+n}} \right]$$

For the 1941 cohort, this gives:

$$NM^{1941}_{1971,1981} = [351,357 - 354,892 + (0.01289 \cdot 354,892)] \cdot \left[\frac{1}{1 - 0.5 \cdot 0.01289} \right] = 1,046$$

and for the 1976 cohort:

$$NM^{1976}_{1976,1981} = [390,149 - 397,603 + (0.02563 \cdot 397,603)] \cdot \left[\frac{1}{1 - 0.5 \cdot 0.02563} \right] = 2,772$$

As we can see in Table 13–1, whatever the procedure, the methods based on life tables yield very similar results for the 1941 cohort. In particular, the difference between *net migrants* and *net migrations* is minimal in this example. By contrast, these approximations and the results obtained with the method

TABLE 13–1 Comparison of intercensal net migration figures for Italian male cohorts born in 1941 and 1976, obtained with different procedures

Method	1941 Cohort		1976 Cohort	
	Net figure	Index value[a]	Net figure	Index value[a]
Deaths method	1856	100	2956	100
Method I (net migrants)	1040	56	3179	107
Method II (net migrants)	1053	57	2809	95
Method III (net migrations)	1046	56	2772	94

[a] Deaths method = 100.
From censuses of October 24, 1971, and October 25, 1981.

involving direct use of death statistics—for that same 1941 cohort—differ by a factor of two. No such difference is found with the 1976 cohort. The main reason is that the number of officially registered births is far more reliable than any cohort population enumerated at a given age. The imprecision of an evaluation based on the difference between observations subject to error is much more important here than any methodologic refinements. Not only are the censuses far from perfect, but also the enumeration errors from which they suffer vary from one census to another—and, sometimes, can even change direction. In any event, of course, these deficiencies must inspire caution in accepting the results for intercensal net migration, whatever the method used.

2. From Overall Net Migration to Age-specific Rates

Whatever the procedure, the methods discussed in the previous sections give only an overall net figure for the intercensal period (10 years in the case of Italy) or for a shorter period of variable length when we study cohorts born between censuses. The next step consists of decomposing this net figure by age, taking the ages reached by cohort studied in the course of the period (i.e., the relevant parallelograms [or triangles] on the Lexis diagram [*ABCD* or *EFG*, Figure 13–3]). Almost all demography manuals recommend a straightforward uniform distribution of the overall net migration between the years of age concerned. This means assigning the same net migration to each age in each cohort, whereas we know that the age distribution of migrations is—on the contrary—far from uniform (Figure 4–19 of Chapter 4) and also displays a fairly similar profile in many cases (Castro and Rogers, 1979; Livi Bacci, 1981; Capocaccia and Caselli, 1990). International migration is fairly significant at the youngest ages, usually falls sharply toward ages 10 to 15 years, increases steeply up to age 30 or so, and declines gradually thereafter, becoming negligible after age 70. In other words, for an accurate distribution of an overall net migration observed in the course of a rather long age interval, we must allow for the age-related variations in the propensity to migrate. We must also remember that migration is sensitive to the economic cycle. Last, we need consider annual fluctuations, even when breaking down an overall net migration figure for a single cohort.

To take simultaneous account of age effects and period effects on the distribution of the net intercensal migration of each cohort, we can use an age-period (AP) model developed for a reconstruction of the Italian population by province at each January 1 (Capocaccia and Caselli, 1990). This method rests on the following two hypotheses:

1. Migration flows follow the same distribution by age and calendar year as that of the movements recorded in the population register (*registro anagrafico*[4]);
2. The age structure of these flows is constant from one calendar year to the next.

The first hypothesis has not been tested empirically in Italy, but it seems fairly logical and consistent with observations made in other countries. The second tallies with the results of a comparative analysis of deletions and new entries, by age, in the population

[4] Italy requires place-of-residence changes to be reported. In theory, a citizen who changes residence must report his or her arrival to the Ufficio Anagrafico (registry) of the new locality and report his or her departure to the registry of the old locality. This registration, however, covers only a portion of the real population flows, as many moves go undeclared. But it is safe to assume that the under-recording is broadly independent of migrants' ages and that it varies little over time.

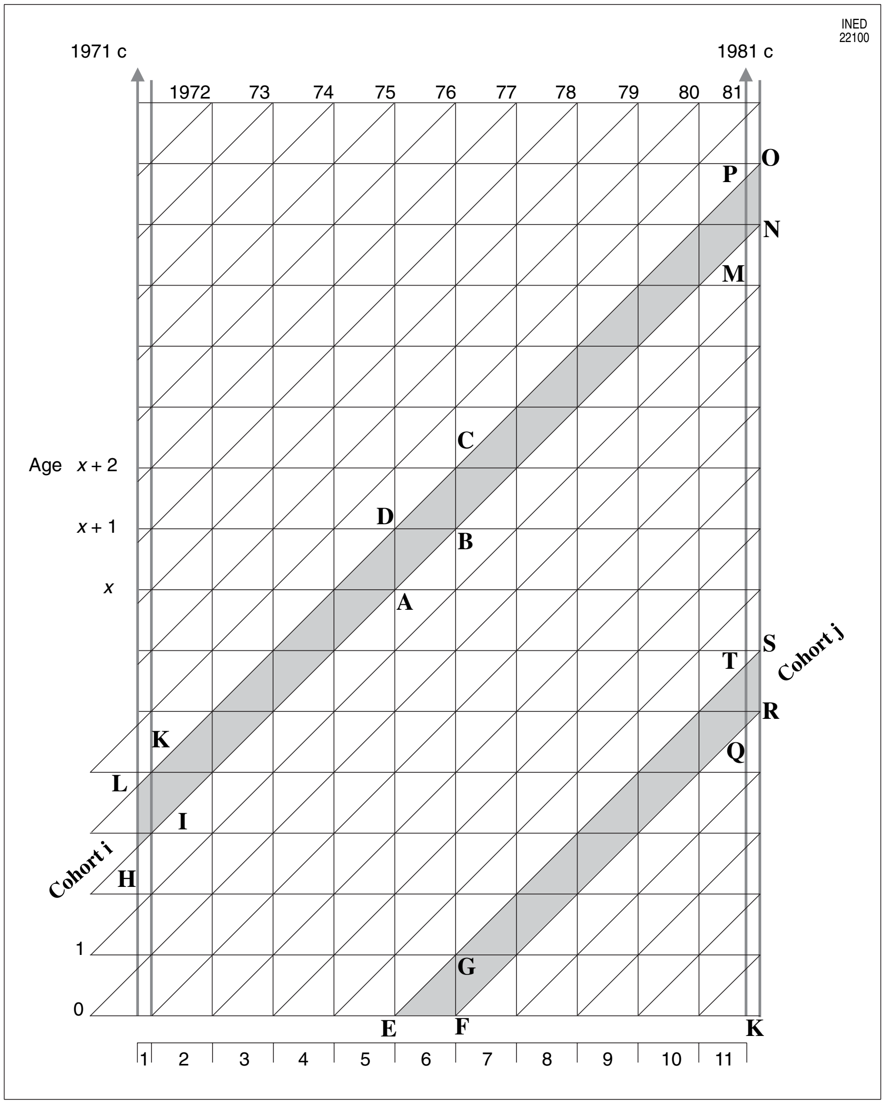

FIGURE 13–3 Visual representation on Lexis diagram of an age-specific net migration within an overall intercensal net migration estimated for a given cohort (Source: Capocaccia and Caselli, 1990).

registers of the 92 Italian provinces during the 1971 to 1976 and 1977 and 1981 periods.[5]

Intercensal net migration by cohort for 1971 to 1981 was estimated using the procedure described above, using death statistics. To estimate the age-specific probabilities of migrating,[6] we use a logistic function whose independent variables are age and calendar year: this is the AP model:

$$pm_{i,t} = (1 + \exp(a_i + b_t + c))^{-1}$$

where $pm_{i,t}$ is the probability for an individual aged i of migrating in t; the parameters a and b denote age effect and period effect respectively, c being a constant that describes the average propensity to migrate for the total population. These parameters are estimated by the least-squares method, applied to the statistics of deletions from the population register: This is preferred to new entries in the register, since Italy was an emigration country during the period. The results for a (age effect) and b (period effect) are reported in Figure 13–4. The age-effect profile is entirely consistent with the descriptions in the specialized literature. The period-effect profile shows that the propensity to migrate was greater at the start of the period and gradually declined thereafter.

[5] A later study has found the same age structure in the 1981 to 1986 and 1986 to 1991 periods.

[6] We can determine probabilities of migrating if we assume that each migration flow involves a different individual: this means treating migration as a nonrenewable event.

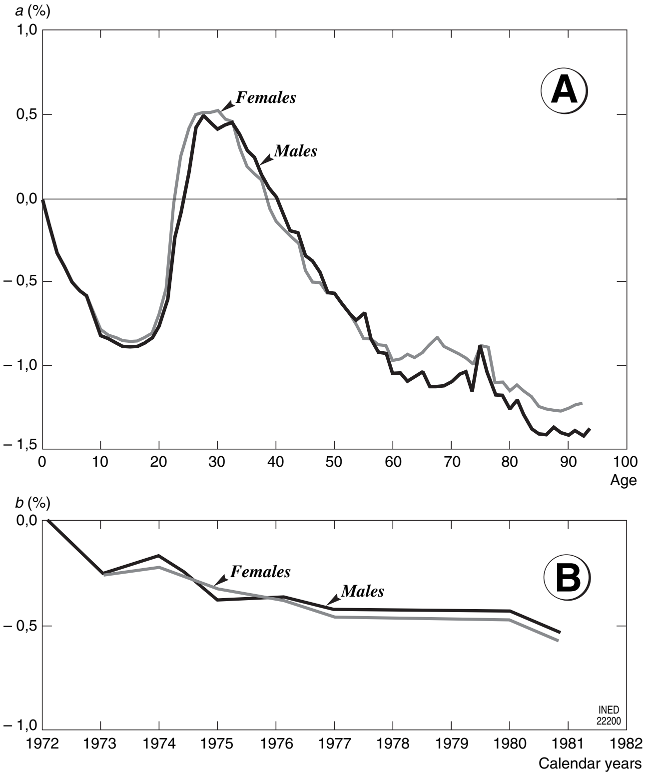

FIGURE 13–4 Profiles by age (parameter *a*) and calendar year (parameter *b*) of Italian net migration between 1971 and 1981, obtained with an age-period model applied to deletions from population registers (Source: Capocaccia and Caselli 1990).

For the cohorts concerned, parameter *a* of the model provides an estimate of probabilities of migrating between two birthdays. However, our goal is to determine prospective probabilities that take into account each cohort's propensity to migrate in the course of a calendar year: we want to fit the equations precisely to the data derived from the comparison between two censuses that have not taken place on January 1 (Figure 13–3). For details of the calculation, see Capocaccia and Caselli (1990).

Once we have calculated the age-specific probabilities of migrating for each cohort, their total intercensal net migration is distributed as follows:

If the cohort is born before the first census:

$$NM^i_{x,t} = NM^i_{(x,x+n),(t1,t2)} \cdot \frac{pm^i_{x,t}}{\sum_{t=2}^{n+1} pm^j_{x,t}}$$

If the cohort is born between the two censuses:

$$NM^i_{x,t} = NM^j_{(0,x+n),(t,t2)} \cdot \frac{pm^j_{x,t}}{\sum_{t=2}^{n+1} pm^j_{x,t}}$$

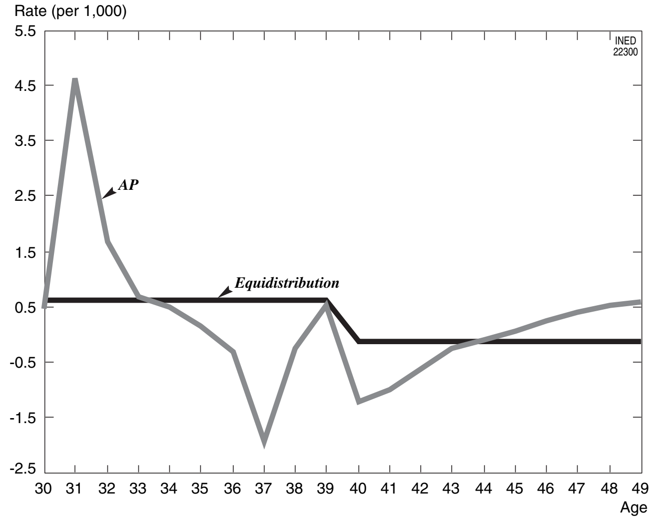

FIGURE 13–5 Age-specific net migration for Italian male 1941 cohort, using two methods for distributing the overall intercensal net figure.

The ratio in the second member of these equations gives the proportion of total net migration to be assigned to each age *x* reached in the calendar year for the cohort studied.

We can then derive indicators for migration *intensity* and *tempo*:

a rate (type 2):

$$nm^i_{(x,t)} = \frac{NM^i_{x,t}}{0.5(P^i_{x,t} + P^i_{(x+1),(t+1)})}$$

an average number of net migrations (total net migration) reached by each cohort in the intercensal interval:

$$NMF = \sum_{x}^{x+n} nm^i_{x,t}$$

and a mean age of these cohorts at net migration in the intercensal interval:

$$\bar{x}(nm) = \frac{\sum_{x=0}^{\omega} x \cdot nm_{x,t}}{\sum_{x=0}^{\omega} nm_{x,t}}$$

Table 13–2 and Figure 13–5 illustrate the results obtained for the Italian male 1941 cohort between the 1971 and 1981 censuses, and between the 1981 and 1991 censuses. This gives us a picture of 20 years of the cohort's life. The table and figure compare the application of the generally recommended method of net-migration equidistribution and the AP model distribution method. In the first case, we obviously obtain

TABLE 13–2 Age-specific net migration and age-specific net migration rate between 1972 and 1991 for Italian male 1941 cohort, using two methods for distributing the overall net figure

Age	Year	Uniform distribution			Distribution based on AP model		
		Net migration by age	Population at Jan. 1	Rate (per 1000)	Net migration by age	Population at Jan. 1	Rate (per 1000)
30	1972	215	354,300	0.61	166	354,300	0.47
31	1973	215	354,000	0.61	1640	354,000	4.62
32	1974	215	355,200	0.61	596	355,200	1.68
33	1975	215	355,300	0.61	240	355,300	0.68
34	1976	215	355,100	0.61	173	355,100	0.49
35	1977	215	354,800	0.61	48	354,800	0.14
36	1978	215	354,300	0.61	–109	354,300	–0.31
37	1979	215	353,600	0.61	–688	353,600	–1.95
38	1980	215	352,300	0.61	–95	352,300	–0.27
39	1981	215	351,500	0.61	178	351,500	0.51

47	1989	–50	343,265	–0.15	135	343,265	0.39
48	1990	–50	342,167	–0.15	177	342,167	0.52
49	1991	–50	340,972	–0.15	203	340,972	0.60
50			339,672			339,672	
Net migration reached between ages 30 and 49		1,650		4.66	1,648		4.66
Mean age at net migration between ages 30 and 49				37.0			36.9

constant rates with identical signs in each intercensal period, whereas the AP method gives a more realistic picture of age-related changes in migration.

In both methods, the total net migration after 20 years is naturally the same, and the difference in mean age is actually minimal (37.0 versus 36.9 years). Only the distribution is radically different. Of course, the problems relating to the quality of census observations remain unsolved!

CONCLUSION

At the start of the chapter, we saw the scope of the problems raised by the analysis of migrations in terms of their contribution to the overall population dynamics. For the natural dynamics (i.e., the balance between births and deaths), the cohort analysis of events occurring in the life of individuals (maternity, death) is used to construct unambiguous indicators of the progressive extinction or cumulative fertility of a cohort. On the other hand, the dynamics of migration (i.e., the balance between inflows and outflows) are a source of multiple difficulties. The first are, of course, observational, as the administrative sources in this field are most often either non-existent or severely deficient. But there is also—and above all—a conceptual difficulty: while emigration can be understood as an endogenous phenomenon, specific to the population studied (although there needs to be an *elsewhere* to which people can migrate), immigration depends on the behavior of external populations to which we should be able to refer in order to construct a satisfactory representation model. In most cases, though, we know nothing about the external areas from which the immigrants come. Traditionally, demographers get around this problem by calculating immigration rates as if inflows could be measured against the number of residents—but this does very little to reduce the sense of dissatisfaction. We can easily see that this is at best an expedient to describe the various components of a population's capacity to grow.

By contrast, migration is a demographic phenomenon in itself that—beyond the overall population dynamics—can, through different channels, affect the population's structure and flows. First, as we shall see, fertility and mortality are not unrelated to mobility, and this would alone be sufficient reason to go back to the analysis of migration processes as a factor in demographic behavior. But domestic migration plays a crucial role in the distribution of a population on its territory, and hence in shaping its structure. This, in turn, can have major indirect effects on the population dynamics. Last, migration is a phenomenon whose economic, social, cultural, political, and other consequences are immense, which is why we will return to migration in Chapter 22, using an entirely different approach to mobility. This approach is capable of taking into account all the categories of movements that occur in the life of an individual—from simple changes of residence to international migrations; it focuses on the act of migration *per se*, as distinct from its direction (inflow or outflow).

PERIOD ANALYSIS REVISITED

The Hypothetical Cohort and its Relations with Actual Birth Cohorts

GRAZIELLA CASELLI AND JACQUES VALLIN

The factors of natural population change affect nothing if not the life and death of individuals. To account for them in the most practical way possible, therefore, we have analyzed at length the relevant processes within birth cohorts whose reproduction can be tracked through their recorded fertility, and their attrition through their death rate. We attempted to address the factors of migration flows (immigration and emigration) in the same way, but with less success due to the difficulties of observation. As a result, we moved from observing concrete events which punctuate the lives of the individuals to calculating rates or probabilities which characterize fertility behavior, propensity to migrate, and the process of attrition within specific sets of individuals—cohorts—sharing the attribute of having been born in the same year and so being the same ages at the same times.

As a result, we somewhat disregarded the population in the sense of the continuously subsisting total population of each birth cohort comprising it. The fertility, mortality or propensity to migrate of a population in a given period is in fact predicated by the period-specific combination of life experiences of the different birth cohorts concerned. Each cohort adds to the population dynamics through its behavior at the age attained in the period of interest.

The combined behaviors of different birth cohorts at different ages are what determines natural and migratory population change. And changes in these combinations are the main focus of population policies, be they public health, migration or family policy.

Longitudinal or cohort analysis is a purely secondary means of tracking both short-term and longer-term trends. Not only because the statistical perspective required means that it can be done only long after the event, but short- or even long-term changes generally affect most of the age groups constituting the population at the time they occur, while new events or new changes occur as the cohorts age. So, to assess the influence of different social, economic, cultural factors on population development, and to give direction to the policies to deal with them, we must have time-specific indicators for fertility, mortality and migration and track their development over time. Whence the need to reconstruct by period analysis what was previously done by cohort analysis.

This is what will be done here, starting with Chapter 14, which applies the theoretical construct of the hypothetical cohort to the three main components of population change in turn: mortality, fertility, and migration.

At this juncture, there is a good case to be made for having simple indicators of these phenomena. Bearing in mind the problems arising from confounding variables, *standardization methods* can be used to define comparative measurements (Chapter 15). Chapter 16 analyzes the relationships between age-specific rates and total rates, and describes various *methods of differential analysis* of two life expectancies or two total fertility rates.

Comparing period and cohort indicators shows how far, in some cases, both can differ from each other, the former taking account of age-specific timing factors pertaining to different birth cohorts with different life histories at a single point in time within the same population, through period-specific recombination within a hypothetical cohort. Chapter 17 will clarify the relations between these two approaches through *translation models*.

Finally, this third part concludes with a discussion of *APC* (age-period-cohort) *models* that seek to link period and cohort analyses to pinpoint what is age-, period-, or cohort-specific in the development of a demographic phenomenon.

The Hypothetical Cohort as a Tool for Demographic Analysis

JACQUES VALLIN AND GRAZIELLA CASELLI

Institut national d'études démographiques (INED), Paris, France

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

To construct period indicators for tracking the changes over time in the basic phenomena of population dynamics, we will resort to artificial constructs known as *hypothetical cohorts* (also known as *fictitious* or *synthetic* cohorts). These imaginary groups are assumed to display throughout their lives the fertility, mortality, and migration behaviors measured by the age-specific rates observed in a given period. The rates obviously reflect the behaviors of different real cohorts during the period. The relationships between these behaviors and the behaviors of the same cohorts at earlier ages and at older ages are presumably quite different from the links between these behaviors and those of other cohorts at other ages in the period considered. But this association of age-specific behaviors in a given period describes the state of the phenomenon studied in the period examined. To track the change in the phenomenon, we will pretend that the age-specific rates observed in each time fraction are those of a single cohort, the hypothetical cohort, for which we can measure life expectancy, mean number of children per woman, and other variables.

We examine mortality, fertility, and migrations.

I. THE PERIOD LIFE TABLE

The *period life table* assigns to a hypothetical cohort the age-specific risks of dying observed in a given period. It can be constructed only by measuring the risks. In this respect, it differs from the life table of a real cohort, which can—in theory, and under certain observation conditions—be constructed directly from actual deaths (see Chapter 11). There is only one set of circumstances in which we could define the observed age-specific deaths as the deaths in the *period life table*. Three conditions would be required: (a) an identical age-specific mortality for all the cohorts contributing to the period measure, (b) an identical initial number of births for all the cohorts, and (c) no change in cohort sizes due to migration flows at any time in their lives. No real population, of course, ever meets these criteria, which are those that define what we will later refer to as a *stationary population* (Chapter 20). Consequently, we can hardly ever regard the age-specific deaths observed in a given period as a possible starting point for a period life table.

1. From Age-specific Risks to the Period Table

We have already seen that, depending on the data available, different approaches can be used to estimate the age-specific risks of dying (Chapter 11). How should we go about describing the reality of a given observation period as faithfully as the available data allow? Let us start with the simplest case: a calendar year for which we want to measure the year-of-age-specific risk of deaths. Figure 14–1 illustrates the position on a Lexis diagram of the various measures of the risk of dying that may be used to construct a life table by year of age for an individual calendar year.

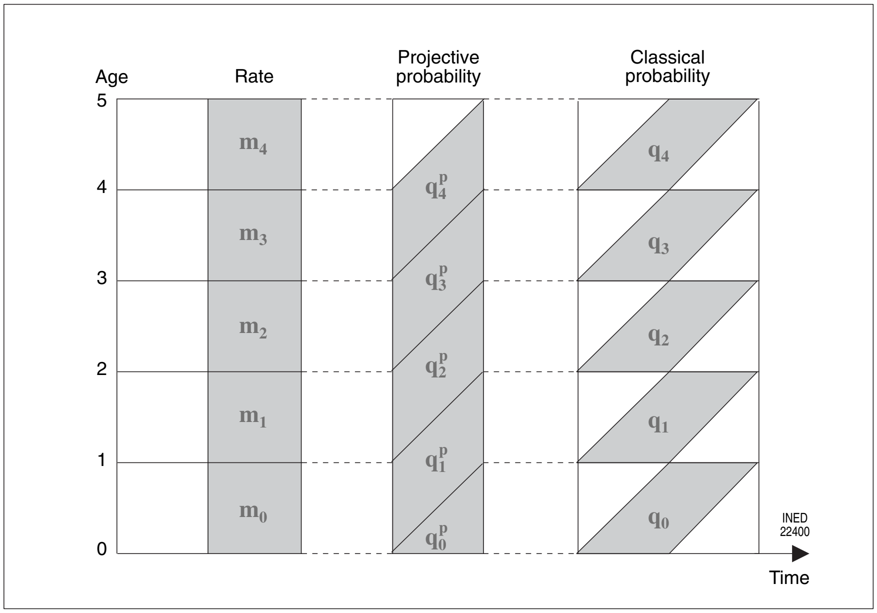

FIGURE 14–1 Positions on Lexis diagram of different measures of risk of dying suitable for constructing a calendar-year life table by year of age.

a. Using Rates as the Starting Point

Obviously we can start with the year-of-age-specific mortality rates (Figure 14–1, first column) and estimate the corresponding probabilities of dying. There are three advantages to this approach: the data are often accessible in the proper form, they concern precisely one calendar year, and they identify each year of age just as exactly. However, the probabilities are only approximations that assume an equal distribution of deaths in the two Lexis triangles. As seen earlier, the conversion formula based on this hypothesis is usually acceptable. But there are two cases where it may not be acceptable: (a) when the two cohorts crossing the same Lexis square were born at a time of abrupt swings in the birth rate and (b) above all, at the ages when the age-related swings in mortality within a given 1-year age interval are too wide (Chapter 11). Although the first exception is rare, the second is always a problem when measuring infant mortality and mortality at the oldest ages. In any event, the oldest ages pose other problems (as seen in Chapter 11), which we shall also discuss later in this chapter.

For infant mortality, two alternatives are possible. First, we can approximate the probability at age 0 by the classic infant mortality rate or, better, by an infant mortality rate obtained after weighting the deaths by the initial number of births in the two cohorts concerned (Chapter 11). We can also use empirical rate-to-probability conversion tables, such as the one published by Reed and Merrell (1939), which we shall discuss in connection with abridged tables.

b. Using Projective Probabilities as the Starting Point

Without stepping outside the specific framework of an observation year, we can calculate the projective probabilities of dying (Chapter 11). This requires a classification of the year's deaths by year of birth of the deceased. The drawback, as we know, is that the probabilities measure mortality not between two birthdays, but between two ages in complete years (Figure 14–1, second column). We can obviously deduct interbirthday probabilities by interpolation between two consecutive values. As a rule, a simple linear interpolation suffices, except at very young or very old ages, when the mortality function diverges sharply from the linear pattern even between two birthdays. However, this offers no solution to the specific problem of infant mortality, which lies somewhere in between a standard projective probability at 1 year and an initial probability at age 0 that concerns only one triangle of the Lexis diagram. Again, we can make up for this by using the classical infant mortality rate or, better, a rate weighted by the population at birth of the two cohorts involved.

c. Using Classical Probabilities as the Starting Point

Finally, if we have the double classification of deaths by age and year of birth, we can construct a period table from the classical probabilities of dying between two birthdays (Figure 14–1, third column). We will, however, encounter the same problem already discussed in connection with the calculation of mortality rates (Chapter 6): Each of these probabilities covers two contiguous calendar years; by combining the set of these age-specific probabilities, the mortality obtained lies somewhere between those of each of these 2 years, without taking either one fully into account. To incorporate the entire mortality of the year studied into this measure, we actually need to determine the classical probabilities over a 3-year period, centered on the year studied (Figure 14–2).

The drawback of this approach is that it involves a partial compensation between the mortality levels of the 3 years in question. This attenuates any possible fluctuations, which might have been worth studying.

d. Using Partial Probabilities as the Starting Point

With aggregated data, the only way to construct an annual life table by year of age from real probabilities is by computing the *partial probabilities* defined in each Lexis triangle (Figure 14–3). We then combine the probabilities two by two to obtain the classical probabilities between two birthdays determined on the sole basis of the data on the year studied (Vallin, 1973):

$$ {}_1q_x = 1 - (1 - q_x^1) \cdot (1 - q_x^2) $$

This assumes that we have the double classification of deaths by year of age and year of birth.

Whatever the method used to establish the probability of dying between two birthdays (estimate or direct calculation), we construct the life table of the year in exactly the same way as a cohort life table, starting from a radix l_0 and proceeding by successive iterations until the gradual extinction of the population. This is done by applying the age-specific probabilities of death, which give us the series of survivors l_x and deaths $d_{(x,x+1)}$ for the table. As we would do with cohort tables, we also calculate the table's other functions, in particular the stationary population of the table (person-years exposed to the risk) ${}_1L_x$ and the life expectancy at birth, e_0 or, at age x, e_x.

2. Closing the Table

Naturally, as with the life table of a real-life cohort, we need to adopt a solution for *closing* the table to minimize the problem of measuring mortality at the oldest ages. For this purpose, we can use the same procedures as those already mentioned in connection with the cohort life table (arbitrary choice of life expectancy at age k, estimation of probabilities at the oldest ages by means of the extinct-cohort method, or extrapolation using a function to provide the best possible fit for risks of dying at earlier ages). If we use the extinct-cohort method, once we have estimated the probabilities longitudinally, we will need to recombine them in cross-sectional form by selecting only those concerning the year studied. The distance from the year studied needs to be all the greater as we must estimate probabilities for ages far removed from the limit age of life.

In addition to these various methods for estimating mortality at the oldest ages, already discussed in connection with cohort tables (Chapter 11), there are two methods more immediately suited to the requirements of period-table computation.

Later on, we will see that—for a *stationary population*—life expectancy at birth is equal to the inverse of the crude death rate (Chapter 20) and, more generally, life expectancy at age x is equal to the inverse of the death rate of the age group x, $x + \omega$:

$$ e_x = \frac{1}{m_{(x,x+\omega)}} $$

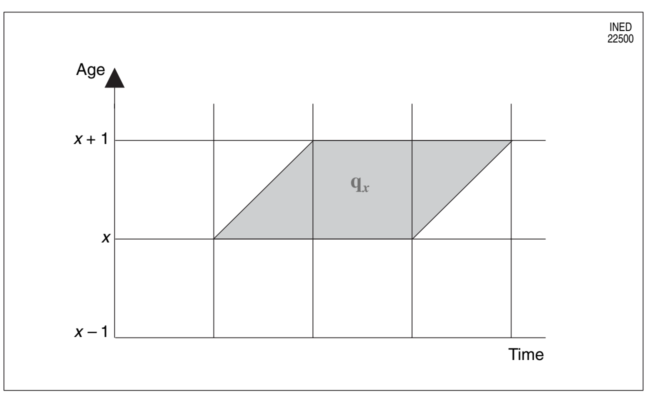

FIGURE 14–2 Probability between two birthdays taking full account of the central year (i.e., the focus of our study).

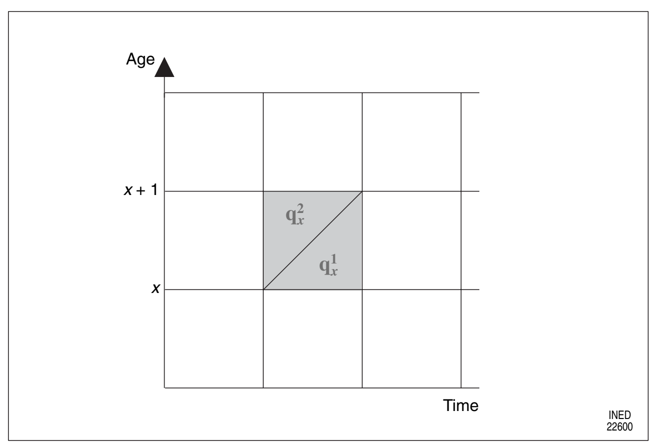

FIGURE 14–3 Partial probabilities between two birthdays allowing an exact coverage of the year studied.

As the stationarity conditions are rarely satisfied, it would of course be totally unrealistic to estimate life expectancy at birth from the crude death rate. On the other hand, given the relatively minor importance of the precision with which we need to estimate life expectancy at an old age k, we can—as Greville (1943) suggests—use the above formula to close a life table. This makes more sense for a period table, because we need only determine the final mortality rate at age x, $x + \omega$, in the open interval of age k, used in the death and population statistics of the year studied.

Coale and Caselli (1990) outlined another method. The authors point out that, thanks to civil registration, reasonably reliable statistics on age-specific deaths are usually available, at least for recent years: As deaths are officially reported, often with certified documentary evidence, the age of the deceased is known with a fairly high degree of precision. By contrast, the population's age distribution is determined far less accurately, as it is based on the census, which collects voluntary declarations without significant checks on the information supplied.

The method consists in calculating the age distribution at the oldest ages from the observation of deaths, a procedure that somewhat resembles the extinct-cohort method. If, as in the latter method, we admit that migrations beyond a certain age are negligible, the ratio of the population size at an age x to the size at the following age, $x + 1$, will depend both on mortality and on the population increase at that age. With ${}_1r_x$ as the population's growth rate at age x, the Coale–Preston equation (1982) gives us:

$$P(x) = P(x+1) \cdot \exp({}_1r_x) + {}_1D_x \cdot \exp\left(\frac{{}_1r_x}{2}\right)$$

where $P(x)$ is the mean population of age x in the observation period and ${}_1D_x$ the deaths at age x, $x + 1$ in the period. If we know the number of deaths, we need only estimate ${}_1r_x$ to determine the population at different ages through successive iterations. If we assume that the population at the oldest ages is closed (i.e., without migration), we can estimate the growth rate of the population aged x from the rate of increase in deaths at age x. To avoid the disturbances due to annual fluctuations in mortality, we use a mean annual growth rate over several years. Once we have calculated the age-specific populations, we can measure the risks of dying at older ages as before.

3. Abridged Tables

The available death statistics are not always detailed enough to calculate the probability of dying by year of age. The figures, for example, may consist in a classification of deaths by 5- or 10-year age groups, or even by age groups of variable size. In such cases, we can construct *abridged life tables*. The direct computation of period probabilities is usually impossible.[1] Our starting point, therefore, will almost always be the death rates by age groups: the problem is to determine to what extent we can use the classical rate-to-probability conversion formula, and what are the possible alternatives.

We know that if, in a given age interval a, deaths are uniformly distributed by age, the probability of dying between ages x and $x + a$ can be deduced from the mortality rates at the same ages as follows (Chapter 8):

$${}_aq_x = \frac{2 \cdot a \cdot {}_am_x}{2 + a \cdot {}_am_x}$$

As we saw in the preceding sections, the hypothesis of a uniform distribution of deaths in an age interval is usually acceptable when dealing with annual age groups. This is generally not the case when we are working with multiyear age groups. All other things being equal, the problem increases as the age interval widens. As we know, the survival function is far from linear and, over a fairly wide age interval, the mean age at death diverges significantly from the interval's midpoint. As a rule, at young ages, the mean age lies below the interval midpoint as long as mortality declines with age; on the contrary, at the older ages, when mortality increases with age, the mean age lies above the midpoint.

Reworking Long's demonstration (1968), Santini (1992) suggests a way to offset this drawback. He proposes that in a given age interval x, $x + a$, the total of years lived is equal to:

$${}_aL_x = a \cdot (l_x - d_{(x,x+a)} + {}_a\delta_x \cdot d_{(x,x+a)})$$

where ${}_a\delta_x$ represents the mean fraction of the interval lived by the deceased. The rate is accordingly equal to:

$${}_am_x = \frac{d_{(x,x+a)}}{a \cdot (l_x - d_{(x,x+a)} + {}_a\delta_x \cdot d_{(x,x+a)})}$$

and the probability to:

$${}_aq_x = \frac{a \cdot {}_am_x}{1 + (1 - {}_a\delta_x) a \cdot {}_am_x}$$

If we postulate the uniform distribution of deaths, this equation obviously yields the classical formula given earlier.

[1] Unless we are working on data from a retrospective survey processed in period form—as is the case, for example, in the Demographic and Health Surveys (DHS).

The problem is to estimate ${}_a\delta_x$ taking reality into account.

Several authors have proposed models to convert rates into probabilities as realistically as possible. Reed and Merrell (1939), analyzing 24 U.S. life tables built between 1900 and 1930, showed that the expression

$$ {}_a q_x = 1 - \exp\left[-a \cdot {}_a m_x - 0.008 \cdot a^3 \cdot ({}_a m_x)^2\right] $$

gives a good estimate of the probability in the universe of tables studied, except for the probabilities ${}_1q_0$ and ${}_4q_1$, for which the authors offer specific coefficients to allow for the under-recording of deaths.

Greville (1943) proposed the following equation:

$$ {}_a q_x = 1 - \exp\left[-a \cdot {}_a m_x - \frac{a^3}{12} \cdot ({}_a m_x)^2 \cdot (\ln {}_a m_x)'\right] $$

but Nathan Keyfitz (1977, p. 43) noted that, when $(\ln {}_a m_x)' = 0.096$, we end up exactly with Reed and Merrell's formula.

Keyfitz and Frauenthal (1975) offered another expression:

$$ {}_a q_x = 1 - \exp(-a \cdot ({}_a m_x + C)) $$

or

$$ C = \frac{({}_a P_{(x-a)} - {}_a P_{(x+a)}) \cdot ({}_a m_{(x+a)} - {}_a m_{(x-a)})}{48 \cdot {}_a P_x} $$

where ${}_aP_x$ is the population aged $(x, x + a)$.

In fact, if we develop the Keyfitz–Frauenthal equation, we realize it is a special case of the Reed–Merrell formula (Santini 1992).

4. Selected Results

Let us return to the French example of the cohort of Jeanne Calment, born in 1875, which we have discussed several times in connection with the cohort life table. It is interesting to compare the cohort table with the period tables compiled for 1875, the year of her birth; 1997, the year of her death; and 1936, the year in which she reached 61 years, the midpoint of her life.

Figure 14–4 compares the age-specific probabilities. The cohort's mortality is obviously equal to that of the year 1875 at age 0 and to that of the year 1997 at the oldest ages. However, it is between ages 0 and 15 that the cohort and the year 1875 are indistinguishable,

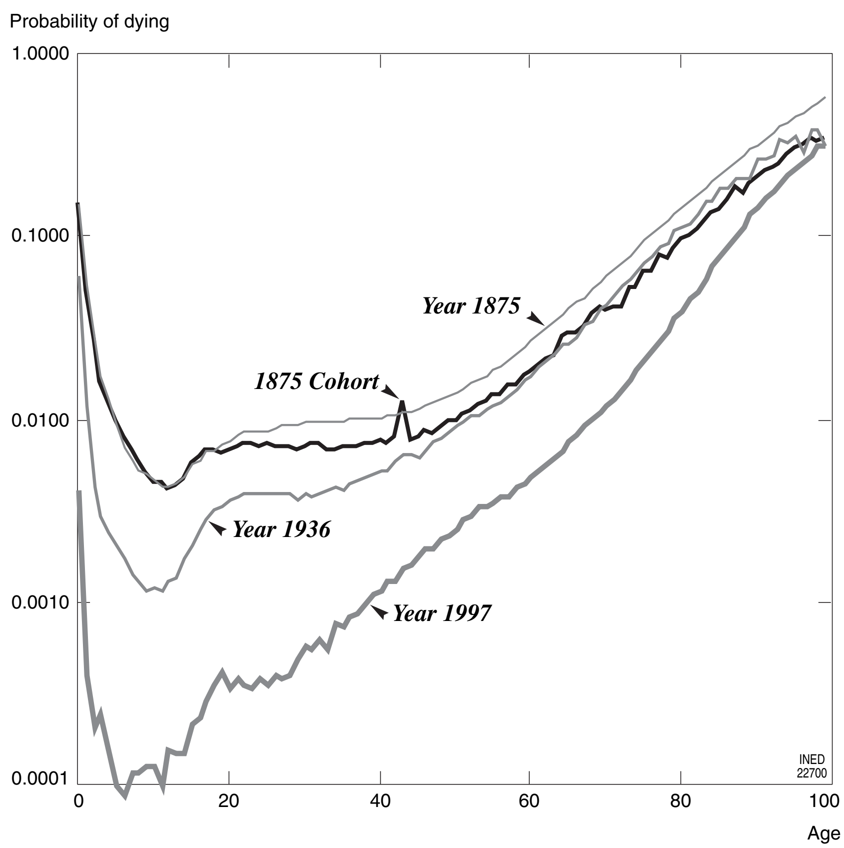

FIGURE 14–4 French female probabilities of dying for Calment's cohort compared with probabilities of period tables for year of her birth (1875), year of her death (1997), and year when she reached her midpoint in life (1936).

given the insignificant gains at the youngest ages between 1875 and 1890. Conversely, the mortality of the 1875 cohort lags behind that of the year 1997, since the gains at the oldest ages have only recently become substantial. The cohort naturally reaches the mortality level of the year 1936 toward age 60. In fact, the most characteristic aspect of this comparison between the cohort and the 3 years selected relates to the steady rise from the 1875 level toward the 1936 level, accomplished between ages 15 and 60. In these 45 years, the cohort reaped the full benefits of health progress, which enabled it to grow older throughout the period without a greater risk of dying (except for the peak due to the Spanish influenza). By contrast, after age 60, the cohort's mortality lingered very close to the 1936 figure, well above the 1997 level. The explanation is that the over-60s hardly benefited from healthcare advances before the 1970s.

This comparison clearly shows the very different possible uses of the cohort tables and period tables. The cohort table resembles none of the period tables. In this sense, it is clear that the device of the hypothetical cohort totally disproves the notions about the life experiences of actual populations that we sometimes derive from a reading of period indicators. On the other hand, only period tables can give us a precise view of the improvement in health standards over time.

Figures 14–5, 14–6, and 14–7 compare the four identical tables on three criteria: survivors at each age, age distribution of deaths in the table, and age-specific life expectancy. The survivor curve shows the extraordinary weight of infant and child mortality. Because it shares the high infant mortality then prevailing with the 1875 table, the cohort's survival rate at nearly all ages lingers far below the values for 1936 and 1997; in fact, it stays very close to the 1875 figure. The divergence does not become significant until after age 40, but this is too late to radically reverse the situation, because more than half the initial population has already died.

The main differentiating factor in the age distribution of deaths is infant mortality (Figure 14–6). But the most significant distinction between the period tables and the cohort table is the greater concentration of deaths around the second peak. From one period table to the next, the peak is increasingly concentrated, but at the same time it shifts rightward. As a result, the deaths are more scattered in the cohort than in any of the three period tables, even including the 1875 table.

For life expectancy, the third criterion, the curves once again display, of course, the weight of infant

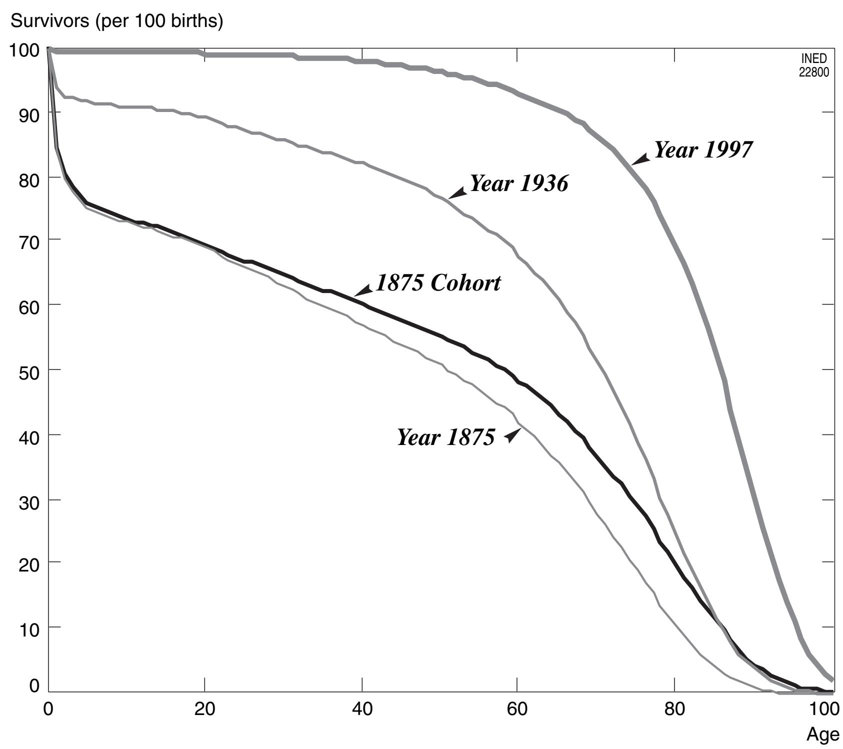

FIGURE 14–5 Survivors of French female life table of Calment's cohort compared with those of period tables for year of her birth (1875), year of her death (1997), and year when she reached her midpoint in life (1936).

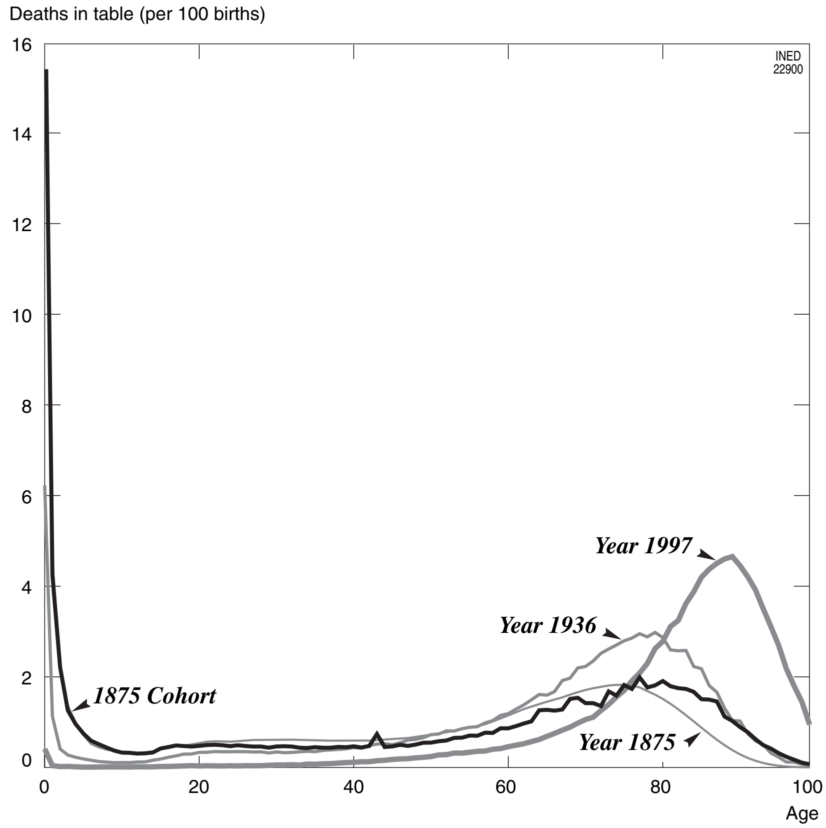

FIGURE 14–6 Deaths of French female life table of Calment's cohort compared with those of period tables for year of her birth (1875), year of her death (1997), and year when she reached her midpoint in life (1936).

mortality. Here, it is also responsible for a close resemblance between the cohort table and the 1875 table: Both are characterized by a sizable increase in life expectancy in the first years of life (Figure 14–7).

Unlike the survival curves, however, the life expectancy curves of the 1875 cohort and the year 1875 are entirely distinct from the outset. Whereas the two infant and child mortalities are very similar, the cohort life expectancy at the youngest ages incorporates the future gains at the adult ages. Indeed, the cohort life expectancy is quick to catch up with that of the year 1936, nearly 20 years ahead of schedule! Yet, the life expectancy at birth for the year 1936 was almost 15 years longer than that of the 1875 cohort. The reason is that unlike the survival curve, which depends only on earlier mortality, life expectancy depends solely on future mortality. The life expectancy curve of the year 1997 lies far above the other three. It embodies all the progress achieved since 1875. Infant mortality has fallen so low that the leap in the earliest ages still visible in 1936 has totally disappeared, and life expectancy decreases almost linearly with age from 0 to 80 years.

The life tables are given in the appendix.

Figure 14–8 compares the change in life expectancy at birth for France since the start of the 19th century given by the period tables with the values shown in the cohort tables. The representation of such a comparison raises several problems. First, we need to choose which observation year (period table) to compare with which birth year (cohort table). Should we compare the life expectancy of a cohort with (1) that given by the period table of the year of its birth, (2) that of the table of the year in which the cohort dies out, or (3) that of the year in which the cohort reaches its mean age at death? None of these solutions is truly satisfactory. In this chapter, we have decided to compare the mortality of each cohort with that shown in the period life table of its year of birth. We can thus measure the gap between (a) the life expectancy that could have been displayed by the cohort if mortality had remained constant and (b) the life expectancy determined from the cohort's actual history. This choice, however, raises a second problem: since we cannot know a cohort's actual history until after its total extinction, we cannot make the comparison on actual data except for cohorts born over a century ago. This would exclude from the comparison the period life expectancies observed in the

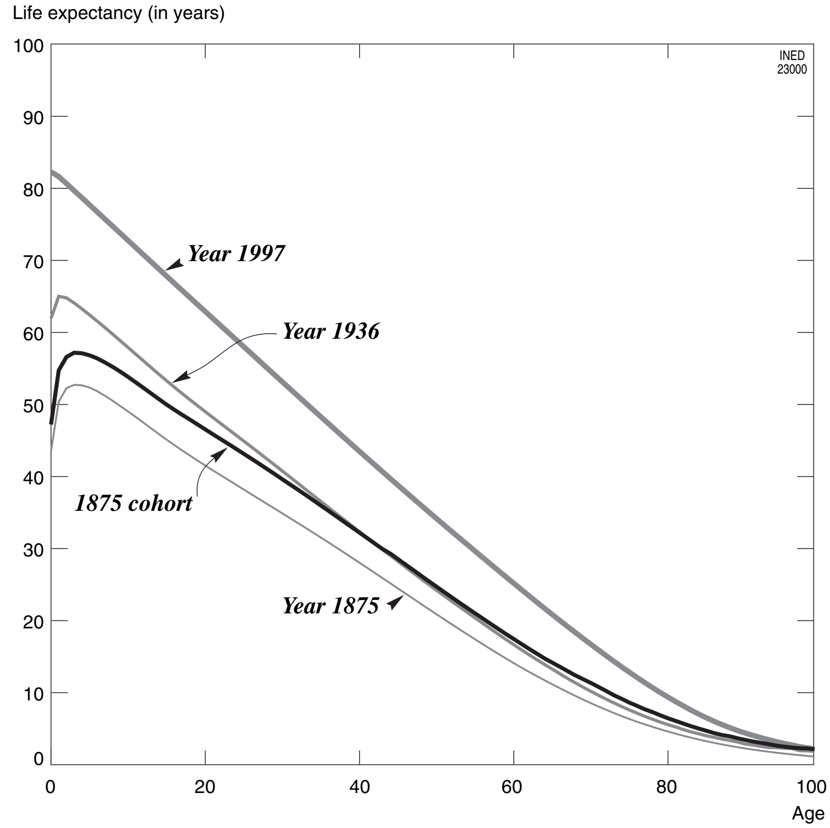

FIGURE 14–7 Life expectancies of French female life table of Calment's cohort compared with those of period tables for year of her birth (1875), year of her death (1997), and year when she reached her midpoint in life (1936).

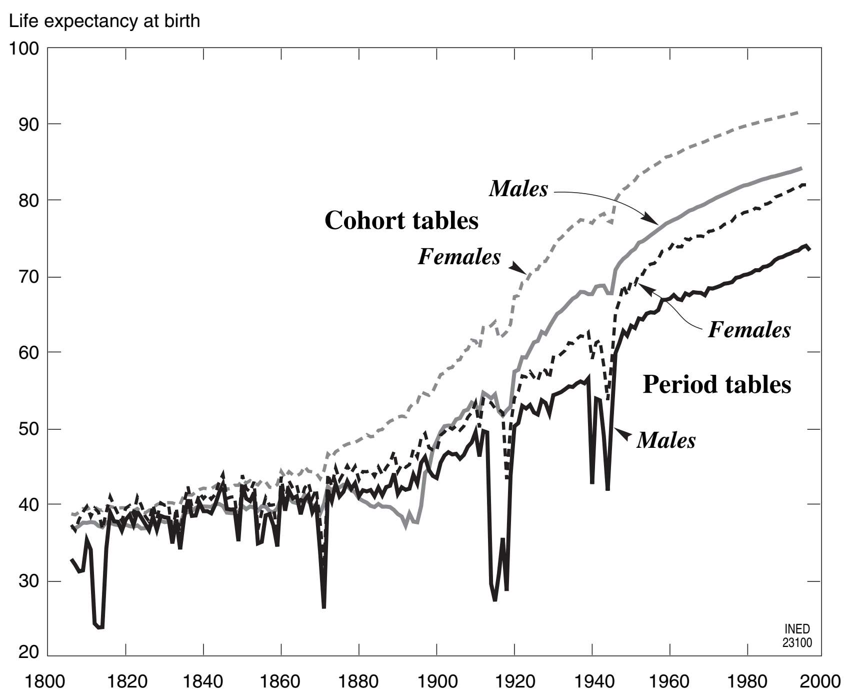

FIGURE 14–8 French female life expectancy at birth since 1806, by calendar year and cohort (cohort values are assigned to year of birth). (Source: Vallin and Meslé, 2001.)

20th century. To overcome this obstacle, we have used the results of an approximately 100-year projection of the period age-specific risks of dying, calculated from a straightforward extrapolation of recent trends (Vallin and Meslé, 2001).

As a rule, of course, the health progress achieved after each cohort's birth enables it, on average, to outlive the life expectancy of its birth-year table. This phenomenon is highly visible here for women. The difference, however, remains very modest for the cohorts born in the early 19th century. The gap does not begin to widen in earnest until the cohorts born after 1850. Initially, it stood at 1 or 2 years, with wide swings due to the persistence of major disturbances at the time. By 1880, the gap had reached 4 years, rising to 9 years at the start of the 20th century. The subsequent pattern naturally depends on the projections but, if these were realized, the gap would continue to widen for some time, reaching about 15 years on the eve of World War II. Beyond, however, it would start to narrow because of the slower gains in period life expectancy, which increasingly depend on the fall in mortality at older ages. In consequence, the gap would be reduced to 13 years for female cohorts born in 1950 and to 10 years for those born 1990 (but, at this point, cohort life expectancy is almost entirely invented by the projection).

The male pattern, which is very different here, shows that significant exceptions to this general phenomenon can result from major historical accidents. In France, male cohort survival was violently disrupted by the two world wars, particularly the first. Despite all the health improvements they enjoyed after their birth, males born between 1880 and 1897 had a far shorter life expectancy than if the mortality conditions of their year of birth had remained constant. All male cohorts born between 1875 and 1902 had a lower life expectancy at birth than the value given by the table for their birth year. In particular, the life expectancy of the 1894 cohort was more than 5 years shorter than that of the year 1894.

II. HYPOTHETICAL INTENSITY AND TEMPO OF FERTILITY

As we have already emphasized (Chapter 8), the subject of the study of fertility (childbearing) differs from the subject of the study of mortality (deaths) on two counts: First, it is not fatal; second, it is renewable. The analysis of fertility must therefore aim to measure two different variables: tempo and intensity. The intensity will seldom equal unity. Its value is just as likely to exceed unity (because fertility is a renewable event) as to be below unity (because we are dealing with a nonfatal event). The probabilistic approach, therefore, cannot be applied to the treatment of fertility as it can to the study of mortality. However, as we saw in the cohort analyses of Chapter 12, if we distinguish a given mother's childbirths by order, the fertility of each order is determined by nonrenewable events and is open to probabilistic analysis. In this case, for the reasons set out earlier, the phenomenon's intensity within the same cohort obviously cannot exceed unity and is usually below it. The conversion of cohort fertility rates into period fertility rates theoretically obeys the same logic, but—and this is where the artificiality of the cross-sectional computation is most clearly demonstrated—the conversion may sometimes lead to parity-specific intensities greater than unity, whereas no woman can obviously have more than one child of the same order.

1. From Age-specific Fertility Rates to the Total Fertility Rate and Mean Age at Childbirth

As discussed earlier, there are different ways to calculate year-of-age–specific annual fertility rates (Chapter 6). In practice, two methods prevail (Figure 14–9): the year-of-age- and observation-year-specific rate, $f_{x,t}$ (type-1 rate, in a Lexis square), and the year-of-birth– and calendar-year–specific rate $f^{p}_{x,t}$ (type 2 rate, in a *projective* Lexis parallelogram). The determination of the rate is most commonly restricted to the interval between ages 15 and 50, since fertility before 15 years and after 50 years is regarded as negligible. However, in some populations where early or late fertility is more frequent, it may be useful to define a wider interval.

As with mortality, if we assume a uniform distribution of births in the age interval, we can shift from one type of rate to the other simply by taking the half-sum of two consecutive rates. Although theoretically false, this hypothesis generally suffices for a valid comparison between series of different fertility rates. Moreover, unlike with mortality, we do not face any problem at the extreme ages. In particular, whatever the computation mode, the first rate is always comparable with the following ones: the first projective parallelogram is not truncated by age 0, since the calculation is only useless (and not impossible) below the minimum fertility age.

Depending on the data available, we may also need to use age-group–specific fertility rates (Chapter 6). One of the most common situations is having to work with five-year age groups.

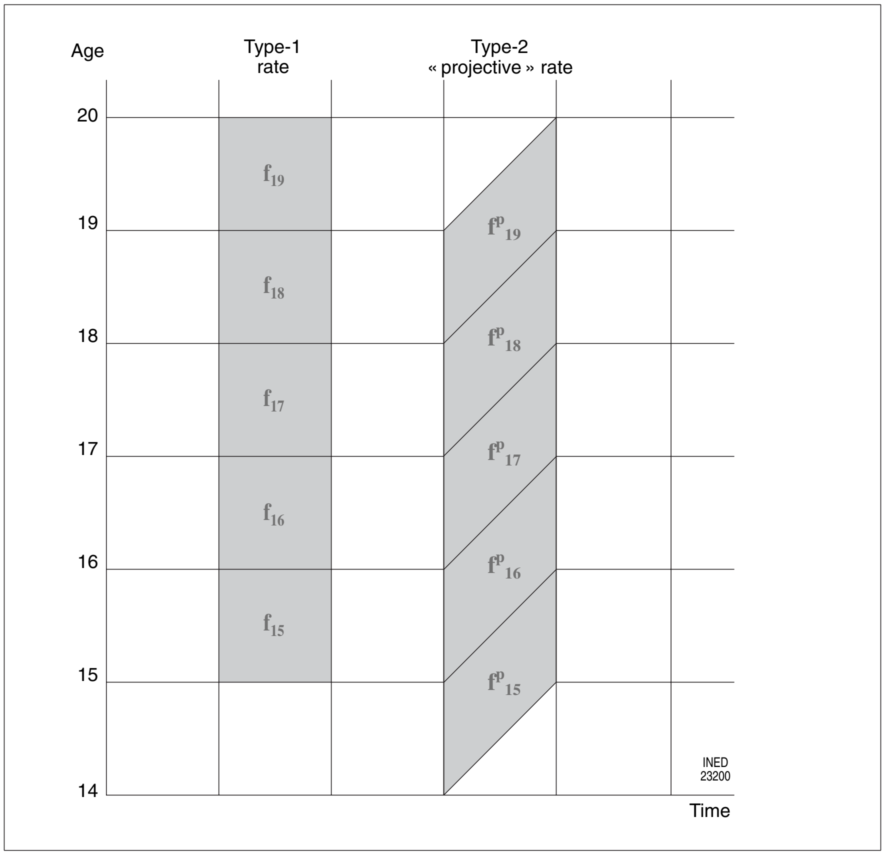

FIGURE 14–9 Position on Lexis diagram of the two most common measures of the age-specific fertility rate allowing the determination of the total fertility rate.

a. Total Fertility Rate

As we did with mortality, we will construct summary or synthetic period fertility indicators that resemble those already compiled on a cohort basis. For this, we combine the age-specific rates observed in a given period within a hypothetical cohort. At the total fertility level, the sum of the age-specific rates gives us the mean number of children per woman of this fictitious cohort. In mortality studies, the convention is to use the term "life expectancy" interchangeably for the hypothetical cohort exhibiting the period rate and for the value measured in real cohorts. In fertility studies, by contrast, the terminology is richer—perhaps too rich—since the expression *completed fertility* is strictly confined to the cohort measure; the period measure is designed differently according to the authors. French-speaking demographers refer in particular to the *sum of reduced births* (*somme des naissances réduites*) (Henry, 1972), *synthetic fertility index* (*indice synthétique de fécondité*) or even "period fertility indicator" (*indicateur conjoncturel de fécondité*) (Calot, 1984). More simply, in the rest of the world and notably among English-speakers, the standard term is "total fertility rate" (TFR) (*tasso di fecondità totale* in Italian, etc.). In our opinion, the *total fertility rate* or *TFR* is the term that best expresses the concept of summing the rates in period form, and we will therefore use it in the remainder of our discussion. However, we will reserve it strictly for period computations, whereas English-language authors often use it interchangeably for real as well as hypothetical cohorts.

If $f_{x,t}$ is the age-x-specific fertility rate in year t, the total fertility rate for the year t is:

$$TFR_t = \sum_{x=\alpha}^{\omega} f_{x,t}$$

where α and ω are the extreme ages of the female child-bearing period.

Naturally, if we are working on age groups, we must multiply each rate[2] by the dimension of the age interval a:

[2] The computation of period fertility rates in a hypothetical cohort effectively consists in applying annual rates to a female population of each age, assumed to be constant. If we are working with rates for 5-year age groups, we must apply each rate five times in a row to this constant female population. Conversely, if we were using month-of-age-specific rates, we would have to divide the sum by 12.

$$TFR_t = \sum_{x=\alpha}^{\omega} af_{(x,x+a),t}$$

If a is the same for all age groups, we obtain:

$$TFR_t = a\sum_{x=\alpha}^{\omega} f_{(x,x+a),t}$$

Most often, we will be dealing with 5-year age groups, and the TFR will be equal to:

$$TFR_t = 5 \cdot \sum_{x=\alpha}^{\omega} f_{(x,x+5),t}$$

The TFR has no standard equivalent in mortality, because its main purpose is to express the total intensity of the phenomenon (necessarily equal to 1 in mortality).[3] On the other hand, we must supplement this intensity indicator by a measure of the tempo of fertility, which does resemble life expectancy: the mean age at childbirth.

b. Mean Age at Childbirth

Unlike with the TFR, but as with life expectancy, the standard terminology does not distinguish at this level between the measure of the tempo of fertility of a cohort and that of a hypothetical cohort reflecting current conditions. In both cases, demographers speak of *mean age at childbirth*. By contrast, we can avoid confusion in regard to the age distribution of the births themselves: the expression *tempo of births* should be confined to the cohort analysis (where it is usually noted α_x), while the term *age-specific proportions of births* should be reserved for period measures. In a hypothetical cohort of women who, at each age, displayed the age-specific fertility measured in year t, the proportion b_x of births to women aged x in this cohort would be equal to:

$$b_x = \frac{f_{x,t}}{\sum_{x=\alpha}^{\omega} f_{x,t}}$$

Continuing the period analysis, we will, of course, find a mean age at childbirth of:

$$\overline{x} = \frac{\sum_{x=\alpha}^{\omega} (x+0.5) f_{x,t}}{\sum_{x=\alpha}^{\omega} f_{x,t}}$$

[3] We should note, however, that Sardon (1993) suggested using this method to construct a summary mortality indicator. In fact, this involves calculating a comparative mortality rate (see Chapter 15) on the basis of a population with equal numbers of individuals at all ages.

if type 1 rates are used, or

$$\overline{x} = \frac{\sum_{x=\alpha}^{\omega} x \cdot f_{x,t}}{\sum_{x=\alpha}^{\omega} f_{x,t}}$$

if type 2 rates are used.

If we work with 5-year age groups, we obtain

$$\overline{x} = \frac{\sum_{x=\alpha}^{\omega} (x+2.5) f_{(x,x+5),t}}{\sum_{x=\alpha}^{\omega} f_{(x,x+5),t}}$$

2. Comparison Between Cohort Indicators and Period Indicators

We will take as an example here the change in the fertility of Italian women, using the abundant database compiled by Santini (1995), which he kindly made available to us. Figure 14–10 compares the age-specific fertility rates of the 1952 cohort with those of (1) its birth year; (2) the year 1967, in which it reached age 15, the presumed start of the childbearing period; (3) the year 1981, in which it reached its mean age at childbirth (29 years); and (4) a year close to that of the end of its childbearing period (here, 1994, the most recent year for which data are available).

This comparison illustrates—as we already did for mortality—how the information supplied each year by period measures diverges over time from actual cohort fertility.

The 1952 cohort obviously has a much lower fertility (1.85 children per woman) than the period rates for its birth year (2.34), and we can see here that the discrepancy is entirely due to a tempo difference. Both curves peak at exactly the same level. In contrast, the cohort completed its fertility earlier than we would have expected from the pace indicated by the age-specific rates of its birth year: its fertility rates rose faster at the earliest ages; more important, they fell much sooner and more quickly after the age of peak fertility. This results from the combination of opposing period trends.

Between the year of the cohort's birth and the year in which it entered its childbearing period, Italy experienced the baby boom tied to the acceleration of its economic development in the 1960s. The TFR rose to 2.53 in 1967, well above the completed cohort fertility (CFR) of 1.85, but also above the *TFR* for 1952. We can see here that the difference between the years 1952 and 1967 is essentially due to the rise in fertility at early

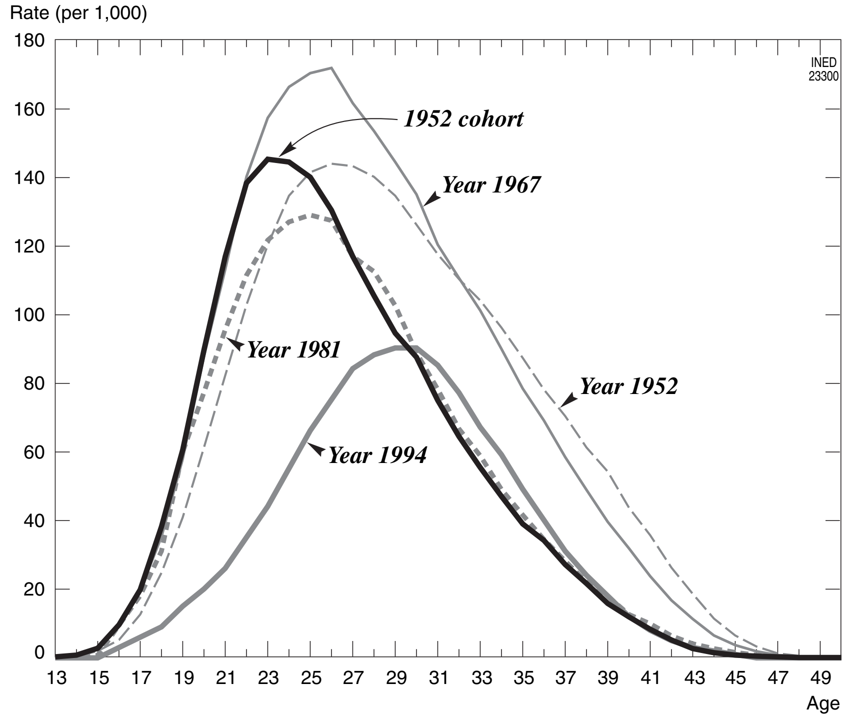

FIGURE 14–10 Age-specific fertility rates of the cohort of Italian women born in 1952 compared with those of its birth year (1952), of the year in which it reached age 15 (1967), of the year in which it reached its mean age at childbirth (1981), and the most recent year for which data are available (1994).

ages and to the increase in the peak. By contrast, the fertility rates over age 30 are the same. It is because the 1952 cohort entered its childbearing period in this very special phase of rising fertility that it began with high fertility rates at the young ages. The phenomenon was short-lived, however: The cohort's fertility leveled off very quickly, well below the peak observed in 1967.

Indeed, soon after the baby boom, Italy began experiencing the drop in period rates that drove its fertility to the world's lowest levels. By 1981, the year in which the cohort reached its mean age at childbirth, the TFR had fallen to 1.76, a value very close to the completed cohort fertility. This is understandable, since in both cases the age-specific fertility is heavily concentrated around its mode. We do note, however, that the 1981 TFR is slightly below the completed cohort fertility (1.78 versus 1.85), because of the cohort's higher early fertility due to the baby boom.

By the time the 1952 cohort reached the end of its childbearing period, Italy's period fertility had literally collapsed: the TFR was only 1.19 in 1994. However, this had virtually no effect on the cohort, as the gap between the age-specific fertility rates of 1981 and 1994 was actually confined to the rates at ages below 30 years—rates that the cohort had exceeded well before.

Figure 14–11 compares the change in Italian women's TFR with the pattern of their completed fertility over nearly three fourths of a century. As with mortality, the comparison between these two different kinds of indicators is problematic. For life expectancy, as we have seen, the age-specific mortality function is highly scattered, with two modes located at the two extremes: There is clearly no satisfactory solution, and we must choose one or the other depending on what we want to examine. For fertility, the situation is somewhat different. The phenomenon is heavily concentrated around a fairly central mode, which tends to be close to the mean age at childbirth. The solution that comes naturally to mind, therefore, is to emphasize the comparison of the completed fertility of a given cohort with the TFR of the year in which the cohort reaches its mean age at childbirth.

Two problems, however, immediately arise. First, the mean age at childbirth is not constant, and we must address the following question: Should we shift forward in time all the cohorts of the series studied by an identical number of years, roughly equivalent to the mean value of the mean age at childbirth in all the cohorts, or should we shift each cohort by its exact mean age? The first approach will cause a slight bias in the sought-for comparison, but the second method will create irregular intervals between two successive

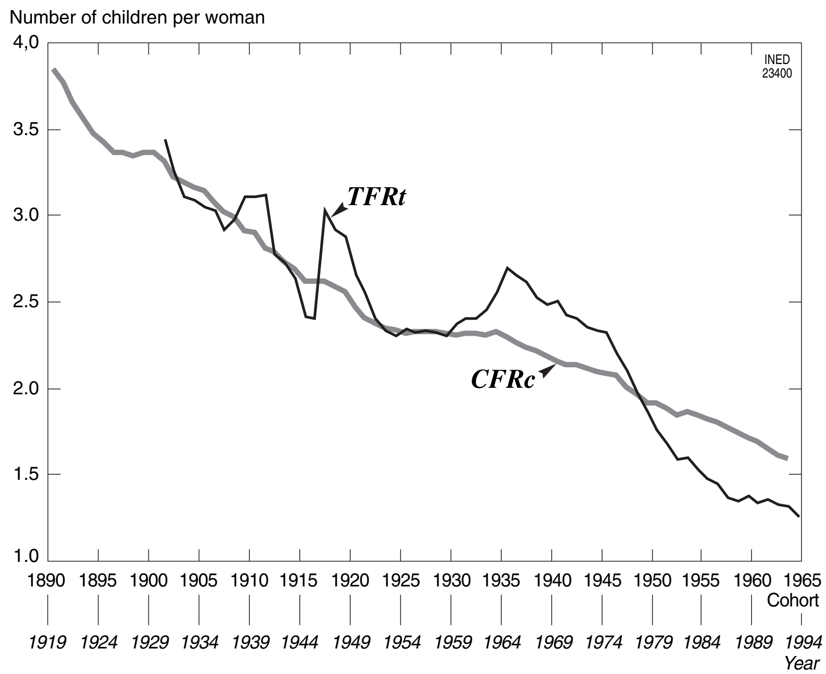

FIGURE 14–11 Change in Italian total fertility rate since 1930 compared with that of completed cohort fertility since 1890.

cohorts, which may make the chart harder to read. In fact this problem is usually minor, as the mean age at childbirth changes slowly; in most cases, demographers choose the first solution. Here, we have shifted all the cohorts by 29 years (Figure 14–12). The second problem is more fundamental: However rational it may seem, this exercise remains a comparison between two indicators of different kinds, which should therefore never be compared without losing sight of their different significance. It is because he forgot (or pretended to forget) this difference that one author, in making the comparison, felt entitled to conclude that one indicator—completed fertility—was objective and hence more trustworthy, while the other—the TFR—was ruled to be deceitful (Le Bras, 1991). In reality, the comparison must, above all, help the analyst and the reader to clearly identify the intrinsic difference between the two measures.

The example of Italy is particularly interesting, as it concerns the tumultuous recent history of the country's fertility (Figure 14–11). In the three fourths of a century observed, the downtrend is unquestionably steep regardless of which indicator is used. From this standpoint, there is no basic difference in the result. However, there is a striking contrast between the sharp swings in the TFR and the steady curve of completed fertility. This highly classic contrast perfectly reveals the intrinsic difference between the two indicators. Although the TFR faithfully registers all the bumps in the cycle, completed fertility may be regarded as a summary of changes in behavior within each cohort. By comparison with the TFR, these changes may seem fairly chaotic. Often, however, they simply represent intracohort phenomena driven by expectations or adjustments aimed at achieving a desired family size.

Indeed, neither the surge in fertility triggered by the profamily incentives of the Fascist regime in the 1930s (also observed in Germany in the same period), nor the birth deficit of World War II prevented Italian women from gradually but steadfastly reducing their completed fertility. The TFR upswing in the Fascist era actually made up for a lag that developed in earlier years, and the official measures enacted at the time presumably anticipated the population's desire to readjust family size. Even more clearly, the birth deficit due to World War II was compensated by a very characteristic recovery phase just after the Liberation; at that time, however, Italy did not experience a baby boom comparable to that observed in many European countries.

However, Italy registered a true baby boom in the 1960s, linked to the acceleration of its economic and social development, as we can readily see from the TFR curve. This phenomenon reflects a deep-seated change in behavior, in that it persisted long enough to produce a distinct upturn in completed fertility. For about 15 years—from the cohorts born in the early 1920s to the cohorts born in about 1935—completed fertility

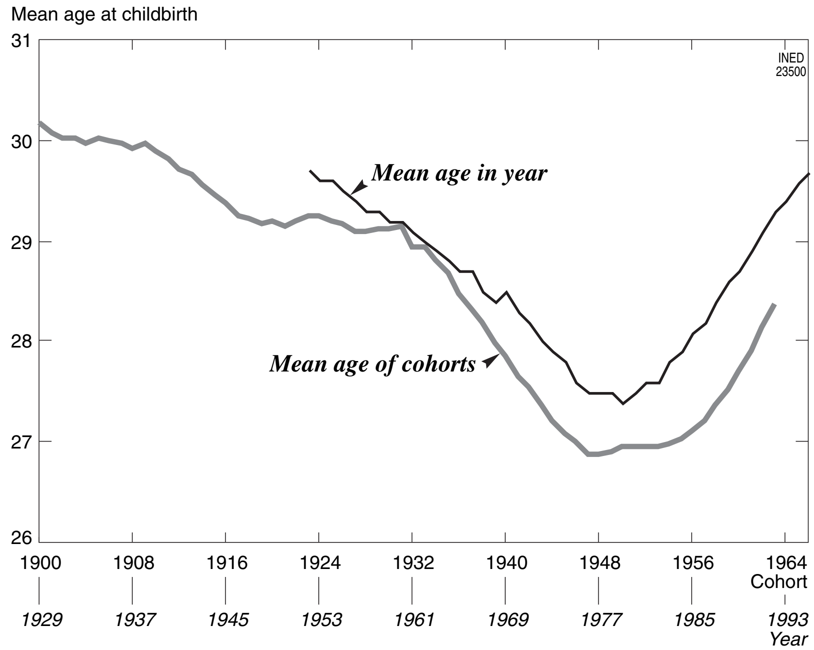

FIGURE 14–12 Period mean age at childbirth since 1952 and mean age at childbirth of cohorts since 1900, in Italy.

stopped falling and stabilized at around 2.3 children per woman.

In the end, though, the long-term decline in fertility resumed: the abrupt collapse of the TFR in the 1970s presumably signals a new, radical change of behavior whose impact on completed fertility cannot yet be fully measured for lack of sufficient historical perspective.

The changes in behavior affect not only the intensity of fertility, but also its tempo. Even if the fluctuations in the mean age at childbirth are confined, as we have said, to a relatively narrow range compared with that of the TFR or even of completed fertility, the mean age has changed significantly during the century in Italy (Figure 14–12). We can see here, however, that unlike the pattern for the intensity indicators, the two indicators of mean age at childbirth move on parallel lines. In both cases, the long-term reduction in the mean age suddenly quickened in midperiod (1960s or cohorts born after 1930); after bottoming out in the mid 1970s and in the cohorts born in the early 1950s, the mean age has since climbed back abruptly.

This similar pattern does come with a major difference, however: Throughout the period, the mean age at childbirth of each cohort was consistently below that of the year in which the cohort reached the mean age. Later, we shall see that what is true of total fertility is not necessarily true of parity-specific fertility.

However, the mean age at childbirth is only a summary index of fertility tempo. Changes in behavior can also alter the age distribution of births, and such shifts are not necessarily measured by the mean age.

To illustrate this point, Figure 14–13 takes up the comparison in Figure 14–10 between the cohort born in 1952 and four selected years: The year of its birth (1952), the year in which it reached age 15 (1967), the year in which it reached its mean age at childbirth (1981), and the most recent year for which data are available (1994). We simply replaced the age-specific fertility rates by the tempo for the cohort and the proportions of age-specific births for the calendar years.

The youngest of all distributions is that of the 1952 cohort. As described earlier, it reached the years of the Italian baby boom in the very first years of its childbearing period and later experienced the return to the downtrend in Italian fertility. These two events combined their effects to give this cohort what ultimately turned out to be a very early fertility.

However, we are more interested here in the changes in the period distribution of births. The contrast is striking between (1) the very steady movement, from 1952 to 1967 and then to 1981, toward a birth distribution increasingly concentrated around an ever-higher mode, and (2) the abrupt switch, from 1981 to 1994, to an entirely different distribution in which the mode, without changing level, suddenly shifted 5 years. Until 1981, the fall in the age at childbirth had been achieved simply through an increased concentration around a near-constant mode. By contrast, the

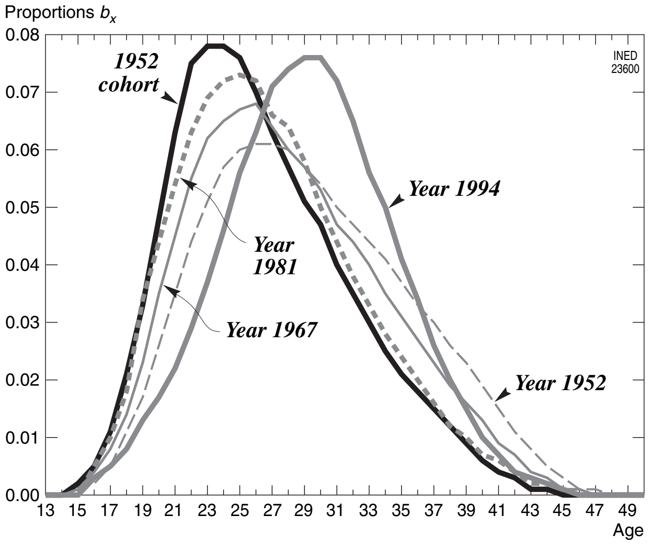

FIGURE 14–13 Fertility tempo of Italian female 1952 cohort compared with proportions of age-specific births observed in 1952, 1967, 1981, and 1994.

recent aging is being accomplished almost entirely through a shift in the mode, without a reduction of the concentration around it.

3. Translation Models

Through several comparisons between period indicators and cohort indicators, we have seen the extent to which circumstances can cause period indicators to diverge from cohort indicators, simply because of the recombination at a given moment, within a hypothetical cohort, of age-specific timing factors among different cohorts that have experienced different histories. The divergence is greater in fertility than in mortality owing to the fact that the change concerns both final intensity and tempo. It is therefore especially interesting to examine how the measure of period fertility may be affected by the changes in fertility tempo and intensity for the cohorts concerned.

Let CFR^i be the sum of reduced events of cohort i and TFR_t the sum of reduced events of year t. From a cohort perspective (but the situation would be symmetrical in a period approach), each rate $f^i_{x,t}$ can be viewed as a proportion of the completed fertility CFR^i achieved by cohort i in t:

$$f^i_{x,t} = \alpha_x CFR^i$$

The quantity α_x denotes the share of final intensity achieved by the cohort in t at age x. The period sum of reduced events of year t can be written as:

$$TFR_t = \sum_{x=15}^{49} \alpha^i_x CFR^i$$

This equation clearly expresses the fact that the period sum of reduced events is a function of the intensity and tempo of cohort fertility. The variations in tempo from one cohort to the next cause changes in the intensity of period fertility; ultimately, the observed cohort intensity is determined by the tempo and intensity that characterize the cohorts living through the period studied. *Translation models* rely on this relationship to measure the influence of changes in successive cohorts' fertility behavior on the variation in period fertility.

The resolution of the problem in its most general form is, however, very complex. We need to take into account all the possible types of change, from one cohort to the next, in both components of cohort fertility: intensity and tempo. Norman Ryder (1963, 1964) was the first to formulate a model for doing so. Keilman comprehensively addresses this issue in Chapter 17.

4. Parity-specific Fertility

As we saw in our discussion of cohorts (Chapter 12), we can study fertility as a series of nonrenewable events by distinguishing births by order. We can thus also consider a translation of parity-specific fertility indicators into period indicators. However, thanks to retrospective surveys (presented in Chapter 12), the current conditions of period observation are very different from those we can use in a cohort approach. Such surveys, provided they cover sufficiently large samples, could no doubt allow period reconstructions, at least for the few years immediately preceding the survey.[4] The Family Survey conducted in France with each population census may, for example, provide the necessary information. But this kind of operation does not allow a computation of parity-specific period fertility indicators except for a few periods scattered in time. Consequently, they cannot provide a steady tracking of phenomena, as we would expect of period analysis. The latter depends essentially on current statistics.

Now, while current birth statistics are fairly often compiled by birth order (or mother's parity), the same is not true of January 1 population estimates. These never give the distribution of women by parity. The standard practice, therefore, is to calculate parity-specific fertility rates, expressed as the ratio of births of each order, not exclusively to women of the parity immediately below (i.e., the mothers who have not yet had a child of the order examined), but to all women

[4] These surveys typically cover samples of women of childbearing age at the time of the survey, and we cannot calculate period rates at all ages except in the most recent period.

regardless of their parity.[5] In other words, instead of computing a specific occurrence-exposure rate (known in French as a *first-category rate* [*taux de première catégorie*]) as follows (see Chapter 8):

$$_1f_x^k = \frac{B_x^k}{\bar{F}_x^{(k-1)}}$$

where B_x^k stands for births of order k of a mother aged x and $\bar{F}_x^{(k-1)}$ stands for the mean number of women aged x and of parity k-1, we calculate a fertility frequency (known in French as a *second-category rate* [*taux de deuxième catégorie*]):

$$_2f_x^k = \frac{B_x^k}{\bar{F}_x}$$

typically written in simpler form as f_x^k, where $\bar{F}_x$ represents the mean number of all women aged x, regardless of their parity. This measure of parity-specific fertility has a drawback and an advantage. The drawback is its bias: By including in the denominator women who are not concerned by the phenomenon, we underestimate the fertility of each order. On the other hand, the values obtained for each order are additive, so that by summation we can obtain the TFR for all orders in the aggregate.

For instance, for order k and observation year t, we find the k-specific TFR:

$$TFR_t^k = \sum_{x=\alpha}^{\omega} f_{x,t}^k$$

and we obtain the all-orders TFR by summing the order-specific TFRs:

$$TFR_t = \sum_{k=1}^{n} TFR_t^k = \sum_{k=1}^{n} \sum_{x=\alpha}^{\omega} f_{x,t}^k$$

We can also determine the proportions of order-k births:

$$b_{x,t}^k = \frac{f_{x,t}^k}{\sum_{x=\alpha}^{\omega} f_{x,t}^x}$$

and an order-k mean age at childbirth equal to:

$$\bar{x}_t^k = \frac{\sum_{x=\alpha}^{\omega} (x+0.5) f_{x,t}^k}{\sum_{x=\alpha}^{\omega} f_{x,t}^k}$$

Let us return to the Italian example. Figure 14–14 illustrates the change in the order-specific TFR for orders 1, 2, 3, 4, and higher. This distinction basically enables us to grasp two phenomena. First, only the order-1 and -2 fertility rates are highly exposed to purely short-term fluctuations (jump in the 1930s, World War II deficit, and postwar catch-up). By contrast, orders 3 and higher are also subject—rather conspicuously—to the more fundamental changes that followed: the baby boom of the 1960s and the sharp drop of the 1970s to 1980s, although these events have a sizable effect on the first two orders as well.

Second, although the order-1 and -2 fertility rates are barely sensitive to the century-long downtrend, the entire burden of the decline has been shouldered, until recently, by orders 3 and higher. We also note, however, that the recent slump also affects order-2 fertility and even, to a lesser extent, order-1 fertility. This clearly denotes a qualitative change in the century-long decline of Italian fertility. Until the 1970s drop, the downtrend not only failed to undermine first-birth fertility, but even coincided with an upturn in the latter, partly thanks to the decline in sterility. Now, the behavior of a growing number of Italian couples is actually compromising the entry into the childbearing period.

This breakdown of fertility by birth order applied to Italy also gives us the full measure of the artificiality of the hypothetical cohort: in a real cohort, the parity-specific TFR can never, by definition, exceed unity, because no woman can have more than one child of the same order; with the hypothetical cohort used here, the order-1 TFR exceeds unity in some years.[6] This phenomenon occurs in the years of unusually high fertility, during the postwar catch-up (1947 and 1948) and in the Italian baby boom (1964 and 1965), despite the fact that the fertility frequencies underestimate real parity-specific fertility.

Table 14–1, illustrated by Figure 14–15, presents the Italian age- and parity-specific rates for the year 1964. Figure 14–16 plots the mean age of mothers at the birth of their first child in Italy, again by comparing the period and cohort data. As already noted with all-parities fertility, the two indicators move in a fairly similar pattern. However, the two curves virtually overlap here; in the all-parities measure, the cohort indicator ran consistently above the period indicator.

[5] The term *fertility rate* is ambiguous, as pointed out in Chapter 8. As in the latter, we distinguish here *occurrence-exposure fertility rates* from *fertility frequencies*.

[6] This is due to the type of indicator used: the anomaly is very visible with the fertility frequencies (*taux de seconde catégorie*) used here, but is eliminated when occurrence-exposure rates (*taux de première catégorie*) are used (see Chapter 8 for definitions).

TFR, total fertility rate.
From Antonio Santini database

5. Age- and Order-specific Birth Probabilities

The paradox of greater-than-unity order-specific TFRs is eliminated by construction when we switch to probabilistic calculus for constructing order-specific fertility tables: This involves a recombination by period not of the fertility rates but of the probabilities of giving birth to a order k child at age x. Since we are dealing here with nonrenewable events, we can indeed (as with mortality) compute order-specific birth probabilities by determining the ratios of order k births occurring between two birthdays to the initial number of women having borne k-1 children. Whelpton (1946, 1954) was the first to use summary fertility indices compiled from fertility tables.

The problem we face again here, however, is data availability. Only surveys provide the identification of female parity needed to correctly determine the number of women in the denominator. We therefore cannot construct order-specific fertility tables except on an occasional basis, when a survey or census offers a favorable opportunity.

In such circumstances, the probabilities are seldom calculated directly, but—as we already saw with mortality—they can be estimated from the rates without risk of serious error. The only requirement is that the rates should be true occurrence-exposure rates as described in Chapter 8 (see also Federici, 1965; Pressat, 1969). We can then construct a fertility table for order k as follows: we take an agreed initial population of women aged α having had k–1 children; through successive iterations—as with the life table—we apply to that population the order-k birth probabilities to obtain the number of parity-(k–1) women remaining at each birthday and the order-k births of the table between two birthdays. The total number of births in the table can never exceed the initial number of parity-(k–1) women, and the final intensity of order-k fertility obtained by dividing the two values will not exceed unity. In fact, the figure will usually be below unity, given that maternity is not a fatal event and that all women having had $k - 1$ children will not necessarily go on to have a kth child.

The problem is that we seldom have the data available on the parity distribution of the female population. This is why the computations are often confined to fertility frequencies. Shryock and Siegel (1973) proposed an indirect estimation of occurrence-exposure rates from frequencies;[7] Giorgi (1993) showed that this procedure yields a result that is very close to that of the direct calculation.[8] The estimate must, however, be determined within each cohort. We can accordingly write, for all orders $k > 1$:

$$_1f_x^k = \frac{f_x^k}{\sum_{15}^{x-1} f_x^{k-1} - \sum_{15}^{x-1} f_x^k}$$

and, of course, for order 1:

[7] See also Santini (1992).
[8] See also the applications by Das Gupta and Long (1985).

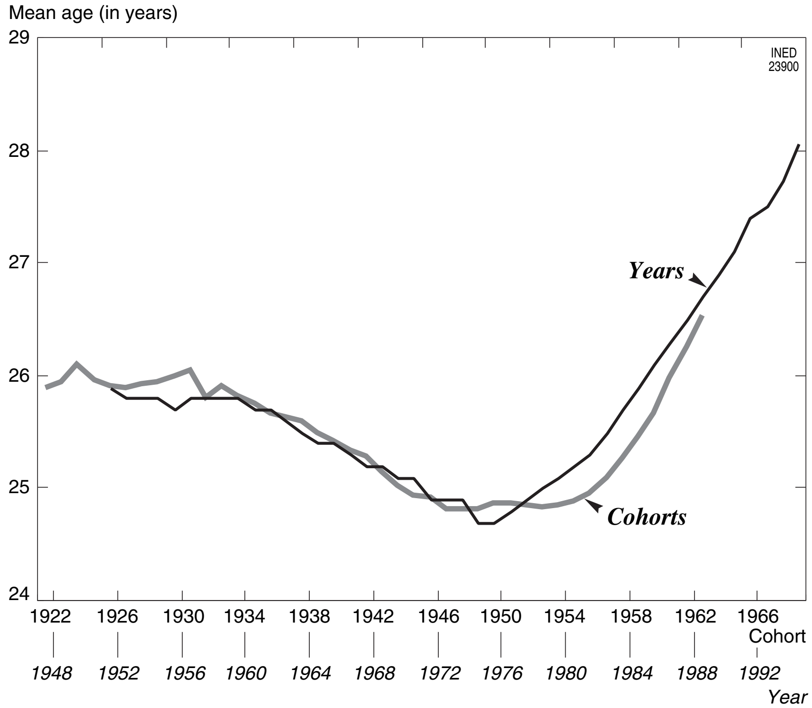

FIGURE 14–16 Mean age of mother at birth of first child, based on period data (1952–1994) compared with mean age observed for cohorts from 1922 to 1963, in Italy.

$$ {}_1f_x^1 = \frac{f_x^1}{1 - \sum_{15}^{x-1} f_x^1} $$

From these occurrence-exposure rates (which, for narrow age intervals, can be equated with birth probabilities), Giorgi (1993) constructed, on a probabilistic basis, *parity-specific period fertility tables* for Italy since 1950. The sum of the table's order-*k births* gives the hypothetical cohort's order-*k* completed fertility. Thanks to these data and the cohort figures compiled by Santini (1995),[9] we can compare over a long period (Table 14–2 and Figure 14–17) the order-1 completed fertilities for each period (CFR_p^1) and each cohort (CFR_c^1) with the order-1 total fertility rate calculated from the fertility frequencies (TFR_{t2}^1). Two facts are immediately obvious: (1) The paradox of greater-than-unity TFRs is eliminated by using occurrence-exposure rates or birth probabilities for calculating the sum of births in the table; (2) the births of the period table closely follow the changes in completed fertility of cohorts reaching their mean age at order-1 childbirth. The inefficiency of the fertility frequencies is evident, as is the imperative need to avoid equating their sum with the completed fertility of a hypothetical cohort.

[9] We thank the two authors for giving us access to the computer files of their findings.

The main goal here, however, is not to compare cohort measures with period measures but to describe the sequence of events with as little bias as possible.

Table 14–2 also gives mean ages at childbirth calculated from fertility frequencies and from the period-table births. Again, we can see the wide gap between the two measures and the need to avoid the measure derived from fertility frequencies (Figure 14–18).

Ultimately, the combination of final intensities of the parity-specific fertility tables and the combination of the final intensities of TFRs expressed as occurrence-exposure rates offer an identical measure of the final intensity of total period fertility—which, however, differs considerably from the *TFR based on fertility frequencies*. Figure 14–19 plots the curves for the two types of rate that measure total fertility regardless of parity distribution. For the sake of comparison, we have added the completed-fertility curve.

The period covered by the chart includes both the baby boom and the recent collapse of Italian fertility. Whatever the measurement method used, the TFR swings are much sharper than those of completed fertility. But the frequency-based TFR greatly exaggerates the real difference indicated by the occurrence-exposure TFR. All the same, the abrupt plunge in the occurrence-exposure TFR after the baby boom and even more so in the 1970s has dragged down completed fertility: Although slower, this decline does seem inevitable.

TABLE 14–2 Order 1 TFR^1_{t2} and Mean Age at Order 1 Childbirth Calculated from Fertility Frequencies, Compared with Sum of Births (Final Intensity) and Mean Age at Childbirth Given by Parity-1 Fertility Tables in Italy, 1952–1990

Cohort		Period

6. Taking into Account Duration Since Last Birth and Constructing New Summary Indicators of Period Fertility

In an interesting article, Rallu and Toulemon (1993) showed that the TFR was only one of several summary indicators of period fertility. The basic approach in period analysis is to measure the fertility of a hypothetical cohort that would be subject throughout its life to the conditions of the year studied. If we want to take this notion to its ultimate conclusion, we should not simply standardize the indicators on the basis of age by summing age-specific rates. We should also incorporate other variables that can influence fertility, notably birth order, but also duration since last birth, marital status, educational attainment, socio-

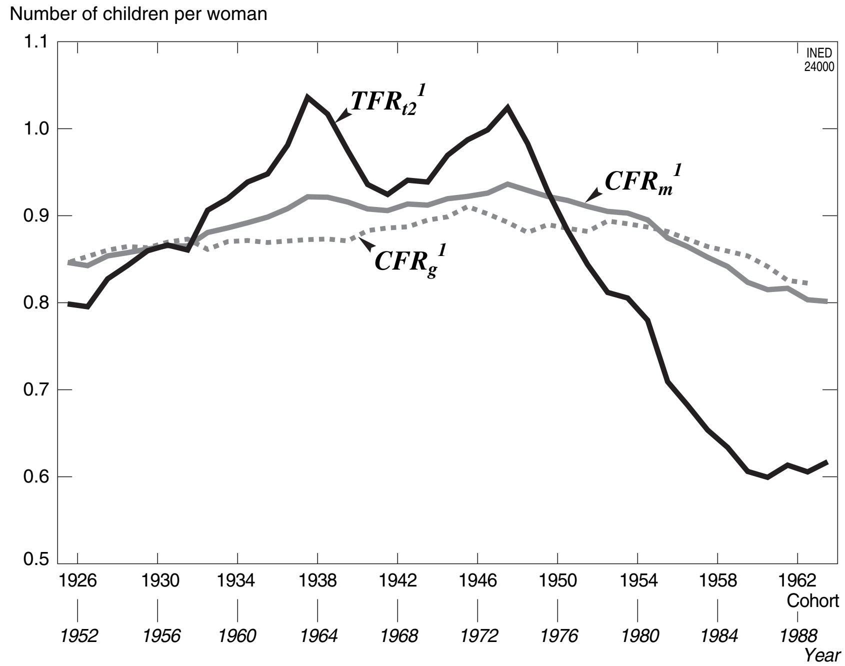

FIGURE 14–17 Order 1 period (CFR^1_m) and cohort (CFR^1_g) completed fertilities compared with order 1 total fertility rate calculated from fertility frequencies (TFR^1_{t2}).

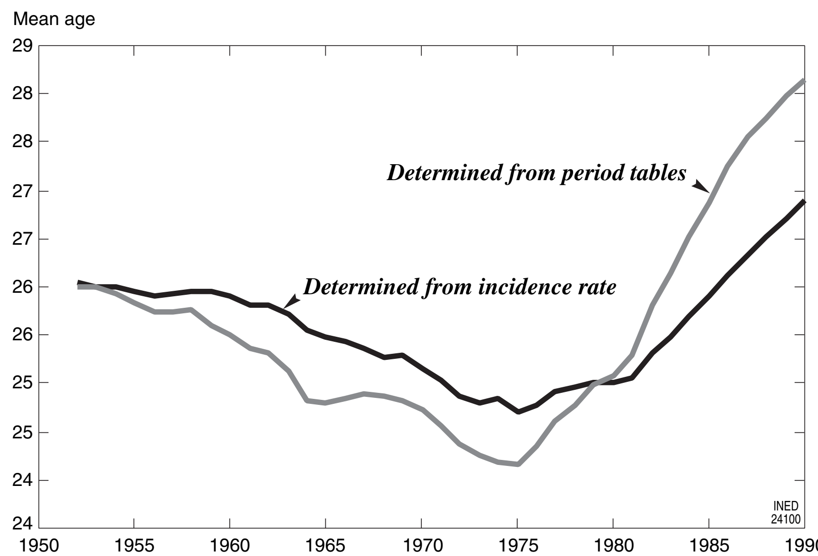

FIGURE 14–18 Mean age at childbirth calculated from period fertility tables compared with value obtained from fertility frequencies (Italy, 1950–1990).

occupational category, and so on. The authors show that, depending on the type and degree of detail chosen for these standardizations, we can obtain summary indicators of period fertility whose values may differ rather significantly.

In particular, Jean-Louis Rallu and Laurent Toulemon compare the classic TFR as defined earlier with two other indicators, each containing an additional refinement. The first is a summary index of parity- and age-specific fertility (*PATFR*); the second is a summary index of parity-, age-, and duration-specific fertility (*PADTFR*).[10]

[10] In French, the authors designate the standard *TFR* as *ISF* (*indice synthétique de fécondité*), and their two new indicators as *ISFRA* (*indice synthétique de fécondité d'après les quotients par rang et âge*: here *PATFR*) and *ISFRAD* (*indice synthétique de fécondité d'après les quotients par rang, âge et durée*: here *PADTFR*).

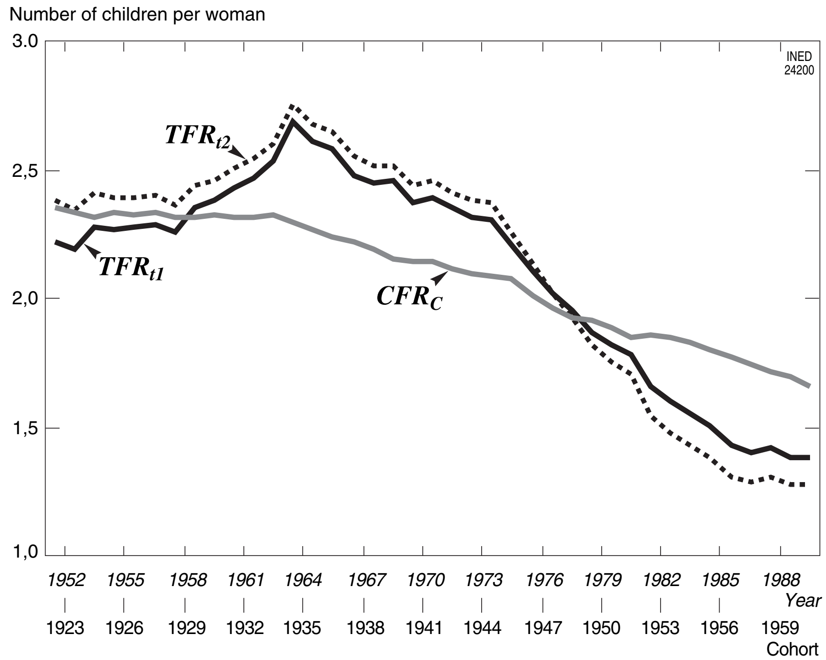

FIGURE 14–19 Occurrence-exposure and frequency total fertility rates 1952 to 1988, compared with completed fertility of cohorts from 1923 to 1959 (Italy).

To measure the impact of parity, the authors take up Guy Desplanques' (1985, 1986) suggestion that fertility behavior in a given year is defined by the probability of childbearing as a function of the mother's age and the number of children already born. Let us assume we can calculate $q^k_{x,t}$, the order-k birth probability at age x in year t (i.e., the probability that a woman aged x who has already had k-1 children at the start of the year will give birth to a child in year t). If so, we can construct a fertility table combining age and parity. As the table radix, we take a number F^0_{15} of childless women aged 15. We can then estimate the number F^k_{50} of women who would have k children at the end of their childbearing period, at age 50, if they experienced at each successive age the age- and order-specific fertility conditions prevailing in year t. The *PATFR* of year t is ultimately expressed as:

$$PATFR_t = \frac{\sum_{k=1}^{n} k \cdot F^k_{50}}{F^0_{15}}$$

Likewise, if we can calculate for year t the birth probabilities $q^{k,d}_{x,t}$ for age x, order k, and duration d since the previous birth, we can construct a fertility table combining age, parity, and duration. Taking a radix of $F^{0,0}_{15}$ childless women aged 15, and making d vary within limits enabling us to compute order-specific probabilities, we obtain—as in the previous calculation—the number of women having given birth to k children by age 50. This assumes that the hypothetical cohort experienced at each successive age the age-, order-, and duration-specific fertility conditions prevailing in the observation year t. Their sum divided by the initial population yields the PADTFR for year t.

Combining, the information drawn from the French 1982 Family Survey (Desplanques, 1985) and the current statistics obtained from civil registration and censuses, Rallu and Toulemon (1993a and b) demonstrated that, from 1975 to 1989, these various summary indicators of period fertility gave significantly different measures of changes in fertility in certain periods (Figure 14–20).

For 1975, the two summary indicators gave roughly the same value for France as the conventional TFR (1.94 for the PATFR and 1.92 for the PADTFR versus 1.93 for the TFR). In 1989, on the other hand, the divergence was substantial: The TFR stood at 1.81, compared with a PATFR of 1.87 and a PADTFR of 1.94.

One can, however, question the significance of such refinements in period measurements. "How far should one go in including additional covariates, provided that we have sufficient data?" asks Nico Keilman (1993; p. 426), adding,

> Statistical tests exist to determine whether an extra covariate improves the model's fit. But more important is the question whether it is easier to understand the time pattern exhibited by a certain summary indicator than the development shown

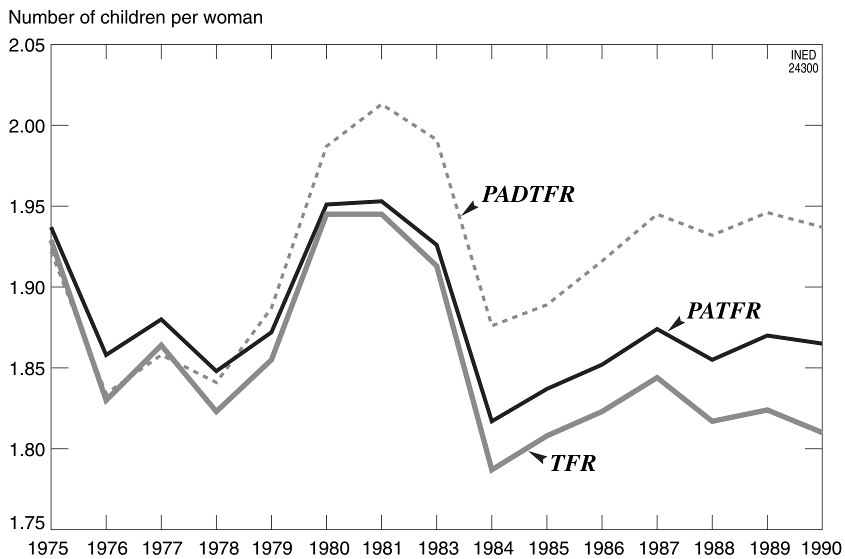

FIGURE 14–20 Period fertility in France as measured by Rallu and Toulemon's parity- and age-specific fertility rate (*PATFR*) and parity-, age-, and duration-specific fertility rate (*PADTFR*) compared with standard total fertility rate (*TFR*) (1975–1989).

by a less detailed one. For a forecaster it would be relevant to know which of these two is easier to extrapolate.[11]

7. Parity Progression Ratios

The mean number of children per woman in a order k period fertility table offers a cross-sectional view of the probability a_k, for a woman having had $k - 1$ children, that she will have at least one more child, in a hypothetical cohort that would exhibit during its entire childbearing period the same behavior as the one displayed in the observation year by the various cohorts involved. This is a period expression of the concept of *parity progression ratio*, defined on a cohort basis (Chapter 12).

For order 1, the complement to unity of the intensity gives a measure of the proportion of infertile women in the hypothetical cohort. We can also take the order k births of the table to compute the order-k-specific mean age at childbirth. We can continue the period reconstruction by combining the final intensities of order-specific fertility to obtain a summary indicator of total fertility by transposing the CFR to the hypothetical cohort:

[11] *Jusqu'où peut-on aller dans cette décomposition si les données sont disponibles? . . . Des tests statistiques permettent de dire si l'inclusion d'un facteur supplémentaire améliore l'ajustement par le modèle. Mais il est plus important de se demander si l'évolution chronologique décrite par un indicateur est plus facile à comprendre que celle décrite par un indicateur plus simple. Pour un prévisionniste, il s'agirait de se demander quelle est la série la plus facile àextrapoler* (Keilman, 1993).

$$a = a_0 + a_0 \cdot a_1 + a_0 \cdot a_1 \cdot a_2 + \ldots + \prod_{k=0}^{n} a_k$$

where n is the final birth order observed in the population.

This second measure of final intensity of all-parities fertility computed for a hypothetical cohort from a period table differs significantly from the TFR calculated from age-specific rates if these are frequency rates, but are instead very similar if we use occurrence-exposure rates.

We can also determine parity progression ratios from frequency parity-specific TFRs. At parity 0, the proportion of women who, in the hypothetical cohort, will have had at least one child is given by the order-1 TFR, which we can interpret as the probability for childless women of having a first child. For the observation year t:

$$a_{0,t} = TFR^1_{t2}$$

Subsequently, assuming the order 2 TFR gives us the proportion of women having had at least two children, we can obtain the probability for a woman having had one child of having a second by dividing this proportion by the preceding one:

$$a_{1,t} = \frac{TFR^2_{t2}}{TFR^1_{t2}}$$

and so on:

$$a_{k,t} = \frac{TFR^{(k+1)}_{t2}}{TFR^k_{t2}}$$

Again, we can recombine these parity progression ratios to determine the final intensity of the hypothetical cohort's total fertility:

$$a = a_0 + a_0 \cdot a_1 + a_0 \cdot a_1 \cdot a_2 + \ldots + \prod_{k=0}^{n} a_k$$

III. EXTERNAL MIGRATIONS

Continuous tracking of external migrations using period indicators is generally hampered by the lack of a system for gathering current statistics on the country's inbound and outbound migration flows. Few countries maintain records of migration flows comparable to the civil registration of births and deaths. Of the countries that do operate such a system, even fewer can claim that it operates efficiently.[12]

1. Countries with Comprehensive Migration Registers

If such a system exists and is sufficiently reliable, we can—as with mortality and fertility—rearrange the emigration and immigration rates in period form to construct summary indicators for hypothetical cohorts that display, at each age, the migration behaviors adopted in an observation year by the cohorts reaching those ages in that year. As with fertility, we can use two types of rates: type 1 rates (in the Lexis squares) if the migrations are classified by age and observation year, or type 2 rates (projective parallelograms), if the statistics are kept by birth year and observation year. But, as with mortality, if we use type 2 rates, we will need to solve the special problem posed by the first year of age, which straddles the first Lexis triangle and the first projective parallelogram. Migration, like fertility, consists of renewable events, and we need to distinguish between two situations. In the first, we do not identify the migration order: as a result, we can calculate only *migration frequencies*. In the second case, we can classify migrations by order, which theoretically paves the way for a computation of occurrence-exposure rates. Obviously, the first situation is more common.

For emigration, we can accordingly sum the *age-specific emigration rates* (or emigration frequencies), $e_{x,t}$, of year t (whether they are type 1 or type 2 is of little importance here). We thus obtain a *total emigration rate* (*TER*) for year t:

$$TER_t = \sum_{x=0}^{\omega} e_{x,t}$$

By contrast, to compute the mean age, we will need to take into account the type of rate used. For a type 1 rate, the expression is very simply:

$$\overline{x}_t = \frac{\sum_{x=0}^{\omega} (x+0.5) e_{x,t}}{\sum_{x=0}^{\omega} e_{x,t}}$$

but, for a type 2 rate, the expression becomes:

$$\overline{x}_t = \frac{0,25 \cdot e_{0,t} \sum_{x=1}^{\omega} x \cdot e_{x,t}}{\sum_{x=0}^{\omega} e_{x,t}}$$

Of course, as with fertility, we can also work on age groups. The formulas are the same (see previous section).

On the immigration side, we face the same problem here as the one already encountered in cohort analysis: As a rule, we do not know the immigrants' population (or, more accurately, populations) of origin. For lack of a better method, demographers usually divide the age-specific inflows by the receiving population of the same age to obtain the immigration rate at age x in year t, $i_{x,t}$. This rate, of course, differs radically from the emigration rate, because none of the individuals included in the numerator belongs to the population forming the denominator. The inconsistency of such rates is vividly illustrated by some extreme situations. In the United States, for example, at the time of the westward Gold Rush, it was not uncommon for the number of immigrants in a given area to exceed that of the native inhabitants. Here is an even more striking example: If we had had to calculate immigration rates to Reunion Island (in the Indian Ocean) when the island was discovered totally devoid of human inhabitants, we would have had to divide the number of immigrants by a zero denominator. In most cases, however, the calculation is of some value, as it gives a measure of the scope of the immigration phenomenon relative to the host population, as well as its age- and sex-specific distribution.

Once the basic principle is accepted, the computations are exactly identical to those for emigration: we merely need to replace $e_{x,t}$ by $i_{x,t}$ in the previous equations to obtain the *total immigration rate* (*TIR*) and the mean age at immigration.

One important consequence should be noted, however. If, instead of a country's total population, we

[12] In Europe, for example, a system of this kind operates fairly efficiently in the Scandinavian countries but very poorly in Italy; most countries have no migration register at all.

TABLE 14–3 Age-specific Net Migration Rate (per 1000) Between ages 30 and 50 of the Italian Male Cohort Born in 1941 Compared with Rates for 1972 and 1980

Age	Cohort		Year

examine the population of one of its territorial units by using the registration data, we can avoid the difficulty inherent in measuring immigration. For this purpose, we treat immigration as the emigration from all the territorial units toward the unit studied (but this does assume that international migrations are negligible).

2. Estimating Intercensal Annual Age-specific Net Migration

In the absence of a continuous recording of inflows and outflows, we can—as in cohort analysis (Chapter 13)—confine our study to net migration by subtracting the natural surpluses provided by vital statistics from the intercensal excesses. The $nm_{x,t}$ rates of age- and cohort-specific net migration estimated by means of the method described in Chapter 13 can be used here for a period computation. They will provide summary intensity and tempo indicators for hypothetical cohorts: the TMR of year t (TMR_t) and the *mean age at migration* of year t ($\bar{x}_t$).

We must naturally be careful not to confuse such rates, which measure relative balances, with the rates reflecting propensities to die, have children, emigrate, and so on. These rates can be negative or positive, depending on the direction of the net flow, and their sum within a hypothetical cohort, as within a real cohort, can be equal to zero without signifying the total lack of migration in the cohort. Accordingly, as we saw in cohort analysis, it makes more sense to sum the absolute values of the net rates. Table 14–3 and Figure 14–21 compare the results obtained for Italian males in the years 1972, 1980, and 1990 with the values for the 1941 cohort.

For practical reasons, we have included in the table only the adult ages from 30 to 50.[13] This is because the data used to construct the table are the ones already described in Chapter 13: They were obtained from an age breakdown of the intercensal 10-year net migra-

[13] The age reported in the table is the complete age on the initial January 1. The age listed as 48 therefore covers the exact ages from 48 to 50 years.

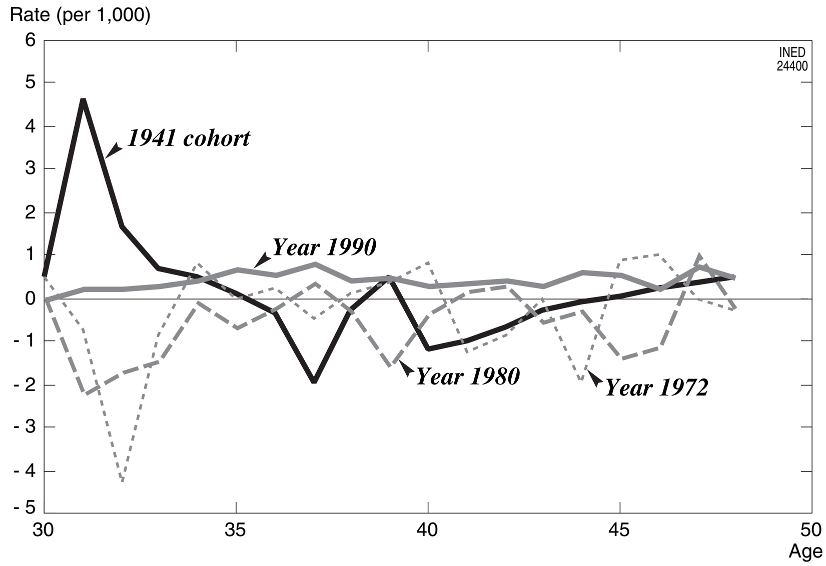

FIGURE 14–21 Age-specific net migration rate between ages 30 and 50 of the Italian male cohort born in 1941 compared with rates for 1972 and 1980. (Author's calculation based on Italian census data.)

TABLE 14–4 Age-specific External Immigration Rate, 1986–1991, for Individuals Older than 5 Years, as given by 1991 Italian Census

Age	Population enumerated in 1981	Population residing abroad in 1986	Immigration rate 1986–1991 (per 1000)	Annual average rate (per 1000)
5–14	6,260,054	53,556	8.59	1.72
15–24	8,832,952	76,451	8.69	1.74
25–34	8,753,829	133,957	15.42	3.08
35–44	7,736,280	71,141	9.24	1.85
45–54	7,086,236	41,929	5.93	1.19
55–64	6,659,574	38,252	5.76	1.15
65–74	4,907,618	17,818	3.64	0.73
75+	3,792,567	5,863	1.55	0.31
Total	54,029,110	438,967	8.16	1.63

tion values for each cohort. For this purpose, we used a model of additions to and removals from the municipal population registers by age and year, which requires substantial reconstruction work.

The cells of the table framed in heavy black lines are those in which we find an exact correspondence between the cohort rate and the rate of one of the selected years (this is because the rates are type 2 rates, in projective parallelograms of the Lexis diagram).

The table effectively summarizes Italy's recent external migration history, which has witnessed a shift from a long period of net emigration to a new period of net immigration. The total net migration observed here between ages 30 and 50 is negative in 1972 and 1980, but positive in 1990. In the same interval, we see an increase in the mean age at net migration of the 30 to 50 age group. Unfortunately, the detailed reading of the age-specific results is complicated here by the inconsistencies of the databases used. For example, the peak observed at age 31 in the 1941 cohort seems to be directly linked to the pre- and postcensal deletion and reregistration procedures discussed in Chapter 13, since the cohort reached age 31—marked by heavy migration—just after the 1971 census.

3. Estimating Migration Flows from the Retrospective Questions in the Census Schedules

Many census schedules include retrospective questions on migrations covering such variables as place of birth, date of arrival in current place of residence, and place of residence at an earlier date. The question on

TABLE 14–5 Lazio: Age-specific rates of emigration (for individuals aged over 5 years) to other regions and rate of immigration from other regions or abroad, 1986–91, as given by 1991 Italian census

Age	Population enumerated in region in 1991	Population residing in other regions or abroad in 1986	Immigration rate (per 1000)		Population enumerated in other regions in 1991 residing in the region in 1986	Emigration rate (per 1000)		Population of rest of Italy enumerated in 1991	Rate of emigration of rest of Italy to Lazio (per 1000)

the place of residence at an earlier date is the one that lends itself most easily to the calculation of age-specific migration rates. However, in terms of external flows for a given country, the only information yielded by the question concerns immigration: this can be seen in Table 14–4 for precensal Italian migrations in the years 1986 to 1991.

The only emigration that can be measured on the basis of this information consists in internal migrations. We can identify the emigrants from any administrative division thanks to the questions put to the inhabitants of all the others. If we are studying the population of a specific administrative division, we can use the census data to measure both immigration and emigration, as already mentioned in our discussion of population registers.

For example, from a matrix of migration flows between Italian regions (Table 14–5 gives an example for the region of Lazio) for the period 1986 to 1991 (of which Table 14–6 reports only the all-ages totals) we can calculate, for any region, the age-specific emigration rates as well as the immigration rates.

Confounding Variables, Standardization, and the Problem of Summary Indices

GUILLAUME WUNSCH

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

In several chapters (Chapters 3 and 11, among others), it was pointed out that crude death rates were not the best indicators of mortality for temporal or spatial comparisons, as the crude death rate is highly dependent upon the age structure of the population. It was stated that a better measure could be obtained by *controlling* for age, the latter being a *confounding variable* in this case. Death rates specific for age and sex were therefore computed for this purpose and served for constructing the life table. The present chapter will deal first with the concept of confounding variable, then move on to the problem of controlling for the confounding variable(s), and finally to the topic of deriving suitable summary measures or indicators controlling for the effect of possible confounders. As a byproduct, this chapter will also tackle the problem of *interaction* between variables, in a causal framework. The illustrative example discussed in the following section is drawn from the field of morbidity; it has the advantage over others of dealing with variables that are well documented and understood, and for which the causal structure is well established.

I. CONFOUNDING VARIABLES

Suppose that one is interested in the determinants of cardiovascular diseases (CVD), one of the major medical causes of death in the low-mortality countries. It is known that high blood pressure has an adverse effect on CVD; therefore, in a primary prevention approach one would wish to reduce the causes of excess blood pressure. One such cause could be coffee drinking[1]; one should therefore test if there is an association between coffee drinking and blood pressure in a random sample of individuals. To simplify the presentation, we will use simple dichotomies such as drinkers versus nondrinkers; in an actual study, the measurement would be more precise. Suppose 600 people have been included in the study, among whom 400 are drinkers and 200 are nondrinkers. The average diastolic[2] blood pressure in the two groups is 89 mm Hg and 75 mm Hg, respectively, the absolute difference being a significant[3] 14 mm Hg. The possible conclusion is that coffee drinking has a considerable impact on (or at the least has a high association with) blood pressure, represented by the causal graph

$$C \rightarrow B$$

where *C* stands for the variable *coffee drinking* and *B* for *blood pressure*. The arrow means in this case that *C* is a cause of (or influences) blood pressure. The obvious conclusion is that people should stop drinking coffee to reduce blood pressure to avoid CVDs.

[1] The example is taken from Anderson *et al*. (1980), Chapter 2.
[2] The pressure between two heart contractions.
[3] In practice, significance tests should be performed to determine if the difference is not obtained by chance. We will not consider this particular issue here.

TABLE 15–1 Population Numbers and Diastolic Blood Pressure (in mm Hg) According to Coffee Drinking and Weight

Drinking	Weight		
	Overweight	Not overweight	Total
Drinkers	300 (94.0)	100 (74.0)	400 (89.0)
Nondrinkers	50 (90.0)	150 (70.0)	200 (75.0)
Total	350 (93.4)	250 (71.6)	600 (84.3)

Source: Anderson *et al.*, 1980.

TABLE 15–2 Distributions According to Weight

Drinking	Weight		
	Overweight	Not overweight	Total
Drinkers	75	25	100
Nondrinkers	25	75	100
Total[a]	58	42	100

[a] Weighted average.

Coffee drinking is however not the only possible cause of higher blood pressure. Obesity for example is also a well-known cause of this risk factor. What happens then if one takes body weight also into account? Once again, this variable is dichotomized for simplification into overweight and not overweight. Let *W* represent the variable *weight*. The assumed causal graph is then

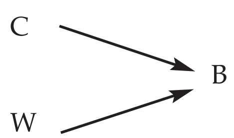

Table 15–1 gives the cross-classification of the number of individuals in the sample according to their coffee drinking behavior and their weight. Blood pressure is given for each cell of the table between brackets.

One sees that being overweight leads to a much higher blood pressure, on average, than not being overweight, both for drinkers and nondrinkers. Indeed, the difference is equal to a high 20 mm Hg in both groups (94–74 and 90–70). On the other hand, if one *controls* for weight (i.e., if one considers separately those overweight and those not overweight), the impact of coffee drinking is very slight: only 4 mm Hg in both groups (94–90 and 74–70). Should one then discourage people from drinking coffee,[4] as the difference between both groups is slight?

Consider now the two extremes. The highest blood pressure can be found on average among those who both drink and are overweight (94.0 mm Hg), while the lowest blood pressure is to be found in the nondrinkers and nonoverweight group (70.0 mm Hg). The difference between the two groups is 24 mm (i.e., the effect of weight [20.0 mm Hg] plus the effect of coffee [4.0 mm Hg]). The two effects are *additive* in this example; in other words, as will be discussed later, there is no *interaction* between weight and coffee drinking (the two causes or risk factors) on blood pressure (the effect or outcome variable).

[4] The answer might depend upon the coffee one is drinking, Italian or American!

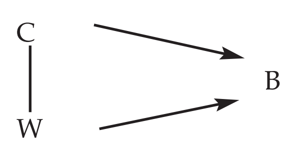
How did one reach the wrong conclusion in the first place, i.e. that coffee is bad for one's health? Computing the distribution of individuals according to the two variables, one obtains the results shown in Table 15–2. The distributions according to body weight are quite different between the drinkers and the nondrinkers, as overweight individuals also tend to be strong coffee drinkers. It is indeed well known in epidemiology that there is often a clustering of risk factors for a variety of health conditions. One observes in this case a positive relationship between weight and coffee drinking, leading to an overall difference of 14 mm Hg biased in favor of those who both drink and are obese. The converse is true for the nondrinkers.

Body weight is therefore a *confounding factor* in this example; it masks the true impact of coffee drinking, the possible risk factor one is studying.

Two conditions have to be both satisfied to have a confounding variable:

1. The risk groups must differ on this factor.
2. The factor itself must influence the outcome.

These conditions are both satisfied in this example, as the structure according to body weight differs among the drinkers and the nondrinkers (condition 1). There is indeed an *association* between weight and coffee drinking, the overweight individuals drinking more coffee than the others. Furthermore, excess weight is itself a cause of high blood pressure (condition 2). The causal graph is therefore as follows, the nonoriented line between body weight, *W*, and drinking, *C*, indicating an association between both variables.



If one or both of these conditions is not fulfilled, the variable is not a confounder and does not have to be

TABLE 15–3 Distributions According to Weight of Drinkers and Nondrinkers

Drinking	Weight		
	Overweight	Not overweight	Total
Drinkers	25	75	100
Nondrinkers	25	75	100

TABLE 15–4 Average Diastolic Blood Pressure (in mm Hg)

Drinking	Weight		
	Overweight	Not overweight	Total
Drinkers	84	84	100
Nondrinkers	80	80	100

controlled for. Take the case where both drinkers and nondrinkers have the same distribution according to body weight,[5] waiving the first condition, such as in Table 15–3.

In this case, the blood pressure of drinkers is equal to $(94 \times 25 + 74 \times 75)/100 = 79$ mm Hg, and for the nondrinkers $(90 \times 25 + 70 \times 75)/100 = 75$ mm Hg. The difference $79 - 75 = 4$ mm Hg gives the right answer. Consider now the case (Table 15–4) where blood pressure does not differ according to body weight (condition 2 not satisfied), the distribution of patients being the same as in the original situation.

The average blood pressure for the drinkers will now be $(84 \times 300 + 84 \times 100)/400 = 84$ mm and for the nondrinkers $(80 \times 50 + 80 \times 150)/200 = 80$ mm, which is a simple application of the rule that the average of a constant is the constant itself!

Returning to the impact of age structure on the crude death rate, the example given at the beginning of this chapter, one can now conclude that in a comparative analysis one must control for age if the populations being compared have a different age structure (condition 1), which is not always the case, and if age has an impact on mortality (condition 2), which is indeed the case. Therefore, crude death rates are perfectly adequate summary measures of mortality if the populations being compared have more or less the same age structures.[6] However, one does not have to

[5] There is therefore no association in this case between body weight and coffee drinking.

[6] This also explains why crude birth rates are usually better summary measures than crude death rates, as the age structure of the population *at fertile ages* is rather similar whatever the global age structure of the population, young or old.

TABLE 15–5 Population Numbers and Blood Pressure (between brackets) According to Drinking and Bodyweight

Drinking	Weight		
	Overweight	Not overweight	Total
Drinkers	300 (94.0)	100 (74.0)	400 (89.0)
Nondrinkers	50 (90.0)	150 (60.0)	200 (67.5)
Total	350 (93.4)	250 (65.6)	600 (81.8)

control the structure of the population according to the length of one's hair, for example, as this variable probably has no impact on mortality.[7]

In the presence of confounders, one's conclusion may differ dramatically according to the fact that one controls or one does not control for the confounding variables. Rouanet (1985) provides a good example, called the Bombach paradox. In this example, the initial conclusion is *reversed* when one controls for the confounding variables![8] Note that if body weight is a confounding factor when one examines the impact of coffee drinking on blood pressure, conversely coffee drinking is itself a confounding variable in the study of the relationship between weight and blood pressure. All depends on the assumption one is testing (i.e., the topic of the research project). Finally, one is never sure in actual research that one is controlling for all the confounders without exception; there may be hidden (i.e., unknown) variables that may wreak havoc with our results.[9] Science is an endless game in pursuit of knowledge.

II. INTERACTION BETWEEN CAUSES

Consider the following situation (Table 15–5), very similar to the original example given in Table 15–1, except that the average blood pressures are slightly different.

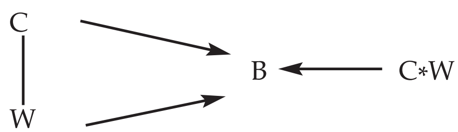
One sees that the impact of coffee drinking on blood pressure remains slight for those overweight (4 mm Hg), but for those not overweight, coffee drinking leads this time to a significant increase in blood pres-

[7] No bias is introduced if one does control for this variable, but it is a waste of time. In addition, decomposing the population into categories leads to smaller numbers in the cells and thus to greater random fluctuations.

[8] To take another example, a ranking of countries by mortality level may significantly differ according to the indicator one takes, the crude death rate or the expectation of life at birth. The latter controls for the age structure of the population, whereas the former does not.

[9] The randomized experimental approach should therefore always be preferred if feasible; see however Wunsch (1994).

sure (14 mm Hg). The difference between the extremes (94.0 − 60.0 = 34.0) is no longer the sum of the drinking effect and the weight effect, as these effects differ among categories. In other words, the impact of drinking depends on the modality of the confounding variable (overweight or not) and one speaks in this case of an *interaction effect* between causes on the outcome factor (blood pressure). The causal graph corresponding to this situation is the following, where the symbol $C{*}W$ represents the interaction effect.



In this example, there is a *weak interaction* between causes, in the sense that for overweight and nonoverweight individuals, coffee drinking increases the blood pressure; the impact has the same direction for both categories. In some situations one can have *strong interaction* effects, with crossovers between the series of rates, as shown in Table 15–6.

In this case (which is not a true situation), coffee drinking would increase blood pressure among those not overweight but decrease the pressure among overweight individuals. It has been shown, to give a true example, that smoking has a negative impact on Alzheimer disease except for carriers of the APOEε4 allele, for whom it has on the contrary a protective effect!

Interaction effects can sometimes be removed by a change in *scale*; for example, absolute differences may not be the same between the modalities of the confounding variable (as in the example of Table 15–5) but in some cases the relative differences or the odds are the same. One can therefore observe interaction effects on a linear scale but they disappear on a log-linear or logit-linear scale (Anderson, 1980; Wunsch and Thiltgès, 1995). Moreover, as Wilcox and Russell (1983) have shown, apparent strong interaction effects may disappear if one *norms* the distributions of the confounding variables, that is if one transforms them into distributions of zero average and a standard deviation of one.

TABLE 15–6 Population Numbers and Blood Pressure (between brackets) According to Drinking and Weight

Drinking	Weight	
	Overweight	Not overweight
Drinkers	300 (90.0)	100 (74.0)
Nondrinkers	50 (95.0)	150 (60.0)

III. STANDARDIZATION AND THE PROBLEM OF SUMMARY INDICES

One has just seen in section II that the variable body weight can be controlled for by measuring the blood pressure of drinkers and nondrinkers according to the fact that one is overweight or not. More generally, in mortality studies, one can control for the age structure by computing death rates specific for age. In regression analysis, a variable can be controlled for by including it in the regression equation, if a suitable functional form of the regression equation is chosen. Suppose now that one has computed death rates by single ages for the 52 countries one wishes to compare. Assuming approximately 100 age groups, this gives a table of $100 \times 52 = 5200$ cells. No ordinary human being can visually process such a large table unless he or she has exceptional cognitive abilities. One can also put the 52 graphs of death rates by age on the same figure, but once again, the result will probably not be visually interpretable as many graphs will overlap. Demographers therefore usually summarize their data for comparative purposes, even if this means losing valuable information. If one is comparing only two or three countries, it is therefore much preferable to put the data on a graph and discuss the results.

In the field of mortality, a summary measure of the death rates m_x often used is the *expectation of life at birth*,[10] given by the expression:

$$e_0 = \frac{\sum x \cdot d_x}{\sum d_x} = \frac{\sum x \cdot L_x \cdot m_x}{\sum L_x \cdot m_x}$$

where d_x and L_x are the life-table deaths and the stationary population at completed age x, respectively. As the number of deaths depends on the size of the stationary population at age x, one could also compute an average age at death based not on the absolute numbers of life-table deaths d_x, but on the relative numbers d_x/L_x. As the latter ratio is equal to the death rate at age x, the average age at death would simply be equal to $\Sigma x m_x / \Sigma m_x$. The difference between the two measures depends on the form of the weights applied to the ages x. Life-table deaths vary according to an overturned S, while death rates follow a U shape that continuously increases with age after adolescence.

[10] One can transform rates into probabilities, draw up a life table, compute the life expectancy at birth, and use this measure as a summary indicator of mortality. Note that the life expectancy is *not* a standardized index, even if it is independent of the actual population age structure, as the weights L_x (the stationary population by age) applied to the death rates vary from one life table to the other, contrary to a standard population.

1. Direct Standardization

A variable such as the death rate by age can also easily be summarized by one of the ordinary techniques in elementary descriptive statistics. For example, in comparative studies, one can simply take for each country the *arithmetic average* of death rates as a summary measure of mortality for this country. This would give equal weight to each age group. Alternatively, one can compute a *weighted average* of rates, where the various age groups would be given different weights according to the average age structure of the various populations one is comparing. Let m_{xj} and p_x represent respectively the death rate at age x (for a country j) and the relative average population number at that age (i.e., relative to the total average population of all the countries being compared). The death rate for country j would then be:

$$\sum m_{xj} p_x \Big/ \sum p_x = \sum m_{xj} p_x$$

as Σp_x equals 1.

In demography and in epidemiology, this method is known as the *direct standardization* of rates and the series p_x according to age as the *standard population.* The method is a simple *linear combination* of death rates, the standard population acting as weights. The basic principle is to use the *same standard population* for all the cases being compared. As seen above, one of the two conditions for having a confounding variable (age, in the present case) is that the risk groups differ on this factor. If one uses the same standard population structure p_x for all the series of rates being compared, this condition is obviously not satisfied and the age structure is therefore not a confounder. For example, the World Health Organization (WHO) is using a standard world population for direct standardization purposes. Unfortunately, the WHO decided in 1992 to alter this standard (Davies, 1995). Changing the standard has made comparisons over time and between sexes impossible without recalculation.

There is nothing about the technique that restricts its applicability to age. One can, for example, standardize the effects of differences in birth-order distributions between populations whose infant probabilities of dying we are comparing (Preston *et al*., 2001).

Standardized indices are used for comparative purposes only; the value of the index is of no interest per se. The choice of weights is actually completely arbitrary, and therefore different choices of weights will yield different results. One can for example set the weights equal to one, as in the numerator of the simple arithmetic average of rates. This is done in fertility analysis: the *total fertility rate* (a summary measure of fertility in period analysis) is indeed taken as the sum of age-specific fertility *rates* (frequencies) (i.e., as a linear combination of fertility rates with equal weights at each age). The *total fertility rate* is therefore a directly standardized measure of fertility, with a *rectangular* standard population of one person per age group.

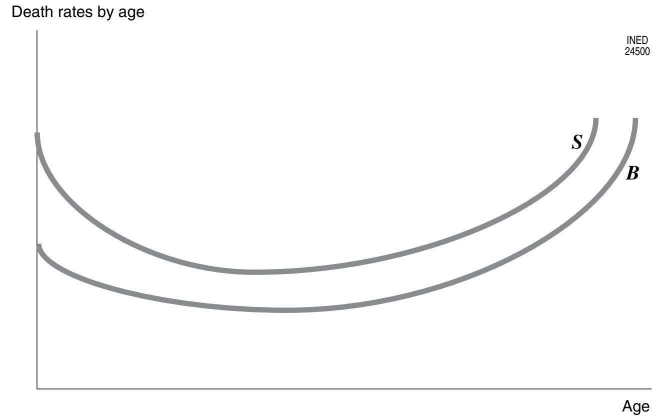


FIGURE 15–1 Age-specific death rates for countries Borduria (*B*) and Syldavia (*S*) in the absence of interaction.

Do standardized measures adequately represent the actual differences between the rates? This problem is similar to computing the averages of two distributions and asking if the difference between the means correctly represents the difference between the distributions themselves. Consider two sets of death rates by age for two imaginary countries,[11] Syldavia (*S*) and Borduria (*B*), as in Figure 15–1. In this example, the difference between rates $m_x(S)$ and $m_x(B)$ is the same whatever the age. In this case, it is easy to show (Wunsch and Thiltgès, 1995) that the absolute difference between standardized measures correctly represents the actual difference between rates, whatever the standard population. This is due to the absence of interaction effects between country and age in this example. Consider now data shown in Figure 15–2. In this case, Syldavia still has a higher morality at all ages than Borduria, but the difference is more marked at young ages than at older ages. There is *weak interaction* (as defined in section II) between country and age on mortality in this situation. Standardization will always yield a higher measure for Syldavia than for Borduria, whatever the standard population, but the difference between the two summary measures will depend on the choice of the standard population. Standardization correctly gives the order (higher versus lower mortality) but not the difference between rates by age. As these differences vary according to age, no

[11] My thanks to Hergé and his comic strips.

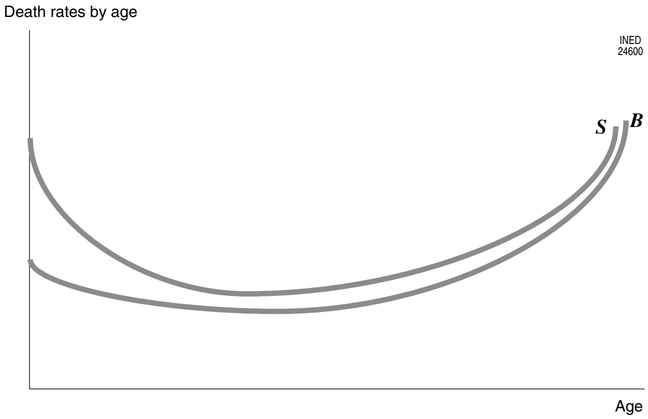

FIGURE 15–2 Age-specific death rates for countries Borduria (*B*) and Syldavia (*S*) in the presence of weak interaction.

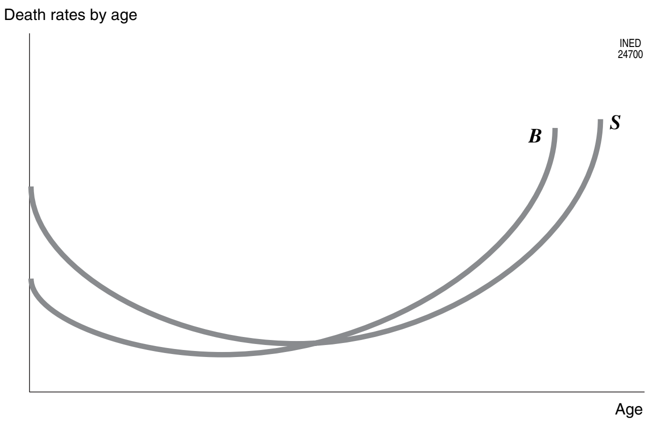

FIGURE 15–3 Age-specific death rates for countries Borduria (*B*) and Syldavia (*S*) in the presence of strong interaction.

single summary measure can correctly represent this fact.

Figure 15–3 presents a case of *strong interaction* between country and age: Syldavia has a higher mortality at young ages but a lower mortality at higher ages, i.e. a crossover of age-specific mortality curves. No single summary measure can adequately represent this situation. According to the choice of the standard population, one will conclude that Syldavia has a higher, an equal, or a lower mortality than Borduria, which is not a very helpful result! Having recourse to standardization, one must therefore test for interaction effects. If there is no interaction or if it is weak, standardized measures can be used with confidence to rank the countries one is comparing according to the variable of interest (e.g., mortality), whatever the standard population. If there is strong interaction, standardization breaks down and should not be used, as no single summary

TABLE 15–7 Deaths, Populations, and Death Rates by Region and Age

Variables	Age		
	1	2	Total
Syldavia			
Deaths	60	80	140
Persons	600	400	1,000
Rate	0.100	0.200	0.140
Borduria			
Deaths	60	393	453
Persons	200	800	1,000
Rate	0.300	0.491	0.453
Total			
Deaths	120	473	593
Persons	800	1,200	2,000
Rate	0.150	0.394	0.297

measure can adequately represent the actual situation in this case.[12]

2. The Mantel-Haenszel Statistic

The *Mantel-Haenszel (M-H) statistic* is useful when working with odds and *odds ratios* instead of absolute or relative rates or risks, the *odds* being the ratio of a rate to its complement to unity. Consider Table 15–7, which shows the number of deaths, the populations exposed to risk, and the death rates for the two countries Syldavia (S) and Borduria (B) and for two age groups 1 and 2.[13] In this example, one observes that there is no interaction at the odds level between country and age. Indeed, one derives from the data:

$$\frac{\text{Odds } 0.300}{\text{Odds } 0.100} = \frac{\text{Odds } 0.491}{\text{Odds } 0.200} = 3.86$$

Applying the definition of the odds, this is equivalent to saying that

$$\frac{k'60(600-60)}{k'60(200-60)} = \frac{k''393(400-80)}{k''80(800-393)} = 3.86$$

where k' and k'' are two arbitrary constants ($\neq 0$). Using some elementary mathematics, one derives

[12] This would also be the case with the expectation of life at birth, as it is also a sole indicator of the level of mortality.

[13] The example is drawn from Wunsch and Thiltgès (1995).

$$\frac{k'60(600-60)+k''393(400-80)}{k'60(200-60)+k''80(800-393)}=3.86$$

The (M-H) statistic (Kahn and Sempos, 1989) takes k' and k'' equal to the reciprocal of the total populations in the two age groups, respectively 800 and 1,200. This leads to:

$$M-H=\frac{60(600-60)/800+393(400-80)/1200}{60(200-60)/800+80(800-393)/1200}=3.86$$

The result is 145.3/37.6 = 3.86: the relative difference in odds or odds ratios obtained above. The M-H statistic gives the true difference between odds in the case of a logit-linear model with no interaction, controlling for age. If there is a common odds ratio (no interaction), the M-H statistic provides it. If interaction is present, the M-H statistic provides a weighted average of the odds ratios. Significance tests for the overall odds ratio can be found in the epidemiologic literature (Kahn and Sempos, 1989). Note that the M-H statistic is not a standardized index, as the cross-products involve the actual population numbers.

3. Indirect Standardization

Suppose now that the death rates by age are unknown because one has no breakdown of the number of deaths by age. One only knows the total number of deaths and the age-structure of the population. In this case, *indirect standardization* can be used. Suppose one compares once again Syldavia (S) and Borduria (B). Let $P_x(S)$ and $P_x(B)$ represent the population of the two countries decomposed by age x, and let $D(S)$ and $D(B)$ stand for the total number of deaths in the two countries. Take this time an arbitrary standard set of death rates by age m_x and compute the two ratios

$$\frac{D(S)}{\sum P_x(S)m_x} \quad \text{and} \quad \frac{D(B)}{\sum P_x(B)m_x}$$

These *standardized mortality ratios* (or more generally, the *standardized incidence ratios*) are simply ratios of the observed deaths to the expected deaths for the two countries, for any particular arbitrary set of standard death rates by age. The same standard set is applied to the two situations. One can also compute *indirectly standardized rates* by multiplying the standard mortality ratios by the crude death rate for the standard population. Indirectly standardized *relative risks* are then taken as the ratios of the indirectly standardized rates or of the standard mortality ratios. Once again, as with direct standardization, the standard is perfectly arbitrary, but Hoem (1991) has devised an iteration method to derive a unique standard series of rates from the data set itself.

How adequate is indirect standardization for controlling for confounders? Let $m_x(S)$ and $m_x(B)$ represent the unknown death rates by age for the two countries. As the number of deaths is equal to the sum of the products of death rates by the actual population numbers at each age, one can write the two ratios above as

$$\frac{\sum P_x(S)\cdot m_x(S)}{\sum P_x(S)\cdot m_x} \quad \text{and} \quad \frac{\sum P_x(B)\cdot m_x(B)}{\sum P_x(B)\cdot m_x}$$

The standardized mortality ratios are therefore respectively equal to the weighted average of $m_x(S)$ divided by the weighted average of the standard set of rates m_x and to the weighted average of $m_x(B)$ divided once again by the weighted average of m_x. Indirect standardization therefore compares the averages of the unknown rates in terms of the averages of the standard set of rates. Note however that the latter are not identical, as the weights applied to the set m_x are not the same. In the first case, the weights are the population numbers by age of Syldavia $P_x(S)$ whereas in the second case, they are equal to $P_x(B)$, the population numbers of Borduria.

Indirectly standardized ratios are therefore not independent of the actual population structures, contrary to the case of direct standardization. However, suppose that one knows one of the series of rates, say $m_x(B)$, and that one takes this series as standard. The standardized ratios become

$$\frac{\sum P_x(S)\cdot m_x(S)}{\sum P_x(S)\cdot m_x(B)} \quad \text{and} \quad \frac{\sum P_x(B)\cdot m_x(B)}{\sum P_x(B)\cdot m_x(B)}$$

The last ratio is equal to one while the first is equal to the ratio of the weighted average of $m_x(S)$ to the weighted average of $m_x(B)$, using the same weights $P_x(S)$. In this case, indirect standardization does give a meaningful result: the comparison between the averages of the two series of rates, using the same set of weights. Indirect standardization can thus be recommended here, as the result is similar to the ratio of two *directly* standardized indices using $P_x(S)$ as the standard population.

Indirectly standardized rates are biased, in the sense that their difference does not reflect the true difference between death rates by age even in the absence of interaction (Wunsch and Thiltgès, 1995). This was not the case with direct standardization, which is an unbiased procedure in the absence of (linear) interaction. On the other hand, it has been shown (Anderson *et al*. 1980) that indirect standardization is more precise (lesser variance) than direct standardization. It could then be recommended before direct standardization when population numbers are small. Procedures for computing confidence intervals for directly standardized or indirectly standardized rates can be found in Estève *et al*. (1993) and Kahn and Sempos (1989).

4. Double Standardization

The purpose of the methods presented in the preceding sections was to eliminate the influence of population structures (i.e., the composition of the population according to the confounding variable or variables) in the study of population change, by holding these structures constant over time or from one area to the other. One may also adopt the opposite point of view: Frequencies on the outcome factor can be held constant in spatial or temporal comparisons to determine the sole impact of changes in population structures on population movement.

Let E and E' represent the total number of events observed during periods (e.g., years) t and t' for two populations, say K and K'. Let P_x and P'_x be the corresponding midperiod population structures according to the confounding variable (e.g., age) and f_x and f'_x the corresponding frequencies. The sole influence of differential frequencies will be given by the standardized indices $\Sigma P_x f_x$ and $\Sigma P_x f'_x$ for example, taking P_x as standard. As to the sole influence of differential population structures, it can be expressed by the comparison between $\Sigma P_x f'_x$ and $\Sigma P'_x f'_x$, taking this time f'_x as standard. Multiply both relative differences between the standardized indices:

$$\frac{E'}{E} = \frac{\sum P_x f'_x}{\sum P_x f_x} * \frac{\sum P'_x f'_x}{\sum P_x f'_x}$$

As $\Sigma P_x f_x = E$ and $\Sigma P'_x f'_x = E'$, the above product yields the relative difference between the total number of events observed. The product can therefore be considered as a *double standardization* for both structures and frequencies. The relative difference between the total number of events at time t and t' can thus be decomposed into two parts, the first indicating the impact of changes of frequencies and the second the impact of changes in population structures.

Instead of applying double standardization to the *relative* difference between the total number of events observed, one can also have resort to the double standardization of the *absolute* difference between the number of events as follows:

$$E' - E = \sum P'_x f'_x - P_x f_x$$

or

$$E' - E = \sum (P'_x - P_x) f'_x + \sum (f'_x - f_x) P_x$$

The first sum represents the component due to differential population structures and the second sum the component due to differential frequencies.

Letting $f'_x = f_x + a_x$ and $P'_x = P_x + b_x$, one can also write

$$E' - E = \sum (P_x - b_x)(f_x + a_x) - \sum P_x f_x$$

i.e.,

$$E' - E = \sum (P'_x - P_x) f_x + \sum (f'_x - f_x) P_x + \sum a_x b_x \quad \text{(Eq. 1)}$$

If one neglects the last term, one breaks down the difference $E' - E$ into the two components $\Sigma(P'_x - P_x)f_x$ and $\Sigma(f'_x - f_x)P_x$. Note that as:

$$\begin{aligned}\sum f'_x (P'_x - P_x) &= \sum f_x (P'_x - P_x) + \sum a_x (P'_x - P_x) \\ &= \sum f_x (P'_x - P_x) + \sum a_x b_x,\end{aligned}$$

the *interaction* term $\Sigma a_x b_x$ is in fact included in the first term of Equation 1. The two relations are therefore identical.

The method described above can easily be modified to measure the components of a difference between two *crude rates*. If $P = \Sigma P_x$ and $P' = \Sigma P'_x$, then

$$\frac{E'}{P'} = \frac{E}{P} = \sum f'_x \left(\frac{P'_x}{P'} - \frac{P_x}{P} \right) + \sum (f'_x - f_x) \frac{P_x}{P}$$

Variants of this formula can be found in the literature (see for example the various papers on standardization included in Clogg, 1993).

5. An Example

Table 15–8 presents the age-specific fertility rates and the proportions of females at reproductive ages for two countries,[14] the United States and Ireland. The *crude female birth rates*[15] in these populations are, respectively, 34.78/1000 and 42.96/1000, a relative difference of +24%. As the age structures differ between the two countries, one seeks to compare their fertility on the basis of two summary indexes that, contrary to the crude rates, are independent of the population structures.

[14] The example is based on data from the end of the 1960s for the United States and Ireland, and is taken from Wunsch and Termote (1978).

[15] Number of births divided by the total *female* population.

TABLE 15–8 Age-specific Fertility Rates (ASFRs) and Proportions of Females by Age–Groups

Age groups	*ASFRs per* 1000		*Proportions of females per* 10,000	
	United States	Ireland	United States	Ireland
15–19	68.9	13.4	868	878
20–24	174.0	127.1	744	631
25–29	142.6	230.6	601	517
30–34	79.3	211.3	547	507
35–39	38.5	143.2	582	542
40–44	10.6	54.5	626	574
45–49	0.7	4.2	602	577
All ages 0 to ω			10,000	10,000

To compare the average fertility between the two countries, the following summary indexes have been computed:

a. the sum of age-specific fertility rates (ASFRs) (per 1000):

United States: 514.6
Ireland: 784.3
Ratio Ireland/United States: 784.3/514.6 = 1.5241

b. The arithmetic average of ASFRs (per 1,000):

United States: 73.51
Ireland: 112.04
Ratio: 112.04/73.51 = 1.5241

c. The geometric average of ASFRs (per 1,000):

United States: 32.55
Ireland: 59.75
Ratio: 59.75/32.55 = 1.8356

d. Direct standardization, American structure as standard (per 1,000):

United States: 34.78
Ireland: 48.04
Ratio: 48.04/34.78 = 1.3813

e. Direct standardization, Irish structure as standard (per 1,000):

United States: 31.16
Ireland: 42.96
Ratio: 42.96/31.16 = 1.3787

f. Indirect standardization, American ASFRs as standard (per 1,000):

United States: 34.78/34.78 = 1
Ireland: 42.96/31.16 = 1.3787
Ratio: 1.3787/1 = 1.3787

g. Indirect standardization, Irish ASFRs as standard (per 1,000):

United States: 34.78/48.04 = 0.7240
Ireland: 42.96/42.96 = 1
Ratio: 1/0.7240 = 1.3813

In all these cases, the average fertility of Irish women is higher than the average fertility of American women. Nevertheless, the proportional difference between the fertility schedules varies from 38% to 83% according to the index chosen. There is however a crossover between the two fertility schedules, American fertility rates being higher at lower ages and lower at higher ages. This strong interaction effect between age and country could lead to opposite conclusions depending on the standard age structure chosen. For example, taking a very young age structure would bias the index in favor of American fertility whereas taking an older structure would lead to the opposite conclusion. The use of a sole indicator by country can never translate the fact that American age-specific fertility is higher than the Irish at young ages and lower afterward. It is therefore always necessary to check for possible interaction effects before comparing standardized indexes.

6. Statistical Methods

When possible confounding variables are numerous, standardization is no longer practical and has to give way to the more convenient and powerful techniques of statistical analysis. Due to lack of space, only a brief presentation of some statistical adjustment approaches can be given here. The reader is therefore referred to the works given as reference for further details.

Firstly, consider the data themselves. If they are derived from a sample, the number of events or persons per cell can be small or even nil. Before proceeding to standardizing the data, it can be useful as a first step to fit a *log-linear model* in view of smoothing the observed data and obtaining nonzero counts in the cells. It also enables testing for interactions. As Bishop *et al*. (1975; p. 131) stress, fitting log-linear models before standardizing has actually two purposes:

> 1. Knowledge of the structure of the data enables us to determine whether the whole array can be described by a simple statistic or whether partitioning the array into smaller segments is appropriate;
> 2. Computing the statistics from the fitted values rather than from the observed counts removes some of the variability due to random fluctuations.

As to improving direct standardization by statistical techniques, one can for example apply *principle* *components analysis* and compute the *first* principle component from the set of data on age-specific death rates by country, which is equal to deriving the first eigenvector of the variance-covariance matrix, then use the factor score coefficients as weights in the linear combination of rates (Duchêne and Wunsch, 1980). The factor score on this first principle component would then be a summary measure of mortality independent from the actual age structure of the population. There are several advantages to this procedure. First, the choice of the standard population is no longer arbitrary, as the vector of coefficients is derived from the data themselves. Second, the first principle component is the *best* linear combination of rates, because it is the vector representing the maximum spread of the scatterplot. Third, the method yields a measure of the loss of information due to the combination of rates (i.e., the ratio of the first eigenvalue to the sum of all eigenvalues of the data matrix).

Other demographers (Hoem, 1987) have used *multiplicative models* of the type

$$m_{xk} = \Theta_k \alpha_x$$

where Θ_k is a group- or risk-specific scaling factor and α_x is an age- or confounder-specific process factor. This type of specification is similar to a two-component age-period-cohort model. It can also be considered, as Hoem has shown, as a special kind of proportional hazard model.

More simply, one can apply a *linear regression model* without interaction (Leridon and Toulemon, 1997), such as:

$$m_{xi} = m + a(x) + b(i) + \varepsilon$$

where x refers to age (the confounding variable) and i to the variable of interest (country, for example). Variable ε is an error term, normally distributed and of zero mean. Once the parameters are estimated, rates adjusted for the confounder can be obtained from the estimates derived from the regression equation, using the direct standardization approach. Instead of a normally distributed variable model, as in the case of ordinary linear regression, one may prefer in some situations a Poisson model, such as when dealing with small-sample data, leading to a *log-linear regression* equation estimated by maximum likelihood (Estève *et al.*, 1993). A convenient approach for adjusting data with multivariate models is using *multiple regression for categorical variables* (Kahn and Sempos, 1989), such as logit or logistic regression models. Both the outcome variable and the predictors are attributes in this case (i.e., take the values 0 or 1) and are usually computed from individual sample data. Once again, this approach is analogous to direct standardization but includes the possibility to control for many confounders at one time. Using the regression coefficients, we can easily modify the crude rate into various adjusted rates assuming that everyone has a same attribute (e.g., the same sex) with all the other variables including the confounder(s) unchanged. We can then compare the differences on the adjusted rates of the outcome variable (e.g., survival or death) between males and females in this case, holding all covariates constant.

Toulemon (1992) has compared the results of some of these approaches, using data on abortions for females by occupational categories and controlling for the confounding impact of age and marital status. Three types of models are fitted: linear, log-linear (i.e., multiplicative), and logistic, taking account of direct and indirect standardization and having recourse both to the classical methods of standardization and to regression analysis. Due to the presence of interaction effects, there are significant differences between the results. In particular, the common method of direct standardization cannot be recommended in this example, as it overestimates significantly the abortion rates in some categories. The other methods lead to more coherent conclusions in this case; they are also less sensitive to small cell counts than direct standardization.

Consider now a comparison of fertility or mortality rates by geographical areas (such as states, provinces, municipalities, and so forth), a common situation in demography. In this case, it is not only necessary to control for the age structure of the populations in the various areas, but also to check if the data are structured geographically. For example, is there a spatial clustering of death rates possibly indicating common risk factors among areas? Standardized mortality rates by areas can be computed as usual and the resulting map inspected for geographical structure, but if the areas are small and/or the outcome variable rare (such as for example, mortality due to lip cancer by districts), the map showing the standardized rates will often emphasize the areas with small population numbers leading to extremely high or low rates due to chance fluctuations. Moreover, the method is not well suited for taking account of multiple confounders and other covariates, as pointed out previously, and of hierarchical data structures. In this case, use a *multilevel spatial model* incorporating some form of local clustering taking account of possible area effects.

A commonly used solution is a conditional autoregressive spatial model where the effect of an area depends upon the effects in the neighboring areas (Leyland, 2001). A clustering model of this type can also include covariates representing possible risk factors. For example, in an analysis of lip cancer by districts in Scotland (Leyland, 2001), one may also include in the model the percentage of the population employed in agriculture, fishing, and forestry as a measure of exposure to sunlight, a potential risk factor. Further levels can be included in the spatial model, such as considering the effect of the country in addition to that of the district, in an intercountry and interdistrict comparison. Country effects may reflect cultural or behavioral differences among the countries having an impact on the outcome. Spatiotemporal models can furthermore be fitted if the data are available, taking account not only of differences in space but also in time.

If differences are observed in standardized rates among areas for example, one should try to find the causes or determinants of these differences. It is sometimes possible to postulate the relations between presumed causes and effects; one may then try to test this causal structure by statistical techniques, if suitable data are available. To take an example from Lopez-Rios *et al*. (1992), we examined the impact of health care use on regional adult mortality differences in Spain, assuming that use depends on the supply of health care and on the level of social development of the regions, these two variables being influenced themselves by the level of regional economic development. Each of these *latent variables*, latent in the sense that they cannot be measured directly, are represented by a set of measurable manifest variables or multiple indicators. The confounding variable is once again the age structure of the populations of the regions. A *covariance structure model* was fitted to the data with the LISREL software, outcome and predictor latent variables being linked by a series of linear equations.

Let

$$\eta' = (\eta_1\ \eta_2 \ldots \eta_m)$$

and

$$\chi' = (\chi_1\ \chi_2 \ldots \chi_n)$$

stand, respectively, for the vectors of latent outcome variables and predictor variables. The structural equation model can then be written, in matrix notation:

$$\eta = B\eta + \Gamma\chi + \sigma$$

where B and Γ are matrices of parameters between latent variables and

$$\sigma' = (\sigma_1\ \sigma_2 \ldots \sigma_m)$$

is a vector of residuals (errors in equations). The elements of B represent the direct effect of variables η on the other variables η, while the elements of Γ represent the direct effects of the variables χ on the variables η. The vector variables η and χ are latent or unobservable, but they can be represented by measurable indicators:

$$y' = (y_1\ y_2 \ldots y_p) \textit{ and } x' = (x_1\ x_2 \ldots x_q)$$

For example, the indicators for the latent variable *social development* in this example are the proportion of women per region with secondary education, the proportion of females occupied in the tertiary sector, the proportion of accommodations with no running water, and so forth. Measurable and latent variables are related by the equations:

$$y = \Lambda y\eta + \varepsilon \textit{ and } x = \Lambda x\chi + \delta$$

where ε and δ are vectors of error terms (measurement errors). These equations stand for the multivariate regression of y on η and of x on χ.

Results can be expressed in terms of *path coefficients* (or standardized regression coefficients) between causes and effects, as shown by the causal graph in Figure 15–4, all coefficients being in this case statistically significant.

We have dealt in more detail with this approach because a structural equation model implies clarifying the relational structure between variables, according to one's conceptual framework dealing with the problem at hand. It thus forces the researcher to define his or her concepts, to justify the indicators chosen, and to specify the explanatory variables, covariates, confounders, and the postulated relations between them, based on the theoretical assumptions he or she has. For example, one sees that in addition to the age structure of the regions, one needs in this case to control also for the impact of the level of social development, as this variable is significantly related to both mortality and health care use. It is therefore a confounder, as defined in section I, in the relationship between these two latter

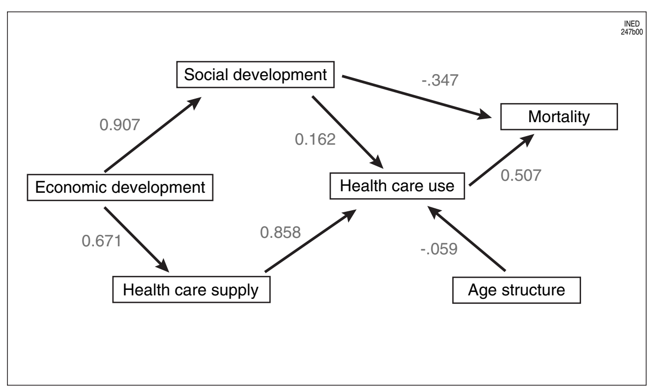

FIGURE 15–4 The health care system and regional mortality in Spain (1985). Path coefficients between latent variables.

variables. Actually, the impact of differential age structures between regions on health care use is quite slight in this example, and induces no important confounding effect.

To conclude, there are no roundabout statistical models: Each problem must be analyzed and the best model selected according to the problem, the data, and the underlying theory. Models are simplifications of reality; one should therefore always test the fit of the model (i.e., to see to what extent the model reproduces the data). Linear models, for example, are not adequate if the relationship between the outcome and explanatory variables is not linear, although a change in scale can sometimes improve the linear fit. To give a simple example, an exponential relationship between two variables can be made linear by taking logarithms. Moreover, except being God (or one's equivalent according to one's faith), one is never sure that all confounding variables have been taken care of. If there are hidden (i.e., unknown confounders), the statistical exercise can lead to false conclusions. As stated previously (see also Wunsch, 1988), science is therefore a game of (endless?) pursuit in search of better theories, data, and models.

Relationships Between Age-Specific Rates and Synthetic Indicators: Decomposition of a Difference

JACQUES VALLIN AND GRAZIELLA CASELLI

Institut national d'études démographiques (INED), Paris, France

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italty

Synthetic indicators are a convenient means to track changes in demographic phenomena. However, it is just as important to assess the influence of individual components on a synthetic indicator to (1) understand those changes, (2) evaluate the differences observed between countries or regions, and (3) identify the main issues that can be addressed by demographic or social policies. For this purpose, we shall examine how the difference between two values of a synthetic indicator can be decomposed into fractions attributable to each of those components.

Concerning mortality, our approach at this stage merely involves assessing the impact of each age-specific or age-group-specific difference in mortality on a difference between two life expectancies.[1] For fertility, our emphasis will not be so much on decomposing a difference in average age at childbearing into the specific effects of each difference in age-specific fertility; rather, we will try to identify the distinctive roles of intensity (quantum), rank, and tempo of births in the expression of a difference in the total fertility rate.

[1] In Chapter 42 on causes of death (Volume II of this treatise), France Meslé shows that it is also interesting—if not even more so—to apply the same approach to mortality by causes of death.

I. HOW DIFFERENCES IN AGE-SPECIFIC MORTALITY AFFECT A DIFFERENCE IN LIFE EXPECTANCY

To what extent do each of the differences observed at different ages affect the difference between two life expectancies—for example, those of males and females, those of France and Russia, or those of France in 1950 and in 1995? There is no simple answer. In the life table, the change in a death probability for a given age has a dual effect: (1) a main effect, namely, a change in the number of deaths in the table at that age; and (2) an interaction effect (i.e., a change in the number of survivors at the following age, which will, in turn, alter the number of deaths at all subsequent ages).

In a continuous approach, the problem can be solved by means of a minor approximation (Pollard, 1982); for discrete data, the solution is harder to apply. Many authors have proposed solutions. Korchek-Tchepurkovski (1968) was the first to tackle the issue, followed by Andreev (1982), Pollard (1982, 1988), Arriaga (1984), Pressat (1985), and Valkovics (1991).

Using a somewhat different method, Andreev (1982) and Arriaga (1984) actually come up with the same solution, where the contribution $\varepsilon_{(x,x+a)}$ of the change in mortality at a given age to the life-expectancy difference ($e_0^2 - e_0^1$) equals

$$\varepsilon_{(x,x+a)} = l_x^1(e_x^2 - e_x^1) - l_{x+a}^1(e_{x+a}^2 - e_{x+a}^1)$$

The drawback of this formula is that it yields a different result when we measure the contributions to the same life-expectancy difference expressed in reverse ($e_0^1 - e_0^2$). One remedy is to perform the calculation in both directions and take the average of the two values obtained as the final estimate.

The method proposed by Pollard avoids this drawback. The author shows that the problem can be solved analytically using either of the two formulas:

$$e_0^2 - e_0^1 = \int_0^{\omega} (\mu_x^1 - \mu_x^2)\,{}_xp_0^2 e_x^1 dx \quad \text{or}$$

$$e_0^2 - e_0^1 = \int_0^{\omega} (\mu_x^1 - \mu_x^2)\,{}_xp_0^1 e_x^2 dx$$

where ${}_xp_0^1$ is the probability of survival from birth to age x in the first table and ${}_xp_0^2$ that of the second table, μ_x^1 and μ_x^2 being the forces of mortality at age x.

Arguing that there is no reason to prefer one method to the other, Pollard suggests using a third by averaging the two weightings that differentiate them:

$$w_x = 0.5 \cdot ({}_xp_0^2 e_x^1 + {}_xp_0^1 e_x^2)$$

which gives:

$$e_0^2 - e_0^1 = \int_0^{\omega} (\mu_x^1 - \mu_x^2)\, w_x dx$$

To return to the discrete calculation, Pollard estimates the integral of the instantaneous rate from the table's survivors:

$$\int_0^a \mu_x dx \cong -\ln \frac{l_{x+a}}{l_x} = {}_aQ_x$$

from which he obtains:

$$e_0^2 - e_0^1 \cong \sum_{x=0}^{\omega} ({}_aQ_x^1 - {}_aQ_x^2)\, w_{(x+0.5a)}$$

The approximation is good if we are using a complete life table (by year of age) and if it is not arbitrarily cut off at too low an age. The wider the age intervals, the less precise the result; typically, it is the final age interval that is the most problematic. If, for example, the table stops at 80 or 85 years of age, as is often the case, there can be a significant disturbance in the result, in particular when the rise in life expectancy depends heavily on the change in mortality at the most advanced ages.

Table 16–1 reports an initial decomposition of the difference between French male life expectancy in 1996 and 1989, based on complete life tables. We can see, for example, that of the total 1.46-year gain in life expectancy at birth recorded during this period, 0.23 years is due to the fall in infant mortality alone. The changes in mortality in all the other age groups produced far more modest gains. Another peak in gains

is observed at around age 55, but its level is well below the gain registered in the first year of life. By summing all these gains we obviously find the total difference between the two life expectancies.[2]

One of the major advantages of Pollard's formula is that it allows the contributions of each age to be estimated from the mortality rates (i.e., we can estimate ${}_aQ_x$ using $a \cdot {}_am_x$). This makes it very easy to extend the formula's application to measuring the contribution of causes of death, for which mortality rates rather than life tables are generally available. In so doing, however, we increase the estimation error, especially if we are working on age intervals of more than 1 year. It is better, therefore, to work with the smallest possible age intervals and combine the results, which are always additive.

Using Pollard's approach as his starting-point, Pressat proposes a different weighting formula,

$$e_0^2 - e_0^1 \cong \sum_{x=0}^{\omega}\left[\frac{l_x^1 + l_x^2}{2}(e_x^2 - e_x^1) - \frac{l_{x+a}^1 + l_{x+a}^2}{2}(e_{x+a}^2 + e_{x+a}^1)\right],$$

which, however, will not work with mortality rates.

In fact, at the practical level, all these methods yield very similar results. The differences in the degree of precision of the initial data (fineness of age groups, method for computing the life tables used, consistency between these tables and age-specific rates, etc.) are much more important than the ones due to the theoretical distinctions between the methods employed (El Makrini, 1998).

We use Pollard's method here to illustrate the contributions of differences in age-specific mortality to a difference between two life expectancies. Our example concerns the life-expectancy gains registered in France for 10-year periods, since 1899 (Table 16–2 and Figure 16–1).

In the early 20th century, most of the increase in life expectancy was due to the fall in infant mortality and juvenile mortality. Between 1899 and 1909, the fall in male mortality among those younger than 15 years was single-handedly responsible for a 4.3-year gain in life expectancy, or 98% of the total 4.4-year gain achieved by males. The situation was very different in the subsequent 10-year period (1909–20) owing to the disturbance caused by World War I, but the fall in infant mortality soon became the predominant factor again—until World War II upset the pattern once more. The decline in infant and juvenile mortality regained its pre-eminence in the postwar years. After the 1950s, however, mortality at early ages fell to very low levels, and the potential gains from its further reduction are dwindling. Indeed, life expectancy would eventually have leveled off if an entirely novel phenomenon had

[2] Or at least an approximation of that total, insofar as concrete computations always give rise to small discrepancies due to data flaws.

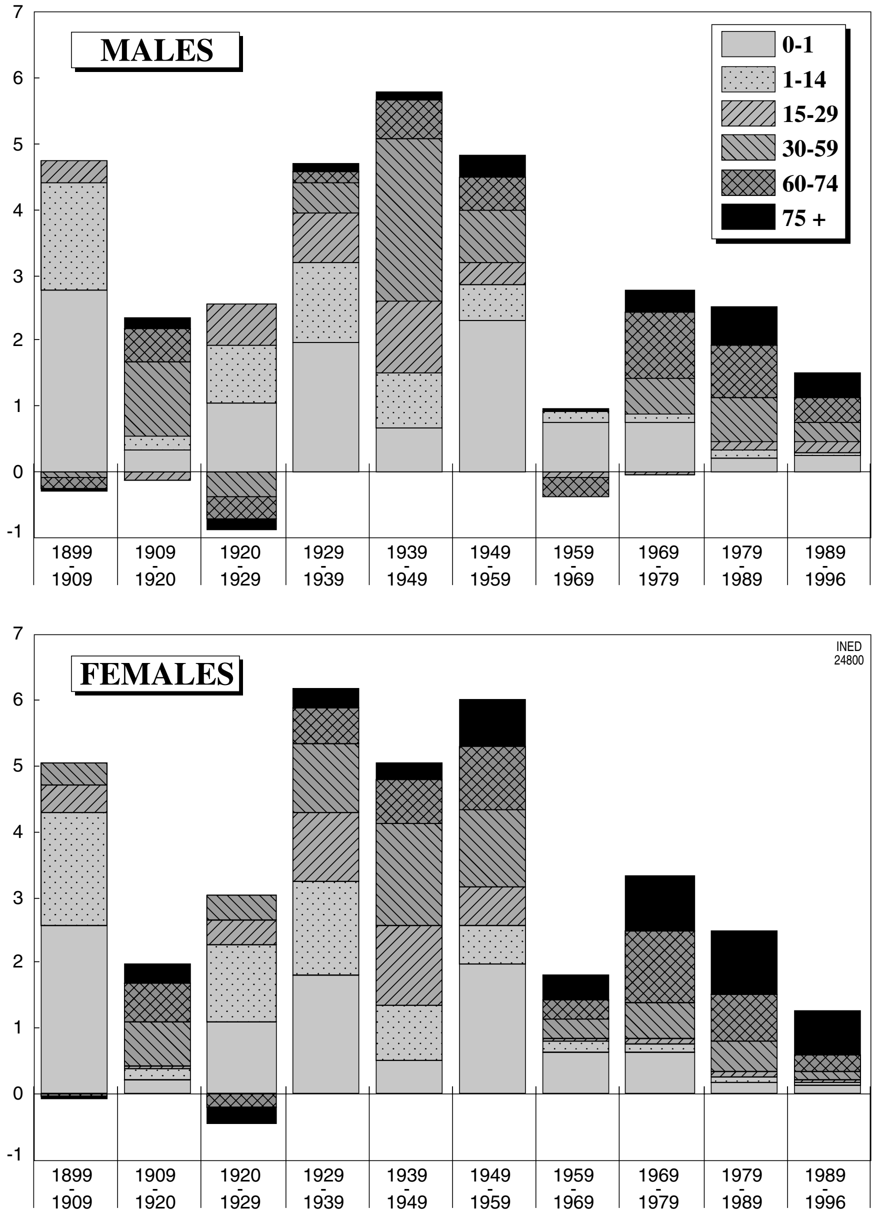

FIGURE 16–1 Contributions of changes in mortality for different age groups to life-expectancy gains registered in France for 10-year periods since 1899.

not taken over since the 1970s: the massive fall in mortality at older ages (after 60 and even after 75).

II. TEMPO EFFECT AND INTENSITY EFFECT ON THE DIFFERENCE BETWEEN TWO TOTAL FERTILITY RATES

Turning now to fertility, if we compare two total fertility rates (TFR^1 and TFR^2), the question generally raised is of an entirely different nature. As a rule, demographers want to know how much of the difference is due to a tempo change and how much is due to an actual change in the intensity of fertility in the cohorts involved.

Let I be the contribution of the change in intensity and C that of the tempo change. Ryder (1960, 1980) proposes the following formula for measuring them (Santini, 1992):

$$TFR_{t2} - TFR_{t1} = \left[\frac{\alpha^1 + \alpha^2}{2} \cdot (TFRC_{t2} - TFRC_{t1})\right] + \left[\frac{TFRC_{t1} + TFRC_{t2}}{2} \cdot (\alpha^2 - \alpha^1)\right] = I + C$$

where α_x is the fertility timing, equal to:

$$\alpha_x = \frac{f_{x,t}}{\sum_{x=15}^{50} f_{x,t-x}}$$

and

$$TFRC_t = \frac{TFR_t}{\sum_{x=15}^{50} \alpha_x},$$

where, generally:

$$\alpha = \sum_{x=15}^{50} \alpha_x \neq 1$$

In Italy, for example, the TFR fell from 2.337 in 1952 to 1.187 in 1994, a difference of –1.150 children. To decompose this difference into the intensity-change effect and the tempo-change effect, we must start by calculating the α values. For this, we divide each age-specific fertility rate f_x by the completed fertility of the cohort that has reached its mean age at childbearing in the year examined. For 1952, we divide the rates by 2.414, the average number of children per female of the 1923 birth cohort; for 1994, we divide by 1.593, the average number of children per female of the 1963 cohort (Table 16–3).

Applying the formula given above, the fall of 1.15 children per female in the Italian period fertility rate is decomposed as follows:

$$1.187 - 2.337 = \left[\frac{0.745 + 0.968}{2} \cdot \left(\frac{1.187}{0.745} - \frac{2.337}{0.968}\right)\right] + \left[\frac{\frac{2.337}{0.968} + \frac{1.187}{0.745}}{2} \cdot (0.745 - 0.968)\right] = (-0.703) + (-0.447)$$

Of the total reduction, 61% (–0.70 children) is therefore due to the fall in intensity and 39% (–0.45 children) is due to an intergenerational shift in birth timing.

If the necessary historic data are available, we can thus track the effects of intensity and tempo on the change in the total fertility rate. To continue with the example of Italian data for 1952 to 1994, we can, for example, distinguish two periods on either side of the year 1967, already used as an example earlier (Chapter 14): The first (1952–1967) corresponds to a rise in fertility due—as we have already suggested—to an earlier completion of fertility by the generations involved; by contrast, the second period (1967–1994) reflects a gradual postponement of the timing (Table 16–4).

TABLE 16–4 Effects of Changes in Intensity and Tempo of Cohort Fertility on Period Fertility in Italy, 1952–1967 and 1967–1994

	1952–1967	1967–1994	1952–1994
Initial TFR	2.34	2.53	2.34
Final TFR	2.53	1.19	1.19
Difference	0.20	–1.35	–1.15
Intensity effect	–0.20	–0.59	–0.70
Tempo effect	0.40	–0.75	–0.45

TFR, total fertility rate.

Figure 16–2 shows that the rise in period fertility between 1952 and 1967 is entirely due to the lead taken by successive cohorts in completing their fertility. This phenomenon even offsets the mild decline in intensity of cohort fertility. Whereas the timing lead should have single-handedly driven up the TFR by 0.4 children per between 1952 and 1967, the loss of intensity in the cohort fertility halved that gain to 0.2 children. By contrast, while the acceleration of this decline in cohort fertility made a substantial contribution of –0.6 children to the fall in total fertility between 1967 and 1994, this effect is, in itself, weaker than the effect of the

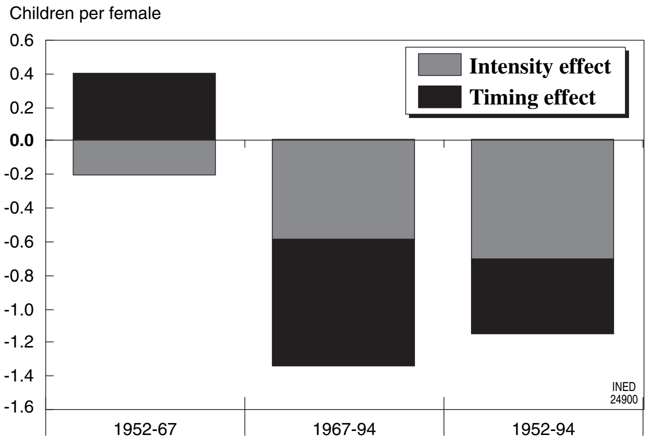

FIGURE 16–2 Effects of changes in intensity and tempo of cohort fertility on period fertility in Italy, 1952–1967 and 1967–1994.

delay by recent cohorts in completing their fertility (–0.8 children).

In fact, this attempt to interpret the difference observed between two total fertility rates is a first step toward the more general approach—known as the *translation* approach—aimed at interpreting period indicators in terms of cohort and vice versa, a topic discussed in the next chapter.

Demographic Translation

From Period to Cohort Perspective and Back

NICO KEILMAN

Department of Economics, University of Oslo, Oslo, Norway

I. THE NEED FOR BOTH COHORT AND PERIOD ANALYSIS

In his account of fertility levels and trends in England and Wales since the 1930s, Hobcraft (1996) noted that the mean age at birth had fallen rapidly after the Second World War. In 1972, women were 26.2 years old on average when they gave birth—3 years younger than in 1945 to 1946 (29.2 years). The decrease corresponds to more than 1 year per decade. This change in the timing of fertility had an upward effect on period total fertility rates (TFRs). Hobcraft argues that if successive cohorts of women have their children at progressively lower ages, such that the mean age falls every year by one tenth of a year, births that would have occurred during a period of 10 years without changes in the timing, are now squeezed into a period that is 1 year shorter. This pushes period fertility upward, and the period TFR will be inflated by 10%, compared to the TFR that would have occurred *without* changes in the timing.

Hobcraft's example demonstrates the point repeatedly stressed by Norman Ryder (1956, 1964, 1980): Even with constant completed cohort fertility, period fertility levels may vary. They are inflated in years in which childbearing is accelerated, and deflated when women postpone childbearing. Figure 14–11 and Figure 14–12 in Chapter 14 illustrate this point further: The increase in the period level of fertility in Italy in the 1960s was caused by a change in the tempo of childbearing among Italian women born in the 1930s. These women did *not* have more children than women born earlier, but their children were simply born at progressively younger ages. As a result, the period level of fertility was artificially high. This example shows that period fertility cannot be used as a reliable indicator for the level of cohort fertility: period fertility may be *distorted* in times of tempo changes in cohort fertility. At the same time, cohort fertility cannot be fully understood without studying periods.

The detailed interplay between period and cohort fertility, both its quantum (level) and tempo (timing) aspects, can be formalized mathematically. The resulting expressions constitute the core of what has become known as the *theory of demographic translation*, a term first used by Norman Ryder. The starting point is a table with age-specific birth rates for many calendar years. Since the period quantum (TFR) and the cohort quantum (completed cohort fertility [CFR]) are obtained on the basis of the same age-specific rates, but by summation in different directions (vertically for the TFR, diagonally for the CFR), there must be a relationship between the two quantum measures. In certain cases, when fertility changes show strong regularities (e.g., the TFR falls linearly, while the age pattern is constant), the resulting relationships are very simple mathematic expressions. The purpose of deriving such expressions is to gain insight into the degree of *translational distortion*, in other words to predict the quantum and tempo of cohort fertility, given trends in period fertility, and the other way round.

This chapter will give a brief overview of the theory of demographic translation. The theory can be applied to fertility and other demographic processes, such as first marriage and divorce. However, two conditions have to be fulfilled. First, the quantum and tempo indicators must develop sufficiently smoothly over a long period. Second, the sum of age-specific (or duration-specific) rates in either period or cohort dimension, or a transformation of this sum, must have a clear demographic interpretation. This must also be the case for the moments of the age schedule.

II. EARLY EXPRESSIONS BY RYDER FOR THE CASE OF AGE-SPECIFIC FERTILITY

Translation formulae can be used in two directions. From a theoretical point of view, one could be interested in expressions for the development of period quantum and tempo indicators, given certain trends in cohort indicators. Such expressions give insight in possible cohort mechanisms behind observed period developments, since period developments are considered a function of cohort developments. However, in practice, data for period developments are easier to obtain than those for cohort trends. Therefore, it is also useful to take the opposite point of view, and analyze cohort developments based on period developments.

1. From Cohort to Period

The starting point is a table with age-specific fertility rates for 1-year age groups and a number of calendar years. When we sum the rates over childbearing ages for calendar year t, the result is the TFR in that year, written as $TFR[t]$. It expresses the period quantum of fertility; see also Chapter 14. The cohort quantum is expressed by means of the CFR (Chapter 12), which is obtained by summing the rates diagonally. For example, for women born in year g, the $CFR[g]$ consists of the sum of rates for calendar year g at age 0, year $g+1$ at age 1, . . . year $g+48$ at age 48, and finally the rate in year $g+49$ at age 49. (Obviously, the rates below age 13 or 14 are zero.) Figure 14–11 in Chapter 14 plots the TFR for Italy for the years 1930 to 1994, and the CFR for the generations born in 1890 to 1962.

The TFR and the CFR express the *quantum* of fertility: To how many children does an average woman give birth in a period or a cohort perspective? The *tempo* aspect of fertility is expressed by the mean age at childbearing, which summarizes, in one number, the age at which women on average get their children. The period mean age for the year t is written here as $\bar{x}[t]$. Chapter 14 explains how it is computed based on a series of age-specific fertility rates for year t. The cohort mean age for a certain generation g, is written here as $\mu[g]$; it is computed analogously on the basis of a series of rates for generation g. Figure 14–12 in Chapter 14 plots the period and the cohort mean ages for Italian women, for the years 1953 to 1993 and the birth cohorts for 1900 1960. The mean age is one indicator that characterizes the age pattern of fertility. A second indicator is the variance, which tells us how wide the age pattern is for a certain birth cohort, or a given calendar year: A large variance implies that many women had their children at a much younger or much older age than the mean age.

Ryder derived mathematic expressions that predict the period quantum for a certain year as a function of cohort indicators for various cohorts: the CFR, the mean age, the variance, and other cohort indicators. Another expression gives the period mean age as a function of cohort indicators. The appendix to this chapter contains these expressions, together with their derivations. Under certain conditions, for instance, when the CFR is the same for all women born in successive generations, or when it varies linearly with time, the expressions become very simple. Here I shall study three such simplified cases.

First, I assume that both the cohort quantum and the age pattern of cohort fertility are constant, while only the mean age changes linearly. This would be the case when women born in successive generations on average would have the same number of children, whereas the curve of age-specific birth rates shifts progressively toward higher (or lower) ages. The second case is one with constant cohort tempo and a linear change in the cohort quantum. In this case, all rates grow or diminish from one cohort to the next with the same relative amount. The third case combines linear changes in both cohort quantum and mean age. Although these cases are clearly unrealistic, they provide nonetheless insight into the basic mechanisms of translation.

a. Constant Cohort Quantum and Linear Change in Cohort Mean Age

Constant cohort quantum implies that $CFR[g] = CFR$ for each cohort g. When the cohort mean age $\mu[g]$ follows a straight line, its increase or decrease is equal to $\Delta\mu$ years of age per birth year.[1] Finally I assume that other indicators of the fertility age schedule are constant. In that case we find that the period quantum TFR is constant, and that it equals (expression [A3] in appendix)

$$TFR = CFR \times (1 - \Delta\mu) \quad \text{(Eq. 1)}$$

When the mean age falls by one tenth of a year from one cohort to the next, the TFR is 10% higher than the CFR, and the translational distortion is 10%. In general, when childbearing is progressively concentrated in younger ages, the period TFR is inflated, other things being equal. However, the translational distortion in the mean age goes in the opposite direction (expression [A4] in appendix):

$$\bar{x}[t] = \frac{\mu[t]}{1-\Delta\mu} \quad \text{(Eq. 2)}$$

where $\mu[t]$ is the mean age for the cohort born in year t. When the cohort mean age falls by one tenth of a year from one birth cohort to the next, the period mean age is 10% *lower* than the cohort mean age, and *falls steeper*, namely by 0.1/0.9 = 0.11 years annually.

b. Constant Cohort Mean Age and Linear Change in Cohort Quantum

With constant cohort mean age ($\mu[g] = \mu$) and a linear change in the cohort quantum equal to ΔCFR per birth year, one obtains (see expression [A6] in appendix)

$$TFR[t] = CFR[t] - \mu \times \Delta CFR \quad \text{(Eq. 3)}$$

Thus, the TFR in year t equals the CFR for the cohort born in year t, minus the slope in the CFR times the mean age. In other words, the TFR changes linearly as well. With a mean age of 30 years and a CFR that falls by 0.05 children per woman each generation, the TFR is higher by 0.15 children, compared with the CFR. Because the CFR falls by ΔCFR = 0.05 child per generation, the decrease is $\mu \times \Delta$CFR = 0.15 children over μ = 30 cohorts. In other words, the TFR in year t equals the CFR for cohort t – 30. More generally,

$$TFR[t] = CFR[t - \mu] \quad \text{(Eq. 4)}$$

as expected. This simple relationship justifies common practice among demographers to shift the CFR curve between 25 and 30 years, when it is plotted in one graph together with the period TFR. See, for example, Figure 14–11 in Chapter 14, where the shift is 29 years.

[1] I use square brackets, i.e., [and], to denote the argument in a function. Parentheses, i.e., (and) indicate grouping of terms in an expression. For reasons of readability, I use the symbol Δ here to indicate annual change, both in terms of the mean age and the quantum. In the appendix, I have used a prime instead, indicating derivation with respect to time.

c. Linear Changes in Cohort Quantum and Cohort Mean Age

When both the CFR and the cohort mean age change linearly, one obtains (expression [A8]):

$$TFR[t] = CFR[t] \times (1 - \Delta\mu) - \mu[t] \times \Delta CFR \quad \text{(Eq. 5a)}$$

or the equivalent expression

$$TFR[t] = CFR[\gamma] - \Delta\mu \times CFR[t], \quad \text{with } \gamma = \gamma[t] = t - \mu[t] \quad \text{(Eq. 5b)}$$

Thus an increasing CFR and a fall in the mean age imply, according to expression (5a), an additional inflation of the TFR by an amount equal to $\Delta\mu \times CFR[t]$, compared with the situation in which only the CFR increases (expression [3]). This is close to the situation in England and Wales during the years of the baby boom: the CFR of cohorts born from 1905 to 1935 showed a near linear increase, from approximately 1.8 to 2.4 children per woman (Festy, 1979). As a result, the TFR from 1935 to 1965 rose also; see expression (4). However, the TFR was *extra* high (by an amount of $-\Delta\mu \times CFR[t] \approx (2/25) \times 2.1 = 0.17$) because the mean age for cohorts 1910 to 1935 fell by 2 years; see also the period indicators mentioned in the introduction. Denmark, Sweden, Finland, Norway, France, Netherlands, Switzerland, Canada, Australia, and the United States (white women) are other baby-boom countries in which an increase in CFR for women born in the first few decades of this century went together with a fall in the cohort mean age (see Festy, 1979).

2. From Period to Cohort

When cohort developments are considered a function of period developments, expressions similar to those given above can be derived. Assuming constant period quantum and a linear change in the period mean age gives the following result for the cohort quantum:

$$CFR[g] = CFR = TFR \times (1 + \Delta\bar{x}) \quad (1')$$

Thus a rise in the period mean age is reflected in a cohort quantum that is larger than the period quantum by a constant factor. Similarly, when the period mean age is constant, and the TFR varies linearly, one finds:

$$CFR[g] = TFR[g + \bar{x}] \quad (4')$$

The cohort quantum for women born in a certain year equals the period quantum $\bar{x}$ years later. Finally, when period quantum and period tempo are linear, the result is:

$$CFR[g] = TFR[g] \times (1 + \Delta\bar{x}) + \Delta TFR \times \bar{x}[g] \quad (5a')$$

or, equivalently

$$CFR[g] = TFR[\tau] + \Delta\bar{x} \times TFR[g] \quad (5b')$$

with

$$\tau = \tau[g] = g + \bar{x}[g].$$

It should be noted that assumptions of a linear trend in quantum or tempo indicators are primarily used for mathematic convenience because higher order derivatives in the relevant expressions vanish. When trends are nonlinear, polynomials of increasing order may be used instead. Although the mathematics still remain tractable, such polynomials cannot describe actual trends accurately over a long period, since they tend to result in unrealistically large positive or negative values in the long run. In practice, two solutions are followed. First, one may fit a low-degree polynomial over successive rather short intervals (Calot, 1992)—in other words, the polynomial holds only locally. A second solution is to use a bounded nonlinear function, for instance a logistic or a periodic curve (see De Beer, 1982; Foster, 1990).

III. EXPRESSIONS FOR NONREPEATABLE EVENTS

The expressions in the prior sections apply to age-specific fertility. They are based on the fact that when age-specific rates, either for a given calendar year or a given cohort, are summed over all ages, the sum reflects the quantum of the process. This is typically the case for repeatable events, such as childbearing regardless of parity. The rates are additive because a woman who gives birth to a child remains at the risk for a new birth (except for a short period immediately after delivery): The denominator of the rate is not affected by the event.

In contrast, we have *nonrepeatable* events such as childbearing broken down by birth order, or first marriage, or emigration. Events of this type are usually characterized by means of occurrence-exposure rates (o-e rates, *taux de première catégorie*).[2] Whelpton (1946) gives an early contribution for the case of age- and parity-specific fertility. An o-e rate expresses the risk of the event in question, for instance births of a certain order relative to all women of the corresponding parity, or first marriages relative to the number of never-married persons. When the o-e rates for such an event are age-specific, the sum of the rates over all ages does not reflect the quantum of the process in question.[3] For instance, whereas the quantum of first birth usually takes on values of between 80% and 95% (implying that 5% to 20% of the women remain childless), the rate sum is typically between 1.5 and 2.5.

Nevertheless, for some nonrepeatable events the translational distortion *can* be analyzed along the lines described, because the rate sum for these events, after an appropriate transformation, can be interpreted as the quantum of the process in question. As an example, take the case of births of order one. Consider the age-specific o-e rate for first births, and write the sum of these rates over all fertile ages for cohort g as $B[g]$. A traditional life table calculation shows that the cohort quantum of the process, expressed as the proportion of women in that cohort who at the end of the reproductive period ever had experienced a first birth, can be written as[4]

$$Q_c[g] = 1 - \exp(-B[g]) \quad \text{(Eq. 6)}$$

A similar expression holds for the period quantum of the process. Hence, the translation expressions given in the previous section can be applied to nonrepeatable events if one performs the exponential transformation of the predicted rate sum. For instance, in case the period rate sum of o-e rates for first births is constant, while the first moment follows a straight line, expression (1′) may be used to predict the cohort rate sum. Next, expression (6) predicts the cohort proportion of women who ever gave birth to a first child, see for instance Keilman (1994), Keilman and Van Imhoff (1995), and—for time-continuous expressions—Calot (1992). Empirical illustrations will be given in section IV. A number of points should be noted.

1. Because of the mathematics of the life table, the mean age of the process does not coincide with the first moment of the age schedule of o-e rates (Keilman, 1994). Translation formulas for the mean age or other tempo indicators are not known—only quantum expressions have been derived for nonrepeatable events. However, it will often be reasonable to assume that the slope of the mean age may be approximated by the slope of the first moment.

[2] Sometimes, incidence rates (epidemiology), also called frequencies (Coale), or *taux de deuxième catégorie* are used; see Chapter 8. Incidence rates are additive, but they exaggerate period distortions. See Chapter 14 and section IV this chapter.

[3] In certain cases the rate sum is a reasonable approximation for the quantum, see below.

[4] Expression (6) assumes piecewise constant intensities.

2. Although the procedure sketched in this section may be applied to such nonrepeatable events as birth of the first child, first marriage, emigration, and many others, some events cannot be analyzed this way. Examples are births of order two or higher by age of the mother and remarriage of divorced persons by age. The risk population of such processes may decrease and increase (for instance caused by births of the previous order or divorce). Such an increase is impossible in the case of first births or first marriage. As a consequence, the multistate life table that traces the fertility or nuptiality history of the real or synthetic cohort over its life course results in intractable matrix expressions for the quantum of these events. Another example is age-specific mortality. Because everyone dies, the quantum for mortality is 100%, and the interest is solely in the tempo aspects. As noted in the previous point, expressions for tempo indicators are unknown.
3. For low-intensity processes, the rate sum in expression (6) is small. In such cases, the rate sum itself approximates the quantum reasonably well, and all the expressions derived in the prior sections apply. Rate sums up to 0.2 are up to 10% higher than the corresponding quantum values. Examples of low-intensity processes are long distance migration, out-migration from large areas, and divorce in Mediterranean countries (broken down by marriage duration).

IV. THE BONGAARTS—FEENEY METHOD FOR TEMPO ADJUSTMENT OF PERIOD FERTILITY

Bongaarts and Feeney (1998) have proposed a method that corrects age- and parity-specific period fertility for distortions caused by tempo changes (see also Bongaarts, 1999). The purpose of the method is to obtain a tempo-free TFR (i.e., a TFR that would have been observed in year t if the age pattern of fertility had been the same as that in year $t - 1$). The starting point is the birth-order—specific TFR for year t defined as $TFR_p[t] = \Sigma f_p[t,x]$, where the fertility rate $f_p[t,x]$ expresses the number of births of order p by mothers aged x in year t, relative to the number of women aged x regardless of parity. The sum is taken over all fertile ages x. Assuming a constant shape of the age schedule of fertility (i.e., women of all ages defer or advance their births to the same extent), an adjusted TFR is computed as $TFR_p'[t] = TFR_p[t]/(1 - \Delta M_p[t])$, where $\Delta M_p[t]$ is the annual change in the mean age at childbearing for parity p. Summing the results over different birth orders gives the overall tempo-free total fertility $TFR'[t] = \Sigma TFR_p'[t]$.

Note the differences with Ryder's approach. First, Ryder did not include birth order. Second, he saw the tempo distortion in period fertility as caused by changes in cohort tempo. In contrast, Bongaarts and Feeney (B&F) (1998) assume that all changes are period driven. They do not attempt to predict cohort fertility because they assume that period-by-period changes are independent of age and cohort. In spite of these differences, for small changes in the mean age, the B&F approach (given birth order) gives the same result as Ryder's expression (1′),[5] although the interpretations of the two results are entirely different.

The B&F adjustment procedure is attractive because it is based on period data only. However, it has two major weaknesses (Van Imhoff, 2000; Van Imhoff and Keilman, 2000; Kohler and Philipov, 1999; Lesthaeghe and Willems, 1999). First, the method is based on fertility rates unsuitable for the purpose of tempo adjustment. The incidence rates used by B&F express the number of births of order p by mothers aged x in year t, relative to the number of women aged x *regardless of parity*.[6] The use of such rates in a period perspective introduces *extra* tempo distortions, compared to o-e rates. Whelpton noted this in 1946. When age-specific incidence rates for first births (for example) are summed for a given year, one erroneously assumes that the share of childless women at the end of one age interval is equal to that share at the start of the next interval. This is not necessarily the case because the age intervals refer to different cohorts. The stronger the tempo changes between cohorts, the more the shares for subsequent ages differ, and the stronger the effect of tempo distortions is exaggerated (Chapter 14, Figure 14–17). Quantum measures based on o-e rates of the type used in the prior section do not display this kind of bias. Therefore, Smallwood (1999; p. 40) concluded about the B&F adjustment that it ". . . provides a way of making a synthetic measure even more synthetic." The second problem is that the constant shape assumption underlying the B&F method is not supported by the data for a number of European countries: The age schedule is not only shifted toward higher or lower ages, but its shape changes as well. Hence period-by-period changes are not independent of age

[5] The formulas are different, because Bongaarts and Feeney assume a constant shape of the age-specific fertility schedule, whereas Ryder assumes constant period moments of orders two and higher. These assumptions are not equivalent (see the appendix, and, for a general treatment, Van Imhoff 2001, p. 62–64).

[6] The same disadvantage applies to the use of the method described by Pressat (1983), when applied, as Pressat proposes, to incidence rates.

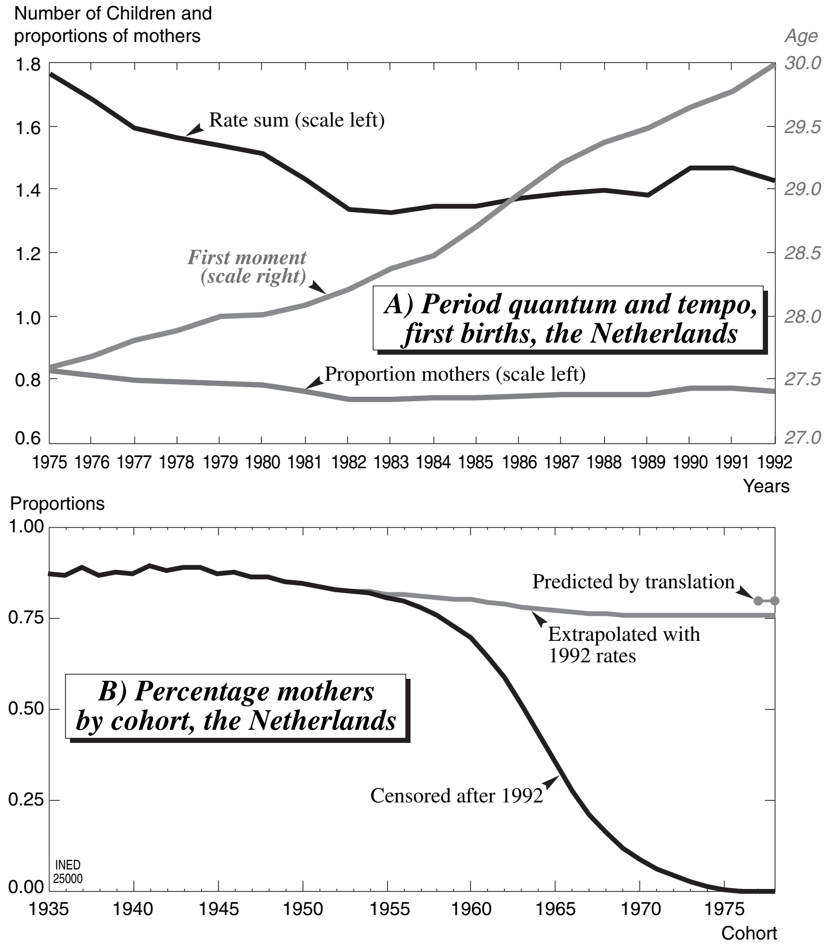

FIGURE 17–1 First illustration: first births in The Netherlands. (Source: BOSVELD WILLY, 1996. *The ageing of fertility in Europe: a comparative demographic-analytic study*. Amsterdam, Thesis Publishers, 285 p.)

and cohort, contrary to what B&F assume.[7] Thus period changes *are* dependent on cohort, and a pure *period quantum* is an untenable concept: cohort data are necessary to understand period effects fully (just as cohort effects cannot be fully understood without studying periods).

V. NUMERIC ILLUSTRATIONS

1. Childlessness in The Netherlands

Dutch population forecasts from the mid 1990s assumed a level of childlessness among women born in the 1970s and 1980s equal to 25% (De Beer, 1997). Indeed, the period level of first births suggested a proportion of women having at least one child equal to 75% (Figure 17–1A and 1B). For each year, this proportion was computed on the basis of the period sum of age-specific first birth rates of the occurrence-exposure type (Bosveld, 1996) and expression (6) was applied to that sum. The fall in the proportion of mothers between cohort 1945 and cohort 1955 in Figure 17–1B is real, but the further decline for later cohorts depends on the extrapolation method used. Compare the two lines *extrapolated with 1992 rates* and *censored after 1992*. Since 1981, the period sum of first birth rates (ages 15–39 years) in Figure 17–1A fluctuated around a level of 1.4 (with a slight tendency to increase), which led to an essentially constant proportion of mothers from that year onward. However, the period first moment (which reflects the mean age computed as $V_1[t]/V_0[t]$; see appendix) rose sharply during the years 1975 to 1992, with a slope equal to 0.14 years per year. Dutch women postponed the birth of their first child, and this depressed the period quantum.

[7] Kohler and Philipov (1999) extend the B&F approach to allow a changing variance of the fertility schedule. This reduces the empirical problem connected to the constant shape assumption, but not the methodologic one caused by the use of unsuitable fertility rates. Moreover, the adjusted TFR that they obtain is as unclear as that of Bongaarts and Feeney. In later work on fertility by age and parity, Kohler and Ortega (2001a, 2001b) introduce occurrence-exposure rates in an attempt to deal with the problem caused by the use of incidence rates, but the problem mentioned as point 2 in section III here is not solved.

Although the forecasters acknowledged this postponement effect, it was stronger than they believed in the mid 1990s. Indeed, the forecast published in 1999 assumes lower childlessness than previously: 20%, instead of 25% (De Beer, 1999). Translation theory could have predicted this in 1993 already. Assuming a constant period rate sum from 1981 onwards, and a linear first moment, expression (1′) predicts the cohort rate sum for the cohorts born in 1981 and later as $1.4 \times (1 + 0.14) = 1.60$, which implies a cohort quantum equal to 80% (expression [6]), and thus 20% childlessness.

2. Divorce in Norway

Figure 17–2A shows period proportions divorced in Norway. The underlying data are o-e rates for divorce, broken down by marriage cohort and marriage duration (Mamelund *et al.*, 1997). The year of divorce equals marriage year plus marriage duration. For each year, divorce rates were summed across marriage durations (up to 60 years in the original data); expression (6) resulted in period proportions divorced. The period proportion for year t is interpreted as the proportion of a fictitious marriage cohort that has experienced divorce by duration 60, given the divorce rates for the year t. Until the beginning of the 1970s, proportions divorced were very low in Norway, and the rate sum in Figure 17–2A is only slightly higher than the proportion, as expected.

The first moment fluctuated between 13 and 15 years since 1950, whereas the rate sum was more or less linear between 1970 and 1993. When we assume a constant first moment equal to 14 years, and a linear rate sum, expressions (4′) and (6) predict the proportion divorced for marriage cohort g as the period proportion in year $g + 14$. Figure 17–2B shows that the fit is remarkably good. Thus although no Norwegian

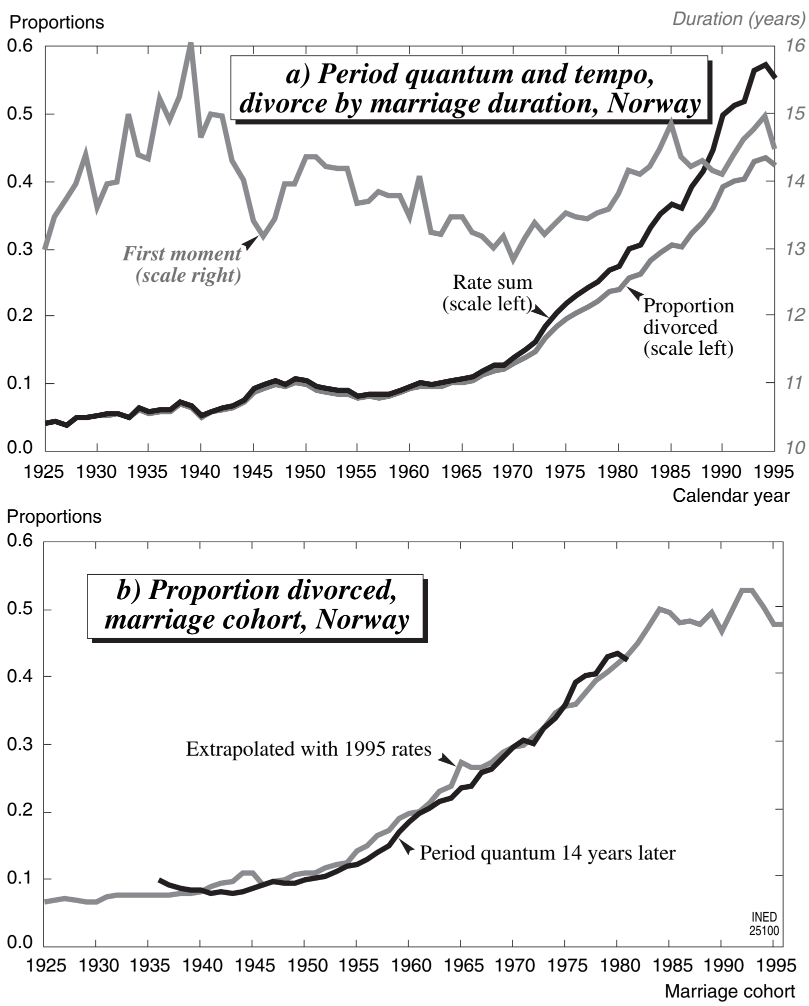

FIGURE 17–2 Second illustration: divorce in Norway. (Source: Svenn-Erik Mamelund, Helge Brunborg, and Turid Noack, 1997. *Skilsmisser i Norge 1886–1995 for kalenderàår og ekteskapskohorter*. Oslo, Statistics Norway, 115 p. [Rapporter 97/19].)

marriage cohort has ever had a proportion divorced that exceeds 25%, it is not unlikely that couples married in the last half of the 1960s will be the first ones to experience such a high share.

CONCLUSION

Translation theory provides expressions for the relationships between period and cohort quantum and tempo. The expressions can be applied to age-specific fertility, spanning several years and birth cohorts. With a slight modification, they can also be used to study other events, such as first marriage by age, divorce by marriage duration, emigration by age, or the birth of the first child by mother's age.

One of two perspectives can be adopted. First, the interest may be in period trends, and in tracing the effects of changing cohort behavior on those period trends. Applied to the case of age-specific fertility, the formulae show that when the CFR is constant, a fall in the cohort mean age at birth results in an inflated period TFR because women accelerate childbearing and births are *squeezed* into shorter periods. The TFR is pushed upward even more strongly when the CFR rises, in addition to the decrease in the mean age. In contrast, the TFR falls when women postpone childbearing (i.e., when the cohort mean age rises together with a constant or falling CFR). When the CFR and the cohort mean age move in the same direction, there are two opposite forces, and it is an empirical question whether the TFR is inflated or deflated. The second perspective is to take observed period trends as given, and to use translation theory to infer cohort developments. For example, the theory predicts, as expected, that the CFR is lower than the TFR by a 10% factor in case the period mean age falls by 1 year per decade and the TFR is constant.

From a mathematic point of view, the two perspectives are symmetric. However, there are strong empirical differences for age-specific fertility, and probably for other phenomena as well. The TFR shows much larger annual fluctuations than the CFR. Thus it is relatively easy to predict the CFR based on period quantum and tempo indicators: The model is more parsimonious than one that explains the TFR on the basis of cohort indicators. For instance, Calot (1992) analyzes age-specific fertility in France for the years 1900 to 1980 and cohorts in 1870 to 1950. He finds that period moments that develop linearly with time describe the CFR accurately. However, when he takes the opposite perspective and fits cohort moments to polynomials of increasing order when explaining the TFR, the accuracy he obtains is much less, even with fourth-degree polynomials (and the accuracy does not improve for higher order polynomials). Similarly, Foster (1990) concludes that period-based models provide a more parsimonious description of the observed patterns of age-specific fertility in eight countries in Europe and Northern America than cohort-based models do.

The primary use of translation theory is to improve the formal demographic analysis of historical developments.[8] Consider, for instance, the baby boom in Western countries (i.e., an increase in the TFR starting in the 1930s, and next a plateau in the 1950s and 1960s). Translation theory explains this trend by the fact that cohorts born in the first three or four decades of this century had increasingly larger numbers of children, and, at the same time, they accelerated childbearing. When quantum and tempo indicators develop according to a straight line over several decades, the resulting translation expressions are simple. This is seldom the case for period indicators. This makes translation theory less useful for predicting the behavior of cohorts, which the theory sees as a function of trends in period indicators.

APPENDIX 17–1 MATHEMATIC DERIVATIONS

Norman Ryder (1956, 1964) gave the first formal derivations. Alternative treatments of some special cases are contained, among others, in Pressat (1983) and Wunsch and Termote (1978). I will use the short and comprehensive general analysis of Yntema (1977).

Denote by $m[t,x]$ the fertility rate in year t at age x. Denote further the k-th *period* moment of these rates by $V_k[t] = \Sigma x^k \cdot m[t,x]$. Similarly, define the k-th *cohort* moment of those rates by $W_k[g] = \Sigma x^k \cdot m[g+x,x]$. In both cases, the sum is taken over all fertile ages. $V_0[t]$ is the TFR, or the period sum of rates in year t. Also, $W_0[g]$ is the Completed Cohort Fertility for cohort g.[9] Taylor series approximation of $m[t+x,x]$ about t gives

$$m[t+x,x] = \sum_i \frac{x^i}{i!} m^{(i)}[t,x].$$

Differentiation applies to time. Inserting this in the expression for W_k leads to

$$W_k[g] = \sum_i \frac{1}{i!} V_{k+i}^{(i)}[g].^{10} \qquad \text{(Eq. A1)}$$

Similarly, we find for period moments the following expression

$$V_k[t] = \sum_i \frac{(-1)^i}{i!} W_{k+i}^{i}[t]. \qquad \text{(Eq. A2)}$$

Expressions (A1) and (A2) are the general translation equations, which express cohort moments in terms of period moments, and vice versa. I will investigate a few special cases on the basis of the assumptions that quantum ($k = 0$) and mean age ($k = 1$) indicators are independent, or linearly dependent of time.

1. From Cohort to Period

a. Constant Cohort Quantum and Linear Cohort Mean Age

Assume that the cohort quantum W_0 is independent of time, and that the cohort mean age $\mu[g] = W_1[g]/W_0$ is a linear function of time. Assume further that all second and higher order moments $W_k[g]$ are independent of time. Thus, for $i > 1$, the terms in (A2) vanish and we find

$$V_k[t] = W_k[t] - W'_{k+1}$$

A prime indicates the first derivative with respect to time. This expression implies that the TFR ($k = 0$) is independent of time, and that it equals

$$TFR[t] = TFR = CFR - CFR \cdot \mu' = CFF \cdot (1 - \mu') \qquad \text{(Eq. A3)}$$

where μ' represents the slope in the mean age. The period mean age $\bar{x}[t]$ appears to be linear:

[9] Note that these moments are not normalized, in the sense that $V_0[t]$ and $W_0[g]$ do not equal one. Normalized moments are obtained as $V_k[t]/V_0[t]$ and $W_k[g]/W_0[g]$, k = 0, 1, 2, . . . For instance, the cohort mean age $\mu[g]$ equals $W_1[g]/W_0[g]$.

[10] Here and elsewhere, I shall write $V_k[g]$ to indicate the k-th moment for the calendar year $t = g$, and similarly for the derivatives of these moments. Likewise, $W_k[t]$ indicates the k-th moment for the cohort born in year t.

$$\bar{x}[t] = \frac{V_1[t]}{V_0[t]} = \frac{\mu[t]\cdot CFR}{CFR\cdot(1-\mu')} = \frac{\mu[t]}{1-\mu'} \quad \text{(Eq. A4)}$$

In some analyses (i.e., the Bongaarts–Feeney method) it is assumed that the shape of the age-specific fertility curve remains the same, but that this curve is shifted progressively toward higher (increasing mean age) or lower (falling mean age) ages. Clearly, this implies that the quantum is constant. But, as Evert van Imhoff pointed out to me, it does *not* imply time-independent moments of order two and higher, as assumed in this section. For instance, constant shape means that the variance is constant. Since the variance of any distribution equals the second (normalized) moment minus the square of the mean, a linear mean age must result in a quadratic second moment. Similar arguments hold for higher order moments. I will now treat the case of a linear mean age and a constant shape of the age-specific fertility curve.

Assuming linear mean age and constant shape, and writing the variance of the age schedule as σ^2, the second moment $W_2[g]$ equals $CFR\cdot\{\sigma^2 + (\mu[g])^2\}$, so that its second derivative is $2CFR\cdot(\mu')^2$. Similarly, the third moment $W_3[g]$ equals $CFR\cdot\{\gamma\sigma^3 + 3\sigma^2\mu[g] + (\mu[g])^3\}$. The symbol γ represents the coefficient of skewness, which is independent of time by assumption. The third derivative of $W_3[g]$ equals $6CFR\cdot(\mu')^3$. In general, the k-th derivative of the moment $W_k[g]$ equals $k!CFR\cdot(\mu')^k$ (see Van Imhoff, 2001, p. 62–64) for a general proof. This means that for $k = 0$, expression (A1) leads to

$$\begin{aligned} TFR[t] &= TFR \\ &= CFR\left(1-\mu'+(\mu')^2-(\mu')^3+\ldots\right) \\ &= \frac{CFR}{1+\mu'},\quad |\mu'|<1. \end{aligned} \quad \text{(Eq. A5)}$$

When comparing expressions (A3) and (A5), we see that when the mean age increases linearly, both a constant moments assumption and a constant shape assumption imply a *TFR* smaller than the *CFR*, but by different amounts. For weakly increasing mean ages, for instance by less than 0.1 year per calendar year, the difference is small.

b. Linear Cohort Quantum and Constant Cohort Age Pattern

A constant age pattern for cohort fertility, and a cohort quantum which depends linearly of time with slope W_0', implies that $V_0[t] = W_0[t] - W_1'[t] = W_0[t] - \mu W_0'$. In other words,

$$\begin{aligned} TFR[t] = CFR[t] - \mu\cdot CFR' = CFR[t-\mu],\\ \text{or } TFR[t+\mu] = CFR[t]. \end{aligned} \quad \text{(A6)}$$

Furthermore, $V_1[t] = W_1[t] - W_2'[t]$, so that we find for the period mean age $\bar{x}[t] = V_1[t]/V_0[t]$ that

$$\bar{x}[t+\mu] = \mu\cdot\frac{CFR[t-\sigma^2/\mu]}{CFR[t]}. \quad \text{(Eq. A7)}$$

The period mean age equals the cohort mean age times an adjustment factor (*distortion factor*), which depends on two quantities: the development of the cohort quantum and the relationship between the mean age and the variance of the cohort fertility age schedule. Assume that the variance is zero: All women get their children at the mean age. In this extreme case, the distortion factor equals one and the period mean age is constant, equal to the cohort mean age. In practice, the variance is larger than zero, and the distortion factor is larger/smaller than one, when cohort fertility falls/increases. Thus under the assumptions stated, the period mean age in year t is *higher* than the cohort mean age for women born in year t when the *CFR falls*, and vice versa. When women spread their births over a longer period in the life course, the variance of the fertility age schedule increases, and the distortion becomes stronger.

c. Linear Cohort Quantum and Linear Cohort Mean Age

Assume that both the cohort quantum and mean age are linear, whereas all the other moments are independent of time. This implies that

$$TFR[t] = CFR[t]\cdot(1-\mu') - CFR'\cdot\mu[t]. \quad \text{(A8)}$$

As expected, expressions (A3) and (A6) are special cases of (A8). The expression for the mean age is a complicated formula, which does not provide much insight. It is left out here.

2. From Period to Cohort

Expressions (A3)–(A8) for period quantum and mean age are based on expression (A2), assuming that cohort indicators are given. In the reverse situation, when the interest is in cohort quantum and mean age based on known period developments, expression (A1) is the starting point. The following results are easily verified.

3. Constant Period Quantum and Linear Period Mean Age

$$CFR[g] = CFR = TFR\cdot(1+\bar{x}') \quad \text{(Eq. A9)}$$

$$\mu[g] = \frac{\bar{x}[g]}{1+\bar{x}'}. \quad \text{(Eq. A10)}$$

$\bar{x}[g]$ is the period mean age in the year $t = g$.

a. Linear Period Quantum and Constant Period Age Pattern

$$CFR[g] = TFR[g + \bar{x}] \qquad \text{(Eq. A11)}$$

$$\mu[g - \bar{x}] = \bar{x} \cdot \frac{TFR[g + s^2/\bar{x}]}{TFR[g]} \qquad \text{(Eq. A12)}$$

where s^2 represents the variance of the period age pattern.

b. Linear Period Quantum and Linear Period Mean Age

It is assumed that second- and higher order period moments are independent of time.

$$CFR[g] = TFR[g]\cdot(1 + \bar{x}') + TFR'\cdot\bar{x}[g]. \qquad \text{(A13)}$$

CHAPTER

Age-Period-Cohort Models In Demography

JOHN R. WILMOTH

Department of Demography, University of California, Berkeley, California

Demographic events such as birth, death, marriage, and migration mark life's most important transitions and, not surprisingly, are influenced by a multitude of factors. These influences are not constant across time or space, and thus demographic rates display considerable variation. A crucial task of demographic analysis is to identify the factors that account for this variability.

One particular approach to this quite general problem is to study the variation in demographic rates along three critical dimensions: age of the event, year (or period) of its occurrence, and cohort of the individuals involved. Within this framework, *cohort* may refer to an individual's year of birth or to the time of some other important transition in the life course (e.g., a marriage cohort in a study of divorce). Likewise, *age* may mean a person's chronologic age at the time of the event or the time elapsed since another important transition (e.g., duration of employment in a study of retirement).

The underlying assumption of age-period-cohort (APC) analysis is that all factors influencing a demographic event or its rate of occurrence can be grouped meaningfully into these three categories. Of course, there may be interactions or overlap between the three sets of factors, but it is assumed, implicitly, that these influences are less important than the main effects associated with each dimension. The typical analytic strategy of APC studies, therefore, is first to identify patterns of change in demographic rates that are associated with these three dimensions or sets of causal factors. Once this elaborate description is available, the analyst attempts to identify the specific influences (biologic processes, historic trends, etc.) that are responsible for the observed patterns in terms of age, period, and cohort.

Based on this description, the logic of APC analysis seems simple and relatively straightforward. There is, however, a fundamental problem with this strategy related to the fact that, mathematically,

$$\text{cohort} + \text{age} = \text{period}.$$

This relationship is illustrated by means of a Lexis diagram in Figure 18–1. In the view of some researchers, the exact mathematic connection between age, period, and cohort renders all forms of APC analysis meaningless, since changes in a demographic process along one of the three dimensions cannot be distinguished statistically from changes along the two remaining dimensions (Glenn, 1976; Goldstein, 1979; Rodgers, 1982). Other researchers have proposed a variety of solutions for overcoming this problem and claim that valid and useful results can still be derived within an APC framework (Fienberg and Mason, 1979; Clogg, 1982; Caselli and Capocaccia, 1989; Wilmoth, 1990). All researchers would agree, however, that the identification problem that plagues APC analysis is a fundamentally difficult and perplexing problem.

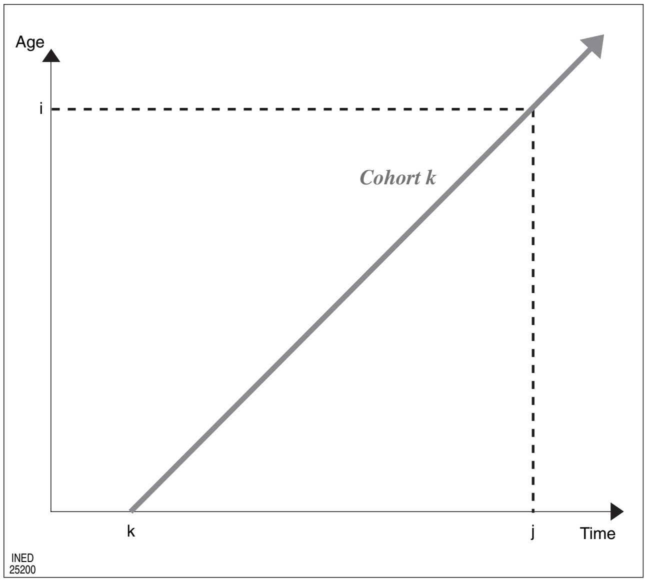

FIGURE 18–1 Lexis diagram showing the relationship between age, period, and cohort of a demographic event. The lifeline of individuals born at time *k* (cohort) is represented by the diagonal arrow. For such persons, a demographic event at age *i* occurs at time $j = k + i$ (period).

In this chapter, we first discuss the theoretical motivation of the age-period-cohort framework. We then provide a formal definition and discussion of the identification problem that affects APC modeling. Although we do not provide a complete literature review, we discuss strategies for estimating APC models that have been proposed in particular contexts. We also describe a small number of empirical applications of APC modeling that seem particularly informative. In conclusion, we offer some general remarks about the applicability of the APC framework.

I. THEORETICAL MOTIVATION

We begin our theoretical discussion by asking, "Why is the age-period-cohort framework useful?" The period of an event, for example, has no direct influence on its outcome but is merely a marker for other factors that may affect a demographic process. Periods may be associated with wars, epidemics, political and legal changes, famines, inventions, scientific discoveries, and changing fashions. It is these occurrences or situations, not the period itself, that account for the variation in demographic rates along the period dimension. Likewise, it is not cohort membership and chronologic age themselves that influence demographic rates, but rather the characteristics associated with those two dimensions.

It is worth considering, however, whether all three dimensions should be important in all situations. In the case of the classical demographic events (birth, death, marriage, and migration) it seems obvious that age, or duration, should be associated with sharp differences in outcomes. Due to biologic mechanisms, both the risk of death and the chance of giving birth vary enormously with age. Owing mostly to social and psychological mechanisms, the risk of divorce varies depending on the duration of marriage and the probability of migration changes over the life cycle. The age pattern of marriage is a complex function of both biologic maturation and social convention.

The immediacy of period-specific events makes their connection to demographic processes self-evident. The role of cohort-specific influences, on the other hand, is less obvious. In an influential article, Ryder (1965) laid out the theoretical justification for the use of cohorts in the study of social change. According to Ryder, fresh cohorts enable the process of social change, since young people are less constrained by history and more capable of adapting to or creating new modes of living. Furthermore, individuals experience certain critical events (e.g., infancy and childhood, education, military service, first employment) alongside peers from their particular cohort and the after-effects of these situations may mark them for life. The imprint of life-defining events may be biologic or social, but in either case we should expect cohorts to represent an important dimension of variation in subsequent demographic processes.

The direction and magnitude of the influence of cohort membership on demographic phenomena have been a matter of considerable speculation, although few firmly established generalizations have emerged. Perhaps the most well-known theory about the influence of cohort membership on demographic events is Easterlin's explanation of the American baby boom (Easterlin, 1961, 1978). According to this theory, smaller cohorts enjoy significant advantages as they enter the job market, which facilitates family formation and thus raises fertility levels. With regard to the baby boom, however, it is difficult to distinguish the effects of cohort size from the effects of an expanding postwar economy, both of which may have influenced life chances and family behavior around the 1950s.

In mortality studies, the discussion of the role of cohorts has focused on the after-effects of adverse events in early life on subsequent probabilities of death or survival (for a review, see Elo and Preston, 1992). Theoretically, it is possible that adverse events in early life could result in either higher or lower mortality in later life. On one hand, the survivors of a traumatic event or situation (e.g., famine, war, poverty) may be weakened by the experience and thus demonstrate unusually high levels of mortality later on. On the other hand, it is possible that the survivors in these situations may be an especially robust subset of the original cohort and thus could display unexpectedly low levels of mortality in subsequent years. These competing explanations are often referred to as processes of *debilitation* and *selection*, respectively. It is possible, of course, that both processes are operating at the same time. In these situations, it is their relative magnitudes that should determine whether an affected cohort experiences unusually high or low mortality in later years.

In summary, there is a sound theoretical basis for believing that age, period, and cohort may all be important dimensions of variation in demographic processes. It is this theoretical interest that has encouraged the development of statistical models incorporating all three components. We now turn our attention to such models.

II. AGE-PERIOD-COHORT MODELS

The standard age-period-cohort model has the following form:

$$f(r_{ijk}) = \mu + \alpha_i + \beta_j + \theta_k + \varepsilon_{ijk}$$

In this formulation, r_{ijk} is an observed demographic rate for some event that occurs at age i in year j for cohort k (thus, $k = j - i$); the function, $f(\cdot)$, is some transformation applied to the observed rates; the parameter, μ, establishes an overall level for $f(r_{ijk})$; the parameters, α_i, β_j, and θ_k, describe patterns of change in $f(r_{ijk})$ by age, period, and cohort, respectively; and the last term, ε_{ijk}, represents error (either in the specification of the model or in the original data) and random fluctuations.

Although the standard APC model is quite simple in form, its parameters are not easily estimated. The central difficulty is that there is no obvious means of identifying a unique set of parameter estimates that provide an optimal fit to the observed data. This identification problem affects not only the statistical estimation of the parameters but also their subsequent interpretation.

1. Identification Problem

The identification problem of the standard APC model is easily illustrated by considering the model in its estimated form:

$$\hat{y}_{ijk} = \hat{\mu} + \hat{\alpha}_i + \hat{\beta}_j + \hat{\theta}_k$$

Thus, the predicted value of the transformed rates, $\hat{y}_{ijk}$, equals the sum of the four estimated parameters, $\hat{\mu}$, $\hat{\alpha}_i$, $\hat{\beta}_j$, and $\hat{\theta}_k$.

The first task in identifying a unique solution for this model involves constraining the levels of the four parameters. A common approach is to require that

$$\sum_i \hat{\alpha}_i = \sum_j \hat{\beta}_j = \sum_k \hat{\theta}_k = 0$$

With this solution, $\hat{\mu}$ gives some average level of $f(r_{ijk})$, and the other three sets of parameters describe changes in the transformed rates with respect to the average. Alternatively, we could require that $\hat{\alpha}_i = \hat{\beta}_j = \hat{\theta}_k = 0$ for some specific choice of i, j, and k. In this case, $\hat{\mu}$ gives the predicted value of this particular $f(r_{ijk})$, and the other parameters describe changes with respect to this point of reference.[1]

Constraints of this sort are common in other statistical applications (analysis of variance, regression, etc.). Obviously, they involve an arbitrary choice about how to obtain a unique solution, but this choice affects only the level of the various parameters and thus does not fundamentally confuse their interpretation. APC models, however, present an additional, more perplexing identification problem involving not only the level of the various parameters but also their slope.

For example, suppose that $\hat{\alpha}_i$, $\hat{\beta}_j$, and $\hat{\theta}_k$ were adjusted such that

$$\alpha_i^* = \hat{\alpha}_i + \lambda \cdot i$$
$$\beta_j^* = \hat{\beta}_j - \lambda \cdot j$$
$$\theta_k^* = \hat{\theta}_k + \lambda \cdot k,$$

where λ is some real number. Now, note that the predicted values in the model are the same for any choice of λ, since $k = j - i$:

$$\begin{aligned}\hat{y}_{ijk} &= \hat{\mu} + \alpha_i^* + \beta_j^* + \theta_k^* \\ &= \hat{\mu} + \hat{\alpha}_i + \lambda \cdot i + \hat{\beta}_j - \lambda \cdot j + \hat{\theta}_k + \lambda \cdot k \\ &= \hat{\mu} + \hat{\alpha}_i + \hat{\beta}_j + \hat{\theta}_k + \lambda \cdot (i - j + k) \\ &= \hat{\mu} + \hat{\alpha}_i + \hat{\beta}_j + \hat{\theta}_k.\end{aligned}$$

[1] Perhaps the best choice, for reasons of mathematic convenience, is to require that

$$\sum_i w_i \hat{\alpha}_i = \sum_j w_j \hat{\beta}_j = \sum_k w_k \hat{\theta}_k = 0,$$

where w_i, w_j, and w_k are weights corresponding to the number of observations for each particular age, period, and cohort. In a rectangular age-by-period array, for example, w_i and w_j would be constant (equaling the number of columns and rows, respectively) and thus would fall out of the equation. In this situation, only w_k would vary, equaling the number of elements in a diagonal of the matrix corresponding to an individual cohort.

Since different sets of age, period, and cohort parameters yield identical predicted values, there is no means of choosing between alternative solutions on the basis of goodness-of-fit. As with the earlier problem of uniquely identifying the level of these parameters, a unique solution demands an arbitrary choice. In this case, however, alternative solutions may have vastly different implications, since the speed and even direction of change in the age, period, and cohort components of the process are affected. In fact, by careful manipulation of λ, the linear trend in the three sets of parameters can be altered *ad libitum*.[2]

Typically, discussions of APC models have focused on the problem of uniquely identifying the linear trend in the age, period, and cohort parameters. Higher order components of these parameters (quadratic, cubic, etc.) and interactions between the three sets of factors have generally been ignored because they make identification of the model even more difficult (Fienberg and Mason, 1985; Clogg, 1982). However, second- and higher order components of the main effects are not uniquely identified if interaction terms are added to the standard APC model (Wilmoth, 1990).

2. Estimation Strategies

In this chapter, we do not attempt to provide a complete review of the literature on APC modeling. For that purpose, we refer the reader to excellent discussions by other authors (Hobcraft, Menken, and Preston, 1982; Mason and Fienberg, 1985). Instead of a review of the literature, we provide an overview of the main strategies that have been proposed for estimating and/or modifying the standard APC model in light of the identification problem discussed earlier. We divide these approaches into three groups: arbitrary assumptions, interaction terms and demographic translation, and direct measurement. See also the excellent discussion of these topics by Holford (1991).

[2] Note that the transformed parameters, α_i^*, β_j^*, and θ_k^*, as defined here, would not normally sum to zero. Alternatively, define them as follows:

$$\alpha_i^* = \hat{\alpha}_i + \lambda \cdot (i - \bar{i})$$
$$\beta_j^* = \hat{\beta}_j - \lambda \cdot (j - \bar{j})$$
$$\theta_k^* = \hat{\theta}_k + \lambda \cdot (k - \bar{k})$$

where $\bar{i}$, $\bar{j}$, and $\bar{k}$ are defined as the means of i, j, and k. It can be shown that the sums of these transformed parameters equal zero if the data matrix is rectangular. If the data array is not rectangular, a convenient solution is to use weights, as defined in Footnote 1, both for defining the parameter constraints and for computing the means of i, j, and k in the above formulas.

a. Arbitrary Assumptions

The first strategy for identifying an APC model is to make some arbitrary assumption about the linear trend in one of the three dimensions. Specific applications differ, however, depending on whether the assumption is viewed by the analyst(s) as an accurate reflection of an underlying reality or merely as a convenient strategy for estimating an arbitrary statistical model.

Unique estimates of the standard APC model (with three main effects, as described in prior sections) can be obtained by assuming that the parameters pertaining to some pair of cohorts (or ages or periods) are equal. For example, one could assume that $\theta_{k'} = \theta_{k'+1}$ for a specific cohort k'. This restriction permits estimation of the model, although at the expense of assuming that the cohort-specific effects for cohorts k' and $k' + 1$ are equal. Arguably, such an assumption is justified in specific cases based on prior knowledge.

In a widely cited paper, Fienberg and Mason (1979) illustrated the application of the standard APC model to the analysis of educational attainment in the United States. Here, the dependent variable consisted of proportions of individuals ages 20 and above who had, at some previous moment in their lives, advanced from one educational level to the next. These proportions were computed using decennial census data from 1940 to 1970. The authors noted correctly that educational attainment should under most circumstances be constant or slightly increasing over the adult life of a cohort (this expectation could be violated only by selective migration or differential mortality). In other words, age effects are of little importance in this model and can reasonably be set equal over some age range. Similarly, period effects can have little impact on the educational attainment of adults (most of whom have completed their schooling prior to the period of observation). Indeed, the authors justify the inclusion of period effects in the model based solely on concerns about changes in the recording of educational data in decennial censuses.

Due to the relative unimportance of these two sets of components (age and period) *a priori*, the choice by Fienberg and Mason to use educational attainment as an illustration of APC modeling is somewhat puzzling. Their resolution of the standard identification problem in this particular case was relatively straightforward and unproblematic, since the authors merely equated age effects for age groups 30 to 34 through 55 to 59 years.[3] This example illustrates the sensible use of

[3] Obviously, the model would have been fully identified if age effects for only two age groups had been set equal. Fienberg and Mason (1979: 53) argue, however, that there are "*a priori* grounds for interpreting age effects primarily at the tails of the age distribution" and thus prefer to equate the coefficients throughout the middle age range.

prior information to resolve the APC identification problem. It provides little guidance, however, about how to resolve the identification problem in situations where there is no strong basis for asserting the equality of at least one pair of effects *a priori*.

In another application of the APC model, Clogg (1982) examines rates of labor force participation in the United States. Here, there are strong reasons for expecting that the dependent variable is influenced by factors related to age, period, and cohort, but there is only a very weak basis for supposing, *a priori*, a particular relationship between some pair of effects. Nevertheless, the author constrains the last two cohort effects to differ by one or two percent (depending on the specific example) as a means of obtaining a unique set of parameter estimates. The substantive justification of this choice can fairly be termed *weak*, although arguably it has little impact on the conclusions of the study.

In general, even if prior knowledge supports the choice of a specific identifying restriction, it is important to recognize the sensitivity of the results to minor violations of the chosen assumption. If $\theta_{k'}$ and $\theta_{k'+1}$ are close but not equal, for example, the error that results from equating them will be slight for adjacent cohorts, but much larger for distant ones (Clogg, 1982). The importance of this imprecision will depend on the application, and the sensitivity of the results to any particular assumption can often be assessed quite easily. Nevertheless, the validity of results derived from APC models in which this last identifying constraint is, allegedly, a reflection of underlying reality remains quite dubious in most cases.

Alternatively, rather than asserting the reality of identifying constraints, certain parameter restrictions can be adopted as a matter of convenience merely to obtain a unique solution. For example, Pullum (1980) fit the standard APC model by equating two adjacent cohort parameters but avoided interpreting the resulting estimates literally. Pullum's main purpose in fitting such a model was merely to determine whether the fit (in a model of American fertility rates) is improved more by the addition of period or cohort parameters. He concluded that cohort parameters provide less explanatory power (per additional parameter) than period parameters. Since he was interested only in the overall fit of each model, not in the parameter estimates, the choice of identifying constraints was irrelevant.

Pullum also noted, however, that the second (and higher) differences of the parameter estimates in the three-factor APC model are invariant to the choice of an identifying assumption. In our notation, first differences depend on the choice of λ, although second differences do not. For example,

$$\begin{aligned}\Delta\alpha_i^* &= \alpha_{i+1}^* - \alpha_i^* \\ &= \hat{\alpha}_{i+1} + \lambda\cdot(i+1) - [\hat{\alpha}_i + \lambda\cdot i], \\ &= \hat{\alpha}_{i+1} - \hat{\alpha}_i + \lambda\end{aligned}$$

whereas,

$$\begin{aligned}\Delta^2\alpha_i^* &= \Delta\alpha_{i+1}^* - \Delta\alpha_i^* \\ &= \hat{\alpha}_{i+2} - \hat{\alpha}_{i+1} + \lambda - [\hat{\alpha}_{i+1} - \hat{\alpha}_i + \lambda]. \\ &= \hat{\alpha}_{i+2} - 2\hat{\alpha}_{i+1} + \hat{\alpha}_i\end{aligned}$$

First differences are related to the linear trend, and thus their dependence on λ is a reminder that the slope of the three sets of parameters cannot be uniquely identified in the standard APC model. Second differences are measures of deviation from the linear trend, and thus these quantities can be accurately estimated in the simple model with three main effects (but no interaction terms).

An analogous solution is to require that the slope of one of the three sets of parameters be constrained to equal zero. Following Wilmoth (1990), a simple three-factor model applied to a rectangular age-by-period array of demographic rates could be estimated by using the following constraints:

$$\sum_i \alpha_i = \sum_j \beta_j = \sum_k w_k\theta_k = \sum_k k w_k\theta_k = 0$$

These constraints on θ_k are equivalent to requiring that both the *level* and the *slope* of a weighted least-squares regression line fitted to the cohort parameters should equal zero.[4]

Thus, one solution to the APC identification problem is to choose, arbitrarily, one dimension whose slope is constrained to equal zero (see also Caselli and Capocaccia, 1989). As a matter of convenience, the chosen dimension may correspond to the diagonals of a rectangular array of demographic rates. The resulting parameter estimates for this third factor have a simple interpretation: They represent deviations from the long-term pattern of change in that dimension. An analysis of such deviations is logically similar to an analysis of second derivatives, since both emphasize deviations from the long-term trend rather than absolute effects.

b. Interaction Terms and Demographic Translation

An obvious shortcoming to the standard APC model, aside from its problems of identifiability, is the absence of interaction terms. To address this inadequacy, Wilmoth (1990) proposed models with the following form:

[4] Here, as in Footnotes 1 and 2, the weights equal the length of the diagonals corresponding to individual cohorts.

$$f(r_{ijk}) = \mu + \alpha_i + \beta_j + \sum_{m=1}^{\rho} \phi_m \gamma_{im} \delta_{jm} + \theta_k + \varepsilon_{ijk}$$ [5]

This model differs from the standard APC model by the addition of ρ (usually one or two) multiplicative terms. The use of these interaction terms is motivated by the fact that the pace of change (over time) in demographic rates often differs by age. For example, mortality rates have typically fallen much more rapidly at younger than at older ages. This component of differential change by age cannot be expressed well in a model with no age-period (or age-cohort) interactions.

The above model is appropriate for an analysis of an age-period array of demographic rates, where the rates of change in r_{ijk} differ by age. The multiplicative terms capture these differential trends by age. The cohort parameters, θ_k, constrained to have zero level and slope, express deviations from the overall pattern of change by age and period. In short, the θ_k captures residual patterns that seem truly to lie along diagonals of the age-period array. Without the multiplicative term(s), however, estimates of θ_k may be heavily influenced by age-period interactions. The introduction of interaction terms by no means resolves the identification problem in the standard APC model. Their use is consistent, however, with the philosophy that the proper means of including all three sets of parameters in the model is to focus the description on two dimensions only and to treat the third dimension as a sort of residual.

The multiplicative interaction terms also help us to understand the notion of demographic translation (Ryder, 1964, 1980; see also Chapter 17). In the above model, the cohort term, θ_k, has been reduced to a residual component, and thus the linear or long-term cohort trend has been translated into the age and period dimensions. Even this residual component of the cohort trend, θ_k, can be expressed as age-period interactions, if a sufficient number of multiplicative terms are added to this model (Wilmoth, 1990). In this sense, the choice to assign any portion of the variability in demographic rates to one of the three dimensions is arbitrary, because it is always possible to re-express the pattern in terms of the other two dimensions by the addition of a sufficient number of interaction terms.

The only resolution of this logical dilemma is to acknowledge, as a matter of plausibility, that certain patterns must be due to changes in one specific dimension. For example, the residual cohort effects that emerge in a complete analysis of an age-by-period array (including at least some form of age-period interaction) cannot plausibly be attributed to age- and period-specific factors. These residual cohort effects tend to vary with high frequency and thus are not easily translated into the age and period dimensions. It is worth noting that Foster (1990) reached a similar conclusion (i.e., that only high-frequency cohort effects are plausibly identifiable) by an entirely different method of analysis.

c. Direct Measurement

Several analysts have noted that the only true resolution of the identification problem affecting APC analysis would be to measure directly the factors whose effects are summarized by the coefficients of the standard APC model. These factors would not typically be linearly related (although they might be strongly collinear), and thus a unique solution for the model could be found. An obvious difficulty with this strategy is the problem of defining and then measuring the proximate variables for which age, period, and cohort are, admittedly, only rough approximations.

In a study of mortality in Italy, for example, Caselli and Capocaccia (1989) use the probability of death in infancy or during the first 15 years of life as a measure of long-term cohort influences, whose magnitude may vary over the life course. In our notation, their model can be written

$$f(r_{ijk}) = \mu + \alpha_i + \beta_j + \gamma_i \cdot Q_k + \varepsilon_{ijk}$$

where Q_k equals either q_0 or ${}_{15}q_0$. This model requires no special identifying restrictions. Because the estimated γ_i's are positive below age 45 and negative above this age, the authors conclude that "higher mortality early in life is associated with higher mortality up to age 45 and lower levels at later ages" (Caselli and Capocaccia, 1989, p. 152).

An alternative interpretation of these results, however, is that the age-cohort term in their model is, in reality, capturing the same sorts of patterns that were treated as age-period interactions by Wilmoth and colleagues (Wilmoth *et al*., 1989; Wilmoth, 1990). Indeed, the multiplicative age-cohort term in the model of Caselli and Capocaccia (1989) is remarkably similar, in both its form and its estimated values, to the multiplicative age-period term in the models by Wilmoth and collaborators. In other words, the age-cohort term in the above model may serve merely to document the relatively more rapid rate of change in mortality at younger than at older ages. Since infant-child mortality has declined almost monotonically for the cohorts in question, its function in the model may be simply to provide a marker for the second dimension of temporal mortality change.

[5] For a full discussion of the constraints required for fitting this model, see Wilmoth (1990).

The innovative applications and clear explanations of the age-period-cohort model by Caselli and Capocaccia (1989) are certainly valuable. Their attempt to measure age, period, or cohort effects directly, however, illustrates some of the statistical difficulties inherent in the task. As noted by Clogg (1982),

> The selection of the proper causal variables to be considered in a modeling procedure is a most difficult theoretical task, one that is at least as difficult as applying the age-period-cohort accounting framework (p. 460).

In other words, although it may seem in principle that direct measurement is an obvious solution for the APC identification problem, the practical application of this technique is perhaps more fraught with difficulties than the problem we are trying to overcome.

3. Empirical Examples

Two specific examples of the application of APC models to demographic data are reviewed here. These examples were chosen to illustrate two kinds of conclusions that can legitimately be drawn from APC models applied to time series of age-specific demographic rates. The first example, Pullum's (1980) study of American white fertility, illustrates the use of the standard APC model to compare the variability by cohort versus period. The second example, Wilmoth's (1990) analysis of French male mortality, employs a more complicated APC model with interaction terms to document the unusually high or low levels of mortality for certain cohorts.

a. American White Fertility, 1920 to 1970

Pullum (1980) analyzed an age-by-period array of age-specific fertility rates for American white women aged 15 to 44 during years 1920 to 1970. He fit all three possible two-factor models and the standard three-factor APC model. Table 18–1 shows χ^2 measures of fit for each model in four time periods, each spanning two decades (lower values indicate a better fit). The period *x* cohort model is clearly inferior to the other two-factor models, reflecting the primary importance of age as a dimension of variation in this case. It is not clear from the comparison in Table 18–1, however, whether age should be paired with period or cohort to obtain the best two-dimensional description of these data.

Table 18–2 reveals the greater importance of periods than cohorts as a dimension of variation in these data by comparing each two-factor model to the full APC model. The values in this table (which can be derived from those in Table 18–1) can be thought of as the improvement in fit when age, period, or cohorts is added as the third and final dimension of the standard APC model or as the loss of fit when one of these dimensions is removed from the full three-factor model. In each case, the improvement or loss of fit is measured relative to the change in degrees of freedom.

Pullum (1980) applied these same four models to an age-by-cohort array of age-specific fertility rates for American white women aged 15 to 44 years born during years 1905 to 1926 (thus including all cohorts whose reproductive lives fell entirely within the observation period) (Table 18–3). He notes that

> In contrast to the previous applications to rectangular [age-by-period] data, the inclusion of period effects appears *much* more useful than the inclusion of cohort effects (p. 236, emphasis in original).

For example, using measures like those presented here in Table 18–2, the loss of fit caused by removing all period parameters from the full APC model is 13.1 (increase in chi-square per degree of freedom) compared to only 0.4 if the cohort dimension is eliminated.

In conclusion, Pullum stated (p. 241)

TABLE 18–1 χ^2 Measure of Fit for Four Models Applied to Age-specific Fertility Rates, American White Women, Aged 15–44 Years, 21-year Time Intervals

Model	*df*	Interval of time			
		1920–1940	1930–1950	1940–1960	1950–1970
Age *x* period	580	148.1	330.2	411.3	93.3
Age *x* cohort	551	90.2	397.8	411.6	800.2
Period *x* cohort	560	13,306.8	14,952.4	20,603.5	21,130.1
Age *x* period *x* cohort	532	21.6	133.1	98.0	40.8

Note: Data for each time interval were in age-by-period format. χ^2 estimate is based on an artificial case base of 630,000 cases for each time interval.

TABLE 18–3 χ^2 Measures of Fit for Four Models Applied to Age-specific Fertility Rates, American White Women, Aged 15–44 Years, Cohorts Born 1905–1926

Model	*df*	χ^2
Age *x* period	580	96.1
Age *x* cohort	609	730.4
Period *x* cohort	588	15,846.8
Age *x* period *x* cohort	560	87.6

Note: Data were in age-by-cohort format. χ^2 estimate is based on an artificial case base of 660,000 woman-years.

Source: Pullum Thomas W., 1980. Separating age, period, and cohort effects in white U.S. fertility, 1920–1970. *Social Science Research*, vol. 9(3), p. 227–244. New York, Academic Press, Table 4.

> Despite the great theoretical appeal of the notion that continuities exist in the behavior of cohorts, we have found that the explanatory gain per cohort parameter is far less than the gain per period parameter. . . . The implications for our understanding of U.S. fertility are that, as a set, changes in those temporal variables which cut across cohorts, such as economic cycles, appear to be more important than changes in those variables which distinguish cohorts, such as shared socializing experiences.

Similar explorations of fertility patterns for other populations and time periods seem warranted. Pullum also suggested that these models could be usefully applied to fertility rates by parity.

b. French Male Mortality, 1946 to 1981

Wilmoth (1990) fit an APC model with two age-period interaction terms to age-specific mortality rates for French males during years 1946 to 1981. The full model, as stated earlier, was as follows:

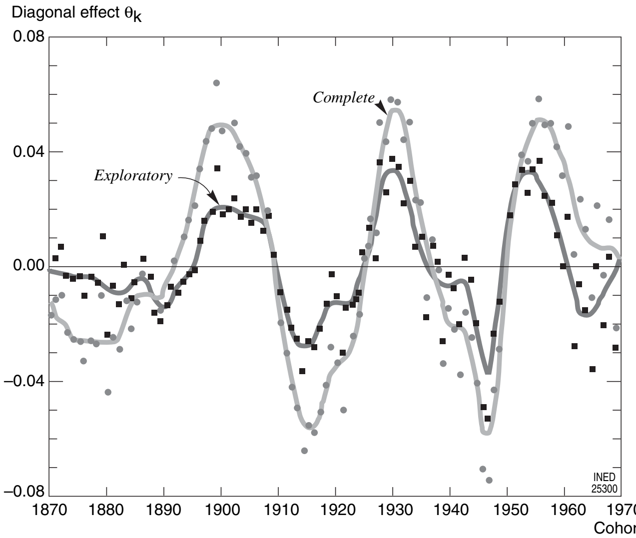

FIGURE 18–2 Residual cohort effects estimated by two methods in age-period-cohort model with interaction terms applied to age-specific mortality rates, French males, aged 0–89, years 1946–1981. Note: Data analyzed were in age-by-period format. The values depicted here are measures of the average level of *excess* or *deficit mortality* for each cohort (as a proportion of predicted levels) over the observation period. (Source: Wilmoth [1990], p. 307).

$$f(r_{ijk}) = \mu + \alpha_i + \beta_j + \sum_{m=1}^{\rho} \phi_m \gamma_{im} \delta_{jm} + \theta_k + \varepsilon_{ijk}.$$

The interaction terms in this model describe variations in the pattern of mortality decline by age: The first term captures the relatively faster decline at younger compared to older ages, while the second term reflects the pattern of increasing (or slowly decreasing) levels of mortality in late adolescence and early adulthood.

The cohort parameters in this model, θ_k, reflect residual levels of mortality relative to the thorough description by age and period. As shown here in Figure 18–2, Wilmoth's model can be used to document the persistence of relatively high or low levels of mortality for certain cohorts. Two sets of estimates for θ_k were derived using different methods for fitting the model, though the *complete* series is considered more reliable.

Wilmoth demonstrated the presence of substantial levels of *excess* or *deficit mortality* for various cohorts, successfully rejecting alternative explanations, for example, that the patterns were artifacts of bad data or of the model itself. Nevertheless, his explanation of their historical or biologic causes was less satisfactory. He acknowledged the inadequacy of existing explanations of these patterns when a comparison of results from different populations is made.

For example, it had been suggested that excess mortality for groups of male cohorts born around 1900 and 1930 may be related to early combat experiences near the end of the World Wars or to nutritional deprivation in adolescence resulting from the social and economic dislocations at these times (see Horiuchi, 1983; Wilmoth *et al*., 1989). However, these explanations fail to account for the presence of similar patterns of excess mortality among Japanese cohorts, both male and female, born around 1900, since Japan was only nominally involved in World War I (see Wilmoth, 1988, p. 107–113). Furthermore, the presence of similar patterns for females suggests that combat experience in the wars may not be the crucial explanatory variable. Finally, the apparent recurrence of a similar pattern for cohorts born after World War II suggests that the phenomenon may operate through mechanisms at least partially unrelated to the two wars.

Although the failure to explain these findings does not invalidate them, it does illustrate the difficulties of interpreting cohort-specific variations in demographic rates.

CONCLUSION

The studies by Pullum (1980) and Wilmoth (1990) illustrate that valid results *can* be derived within an APC framework if one accepts that there is no magic solution to the *identification problem*. Instead, it is necessary to seek findings that are invariant to the choice of identifying constraints (e.g., measures of fit, second differences) or that acknowledge the fundamental arbitrariness of these constraints (e.g., residual cohort effects with zero slope).

It is important to remember that the identification problems affecting APC analysis are not some statistical aberration. Rather, they reflect a fundamental lack of information in the data being analyzed. The first identification problem, involving the level of the various parameters, is not problematic in most situations, since our purpose in estimating these sorts of models is to analyze patterns of change over age or time, which are unaffected by an arbitrary choice of level. Furthermore, this kind of identification problem is familiar and affects other statistical methods as well.

The unusual aspect of APC analysis is that, even for the simplest model, identifying constraints are required in order to obtain unique estimates of the linear trend in the parameters. This situation arises directly from the relationship linking the three sets of causal factors:

$$\text{cohort} + \text{age} = \text{period}$$

In regression analyses, of course, it is standard practice to avoid using independent variables that are highly collinear (either individually, or in some combination). By their very nature, some variants of APC analysis ignore the sound logic of this practice and attempt, by some statistical trick, to perform the impossible, namely, to extract more information than what is contained in the data. Because of this fundamental lack of information, the results of an APC analysis reflect both the underlying patterns in the data and the assumptions adopted by the analyst. This reality does not invalidate the method in all situations, but it serves as an important reminder of the limitations that affect all models used with the purpose of separating age, period, and cohort effects.

IV

A TENTATIVE SYNTHESIS OF THE COMPONENTS OF DYNAMICS: FROM REPRODUCTION TO POPULATION MODELS

GRAZIELLA CASELLI AND JACQUES VALLIN

The components of population change, extensively examined in preceding chapters, must now be linked to population composition, and an attempt made to draw them together. The fact is that all the concepts, methods and measures so far defined form a coherent and relatively comprehensive corpus of analysis (notwithstanding some flaws and failings, as will be described) with which a *synthesis of dynamics and structure* can be made which will give insights into the underlying mechanisms of population development. Two useful approaches can be taken. The relatively simple one is to combine period or cohort fertility and mortality to measure the reproductive potential that a population would acquire from the consistent adoption of such demographic processes. This is what is called *population replacement* (Chapter 19). The other will enable us to go further: What would become of a population whose age-specific fertility, mortality, or migration rates became entrenched at a given period level? What in time would become of its total size, age-sex structure, crude birth, death, and migration rates, and, finally, its growth rate? The population models described in Chapter 20 were developed to address these issues. These will show that, in the final analysis, population structure is entirely determined by the history of its changes, because although structure has a strong duration-specific influence on change, the original structure carries within it the seeds of its own ultimate extinction.

CHAPTER

19

Population Replacement

JACQUES VALLIN AND GRAZIELLA CASELLI

Institut national d'études démographiques (INED), Paris, France

Dipartimento di Scienze Demografiche, Università degli Studi di Roma "La Sapienza," Rome, Italy

At this point, our period measures have given us age-specific mortality and fertility functions that, in principle, express the incidence of two components of the natural increase in a *fictitious* (or *hypothetical or synthetic*) cohort subjected during its entire life to the conditions prevailing in the observation period. How do these functions translate into the overall population dynamics? Can we determine an *intrinsic force* that is always independent of the age-specific structure and strikes a balance between two given fertility and mortality functions? How do these two functions influence a population's size and structure? Demographers have sought to answer the first question by defining a reproduction rate (the subject of this chapter), then by constructing population models (discussed in Chapter 20).

Like life expectancy at birth or the average number of children per female, reproduction is a concept initially defined in cohort (longitudinal) terms and then transposed to a period (cross-sectional) analysis to summarize the actual situation at a particular time. In cohort analysis, demographers want to know how many children in the following generation will replace the men and women who procreated them. The indicator developed to answer this question for a cohort can be subsequently applied to period analysis for the purpose of assessing the potential dynamic inherent in the period fertility and mortality functions. In fact, as fertility rates are generally measured for females, reproduction will be initially defined for an imaginary population composed only of women giving birth to daughters, totally disregarding the male role in reproduction. We will then need to examine ways of addressing the issue for the male population and, most important, determine whether we can reconcile the female and male rates in a sexually reproducing population.

I. FEMALE REPRODUCTION

Since the aim here is to compare the number of daughters with the number of mothers, we must begin by eliminating males from the computation. This will lead us, first, to the concept of gross reproduction. Next, we will need to combine female fertility with female mortality to arrive at the concept of net reproduction, but we will see that the concept translates into different realities depending on whether we use it to describe reproduction of births, reproduction of women of childbearing age, or—more generally—reproduction of years lived.

1. Gross Reproduction

Robert R. Kuczynski introduced the concept of gross reproduction rate (R) in 1931. If we assume the absence of mortality, in a given birth cohort, the number of children to whom a woman gives birth is quite simply (as seen earlier) the sum of age-specific fertility rates, called completed fertility. As this aggregate comprises sons and daughters, we need only weight these offspring by the proportion of births that are female to define a *gross reproduction rate*. Let B be the births to this cohort of women, B^F the female births and $f_{(x,x+1)}$ the fertility rate at age x to $x + 1$. The gross reproduction rate R is written:

$$R = \frac{B^F}{B} \sum_{x=\alpha}^{\omega} f_{(x,x+1)}$$

It should be noted that, in a retrospective cohort observation, the completed fertility of women aged over 50 is given directly by the ratio of the number of actual births to the number of females surveyed; the gross reproduction rate equals the ratio of female births to the females surveyed.

The proportion of females (or males) at birth was one of the stablest demographic parameters until the advent of techniques for selecting fetuses based on their sex. Everywhere and at all times, the sex ratio at birth was about 105 males to 100 females, with very minor fluctuations around this average (between 103 and 107). This rule remains fairly widespread even today, except in certain populations with strong male preference and with access to early fetal sex diagnostics and selective abortion (Chapter 4): the gross reproduction rate can be obtained simply by multiplying completed fertility by 0.488, that is 100 divided by 205.

A gross reproduction rate equal to unity means that in the absence of mortality before age 50 (age taken as the end of the female childbearing period), the cohort of females studied has given birth to a number of daughters exactly equal to their own number. Consequently, to go back to the example of Jeanne Calment, the French women born in 1875 had a completed fertility of 2.6[1] and a gross reproduction rate of 1.28. In the absence of mortality, their fertility would thus have largely sufficed to ensure their replacement, since there would have been almost 30% more daughters than mothers.

In period analysis, we transpose the concept of gross reproduction to a fictitious cohort by weighting the total fertility rate (TFR) by the proportion of female births: this yields a measure of the theoretical reproduction capacity of a closed, mortality-free population that would indefinitely continue the same fertility pattern as the one reflected in a given year t in the period age-specific fertility rates:

$$R_t = \frac{B_t^F}{B_t} TFR_t = \frac{B_t^F}{B_t} \sum_{x=\alpha}^{\omega} f_{(x,x+1),t}$$

Of course, if we are working with age-group–specific fertility rates, we need to allow for age intervals a:

$$R_t = \frac{B_t^F}{B_t} \sum_{x=\alpha}^{\omega} a f_{(x,x+1),t}$$

[1] This is the result obtained for the aggregated 1871–1880 birth cohorts, which include that of Jeanne Calment (Festy, 1979), but the finding is not of great importance because the cohort synthetic indicators evolve slowly and without fluctuations.

This calculation method gives a TFR of 3.44 children per female: The renewal potential inherent in the age-specific fertility pattern of Jeanne Calment's birth year (1.68) was far greater than the actual one for her birth cohort. At that level of fertility, the population of daughters would have been over 70% larger than that of the mothers—in the absence of mortality—whereas we have just seen that the potential increase in the 1875 cohort was 28%.

2. Net Reproduction at Birth

Gross reproduction, however, gives only a very theoretical reproduction potential, as it does not make allowance for mortality. Actually, R is a more strictly female fertility measure than that customarily given by completed fertility or TFR. To measure net reproduction, we must take into account the fact that the mother cohort's initial population at birth is diminished by mortality even before reaching childbearing age. This proportionally reduces its capacity to effectively produce the female births that will replace it in the overall population.

a. Cohort Analysis

Paradoxically, the concept of net reproduction was introduced well before that of gross reproduction: in the late 19th century, by Richard Böckh (1886, 1890). It was then promoted in the United States by Robert R. Kuczynski (1931) and in France by Pierre Depoid (1941). When the gross rate is computed, the age-specific fertility rates are weighted by the probabilities of (female) survival at the same ages. This yields a *net reproduction rate at birth*, R_0:

$$R_0 = \frac{B^F}{B_t} \sum_{x=\alpha}^{\omega} f_{(x,x+1)} \cdot l_{x+0.5}$$

where $l_{x+0.5}$ is the probability of survival from birth to age $x + 0.5$.

In fact, if mortality is low and varies little at peak fertility ages, we need only multiply the gross reproduction rate by the probability of survival at the mean age at net childbearing[2]:

[2] This expression denotes the mean age computed for births actually occurring in the cohort, allowing for mortality. The mean age at net childbearing, $\bar{x}'$, is calculated, like net reproduction, from fertility rates weighted by survival rates:

$$\bar{x}' = \frac{\sum_{x=\alpha}^{\omega} (x+0.5) f_{(x,x+1)} \cdot l_{x+0.5}}{\sum_{x=\alpha}^{\omega} f_{(x,x+1)} \cdot l_{x+0.5}}$$

When mortality is low, there is actually little difference between the mean ages at gross and net childbearing.

$$R_0 \cong l_{\bar{x}'} \cdot R$$

A rate equal to unity means that, in a closed population, a cohort of mothers will have actually given birth to a number of daughters strictly equal to its own initial number.

For example, in Jeanne Calment's birth cohort (1875), we obtain a net reproduction rate at birth of 0.83. The lesson is that, despite its large replacement potential (1.28), the cohort's mortality between birth and reproductive ages made it fall far short of replacing itself by an equal number of daughters: The deficit is nearly 20%.

This below-unity net reproduction rate implies that if all cohorts behaved like that of Jeanne Calment, the population would be decreasing—but by how much and at what pace? The answer obviously depends on the mean interval between a cohort of mothers and that of its daughters, in other words, the mean age at childbearing. As explained in Chapter 3, the annual average growth rate r that causes the population size to increase from P_0 to P_t in a time t is defined by:

$$P_t = P_0 e^{rt}$$

in other words

$$r = \log \frac{P_t}{P_0} \cdot \frac{1}{t}$$

The annual average rate of increase ρ from a population of mothers to a population of daughters can therefore be estimated[3] by replacing (1) the P_t/P_0 ratio by the net reproduction rate, and (2) the duration t by the mean age at net fertility, $\bar{x}'$:

$$\rho \cong \frac{\log R_0}{\bar{x}'}$$

This rate resembles the intrinsic growth rate or Lotka rate, discussed in the next chapter.

The actual experience of Jeanne Calment's cohort thus translates into a Lotka rate of increase of −0.3% per year.

b. Period Analysis

As with gross reproduction, we can transpose the findings to a period analysis to define the net reproduction of a fictitious cohort in a given period:

[3] This formula is only approximate because the distribution of ages at childbearing has a nonnil variance. In this case, one can use the second-order approximation (Brouard, 1982):

$$\rho_{(2)} \cong \frac{\log R_0}{\bar{x}'} + \frac{\sigma^2 (\log R_0)^2}{2\bar{x}'^3}$$

$$R_{0,t} = \frac{B_t^F}{B_t} \sum_{x=\alpha}^{\omega} f_{(x,x+1),t} \cdot l_{x+0.5}$$

or, if we are working with age groups:

$$R_{0,t} = \frac{B_t^F}{B_t} \sum_{x=\alpha}^{\omega} a f_{(x,x+a),t} \cdot l_{x+0.5a}$$

As before, if mortality is low and varies little in the peak fertility years, we simply multiply the gross reproduction rate by the probability of survival at the mean age at childbearing:

$$R_{0,t} \cong l_{\bar{x},t} \cdot R_t$$

This rate measures the actual reproductive capacity of the population inherent in the age-specific fertility and mortality conditions of the period. In the conditions observed in 1875, this period net reproduction rate was 1.08 daughters per mother, a figure significantly above the level strictly needed for replacement and distinctly higher than the final rate for the women born that year. The reason is that between the birth of Jeanne Calment's cohort and the late 1920s, when it ceased to be fertile, the impact of the fall in fertility on reproduction came to outweigh the impact of the decline in mortality.[4] The period net reproduction rate fell from 1.08 in 1875 to 1.02 in 1889, when Calment's cohort entered its reproductive period (15 years of age). The rate dipped to 0.96 in 1904, when the cohort reached its mean age at childbearing (28.6 years) and finally to 0.93 in 1925, when the cohort reached the end of its reproductive period (50 years). In other words, the conditions prevailing at the cohort's birth seemed to offer it a fairly high net replacement potential, which would have allowed a mild increase (8%) in the number of daughters over the number of mothers. When the cohort reached its peak reproductive ages, the period conditions no longer ensured a one-for-one replacement of the population. However, the actual reproductive capacity of the 1875 cohort (0.83) eventually turned out to be far below each of these period measures taken in the course of its reproductive period. The reason is that, for this cohort, we also need to factor in the deficit of births due to World War I. Between 1916 and 1918, the period net reproduction rate was under 0.5.

This net reproduction measure can be expressed as a Lotka average annual rate of increase characterizing the period fertility and mortality rates:

$$\rho_t \cong \frac{\log R_{0,t}}{\bar{x}'_t}$$

[4] Including, at the end of the reproductive period, a measurable effect of the birth deficit of the war years.

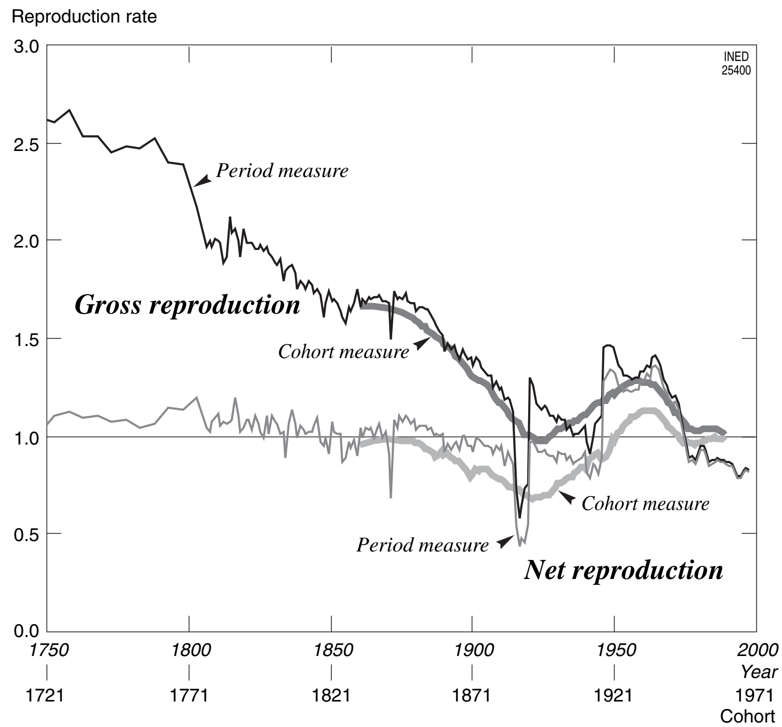

FIGURE 19–1 Long-term changes in gross and net reproduction rates, by birth cohort and according to period conditions. France, 1750–1997.

Between 1875 and 1925, the rate fell from +0.11% to –0.11%, with some sharply negative values during the war (as low as –1.22% in 1916).

c. Illustration

Figure 19–1 compares the long-term changes in the gross and net period and cohort reproduction rates in France. Period rates are shown from 1750 on.[5] Cohort rates are plotted beginning with the women born in 1830. For a meaningful comparison between the cohort-indicator changes and the period-indicator changes, we would need to position each cohort in the year in which it reached its mean age at childbearing. This has varied over time, declining from slightly over 30 years in the 18th century to 27 years in the mid 20th century, then rising to 29 years. For consistency, we have plotted each cohort in the year when it reached age 29.

Predictably, the gross reproduction rates exhibit the same contrast already emphasized in our analysis of TFRs (Chapter 14) between the very steady pattern of the cohort indicator and the highly fluctuating profile of the period indicator. The contrast is less pronounced for net reproduction, as it is subject to the fluctuations in cohort survival, which are rather sensitive to the swings in infant mortality. Again, however, the period indicator displays far more fluctuations.

The most interesting finding here is the spectacular convergence, in two centuries, between net reproduction and gross reproduction, in both the period indicators and cohort indicators. In earlier times, mortality between birth and reproductive ages drastically reduced the replacement potential inherent in the fertility rate. Today, that measure of mortality has collapsed to the point of creating only an insignificant difference between gross and net reproduction.

The figures also clearly show how consistently France's period net reproduction rate stayed close to unity throughout the period of study, with a single noteworthy exception: the baby boom of the 1950s and 1960s.

One final observation: For gross reproduction, the cohort and period indicators move reasonably in step

[5] Data for the 18th century are drawn from Louis Henry's historical reconstitution based on a representative sample of parish registers (Festy, 1979, for fertility; Blayo, 1975, for mortality). Our 19th century fertility data are from Depoid (1941), Festy (1979), and INSEE's *Annuaire Rétrospectif* (1966, 1990), while the mortality data are based on the reconstitution by France Meslé and Jacques Vallin (1989). For the 20th century, our fertility data are taken from INED (1975 and successive official reports annually published in *Population* by INED), INSEE yearbooks, and unpublished computations by Gérard Calot; the mortality data were computed by France Meslé and Jacques Vallin (Vallin, 1971; Vallin and Meslé, 2001).

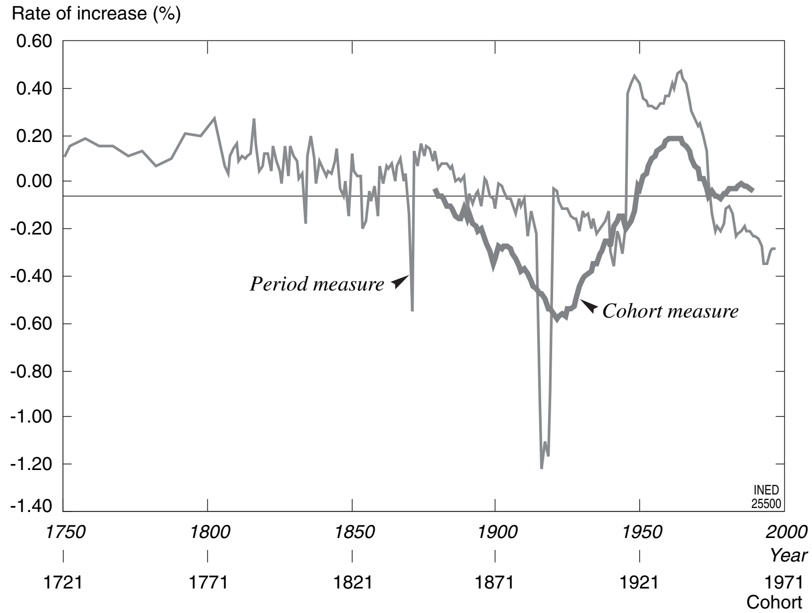

FIGURE 19–2 Long-term changes in average annual rates of increase in period and cohort net reproduction. France, 1750–1997.

(disregarding the period-indicator fluctuations); the net-reproduction indicators display a very different pattern. From the mid 19th to mid 20th centuries, the net reproduction of each cohort runs well below the net reproduction rate of the year in which the cohort reaches age 30. We find the same result, of course, when we compare the changes in the average annual rates of increase corresponding to these two net-reproduction indicators (Figure 19–2). This contradiction is due to the intrinsic difference between the period and cohort measures of net reproduction.

3. Reproduction at Age 15

The difference pointed out at the end of the previous paragraph can be explained as follows. In the cohort analysis, the expression of the net reproduction concept used until now, *net reproduction at birth* (hence the notation R_0), covers only one of several possible meanings. It tells us how many births of daughters will replace a cohort of births of mothers. As we have just seen, however, current mortality conditions evolve between a mother's birth and the time when she reaches reproductive age. Is it not more logical, therefore, to compare how many surviving daughters at age 15 would replace the cohort of mothers entering their reproductive period at the same age? Rather than measuring the replacement of births by births, we would thus measure the replacement of females of childbearing age by females of childbearing age. To obtain this *net reproduction rate at age 15*, R_{15}, for a generation, we should not weight fertility rates at each age by the mothers' probability of survival between birth and childbearing age. Instead, we must weight them by (1) the mothers' probability of survival between age 15 and childbearing age and (2) the daughters' probability of survival between birth and age 15:

$$R_{15} = \frac{B^F}{B} \sum_{x=\alpha}^{\omega} f_{(x,x+1)} \cdot \frac{l^m_{x+0.5}}{l^m_{15}} l^d_{15} = \frac{B^F}{B} \cdot \frac{l^d_{15}}{l^m_{15}} \sum_{x=\alpha}^{\omega} f_{(x,x+1)} \cdot l^m_{x+0.5}$$

where l^m_x and l^d_x are the probabilities of survival between birth and age x in the cohort of mothers and in the cohorts of daughters. As a rule, we lack the necessary data for a precise computation of the survival rate of daughters born to these mothers (as distinct from other daughters of the same cohorts born to mothers of different cohorts). We can, however, estimate the value from the survival rate in the cohort of daughters born in the year in which the mothers have reached their mean age at childbearing.

Moreover, as in the earlier exercise, we can generally simplify the calculation by using the mean age at childbearing to adjust gross reproduction for the probability of survival of mothers between age 15 and their mean age at childbearing and the probability of survival of daughters at age 15:

$$R_{15} \cong R \cdot \frac{l^m_{\bar{x}}}{l^m_{15}} l^d_{15}$$

For Calment's cohort, this net reproduction rate at age 15 was 0.91—significantly above the net reproduction rate at birth, but still well below unity. This sit-

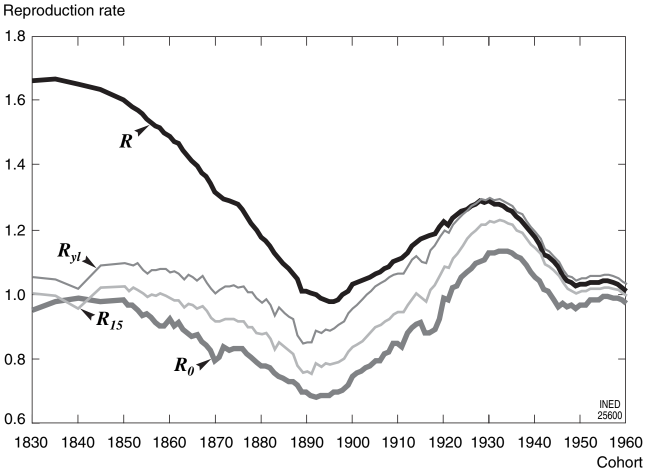

FIGURE 19–3 Net reproduction rate at birth and at age 15 and years-lived reproduction rate, in French cohorts born since the early 19th century.

uation is characteristic of a population whose mortality at early ages is very high but on a steep downtrend. The substitution of the daughters' infant and child mortality for that of mothers in the formula means a milder cut in the gross reproduction rate. Indeed, all French cohorts born since the mid 19th century display a net reproduction rate at age 15 that is substantially higher than their reproduction at birth (Figure 19–3).[6]

We can, of course, compute the net reproduction rate of a cohort at other ages, relative to their reproductive period, for example at their mean age at childbearing, provided there is no major difference in this age between mothers and daughters. In fact, as mortality is rather low at young adult ages, this additional refinement will not have a significant impact.

4. Reproduction of Years Lived

By contrast, to fully measure a population's capacity to ensure its own effective replacement, we should also take into account mortality beyond age 50. Suppose that mothers live 50 years and daughters 80 years. A net reproduction rate (at birth or at age 15) below unity would be enough to ensure the replacement of the total population. Historically, that is what occurred in France for many cohorts in which—thanks to the sharp rise in their life expectancy over age 50—not only the net reproduction rate but also the reproduction rate at age 15 were below unity even as the nation's population was increasing by more than net immigration would have allowed.

Consequently, to gain more insight into the concept of replacement, Louis Henry (1965) set out to calculate a *reproduction rate of years lived*, R_y, by weighting the net reproduction rate by the ratio of the daughters' life expectancy at birth to that of the mothers:

$$R_y = R_0 \cdot \frac{e_0^d}{e_0^m}$$

In Calment's cohort, the net years-lived reproduction rate was 1.02, more than 10% higher than the net rate at age 15, which was already 10% above the net rate at birth. On this measure, therefore, the cohort did succeed in replacing itself.

In France, the years-lived reproduction rate has consistently exceeded the rate at age 15 for all birth cohorts since the relevant data became available (1830). As a result, unlike net rates at birth or at age 15, the years-lived reproduction rate significantly exceeded unity for the cohorts born between 1830 and 1880. On the other hand, it fell below unity in the cohorts born between 1880 and 1900 owing to the enormous deficit of births caused by World War I (Figure 19–3).

Later, thanks to the *baby boom*, all three indicators topped unity, but the years-lived reproduction rate did so 20 cohorts before the net rate at birth. From that point on, in fact, the years-lived reproduction rate caught up swiftly with the gross reproduction rate. Remarkably, since the 1925 cohort, the years-lived indicator has overtaken the gross reproduction rate. The daughters' life-expectancy gains on their mothers have increasingly outweighed the fertility loss due to mortality before the reproductive period.

Obviously, if we calculate these replacement indicators not for a cohort but using period fertility and mortality functions applied to a fictitious birth cohort, all the variants of the net reproduction rate (R_0, R_{15}, R_y) coincide, since the mothers and daughters of the fictitious cohort are assumed to have the same mortality.

This observation suggests another one. For a cohort displaying the same fertility and mortality functions throughout its lifetime, the combination of the two functions into a reproduction rate gives us the exact measure of its presumed renewal capacity. In consequence, if we define the two functions as two constant laws applying to all cohorts, can we not *ipso facto* deduce from the functions the population's capacity to increase (or decrease) in the years ahead? In other words, to what extent does the Lotka rate of increase that we can deduce from the functions tell us the population's real rate of increase tomorrow? If, for

[6] By contrast, the cohorts born in 1840 to 1844 had a net reproduction at age 15 that was below their net reproduction at birth: This is due to the rise in infant and youth mortality in France between 1850 and 1880, plus an exceptional excess mortality in 1870 to 1871 caused by the Franco-Prussian war and the Paris Commune insurrection.

example, the fertility and mortality conditions of 1997 persisted indefinitely in Italy—with a net reproduction rate well below unity—the Italian population would surely decline. But there is little likelihood that the conditions of a given year will endure: 1997 conditions, for example, are subjected to the timing effects described earlier (see Chapter 14). Even if the conditions persisted, we would still have to factor in the role of the population's age structure. As we saw in Chapter 4, that structure would translate the fertility and mortality functions into births and deaths, which, in turn, would cause the structure to change. This issue will be explored in greater detail in the next chapter, devoted to population models.

Beforehand, however, we must go back to the initial simplification of the problem: what is the role of men in the process we designate here as reproduction?

II. MALE REPRODUCTION AND THE SEX-RECONCILIATION ISSUE

The concept of reproduction, which we have hitherto discussed in terms of childbearing, could be just as well examined from the standpoint of paternity, if we had male fertility statistics at our disposal. Unfortunately these are rare, for two reasons. The most important one is practical: paternity outside marriage is hard to observe, and even data on paternity in marriage are scarce. The second reason, no doubt, is a cultural one: most human societies have long regarded the reproduction of the species as the pre-eminent role of women. This is regrettable, as the analysis of male fertility—in those circumstances where it can be carried out—offers a different perspective on the reproduction issue. Incidentally, this raises a question that still awaits a satisfactory answer: how should demographers incorporate male-female cooperation into the measure of a population's fertility and reproduction?

1. Male Fertility and Male Reproduction: the Case of a Monogamous European Population

Male fertility is seldom measured. Some authors in the 1940s attempted to incorporate male fertility indices into the theoretical study of population (Karmel, 1947, 1948, 1949; Hajnal, 1950), but there are hardly any historical descriptions. Nicolas Brouard (1977) tried to reconstitute the evolution of male fertility and male reproduction in France over nearly a century.

Figure 19–4 shows the difference between male and female fertility in France in the late nineteenth century and the mid 1970s. The difference is significant. Men have a later fertility than women. However, in a population such as France's, where marriage is monogamous and the age difference between spouses fairly small, the similarities between the two fertility curves (same overall profile and closeness of the heights of the two modes) outweigh their differences (mostly due to the age difference between spouses). Moreover, these differences have narrowed sharply in a century owing to the sizable reduction in the age difference between spouses.

The fertility differences, however, are sufficient to induce significant differences in gross reproduction between sexes (Figure 19–5). For the late 19th century (1899), Nicolas Brouard finds a male TFR of 3.1 chil-

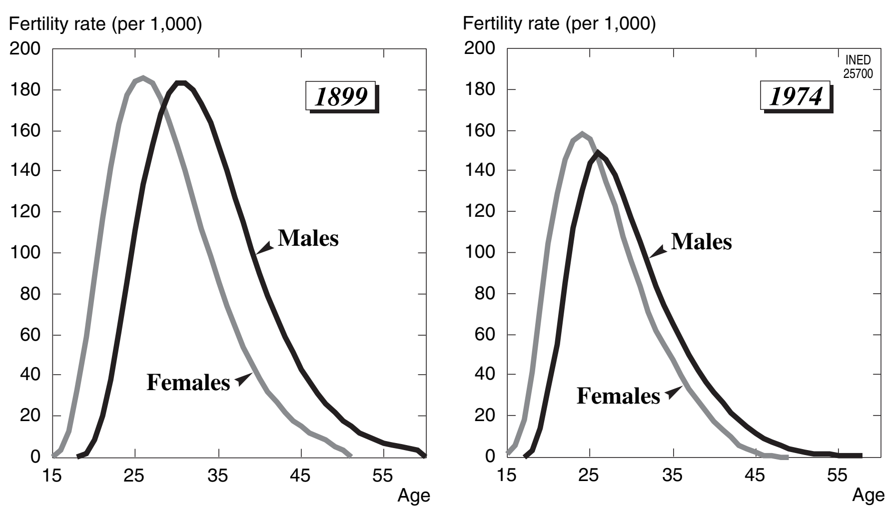

FIGURE 19–4 Age-specific male and female fertility rates in France, 1899 and 1974 (source: Brouard, 1977).

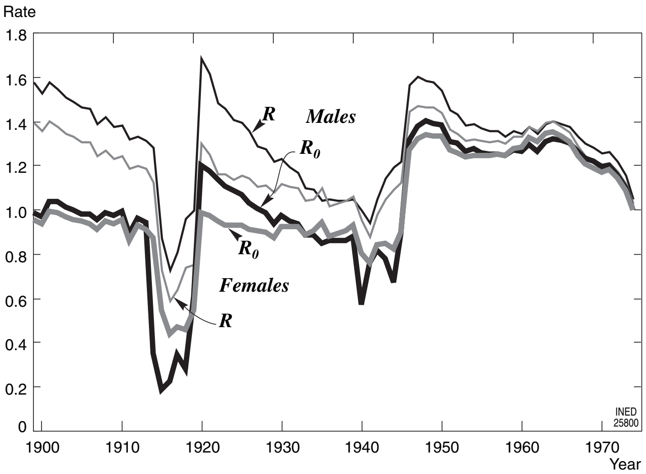

FIGURE 19–5 Comparative changes in female and male gross reproduction rates (R) and net reproduction rates (R_0). France 1899–1974 (source: computed from total fertility rates published by Nicolas Brouard, 1977).

dren versus a female TFR of 2.9 children. The relative gap between gross reproduction rates (1.6 for males and 1.4 for females) was even wider since there were more male than female births. However, as male mortality was greater and the mean age at paternity higher than the mean age at childbearing (33.8 versus 29 years), the sex differential was much smaller in terms of net reproduction: 0.99 for males and 0.95 for females (Table 19–1). With time, these differences have narrowed to near-insignificance in the 1970s.

TABLE 19–1 Indicators of Male and Female Reproduction in France, 1899 and 1974

Indicators	1899		1974	
	Male	Female	Male	Female
Total fertility rate (TFR)	3.08	2.86	2.05	2.11
Proportion of births of each sex	0.512	0.488	0.512	0.488
Gross reproduction rate (R)	1.58	1.40	1.05	1.03
Mean age at procreation ($\bar{x}$)	33.8	29.0	29.7	26.8
Net reproduction rate (R_0)	0.99	0.95	1.00	1.00
Lotka growth rate (first order)	–0.01	–0.07	0.00	0.00

2. Male Fertility and Reproduction: the Case of a Polygamous African Population

The pattern is very different in a population where polygamy is widespread and the age difference between spouses is large. An eloquent example is provided by Gilles Pison's study of the Bandé Fulani in eastern Senegal (1982). The age-specific male and female rates of this population are extremely divergent. Male fertility is later, more dispersed, and higher than female fertility (Figure 19–6). Although female fertility peaks at age 20 to 25 and is concentrated between the ages of 15 and 45, male fertility peaks at age 45 to 49 and is widely spread between the ages of 25 and 70. This does not prevent it from reaching 400 per thousand versus only 300 per thousand for female fertility. As a result, the TFR is much higher among men (nearly 12 children per male) than among women (6.7 children per female).

Such differences are made possible only by polygamy, which seems to allow men to have more children because they beget them later. Indeed, polygamy cannot become a significant phenomenon unless the age difference between spouses is wide.

At the same time, however, the massive differences observed in TFRs and—even more so—in gross reproduction rates (6 for males versus 3.3 for females) are substantially narrowed when we look at net reproduction: the figures are 1.8 for males versus 1.5 for females (Table 19–2). Even though male mortality is barely higher than female mortality in Africa, it exerts a greater downward effect on gross reproduction capacity for men, because it has to be factored in for a period of more than 40 years of mean age at net paternity, compared with only 27 years for female mean age at net childbearing. Last, when we compute the Lotka rate, the fact that reproduction requires 40 years of male life versus only 27 years of female life means that the average annual rates of increase implied by these

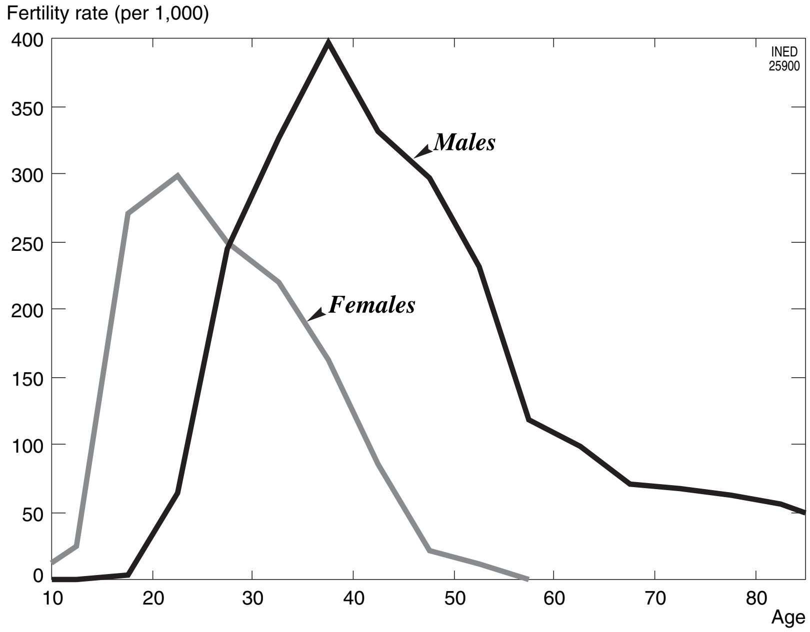

FIGURE 19–6 Age-group-specific male and female fertility rates among the Bandé Fulani of eastern Senegal (source: Pison, 1982).

reproduction figures are—in the end—virtually the same. In this manner, two theoretical gross reproduction capacities, one twice as large as the other, are reconciled in a single rate of actual procreation.

Population Models

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Institut national d'études démographiques (INED), Paris, France

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

With the device of the hypothetical cohort, we have sought to estimate the fertility, mortality, and migrations in a cohort that would be subject throughout its life to the conditions prevailing in the period studied. Let us go one step further and examine the changes in a population whose age-specific fertility, mortality, and migration rates would be frozen at the levels observed at a given moment. In the long run, what would become of its size, its age and sex structure, its crude birth, death, and migration rates, and, ultimately, its growth rate?

In Chapter 4, we discussed the interaction between the population structure and the determinants of its changes. At this stage, however, we have not examined the instruments for measuring the phenomena involved, which will be discussed in the following chapters. For the moment, these instruments enable us to formalize the relationships, to understand how they work, and to attempt an answer to our opening question.

The first demographer to define the equation linking a population's age structure, fertility, and mortality was Alfred Lotka in 1939. In so doing, he demonstrated that, whatever its initial age structure, a closed population subjected indefinitely to constant age-specific fertility and mortality tends toward a constant age structure and a constant growth rate. Lotka's study gave rise to the concept of *stable population*.

To do this, however, Lotka doubly simplified the problem by restricting his model to the female population (the yardstick by which fertility is customarily measured) and specifying a closed population (with no migration). Other authors have since tried to extend the model. Their generalization effort has led them to analyze not only the changes in populations with constant growth rates, but also the changes in populations with variable growth rates.

In its generalized form, Lotka's equation may also provide an answer to a new question. Instead of exploring possible changes in the age structure of a population whose fertility, mortality, and migration rates were frozen at their present levels, we will ask what factors in past fertility, mortality, and migrations have led to the age structure observed at a given moment. For this purpose, we will use the cohort measures of fertility, mortality, and migrations.

I. LOTKA'S THEORY

Provided that mortality and fertility at each age consistently exhibit the same values whatever the initial age structure, birth rate, and death rate, the growth rate will ultimately approach the asymptotic value ρ—the intrinsic value—which expresses the population's fundamental capacity to multiply when freed of the disruptive influence of an arbitrary age structure.

This aspect of the intrinsic rate of natural increase ρ deserves our very close attention. The rate is of interest to us less as a forecasting instrument than because it expresses a current property of a population, its fundamental capacity to multiply. The crude rate of natural increase—i.e., the excess of the birth rate over the recorded death rate—does not give us the true measure of this capacity, as both the latter rates are influenced by the population's age structure, and this structure itself depends on what we can describe as fortuitous factors that have been at work in the past. There can be a sizable gap between the crude rate and the intrinsic rate.[1] (Lotka, 1939)

When we take a closed population in any given initial situation and arbitrarily make its mortality and fertility functions constant, we commit the population to a process of convergence toward a population whose growth rate and age structure will also be constant. The growth rate and age structure will be exclusively determined by the combination of fertility and mortality functions—in other words, they will be totally independent of the initial situation. The theoretical population reached at the end of this convergence (stabilization) process is called a *stable population*. In reality, according to the theory,

> This limit is never reached, as the population oscillates indefinitely around the stable state but the oscillations are increasingly weaker. If we set a limit to the amplitude of the oscillations, the limit is reached at the end of a period T that depends on the [mortality and fertility functions] in t_1 and the age structure of the population in t_1.[2] (Bourgeois-Pichat, 1994).

1. The Concept of Stable Population

The concept of stable population is not new. The Swiss mathematician Leonhard Euler defined its principle as far back as 1760 (Lombardo, 1976; Smith and Keyfitz, 1977).[3] In fact, it is Euler's studies that served as a basis, 50 years later, for the entry on *Population* by Thomas Malthus in the fourth edition of the *Encyclopædia Britannica* (Coale, 1979; Bourgeois-Pichat, 1994). From Euler, Malthus drew his conclusion that human populations expand geometrically whereas the production of food increases only arithmetically, which is why Lotka describes a population whose growth rate is constant as Malthusian.

But the international scientific community had forgotten the concept of stable population until Lotka's studies on the eve of World War II revived interest in it.[4] Lotka's contribution, in turn, took time to receive the full attention it deserved. Only Giorgio Mortara, working in Brazil in the 1940s and 1950s, realized its value for understanding population dynamics in the developing countries (Mortara, 1949). Not until the work of the Office of Population Research in Princeton[5] and the Population Division of the United Nations[6] in the early 1960s did stable-population theory pave the way for a proliferation of theoretical research and practical applications, which are now central to the analysis of population dynamics.

2. The Fundamental Equations

As Lotka reminds us (1939), in a closed population subject to a constant mortality regime defined by the probabilities $p(a)$[7] of survival between birth and age a, and displaying a constant age structure $c(a)$, the total size and the number of births increase (or decrease), according to Malthus's law, at a constant rate r, and the birth and death rates—known as intrinsic rates—are themselves constant.

The intrinsic birth rate b is therefore equal to

$$b = \frac{1}{\int_0^\omega e^{-ra} p(a)da}$$

and the proportion $c(a)$ of the population at a given age is equal to

$$c(a) = be^{-ra} p(a)$$

Naturally, if B denotes births, the population $N(a)$ aged a is at all times equal to

$$N(a) = Be^{-ra} p(a)$$

[1] Pourvu que la mortalité et la fécondité á chaque âge aient constamment les valeurs données, quelle que soit la répartition initiale par âge et les taux de natalité et de mortalité, en fin de compte le taux d'accroissement s'approche de plus en plus à la valeur asymptotique ρ, valeur intrinsèque, qui exprime la capacité fondamentale de multiplication de la population, libérée de l'influence perturbatrice d'une répartition par âge arbitraire.

C'est là un aspect du taux intrinsèque d'accroissement ρ qui mérite notre attention toute particulière. Ce taux nous intéresse moins comme instrument de prévision que par le fait qu'il exprime une propriété actuelle d'une population, sa capacité fondamentale de multiplication. Le taux brut d'accroissement—excédent du taux de natalité sur le taux de mortalité enregistré—ne nous donne pas la mesure véritable de cette capacité, car ces taux sont tous les deux influencés par la répartition par âge de la population, et cette répartition elle-même dépend de facteurs pour ainsi dire adventices qui ont agi dans le passé. Entre le taux brut et le taux intrinsèque il peut y avoir un écart importan.

[2] *Cette limite n'est jamais atteinte, la population oscille indéfiniment autour de l'état stable mais les oscillations sont de plus en plus faibles. Si l'on se fixe une limite pour la grandeur des oscillations, cette limite est atteinte au bout d'un temps T qui dépend des* [fonctions de mortalité et de fécondité] *au temps t_1 et de la composition par âge de la population à l'instant t_1.*

[3] An English translation of Euler's text by Nathan and Beatrice Keyfitz was published in *Theoretical Population Biology* (1970; p. 307–314). In the year following its original publication, Euler's study was discussed by Johann Peter Süssmilch (1761): His commentaries, as well, have been translated (Smith and Keyfitz, 1977).

[4] Lotka's 1939 publication, however, had been preceded by preliminary studies (Lotka 1907, 1922; Sharpe and Lotka, 1911) that had led him to this general statement.

[5] Particularly at the behest of Ansley Coale, Paul Demeny, Alvaro Lopez, and, later, Samuel Preston.

[6] Particularly at the behest of Bourgeois-Pichat.

[7] We adopt most of Lotka's original symbols, now standard in all the current literature on stable populations: We use a to denote age, rather than the x used previously.

which is the fundamental function of the stable population (or *Malthusian population*, as Lotka calls it).

However, as Lotka notes, the first two relationships are not independent and are thus inadequate for completely determining the quantities b and r. The first formula, which expresses a relationship between the birth rate and the growth rate, does not suffice to set their values once and for all. For this purpose, we need a second relationship that is independent of the first and incorporates fertility. This brings us to the difficult problem of finding a complete expression of fertility that allows for the sexuated mode of reproduction inherent in the human species. Like Lotka, we will have to restrict our analysis, at least initially, to a single sex—for convenience, the female sex.

Girls born in year t ($B(t)$) are born to mothers who, that year, have an age a falling within the reproductive period (say, 15–49 years). These mothers, in turn, were born in year $(t - a)$, when the number of births of girls was $B(t - a)$. As a result, in an infinitesimal time interval dt, there were $B(t - a)dt$ births of girls, of whom $B(t - a)p(a)dt$ survived in year t, at age $(a + dt)$, equal to $(a + da)$. Let $m(a)$ be the rate of girls per mother[8] aged a. By definition, this function $m(a)$ is, like the function $p(a)$, independent of time. We can thus define the annual number of births of girls in t as a function of the number of births of women in $(t - a)$:

$$B(t) = \int_0^{\omega} B(t-a)p(a)m(a)da$$

To find the growth rate of the stable population, Lotka solved this equation with an exponential series:

$$B(t) = \sum_{i=0}^{\omega} Q_i e^{r_i t}$$

He showed that each r_i satisfies the relationship:

$$1 = \int_0^{\omega} e^{-r_i a} p(a)m(a)da$$

and that the r_i coefficients are accordingly determined as the roots of the equation:

$$1 = \int_0^{\omega} e^{-ra} p(a)m(a)da$$

independent of the initial conditions, whereas the Q_i coefficients depend on those conditions.

[8] We use the expression rate of *girls per mother* to specify that we are talking not about a female fertility rate in the sense we used earlier (i.e., ratio of births of both sexes to females only) but about fertility rates obtained by calculating the ratio of female births only to females.

The roots of Lotka's fundamental equation are not all real, but obviously the function $p(a)m(a)$, product of a probability and a rate, can assume only real, positive values. In consequence, this equation can have only one real root, ρ, which is positive if the net reproduction rate R_0 is greater than 1:

$$R_0 = \int_0^{\omega} p(a)m(a)da > 1$$

negative for $R_0 < 1$, and null for $R_0 = 1$. In other words, its sign depends on whether the number of births increases, decreases, or stays constant from one generation to another.

Moreover, we can define the number of individuals $N(a)$ living in t as the sum of all those who, born in $(t - a)$, survive at age a in t. In t, the size of the population is therefore equal to

$$N(t) = \int_0^{\omega} B(t-a)p(a)da$$

In the case of the real root ρ, the relationship $B(t) = Q_\rho e^{\rho t}$ makes it possible to transform the previous relationship as follows:

$$N(t) = Q_\rho e^{\rho t} \int_0^{\omega} e^{-\rho a} p(a)da$$

in other words:

$$N(t) = Ke^{\rho t}$$

K is a constant. Thus ρ is, quite simply, the population's intrinsic rate of natural increase (or intrinsic growth rate).

As a result, this single real root ρ of Lotka's fundamental equation enables us to completely define the characteristics of the stable population (Lotka, 1939):

$$b_\rho = \frac{1}{\int_0^{\omega} e^{-\rho a} p(a)da}$$

$$c_\rho(a) = b_\rho e^{-\rho a} p(a)$$

$$1 = \int_0^{\omega} e^{-\rho a} p(a)m(a)da$$

3. From the Determination of *r* to the Calculation of the Stable Population

To obtain a concrete estimate of these characteristics from a given mortality function $p(a)$ and a given fertility function $m(a)$, we need to resolve the last of these three relationships, which will give us a measure of the intrinsic growth rate. Different methods have been proposed for this purpose.

Lotka (1939) suggested a three-level approximation. As a first approximation, he obtained

$$r \cong \frac{\log_e R_0}{\mu_1}$$

where R_0, the 0-order moment of the net maternity function $p(a)m(a)$, and μ_1, the order 1 semi-invariant, are in reality the net reproduction rate and the mean age at childbirth. His second approximation relies on the resolution of a quadratic equation, and his third on the analysis of the complex roots of the equation. John Pollard (1973) took Lotka's complex approach and expanded it on certain points.

Other authors have come up with more advanced solutions (see Coale, 1957; Keyfitz, 1968, 1972). However, matrix calculus offers an easier solution to the problem by placing the overall question of the shift to a stable state in another perspective: that of population projections. William Feller understood this advantage as far back as 1941.

II. MOVING TOWARD A STABLE STATE VIA THE PROJECTION MATRIX

It is fairly easy to deduce the properties of the stable population from a population's *projection matrix* (i.e., the matrix whose rows reproduce the overall female fertility rates[9] and whose subdiagonals reproduce the probabilities of survival in the course of each projection stage). This approach was introduced by Harro Bernardelli in 1941 and extensively described by Paul H. Leslie (1945). Given the constancy of the fertility and mortality rates of a stable population, the *projection matrix* remains identical over time. To make a demographic projection,[10] we simply multiply a vector comprising the number of females by age by the projection matrix for each stage of the perspective. As we are dealing with a stable population, the successive multiplication of the projection matrices is equivalent here to multiplying the matrix by itself and therefore to raising it to successive powers. Because of the strong convergence of stable populations, the projection should yield the characteristics of the stable population if we raise the projection matrix to a sufficiently high power.

[9] This is the net overall fertility rate taking into account survivals in the course of each projection stage (see Keyfitz, 1968).

[10] The issue of demographic projections will be discussed as such in several later chapters of this Treatise (see especially Chapter 72).

Let us take an example provided by Nathan Keyfitz many years ago (1964). It consists of a 3 × 3 projection matrix for U.S. females in the three 15-year age groups of 0–14, 15–29, and 30–44 years for the period 1940 to 1955. If we consider that U.S. fertility is complete at age 45, this submatrix is the only one that matters in terms of population dynamics, because women older than 45 years do not contribute to demographic reproduction. We therefore define the initial matrix

$$A = \begin{pmatrix} 0.32167 & 0.68154 & 0.12110 \\ 0.98610 & 0 & 0 \\ 0 & 0.97203 & 0 \end{pmatrix} = \begin{pmatrix} g(0) & g(1) & g(2) \\ p(0) & 0 & 0 \\ 0 & p(1) & 0 \end{pmatrix}$$

The first row gives the female fertility rates and the subdiagonal the probabilities of survival of the 0–14 age group to ages 15–29, and of the latter group to ages 30–44 years. Let us now raise matrix A to successive powers. By A^3 there are no null terms left. Let us now compare the m_{ij} elements of matrices A^{32} and A^{33}. The respective values of these matrices are

$$A^{32} = \begin{pmatrix} 3.53733 & 2.64654 & 0.440336 \\ 3.29245 & 2.46332 & 0.376344 \\ 3.02079 & 2.26008 & 0.345292 \end{pmatrix}$$

and

$$A^{33} = \begin{pmatrix} 3.74761 & 2.80386 & 0.428371 \\ 0.48877 & 2.60975 & 0.398716 \\ 3.20036 & 2.39442 & 0.365818 \end{pmatrix}$$

Let us start by taking the ratios of elements m_{ij}/m_{1j} of one of the two matrices, say A^{33} (we would obtain the same result with A^{32}). We obtain for $j = 1$, 2, and 3, respectively:

1.00000	1.00000	1.00000
0.93077	0.93077	0.93077
0.85397	0.85397	0.85397

We see, therefore, that the columns (as well as the rows, incidentally) of A^{32} and A^{33} are proportional and identical. We also have the size of the U.S. female population projected to periods 32 and 33, using the constant projection matrix A. The projection shows the following population sizes (to within a multiple of 10)**:**

Age group	Population size in period 32	Population size in period 33
0–14	96,131	101,845
15–29	89,476	94,795
30–44	82,093	86,973

Dividing these numbers by the size of first age groups, we obtain the relative structure of the population in the stable state.

Age group	Period 32	Period 33
0–14	1.00000	1.00000
15–29	0.93077	0.93078
30–44	0.85397	0.85397

The *column-vectors* of matrix A^n (large n) are therefore proportional to the relative structure in the stable state, considering that the stable state is nearly reached at the end of 33×15 projection years.

Let us now calculate the ratio of the elements of A^{33} to those of matrix A^{32}. We obtain the following results:

$$\begin{matrix} 1.05945 & 1.05944 & 1.05944 \\ 1.05945 & 1.05944 & 1.05945 \\ 1.05944 & 1.05944 & 1.05945 \end{matrix}$$

We obtain the same constant, 1.05944, nearly each time. It is the factor by which all the population numbers by age are multiplied to shift from one projection stage to the next in 15-year periods. The annual growth rate of the stable population is therefore equal to $1/15 \ln 1.05944$ since a constant growth rate leads to an exponential increase in the population, here 3.8% a year.

Let us now show that these results can be calculated from the eigenvectors of the projection matrix A associated with the main root (or eigenvalue) λ (see Keyfitz, 1968; Wattelar, 1971). Linear algebra shows us how to calculate the vertical (u) and horizontal (v) eigenvectors, respectively, so that:

$$\mathrm{A}u = \lambda u$$

$$v\mathrm{A} = \lambda v$$

associated with the main root λ.

We must begin by estimating the main root λ corresponding to the ratio of the sizes of the stable population at two different moments in time (Keyfitz, 1968). This is obviously equivalent to the ratio of the elements of matrix A^{n+1} to those of the matrix A^n, for a large n. Taking the previous $A(3 \times 3)$ matrix as an example, the ratio of the elements, as we have seen, yields the value $\lambda = 1.05944$ for $n = 32$. This value is unique, once stability is reached. It corresponds to the intrinsic growth rate of the stable population.

We can also calculate the same result from the characteristic equation of the projection matrix

$$\begin{vmatrix} g(0)-\lambda & g(1) & g(2) \\ p(0) & -\lambda & 0 \\ 0 & p(1) & -\lambda \end{vmatrix} = 0$$

which gives

$$\lambda^3 + \lambda^2\, g(0) + \lambda\, g(1)\, p(0) + g(2)\, p(0)\, p(1) = 0$$

This equation has only one real positive root that corresponds to the stable population's intrinsic growth rate. The uniqueness of the solution is easily demonstrated (Goodman, 1968). Let us write the characteristic equation in the general form:

$$\lambda^{k+1} - \sum_{y=0}^{k} h(y)\lambda^{k-y} = 0$$

where $h(y)$ represents the products $g(y)s(y)$, with $s(y) = \prod_{j=0}^{y} p(j)$, for example, in the characteristic equation:

$$h(2) = g(2)\, p(0)\, p(1)$$

We can also write:

$$\sum_{y=0}^{k} h(y)\lambda^{k-y} = \lambda^{k+1}$$

Dividing the two members by λ^{k+1}, we obtain:

$$\sum_{y=0}^{k} \frac{h(y)}{\lambda^{y+1}}\lambda = 1$$

As the left-hand term decreases from infinity to 0 when λ increases from 0 to infinity, the characteristic equation will admit only one real positive root λ.

Returning to the projection matrix:

$$A = \begin{pmatrix} g(0) & g(1) & g(2) \\ p(0) & 0 & 0 \\ 0 & p(0) & 0 \end{pmatrix}$$

where $g(k)$ are the fertility rates and $p(k)$ the probabilities of survival, and applying the theory of homogeneous linear equation systems with null determinant, we obtain the solution:

$$u(0) = 1$$

$$u(1) = p(0)/\lambda$$

$$u(2) = p(0)p(1)/\lambda^2$$

for the vertical eigenvector u. The horizontal eigenvector v will be equal to

$$v(0) = \lambda$$

$$v(1) = [\lambda - g(0)]/u(1)$$

$$v(2) = \frac{\lambda - [g(0)u(0) + g(1)u(1)]}{u(2)}$$

With the data of the U.S. projection matrix used earlier, we obtain the following for the vertical eigenvector:

$$u = \begin{pmatrix} 1 \\ 0.93077 \\ 0.85398 \end{pmatrix}$$

and for the horizontal eigenvector:

$$v = (1.05944 \ 0.79264 \ 0.12110).$$

We see that the vertical eigenvector u provides the relative stable structure, obtained earlier by raising A to a sufficiently high power. As for the horizontal eigenvector v, it is the discrete expression of the female *reproductive value*, a concept developed by Ronald Fisher (1958), which represents the present value of future births for females at each age i; the present value is obtained by applying the discount rate r, equal to the intrinsic growth rate of the stable population.

Note that Andrei Rogers (1966) generalized this approach to open populations. He divided the population into subsets subject to internal migrations, in addition to their specific fertility and mortality rates. The principle of strong convergence (or ergodicity), specific to the stable model, is also applicable here if the interregional projection matrix remains constant over time.

III. A SPECIAL CASE: THE STATIONARY POPULATION

There are as many stable populations as there are possible combinations between the different fertility and mortality functions imaginable. Depending on the resulting equilibrium between the force of mortality and the fertility rates, the intrinsic growth rate can be—as we have seen—positive, null, or negative.

1. The Stationary Population

When r is null, not only is the structure constant, but the population sizes, the number of births and the number of deaths are as well. The population is said to be *stationary*. It is entirely determined by its forces of mortality. This stationary population is, therefore, quite simply the L_x function of the life table (i.e., the *life-table population*. As we know (Chapter 11) that life expectancy is equal to

$$e_0 = \frac{\int_0^{\omega} l(a)da}{l_0}$$

and that the crude death rate is equal to

$$m = \frac{l_0}{\int_0^{\omega} l(a)da}$$

we see immediately that, in this particular case, life expectancy at birth is equal to the inverse of the intrinsic death rate and, since the growth rate is null, it too is equal to the inverse of the intrinsic birth rate

$$m = b = \frac{1}{e_0}$$

And, at any age x, life expectancy at this age is equal to the inverse of the crude death rate above age x:

$$e_x = \frac{1}{{}_{(\omega-x)}m_x}$$

Thomas Greville (1943; see also Chapter 14) uses this property to close a life table.

2. Growth Potential of the Population

One of the possible applications of the stationary model is to measure what Paul Vincent (1945) has called the *potential for increase* and various English-language authors have used the expression *population momentum*, with a fuller, more general mathematical elaboration (Keyfitz, 1971, 1985; Preston and Guillot, 1997). The idea is simple: By how much will the population vary between the moment when its fertility and mortality functions freeze at the levels strictly needed for cohort replacement (R_0 = 1) and the moment when it reaches the stationary state? The question was first raised in connection with the decline in fertility in the developing countries. Would a very swift decline indicate the end of the population explosion often denounced as an obstacle to development? No, because the populations of those countries had accumulated a high growth potential in their very young age structures. We can also ask the same question today in the developed countries, where the fall in fertility and greater longevity have produced increasingly older age structures: by how much would the population decline if, by miracle, fertility were to recover and settle at the 2.08 children per female needed—in present mortality conditions—to attain the stationary state?

Samuel Preston and Michel Guillot (1997), using Vincent's concept and the work of Keyfitz, have generalized the mathematical definition of the potential and arrived at the following formula:

TABLE 20–1 Growth Potential Observed in 1997 in Main Regions of World and Selected Countries

Region or country	Growth potential
Africa	1.56
West Asia	1.56
Southeast Asia	1.48
Latin America	1.48
South Central Asia	1.47
East Asia	1.22
North America	1.10
Europe	0.98
Austria	0.96
Russia	0.94
Italy	0.91
Germany	0.88
World	1.35

Source: Preston and Guillot, 1997. Population dynamics in an age of declining fertility synthesis, *Genus*, vol. 53(3–4), p. 15–31.

$$M = \int_0^{\omega} \frac{c(a)}{c_s(a)} \cdot w(a)da$$

where $c(a)$ is the age structure of the initial population, $c_s(a)$ that of the population in the stationary state, and $w(a)$ the ratio of net reproduction above age a to the mean age at childbirth in a stationary regime.[11]

It is thus clear that a population's potential for increase is a function of the age-structure disparities between the initial situation and the stationary state. Table 20–1 shows the potentials calculated by Preston and Guillot (1997) for the main regions of the world and selected countries of interest. If the African population had reached stationarity conditions by 1997, it would nevertheless have continued to grow by 56% before becoming stationary. Conversely, if Germany's fertility had returned by the same date to the level needed for strict generation replacement, its population would nevertheless have had to fall 12% before stabilizing.

IV. SOME APPLICATIONS OF THE STABLE POPULATION MODEL

The stable population model has been highly successful and has been applied in many ways in a wide range of fields, from correcting imperfect data.[12] (Coale and Demeny, 1967) to modeling the acquired immunodeficiency syndrome (AIDS) epidemic (Brouard, 1987, 1994). We will limit ourselves to two very different examples here.

1. The Coale–Demeny Models

The most popular tool based on the theory of stable populations is unquestionably the network of Coale–Demeny models (1966, 1983). Coale and Demeny began with four families of model life tables[13] built from real data,[14] and a set of age-specific fertility functions. They derived a vast set of stable populations defined by different combinations of mortality and fertility levels and structures. This set comprises four subsets designated as *West model, East model, North model*, and *South model*, according to the origin of the real data used, although this does not impart any geographic significance to the models. By way of illustration, Table 20–2 lists some population-dynamics indicators (crude birth and death rates, growth rate, and mean age of the population) obtained for selected combinations of mortality and fertility described by the West model.

As expected, the higher the gross reproduction rate, the higher the birth rate (Table 20–2 and Figure 20–1). However, for an identical gross reproduction rate, as the table shows, the birth rate varies according to life expectancy at birth. This variation, in turn, depends on the fertility level: It is near zero when the reproduction rate is below 2, and gradually widens as fertility rises. But the variation is not truly significant except at implausible fertility levels, when the gross reproduction rate exceeds 4 or 5.

For an identical life expectancy, the crude death rate depends, in turn, on fertility. Whatever the life expectancy at the lowest fertility levels, the death rate decreases when fertility increases (Figure 20–2). But when the gross reproduction rate exceeds 2, the death rate varies according to life expectancy. If the latter is below 50 years, the crude death rate increases with fertility, whereas if life expectancy exceeds 50 years, the rate stagnates or actually keeps declining. The mean age of a stable population depends very little on life expectancy, even if some differences appear when the gross reproduction rate exceeds 2 (Figure 20–3). For all gross reproduction rates above 1, the mean age rises with life expectancy. For a gross reproduction rate of 2.5, the mean age falls from 28.5 years with a 20-year life expectancy to 24 years for an 80-year life expectancy.

[11] Or $w(a) = \dfrac{\int_a^{\omega} p(x)m(x)dx}{\bar{x}}$

[12] On this point see also Chapter 127.

[13] The concept will be discussed in greater detail in Chapter 128.

[14] See Chapter 128.

TABLE 20–2 Selected Indicators Characterizing the Stable Populations of the Coale–Demeny West Model: Females

Parameters[a]	Gross reproduction rate								
	0.8	**1.0**	**1.5**	**2.0**	**2.5**	**3.0**	**4.0**	**5.0**	**6.0**

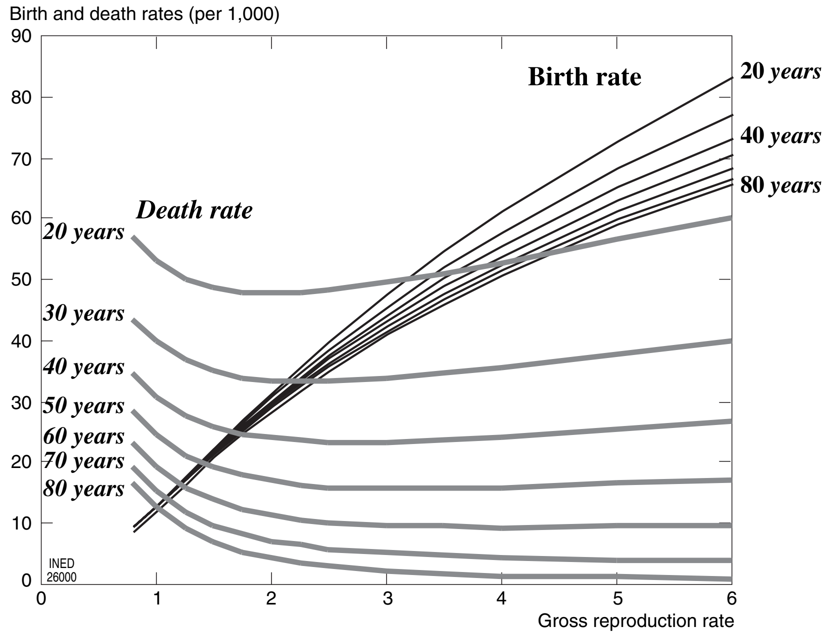

FIGURE 20–1 Crude birth and death rates as a function of gross reproduction rate for selected life expectancies at birth, based on stable populations of Coale–Demeny West model (females).

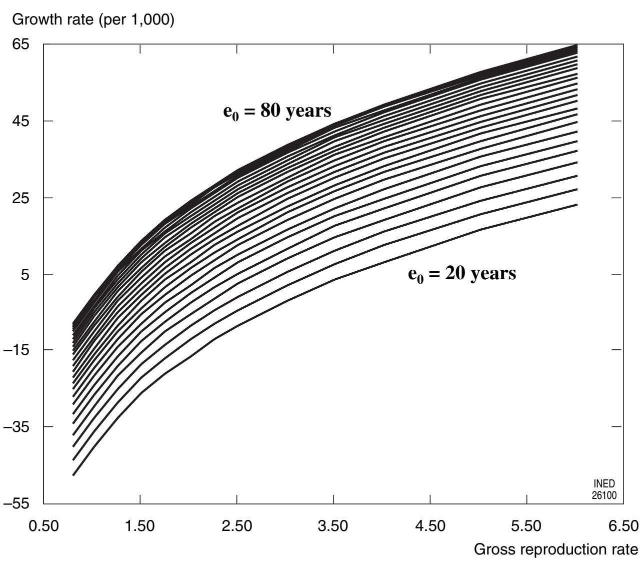

FIGURE 20–2 Growth rate as a function of gross reproduction rate for selected life expectancies at birth, based on stable populations of Coale–Demeny West model (females).

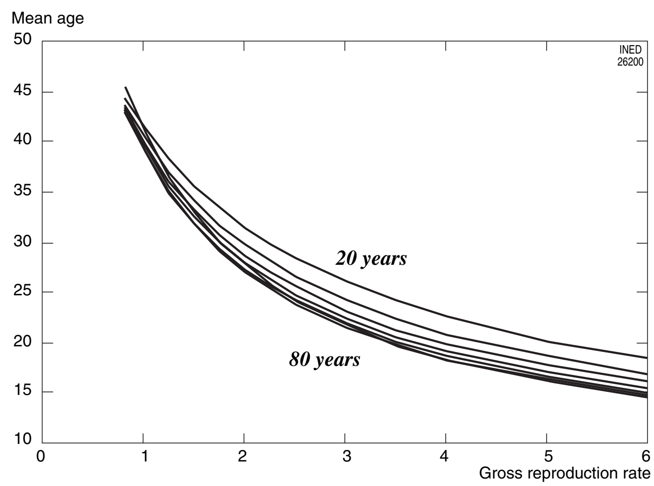

FIGURE 20–3 Mean age of population as a function of gross reproduction rate for selected life expectancies at birth, based on stable populations of Coale–Demeny West model (females).

The mean age is much more sensitive to fertility. Whatever the life expectancy, the mean age literally collapses when the gross reproduction rate rises from 0.8 to 2.5 or 3 (Figure 20–3).

Figure 20–4 gives another perspective on the same relationships by plotting birth and death rates as a function of life expectancy at birth, for selected values of the gross reproduction rate. As long as the gross reproduction rate is below 2, the birth rate remains virtually identical regardless of life expectancy. Even at higher fertility levels, the variation is modest. By contrast, the death rate varies very sharply, as one might expect, with life expectancy. However, this variation depends to a significant degree on fertility: the decline in the crude death rate with the rise in life expectancy is all the steeper as fertility is higher.

Stable-population models are a powerful tool for analyzing real data, in many ways. First, they allow a

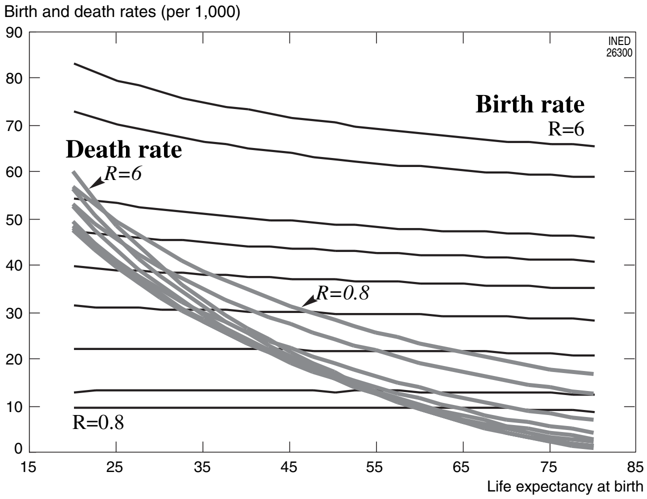

FIGURE 20–4 Crude birth and death rates as a function of life expectancy at birth for selected gross reproduction rates, based on stable populations of Coale–Demeny West model (females).

test of the internal consistency of the data gathered. Some combinations of results are perfectly impossible, and the comparison with models is often the best way to determine this. Better, the models and the underlying theory serve as the basis for building special tools to adjust imperfect data or fill gaps.[15]

Stable-population models are also a starting point for examining the sequence of events that constitute the real history of populations. We will give only one example here, supplied by Gustavo De Santis (1997), who compares (1) the nomograms of the population growth rate for different fertility–mortality combinations proposed by Ansley Coale and Susan Watkins (1986) working from Coale–Demeny models and (2) the values of that rate at the same levels of fertility in Italy since 1861 and in the world since 1950 (Figure 20–5).

The chart shows that with a nearly constant fertility rate of about five children per female from 1861 to 1911, and despite a major increase in life expectancy, the Italian population experienced an initial destabilization due to the progressive shift in the isogrowth line to higher growth zones. Since 1911, the Italian population has backtracked: In the early 1970s, it even seemed to be settling around zero growth, despite continuous gains in life expectancy; it then changed course abruptly in the mid 1980s, sinking into negative-growth zones. Meanwhile, the pattern in the world population, actually observed from 1950 to 1995 and projected through 2050, effectively illustrates two phenomena: first, the growth-acceleration phase combining high fertility and increased life expectancy (1950–1970); second, the rapid deceleration that seems to justify the United Nations projection based on the hypothesis of a shift to zero growth toward the middle of this century.

[15] See especially Chapter 127 on indirect estimation methods.

2. Example of Transition to Stationary State

One of the strengths of the stable-population theory is that it provides a way to rapidly illustrate the longer term evolution of a population whose current fertility and mortality conditions are held constant indefinitely. Its structure and growth rate in the stable state are known in advance, but we still need to determine how long it will take to reach that state, and with what fluctuations. This involves experimentation on concrete cases—a very standard exercise in population projection. A later chapter (Chapter 78) discusses the very–long-term projections of the world population, where different types of transition to the stable state will be examined. For the moment, we shall simply borrow an older example from Jean Bourgeois-Pichat and Si-Ahmed Taleb (1970), but reversing their approach. In other words, we explore what fertility and mortality conditions need to be specified for a population to take it to a given stable state.

In the days when the third world population boom was at its peak, the focus on the goal of stabilizing population size—in the everyday sense of the term—drew special attention to the specific case of stationary populations. What was needed to bring a fast-growing population to zero growth as soon as possible? The stable-population models instantly provide the fertility target needed for a given mortality level. However, the shift from the initial state to the stationary state requires a certain period of time, whose length depends on the difference between initial fertility and the fertility leading to the stationary state. Can this interval be shortened? Certainly not. But there is nothing, at least in theory, to stop us from anticipating the final result by immediately freezing the growth rate at zero. We will not reach the stable state earlier. On the contrary, the growth-rate freeze will trigger massive swings in all the other parameters, and these fluctuations will take time to absorb.

In 1970—following a call by General Draper, U.S. Representative to the United Nations (UN) Population Commission, for a shift to zero growth by the end of the 20th century—Bourgeois-Pichat and Si-Ahmed Taleb took the example of Mexico to illustrate the wide gap between the fulfillment of General Draper's wish and a less unrealistic process that would lead Mexican women to adopt, by the early 21st century, the fertility rate needed to reach stationarity in the long run. For simplicity's sake, the authors confined their discus-

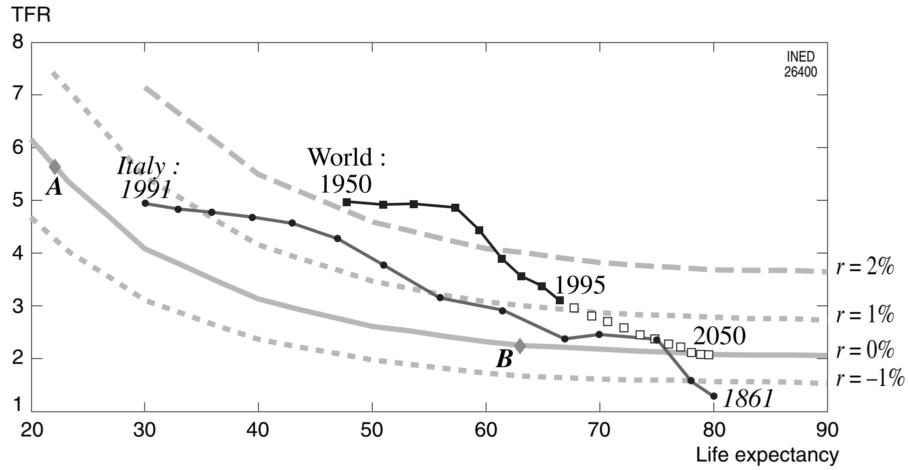

FIGURE 20–5 Long-term changes in growth rate of Italian female population since 1861 and of world female population since 1950 as a function of life expectancy and fertility, compared with Coale–Watkins growth-rate nomogram. (Source: De Santis, 1997. *Demografia ed economia*. Bologne, Il Mulino, 354 p. [Coll. Stuci e Ricerche].)

sion—as in stable-population theory—to the female population.

Figure 20–6 shows, as one might have expected, that the first solution would stabilize the Mexican population much sooner and at a much lower level than the second. In the first scenario, the population would level off, by definition, by 1995 to 1999, at twice its 1960 level; in the second scenario, the population would keep rising until ca. 2045 to 2049, reaching four times its initial size. For neo-Malthusians in a hurry, the result is tempting—but at what price?

Figure 20–7 shows the swings to which the crude birth and death rates would be subjected in an abrupt transition to zero growth (Chart a). In fact, the chart shows only the first of these swings—followed by a long series until the stationary state is reached. If instead, we assume that the fertility conditions obtaining in that stationary state will be realized in the near future, the birth rate and death rate will—on the contrary—gradually converge (Chart b). The equalization of the rates requires more time but quickly produces near-stability.

Figure 20–8 illustrates the violent swings in the size of a special age group—the school-age population—triggered by the realization of the first hypothesis. One can imagine the headaches for planners! The second hypothesis admittedly leaves room for an initial phase of rapid expansion of the school-aged population, but the population reaches a ceiling fairly quickly, after which the swings are very mild.

This example has taken us some distance from the pure theory of stable populations, but gives us a clear picture of the gulf between the theoretical conditions of stability and its practical fulfillment.

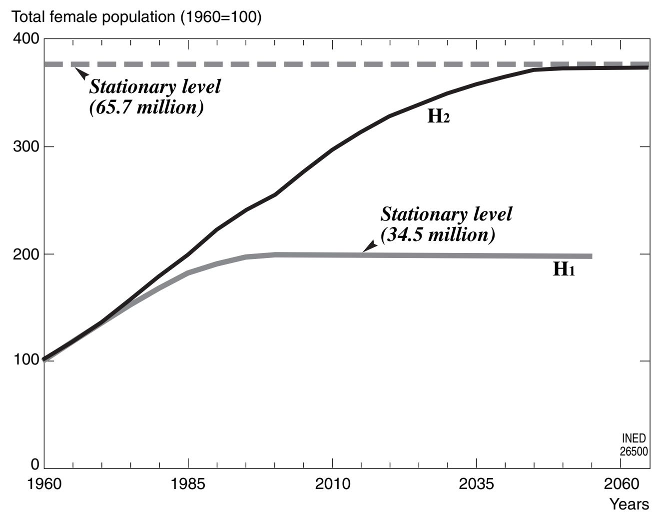

FIGURE 20–6 Century projection of total female population of Mexico in scenarios of Bourgeois-Pichat and Taleb (1960 = 100 = 17.5 million). (Source: Bourgeois-Pichat and Taleb; 1970. Un taux d'accroissement nul pour les pays en voie de développement en l'an 2000: rêve ou réalité? *Population*, vol. 25(5), p. 957–974.)

V. THE PROBLEM OF THE TWO SEXES

While highly useful for many applications, the theory of stable populations unfortunately suffers from a serious flaw: it is based on the simplifying assumption that the population consists of a single sex that reproduces itself, as it were, by parthenogenesis. For the sake of convenience, of course, demographers choose the female sex, since the general practice is to compute age-specific fertility rates for females. This is because the necessary information is easier to compile:

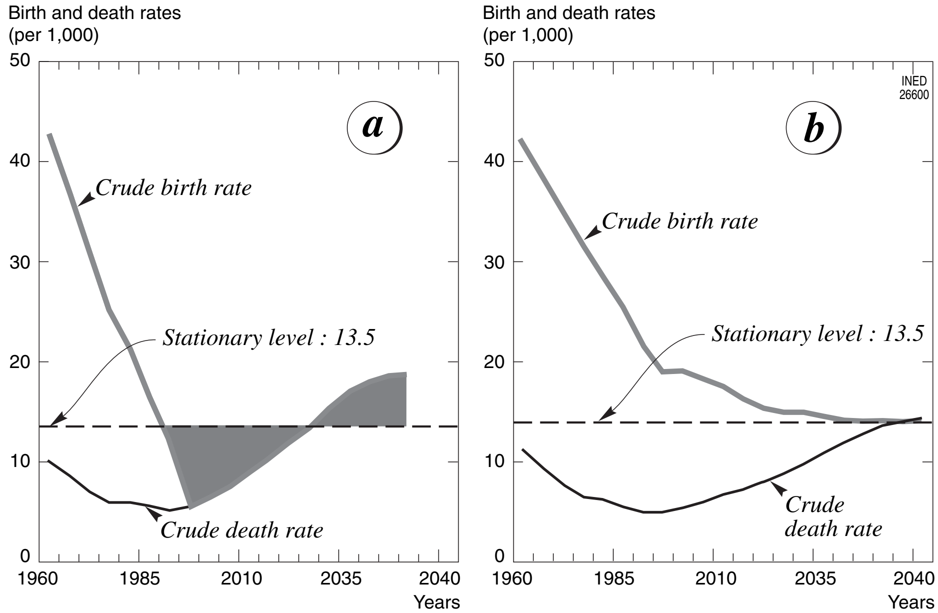

FIGURE 20–7 Changes in crude birth rate **(A)** and crude death rate **(B)** of Mexican female population, on basis of Bourgeois-Pichat and Taleb's two projections (1960 = 100 = 17.5 million). (Source: Bourgeois-Pichat and Taleb, 1970. Un taux d'accroissement nul pour les pays en voie de développement en l'an 2000: rêve ou réalité? *Population*, vol. 25(5), p. 957–974.)

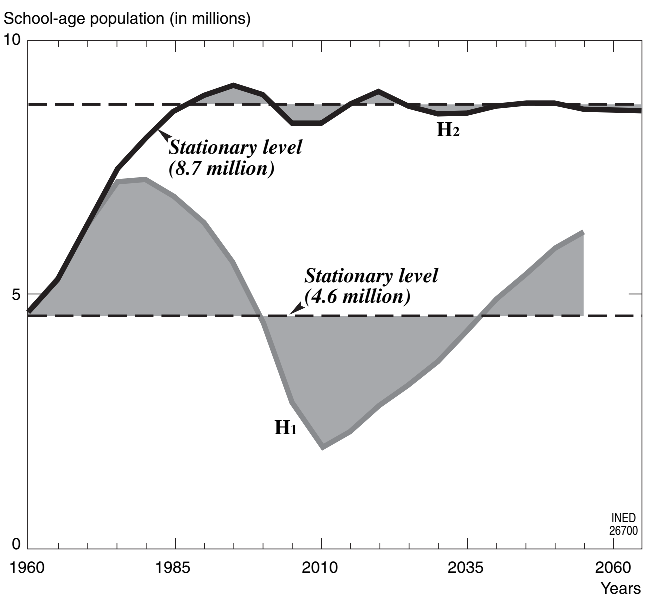

FIGURE 20–8 Change in school-aged population (5–14 years) in Mexican female population, on basis of Bourgeois-Pichat and Taleb's two projections (1960 = 100 = 17.5 million). (Source: Bourgeois-Pichat and Taleb, 1970. Un taux d'accroissement nul pour les pays en voie de développement en l'an 2000: rêve ou réalité? *Population*, vol. 25(5), p. 957–974.)

the reproductive period is shorter, and filial relation is easier to identify for births out of wedlock.

If male fertility rates are available—and they are seldom calculated even though it is often possible to do so (Brouard, 1977)—one could obviously repeat the process with an exclusively male population. On this point, it is interesting to note that, in 1907, when F. R. Sharpe and Alfred Lotka tried for the first time to model the growth of a human population, they used a male population and assumed that the growth of the female population simply had to be compatible with the hypothesis of constant male fertility and mortality.

In a very summary manner, demographers typically skirt the issue by linking a male population to the female population analyzed, on the assumption of a constant sex ratio at birth h (Bourgeois-Pichat 1994). This gives $B_f(t) = b_f N_f(0)e^{rt}$ for female births and $B_h(t) = hb_f N_f(0)e^{rt}$ for male births. The associated male population is therefore a Malthusian population with the same rates as the female population.

Clearly this procedure does nothing to solve the basic problem, which is that a population's fertility cannot be reduced to that of males or females only, but depends on the joint action of both sexes in couples: if we separate the sexes in the same initial population, we will end up with two stable models characterized by two different intrinsic growth rates. For example, Keyfitz (1968), reporting results for several countries, shows that, with the U.S. fertility and mortality of

1964, the intrinsic rate would have been 15.7/1000 using the female population and 17.5/1000 using the male population.

The problem is to determine whether we can refine the model to obtain the true intrinsic rate of the total population taking into account the behavior of each sex.

David Kendall (1949) was probably the first to raise the issue and attempt to solve it. He began by demonstrating the absurdity of a population projection based on an application to each sex of its own intrinsic rate. This would necessarily cause a divergence between the two fractions of the population, with a continuous shift in the sex ratio. Starting, for example, with the U.S. population of 1964, after 100 years, the number of males would be 19% greater than that of females, and after 200 years it would be 43% greater. Such a projection would ultimately eliminate one of the two sexes. Admitting different growth rates for the two sexes not only divorces us from the stable-population model from the outset, but also ultimately yields absurd results.

Leo Goodman (1953, 1967) has examined two approximate solutions, one with female dominance, the other with male dominance, depending on whether one applies female or male fertility. In either case, each sex is assigned its own mortality but, in the first case, male and female births depend on the proportion of females in the population; in the second, they depend on the proportion of males. In either case, the growth rates of the male and female populations converge and the sex ratio stabilizes, but at significantly different levels. The author then proposes a compromise solution, where he adjusts each of the two previous approaches by a factor that depends on the square root of the products of the proportions of males and females. In this case the difference between the two approaches is eliminated but the intrinsic sex ratio does not necessarily lie somewhere in between the two preceding ones; indeed, it can even diverge from these values sharply.

Another solution was proposed by Alfred Pollard (1948), in which the sons depend on the fathers and girls on the mothers. The intrinsic growth rate is given by:

$$r = \frac{T^*\rho^* + T\rho}{T^* + T}$$

where $T\times$ and T are the male and female intervals between two successive generations and $\rho\times$ and ρ the intrinsic male and female rates. This model, which is very ingenious as it eliminates all internal conflict, was expanded by Luitzen Yntema (1952).

These different hypotheses have also been discussed in the context of stochastic models (Goodman, 1967; Keyfitz, 1977). However, a full description of the human reproduction process would have to include the formation of couples and the measurement of their fertility. In societies where marriage is the sole locus of expression of fertility, one can imagine a model based on nuptiality[16] and marital fertility.[17] Indeed, some authors have tried to incorporate these two components into stable-population models (Pollard, 1948; Karmel, 1949; Keyfitz, 1977, 1985). But nuptiality poses two problems: the first, which is analogous to the one discussed earlier in this chapter, is that nuptiality is measured separately for the two sexes; the second is the fundamental difficulty of achieving consistency between the measurement of male and female behavior (Henry, 1968).

VI. FROM SEMISTABLE AND QUASI-STABLE POPULATIONS TO GENERALIZED STABLE EQUATIONS

Lotka's theory shows that if we apply constant fertility and mortality to any initial population, the population converges toward the stable state and a constant age structure independent of the initial age structure.

In the late 1960s, Bourgeois-Pichat showed that the stable-population equations could also apply, in some cases, to variable-growth populations. In particular, he distinguished between what he called semistable populations and quasi-stable populations (Bourgeois-Pichat 1966, 1971; United Nations 1968, 1972).

Subsequently, Neil Bennett and Shiro Horiuchi (1981), followed by Preston and Coale (1982), have shown that Lotka's model could be generalized to cases in which an initial population is assigned time-varying mortality and fertility functions: here as well, the age structure—which varies over time in this case—will nevertheless eventually be redefined independently of the initial population's age structure. This generalized model, often called the *r*-variable model, can also be defined with or without migrations.

1. Semistable and Quasi-stable Populations

In a posthumous volume, INED published the manuscript chapters that Bourgeois-Pichat had drafted to summarize his work on stable populations in preparation for a book that he unfortunately did not live

[16] See the Chapters 25, 26 and 27.
[17] See Chapter 29.

to complete. The gathering notably includes several chapters on semistable and quasi-stable populations (Bourgeois-Pichat, 1994).

a. Semistable Populations

The semistable population is a mathematical concept. It is a population whose age structure stays constant despite the variation in its growth parameters. When its fertility and mortality freeze, it therefore reaches the stable state immediately, whereas an ordinary population will only reach it—under the identical hypothesis—after some time. Bourgeois-Pichat (1994, p. 169) defines the semistable population's fundamental property as follows:

> the age-specific survival function *p(a,t)*, the age-specific fertility *f(a,t)* [*m(a,t)* in Lotka's notation], and the rate of change *r(t)* depend on time *t*, but are linked in a given instant t by relationships that are those of the stable population in *t*.

After demonstrating the concept's mathematical validity, Bourgeois-Pichat identified its usefulness as follows:

> [i]n reality, we observe many populations that, over time, preserve age structures subject to little if any variation. We may therefore qualify these as semistable populations. In consequence, we can apply to these real populations the formulas defined for the stable populations[18] (Bourgeois-Pichat, 1994, p. 116).

b. Quasi-stable Populations

The quasi-stable population is, on the contrary, an experimental concept that rests on the following observational fact: If we project a population with a constant age-specific fertility function but a mortality whose fluctuations are bounded by a network of model life tables, its age structure will vary little. In the same way as we can speak of a stationary population linked to a life table, we can speak of a semistable population linked to a network of model life tables. In fact, experience shows that a network of stable populations calculated on a universe of model tables can itself be virtually equated with the different stages of the quasi-stable population linked to this network (Bourgeois-Pichat, 1994). This is, therefore, another concrete field of application for stable-population equations.

[18] La fonction de survie selon l'âge a, *p(a,t)*, la fécondité par âge *f(a,t)* [*m(a,t)* dans la notation de Lotka] et le taux de variation *r(t)* dépendent du temps *t*, mais sont liés à un instant donné *t* des relations qui sont celles de la population stable à l'instant *t*.

dans la réalité, on observe beaucoup de populations qui conservent, au cours du temps, des compositions par âge, sinon invariables, du moins peu variables. On peut donc les assimiler à *des populations semi-stables. On peut alors appliquer* à *ces populations réelles les formules établies pour les populations stables.*

2. Generalized Equation in a Closed Population

In a period approach (Preston and Coale, 1982; Wunsch, 1989), with $D(a,t)$ and $N(a,t)$ as the deaths and the population aged a in t, we can write that $D(a,t) = -dN(a,t)$. According to the theory of partial derivatives, the total differential $dN(a,t)$ is equal to:

$$dN(a,t) = \frac{\partial N(a,t)}{\partial a} da + \frac{\partial N(a,t)}{\partial t} dt$$

which corresponds to the increases in age and time da and dt. The growth rate $r(a,t)$ of the population $N(a,t)$ as a function of time is therefore:

$$r(a,t) = \frac{1}{N(a,t)} \cdot \frac{\partial N(a,t)}{\partial t} dt$$

The instantaneous death rate in t, $D(a,t)/N(a,t)$, is equal to (Bennett and Horiuchi, 1981):

$$\begin{aligned}\mu(a,t) &= \frac{D(a,t)}{N(a,t)} \\ &= \left[\frac{1}{N(a,t)} \cdot \frac{\partial N(a,t)}{\partial t} da + \frac{1}{N(a,t)} \cdot \frac{\partial N(a,t)}{\partial t} dt\right]\end{aligned}$$

hence

$$\mu(a,t) = -\left[\frac{1}{N(a,t)} \cdot \frac{\partial N(a,t)}{\partial t} da + r(a,t)\right]$$

and last,

$$\frac{1}{N(a,t)} \cdot \frac{\partial N(a,t)}{\partial a} da = -[\mu(a,t) + r(a,t)]$$

Turning to the inverse functions and integrating from a to x, we obtain:

$$N(x,t) = N(a,t)e^{-\int_a^x \mu(x,t)dx - \int_a^x r(x,t)dx}$$

It will be recalled (Chapter 11) that $\exp\left[-\int_a^x \mu(x,t)dx\right]$ is the probability $_{(x-a)}p_a(t)$ of surviving from a to x measured on a period basis for year t. Hence:

$$N(x,t) = N(a,t)_{x-a}p_a(t)e^{-\int_o^a r(x,t)dx}$$

But, for a = 0, $N(a,t) = N(0,t)$, in other words, births $B(t)$ in year t. As a result:

$$N(a,t) = B(t)_a p_0(t)e^{-\int_o^a r(x,t)dx}$$

Within a birth cohort, we therefore have $N(a,t) = N(0,t-a)_a p_0(a)$, where $_a p_0(a)$ is the probability of survival from birth to age a in the cohort aged a in t and therefore born in $t - a$. In this case we must have the equality:

$$N(a,t) = B(t)_a p_0(t) e^{-\int_o^a r(x,t)dx} = N(0,t-a)_a p_0$$

and as

$$N(0,t-a) = N(0,t) e^{\int_{t-a}^{t} r(0,z)dz}$$

allowing for the variation in births between the instants t and $t - a$ (Arthur and Vaupel 1984), we obtain the generalized stable equation in the absence of migration:

$$N(a,t) = N(0,t)_a p_0(a) e^{-\int_{t-a}^{t} r(0,z)dz}$$

The demographic characteristics of the populations subject to this equation are

Crude birth rate:

$$b(t) = \frac{B(t)}{\int_0^\omega N(a,t)da} = \frac{1}{\int_0^\omega p(a,t) e^{-\int_0^a r(x,t)dx}}$$

Age structure:

$$c(a,t) = \frac{N(a,t)}{\int_0^\omega N(a,t)da} = b(t) e^{-\int_0^a r(x,t)dx} \cdot p(a,t)$$

and, introducing the age-specific fertility rates $m(a,t)$ in t, we obtain the *characteristic equation* that enables us to determine the current crude rate of increase:

$$1 = \int_0^\omega e^{-\int_0^a r(x,t)dx} p(a,t) m(a,t) da$$

These three relationships are the generalization of the properties prevailing in the stable state. It is easy to find these properties if we remember that, in the stable state, the growth rate $r(x,t)$ is constant over time. The characteristics of the stable population are thus merely a special case of these general relationships that apply to any closed population.

3. Extension to Migrations and Generalization to all Attrition or Accession Processes

We can take generalization one step further by incorporating the effects of migration flows.

a. General Formula

For this purpose, we must introduce a new function, the force of net emigration (Preston and Coale, 1982). Let $e(x,t)$ be this force at age x and in t. We have

$$N(a,t) = N(0,t)_a p_0(t) e^{-\int_a^x r(x,t)dx} e^{-\int_a^x e(x,t)dx}$$

In fact, as Preston and Coale (1982; p. 221, 227) write

> [N]othing limits us to recognizing only one form of *migration* or even one form of mortality. Any form of attrition or accession can be introduced into [the last equation] simply by recognizing that it must act analogously to migration or mortality from all combined causes. [The equation] is the basis of a surprisingly general set of relations. In particular, one can see that the age composition of any population at any moment (assuming only that age composition and its change through time are continuous) is completely determined by the rate of increase in the number at each age at the given moment, together with the rate of attrition (including negative attrition) at each age from each of a number of independently operating factors. To be more specific, if the rate of increase *r(x)* is known for each age x from 0 to the highest age attained, and if the values of i different attrition factors *i(x)* are also known, the age composition is completely determined and can readily be calculated; conversely, if the age distribution and all but one of the attrition factors are known, the rate of attrition for the omitted factor can readily be calculated.
>
> This set of relations is known in demography for particular instances, and the basic equation in differential form is familiar in mathematical biology and actuarial work, but the full (though simple) generalization seems to have escaped attention.

The general fundamental equation is:

$$N(a,t) = N(0,t) e^{-\int_a^x r(x,t)dx} e^{-\sum_i \int_a^x \mu_i(x,t)dx}$$

Applying this formula to the Swedish population of 1976, Preston and Coale (1982) reconstructed the population by year of age for 1976 from the year's births, the growth rate of the population at each age in 1976, the net age-specific emigration in 1976, and the period life table. The comparison with the real population shows that the error committed never exceeds 1 per thousand except at the oldest ages (over 95).

b. A Cohort Application to the Study of Relationships Between Movement and Structure

Horiuchi (1991) proposed a cohort application of the generalized equation to an open population to separate the effect on the change in the number of persons at each age observed at two given dates from the cohort-specific change in the number of births and in mortality and migration functions. The growth rate $r(a,t)$ of the population aged a in t may be expressed as a function of the rate of increase in births from one cohort to another, $r_B(t-a)$ and the effect of combined changes in the forces of mortality and net emigration, as follows:

$$r(a,t) = r_B(t-a) - \int_0^a \frac{\partial \mu(x,u)}{\partial u}dx - \int_0^a \frac{\partial e(x,u)}{\partial u}dx$$

where $\mu(a,t)$ and $e(a,t)$ are the forces of mortality and net emigration at age a in year t and where the derivatives must be established for $u = t - a + x$.

Using this formula, we can estimate the share of each of the three components (births, force of mortality, and force of net emigration) in the growth rate of the population at a given age, and we can therefore measure the impact of their evolution on the observed changes in population size.[19] Since the model rests on the age-specific forces of mortality and migration, it also enables us—in theory—to break down the total effects of the mortality and migration changes into the age-specific or age-group-specific effects of the changes in the two phenomena. As a rule, however, we do not know the age-specific and cohort-specific force of net emigration. But, if the age-specific population growth is known, we need only calculate two elements (here, the effect of births and the effect of mortality) in order to obtain the third as the difference between them. Here, of course, it is the third element that combines the specific effect concerned (the effect of migrations) and the interactions.

If we multiply each term of the equation by the population $N(a,t)$ aged a in t, we can distribute the absolute difference in population (between the two cohorts at age a) across the three factors. Consolidating the results obtained from age a to age b, we obtain the distribution for the absolute difference observed for the age group (a–b).

To assess the weight of each of the three factors on the relative change in the population's age structure $c(a,t)$, we must solve the following equation, given the formula for the age-specific composition in the r-variable model (Caselli and Vallin, 1990):

$$\frac{\partial c(a,t)}{\partial t} = \left[\frac{\partial N(a,t)}{\partial t}\cdot\frac{1}{N(t)} - \frac{N(a,t)}{N(t)}\cdot\frac{dN(t)}{dt}\frac{1}{N(t)}\right]$$

where $N(t)$ is the total population, or, more simply:

$$\frac{\partial c(a,t)}{\partial t} = \frac{1}{N(t)}\left[\frac{\partial N(a,t)}{\partial t} - c(a,t)\cdot\frac{dN(t)}{dt}\right]$$

[19] Except that the order in which the factors work is not taken into account (net emigration, for example, could have produced births and deaths). Only the direct effect is examined, not the interactions.

Since we have already used the equation yielding $r(a,t)$ to distribute the differences in population size at each age between the three effects (births, mortality, migrations), the last equation enables us to measure the role of each of the three factors in the age-structure variation.

We applied this model to French and Italian data to determine the influence of the natural-increase and migration components on the change in the proportion of elderly persons between 1952 and 1986. In Italy, for a total increase of 8 percentage points in the proportion of women aged 60 and older, we estimate that only 2 points were due to the steep fall in the number of births, more than 5 points were due to the decline in mortality, and a mere 0.7 to migration. In France, the contrast is even sharper, since the change in births has sharply slowed aging: this has almost entirely offset the aging effect of the decline in mortality (Table 20–3).

CONCLUSION

The principles of stable-population theory and their generalization have paved the way for a vast range of applications in two areas: the reconstruction of incomplete or defective data and the analysis of past and future population change. We will return to both issues throughout this treatise.

The reconstruction of incomplete data may involve compensating for the lack of detailed information on populations of the past or even of certain countries or regions today. Alternatively, we may want to assess the

TABLE 20–3 Respective Contributions of the Cohort-specific Changes in Births, Deaths, and Migrations to the Increase in the Proportion of Persons Aged 60 and Over, France and Italy, 1952–1986

Factors	France		Italy	
	Male, %	Female, %	Male, %	Female, %
Proportions of persons aged 60 and over				
1952	13.43	18.77	11.15	13.12
1986	15.34	21.14	16.15	21.14
1986–1952 difference	1.91	2.37	5.00	8.02
Contribution of change				
Births	–4.13	–5.04	1.48	1.99
Deaths	5.26	6.32	2.34	5.30
Migrations	0.78	1.09	1.17	0.73

quality or make up for the deficiencies of data collected in insufficiently reliable conditions. In all these applications, population models have yielded many procedures, often highly efficient. For demographers the world over, the stable populations defined by Coale and Demeny from their families of model life tables now play a rather similar role to what the log table used to represent for mathematicians. Many demographers have helped to develop methods based on population models for solving specific problems (Coale and Trussell, 1996). The UN (1967, 1983), realizing the value of these methods for improving our knowledge of the international demographic situation, has developed an array of instruments for use by countries with incomplete or deficient statistics.

Stable-population models have also powerfully contributed to the analysis of the demographic past and future. The theory of demographic transition—which will be abundantly referred to in the subsequent chapters of this treatise—rests on the following postulate: All populations undergo a crucial, historical phase of modernization that takes them from a quasi-stationary *old regime* characterized by high mortality and fertility to a modern regime, also quasi-stationary, in which these two natural-increase factors have fallen to distinctly lower levels. There is obviously a special link between the discussions on this theory and the use of population models. And both these discussions and these models underlie most of the population-projection studies that seek to forecast and explore the scenarios for future population change.

APPENDIX 20–1 Key Functions in Stationary, Stable, and Ordinary Populations

Function	Notation	Formula: Stationary population	Formula: Stable population	Formula: Ordinary population
Age structure	$c(a)$	${}_np_a$	$be^{-ra}p(a)$	$b(t)e^{-\int_0^a r(x,t)dx}\,p(a,t)$
Ratio of populations at two ages	$\frac{c(a+n)}{c(a)}$	${}_np_a$	$e^{-rn}\,{}_np_a$	$e^{-\int_a^{a+n} r(x,t)\,dx}\,{}_np_a$
Birth rate	b	$b=\frac{1}{\int_0^\omega p(a)da}$	$b=\frac{1}{\int_0^\omega e^{-ra}p(a)da}$	$b(t)=\frac{1}{\int_0^\omega p(a,t)e^{-\int_0^a r(x,t)dx}}$
Distribution of births by mother's age	$v(a)$	$p(a)m(a)$	$p(a)m(a)e^{-ra}$	$p(a,t)m(a,t)e^{-\int_0^a r(x,t)dx}$
Life expectancy at birth	e_0	$\frac{1}{b}$	$\frac{\int_0^\omega c(a)e^{ra}da}{b}$	$\frac{\int_0^\omega c(a,t)e^{\int_0^a r(x,t)dx}}{b}$
Net reproduction rate	R_0	1	$\int_0^\omega p(a)m(a)e^{-ra}da$	$\int_0^\omega p(a,t)m(a,t)e^{-\int_0^a r(x,t)dx}da$
Life expectancy in a state G[1]	e_0^G	$\frac{\int_0^\omega g(a)c(c)da}{b}$	$\frac{\int_0^\omega g(a)c(a)e^{ra}da}{b}$	$\frac{\int_0^\omega g(a,t)c(a,t)e^{\int_0^a r(x,t)dx}}{b}$
No. persons aged a^* in terms of deaths after age a^*	$N(a^*)$	$\int_{a^*}^\omega D(a)da$	$\int_{a^*}^\omega D(a)e^{r(a-a^*)}da$	$\int_{a^*}^\omega D(a,t)e^{\int_{a^*}^a r(x,t)dx}da$
No. persons aged a^* in terms of deaths before age a^*	$N(a^*)$	$N(0)-\int_0^{a^*}D(a)da$	$e^{ra^*}\left[N(0)-\int_0^{a^*}D(a)e^{ra}da\right]$	$e^{\int_0^{a^*} r(x,t)dx}\left[N(0,t)-\int_0^{a^*}D(a,t)e^{\int_0^a r(x,t)\,dx}da\right]$
Probability of survival from a^* to a^*+1, in terms of deaths	${}_np_a$	$\frac{\int_{a^*+n}^\omega D(a)da}{\int_{a^*}^\omega D(a)da}$	$\frac{\int_{a^*+n}^\omega D(a)e^{r(a-a^*)}da}{\int_{a^*}^\omega D(a)e^{r(a-a^*)}da}$	$\frac{\int_{a^*+n}^\omega D(a,t)e^{\int_{a^*}^a r(x,t)dx}da}{\int_{a^*}^\omega D(a,t)e^{\int_{a^*}^a r(x,t)dx}da}$

a. *g(a)* is the incidence at age *a* of state *G*.
b. Notation *a* gives exact age; notation *a** gives age in complete years.

PART

V

FROM HOMOGENEITY TO HETEROGENEITY

New Ways Forward for Demographic Analysis

GRAZIELLA CASELLI AND JACQUES VALLIN

To illuminate the fundamental mechanisms of population dynamics, we were obliged in the foregoing chapters, to oversimplify the realities by making two *fundamental assumptions*: (1) all the individuals in a population are, if not identical, at least exposed to completely equal mortality, fertility, and migration risks (the continuity or homogeneity hypothesis); (2) the probabilities of dying, procreating, and migrating are completely independent (independent events hypothesis). This is obviously not the case in real life. So the analysis needs to be fine-tuned to clarify how the *heterogeneity of a population* can distort the measurement of changes in it, and how to go beyond the independent events hypothesis.

One presumptive advantage of using the birth cohort as the unit of analysis, as we have done, is specifically that it enables us to work on more homogeneous sets of individuals than those of a hypothetical cohort constructed from data from as many different cohorts, with their different life experiences, as of ages observed. There is not even complete homogeneity within birth cohorts, in fact. As well as being genetically and biologically diverse, the constituent individuals have a different cultural baggage—either transmitted from their parents or self-acquired during life—belong to different social classes, live in salubrious or unsanitary conditions, and so forth—that tend to refute the argument that all are exposed to exactly the same risks of death, procreation or migration. It is clear that internal heterogeneity (within the same birth cohort or within a same-age population) can be at least partly offset by distinguishing subpopulations by attributes or characteristics relevant to the purpose of analysis, like socio-professional categories for mortality, educational levels for fertility, and so forth. However, the data necessary to correlate all the attributes or characteristics capable of influencing the phenomena studied are rarely available. Taking this to its logical extreme would run the considerable risk of having to take each individual in isolation from all others, which would completely negate any statistical approach. Identifying homogeneous groups of individuals at a given time does not mean that these groups will remain so throughout the period during which their demographic behaviors are to be measured. The degree of heterogeneity may increase or decrease as the individuals live their lives, constantly changing states for a particular attribute or characteristic. Chapter 21 first takes a general look at the *concealed population heterogeneity* as illustrated by the analysis of mortality. Chapter 22 goes beyond the limits of traditional migration analysis to redefine the concepts of mobility associated with different levels of spatial organization and addresses the linkages between internal mobility and the spatial distribution of a population. *Life history analysis* methods (Chapter 23) will take the process a step further by simultaneously countering the homogeneity and independent event hypotheses. Finally, it will be seen that the life history analysis used to account for interaction of phenomena leads to multiple possible levels of aggregation. As a result, the final chapter of this volume (Chapter 24) will consider *multilevel analysis*. Part V, therefore, marshals new approaches intended to overcome the problems of traditional analysis in preparation for moving on from a descriptive analysis of demographic phenomena to explaining the determinants of change, which will be looked at in Section II of Volume I and in Volume II of this treatise.

Unobserved Population Heterogeneity

JAMES W. VAUPEL AND ANATOLI I. YASHIN
Max Planck Institute for Demographic Research, Rostock, Germany

I. POPULATION HETEROGENEITY

All populations are heterogeneous. In demographic analyses, two dimensions of individual differences (age and sex) generally are observed. Many other characteristics may be observed, including date and place of birth, urban versus rural residence, marital status, nationality, religious affiliation, number of children, number of siblings, age of mother and father at an individual's birth, household structure, socioeconomic status, educational achievement, occupation, spouse's occupation, smoking behavior, diet, height, environmental quality at current residence, health status, cognitive and physical functioning, genotype, and so forth. In even the most thorough study, however, most attributes of individuals are not measured. Indeed, most studies focus on only a handful or two of the multitudinous dimensions of differences that distinguish one individual from another.

Observed heterogeneity creates various analytic opportunities for demographers. Multiple regression analysis, logit and probit analysis, survival analysis, and other statistical methods have been developed to estimate the impact of observed covariates. These methods are treated in other chapters and in standard textbooks, and will not be reviewed here.

Unobserved heterogeneity creates analytic problems rather than analytic opportunities: unobserved heterogeneity is a nuisance, a headache, a bête noire. Unobserved heterogeneity creates difficulties for demographers because demographers study how population characteristics change over age and time and place (and unobserved heterogeneity distorts observed patterns of change).

II. COMPOSITIONAL CHANGE

The root of the problem is that the members of population cohorts gradually die off or drop out. Animals and plants die, machines break down, bachelors marry, the married divorce, the childless give birth, those with one child have a second, children leave parental homes, students complete their education, the unemployed find jobs, the well get sick, and the ill recover. Much of demographic analysis focuses on the transition rates associated with such changes. In many instances, demographers are interested in how transition rates vary with age: They study, for instance, age-specific death rates and marriage rates. In other cases, duration matters, as in studies of recovery rates from an illness or divorce rates as a function of the duration of a marriage. In analyses of first, second, and subsequent births, birth rates by parity and time since last birth are of interest.

Hence, much of demographic analysis concerns the estimation and comparison of drop-out rates in cohorts that are changing because their members are dropping out. The problem is that those who drop out probably have a greater tendency to drop out than those who do not. People who die at some age tend to be frailer or more susceptible or at higher risk than those who survive to an older age. Couples who conceive after a month or two of trying may be more fecund than those who first conceive after many months. Marriages that quickly end in divorce may have been shaky marriages from the start. Thus, the composition or structure of a heterogeneous cohort changes as the cohort dies off. The frail or susceptible tend to die first, leaving a more robust surviving cohort.

III. THREE LEVELS OF EXPLANATION

Age- or duration-specific changes in birth, marriage, death, and other transition rates can be interpreted in three alternative ways that might be called level 0, level 1, and level 2 explanations. A level 0 explanation is that the data are erroneous. A level 1 explanation is that the observed change is produced by a corresponding change at the individual level. A level 2 explanation is that the observed change is an artifact of a change in the structure of the population (i.e., a change in the composition of a heterogeneous cohort).

Consider the report that the increase in mortality with age slows at the oldest ages (Vaupel *et al*. 1998; Thatcher, Kannisto, and Vaupel 1998). A direct, level 1 explanation would be that for individuals at advanced ages the probability of death increases relatively gradually with age. A level 0 explanation (bad data) would be that death rates at advanced ages are distorted by age-misreporting problems and that the apparent deceleration of mortality is a consequence of age exaggeration. Finally, a level 2 explanation would be that the leveling off of death rates after age 100 might be "caused by decreases in the average frailty of a population cohort at later ages as frailer members are removed by mortality" (Vaupel *et al*., 1979).

Observed patterns of mortality deceleration in different populations are almost certainly due to a mix of these three levels of explanation, with the importance of the different explanations differing from population to population. In almost all populations there are problems with age-misreporting at advanced ages and in many populations such misreporting is very severe (Jeune and Vaupel, 1999). All populations are heterogeneous, so level 2 explanations must have some validity, although it is currently unclear how much of the deceleration can be explained by compositional change. The level 1 explanation that individuals age more slowly at advanced ages may be partially right—or completely wrong. There is some suggestive evidence that for individuals the chance of death actually rises faster than exponentially at advanced ages, even though population death rates are increasing slower than exponentially (Yashin and Iachine, 1997).

At least since Edmund Halley (1693), demographers have recognized the importance of level 0 and level 2 explanations as alternatives to direct level 1 explanations. All careful demographers are aware of the prevalence of bad data and all well-trained demographers know that demographic rates can differ because of differences in population composition. Nonetheless, level 1 explanations—that what is observed on the population level also holds on the individual level—seem so natural that even careful demographers often find themselves naively and uncritically slipping into direct interpretations of population changes and differences (Vaupel and Carey, 1993).

IV. FRAILTY MODELS

Demographers try to distinguish between type 1 and type 2 explanations using frailty models (Vaupel *et al*., 1979) and the statistical methods of survival analysis (Cox and Oakes, 1984). In this approach, the trajectory of a cohort's rate of death or exit is usually captured by either the survival function $s(x)$ or the hazard function $\mu(x)$. Demographers call this hazard function the *force of mortality* when they are studying death rates and in some contexts the term *intensity* is used instead of hazard. The survival function and the hazard function are interrelated by the following two formulas:

$$\mu(x) = -\frac{ds(x)/dx}{s(x)} \qquad \text{(Eq. 1a)}$$

and

$$s(x) = e^{-\int_0^x \mu(t)dt} \qquad \text{(Eq. 1b)}$$

In the simplest case there is no information about the characteristics of the individuals in the cohort except age (and whatever characteristics describe the cohort as a whole, such as "males born in France in 1948").

Because all populations are heterogeneous, it makes sense to model the population as a mix of homogeneous subpopulations (which might each consist of a single individual). Let $s(x,z)$ be the survival function for the subpopulation with *frailty z*, where frailty in this context simply refers to the susceptibility or liability of the subpopulation to the hazard. In general, frailty models are designed such that the greater an individual's frailty, the greater the individual's susceptibility or liability to the hazard of interest.

Let $\bar{s}(x)$ be the survival function for the population as a whole, such that

$$\bar{s}(x) = \int_0^\omega s(x,z)g(z)dz \qquad \text{(Eq. 2a)}$$

in the continuous case, where $g(z)$ is the probability distribution of z at age zero and

$$\bar{s}(x) = \sum_z \pi(z)s(x,z) \qquad \text{(Eq. 2b)}$$

in the discrete case, where $\pi(z)$ is the proportion of the cohort in subpopulation z at age zero. This general frailty model can be more specifically formulated in several ways.

1. Relative-Risk Models

One specification is the *proportional-hazards* or *relative-risk* model

$$\mu(x,z) = z\mu(x) \qquad \text{(Eq. 3a)}$$

or, equivalently,

$$s(x,z) = s(x)^z \qquad \text{(Eq. 3b)}$$

which was suggested by Vaupel *et al*. (1979). In this model, $\mu(x)$ is the baseline, standard, underlying hazard for individuals of frailty one and $s(x)$ is the corresponding survival function. Vaupel *et al*. (1979) show that

$$\bar{\mu}(x) = \bar{z}(x)\mu(x) \qquad \text{(Eq. 4)}$$

where $\bar{z}(x)$ is the average frailty of those alive at age x. Because z is fixed and does not vary with age, $\bar{z}(x)$ declines with age as the frail drop out of the cohort. Hence, $\bar{\mu}(x)$ increases more slowly than $\mu(x)$ does. Indeed, $\bar{\mu}(x)$ can be declining even though $\mu(x)$ is rising.

For this model z is often taken to be gamma distributed with mean 1 and variance σ^2, because this gamma distribution leads to convenient mathematic relationships. In particular, for gamma-distributed frailty

$$\bar{z}(x) = \left(1 + \sigma^2 \int_0^x \mu(t)dt\right)^{-1} = \bar{s}(x)^{\sigma^2} \qquad \text{(Eq. 5)}$$

where $\bar{s}(x)$ is the survival function for the population as a whole. It follows from Equation 5 that

$$\bar{s}(x) = (1 - \sigma^2 \ln s(x))^{-1/\sigma^2} \qquad \text{(Eq. 6)}$$

As a specific example of this kind of gamma-frailty relative-risk model, suppose that mortality on the individual level follows a Gompertz trajectory:

$$\mu(x) = ae^{bx} \qquad \text{(Eq. 7)}$$

It follows from Equations 4 and 5 that the population trajectory of mortality will follow the logistic pattern

$$\bar{\mu}(x) = \frac{ae^{bx}}{1 + \frac{a\sigma^2}{b}(e^{bx} - 1)} \qquad \text{(Eq. 8)}$$

leveling off at a value of b/σ^2.

2. Accelerated-aging Models

Another specification is the accelerated-aging model

$$\mu(x,z) = \mu(xz) \qquad \text{(Eq. 9)}$$

which is analogous to the accelerated-failure model used in reliability engineering. In the special case where $\mu(x)$ follows the Weibull trajectory

$$\mu(x) = ax^b \qquad \text{(Eq. 10)}$$

where a and b are parameters, this model is equivalent to the relative-risk model, because

$$a(zx)^b = z^b ax^b = z'\mu(x) \qquad \text{(Eq. 11)}$$

In the special case where $\mu(x)$ follows the Gompertz trajectory, given in Equation 7, the accelerated-aging model is of the form ae^{zbx} whereas the relative-risk model is of the form zae^{bx}. Small changes in the slope parameter b can have larger effects on mortality at older ages than big changes in the level parameter a. Hence, much less heterogeneity is needed in an accelerated-aging Gompertz model than in a relative-risk Gompertz model to produce substantial differences between $\mu(x)$ aand $\bar{\mu}(x)$ at older ages. This is illustrated in Figure 21–1.

3. Discrete Frailty Models

The discrete frailty model is also a useful specification of the general frailty approach, as discussed by Vaupel and Yashin (1985). In this case,

$$\mu(x,z) = \mu_z(x) \qquad \text{(Eq. 12)}$$

Thus, z is now an index for the different subpopulations, each of which has a hazard function. Let π_z be the proportion of the population in subpopulation z at age zero. Then

$$\bar{s}(x) = \sum_z \pi_z s_z(x) \qquad \text{(Eq. 13)}$$

and

$$\bar{\mu}(x) = \sum_z \pi_z s_z(x)\mu_z(x) \Big/ \sum_z \pi_z s_z(x) \qquad \text{(Eq. 14)}$$

If it is assumed that z is a relative-risk factor, then $\mu_z(x) = z\mu(x)$ and $s_z(x) = s(x)^z$. Heckman and Singer (1984) suggested that this specification be used to

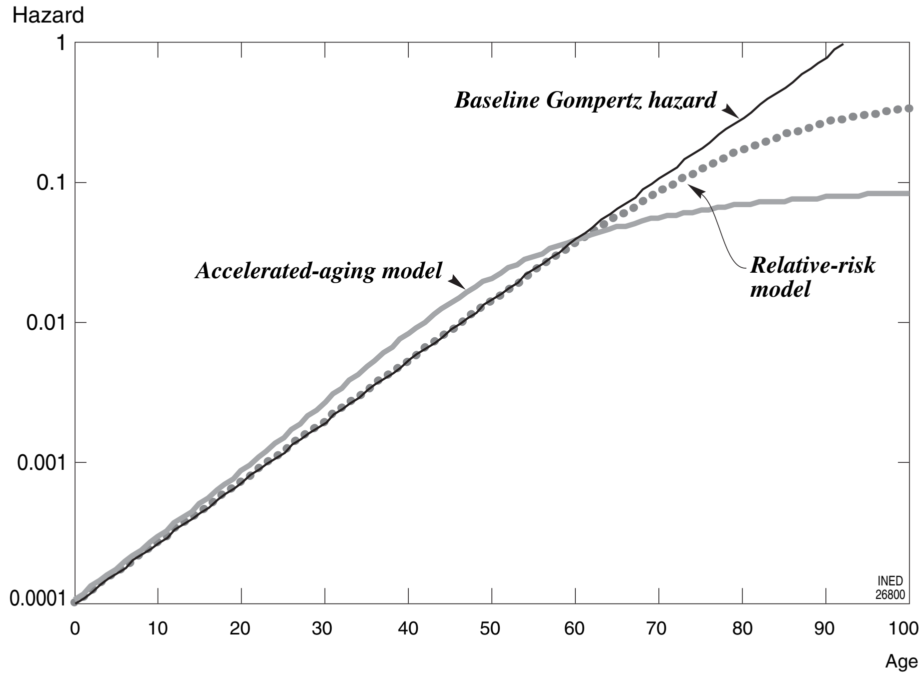

FIGURE 21–1 The accelerated-aging model can produce greater mortality deceleration with less heterogeneity than the relative-risk model baseline Gompertz hazard with $a = 0.0001$ and $b = 0.1$ compared with population hazard in relative-risk model with $\sigma^2 = 0.25$ and in accelerated-aging model with $\sigma^2 = 0.05$. Note that hazards are shown on a log scale.

control for the effects of hidden heterogeneity when fitting models to data. More generally, however, $\mu_z(x)$ can take on a different functional form for each value of z.

A simple example of discrete frailty models is the mover–stayer model (Blumen *et al.*, 1955) in which one group in the population is susceptible to emigration, marriage, divorce, or some disease and the other group is immune. Let π be the proportion of the population that is susceptible. Thus it follows from Equation 14 that

$$\bar{\mu}(x) = \pi s(x)\mu(x)/(\pi s(x) + 1 - \pi) \qquad \text{(Eq. 15)}$$

Even if $\mu(x)$ steadily increases, $\bar{\mu}(x)$ will eventually decline as $s(x)$ approaches zero. Figure 21–2 shows an illustrative example.

Divorce rates in some countries and periods follow the kind of rising–falling pattern shown in Figure 21–2. Does this imply that marriages are shakiest after a few years of marriage? Not necessarily, as Figure 21–2 illustrates. The same general effect could be produced if the second group were not immune but simply at low risk. Indeed the rising–falling pattern could be produced if the hazard steadily increases for the high-risk group but steadily decreases for the low-risk group. For one group marriages strengthen with duration, whereas

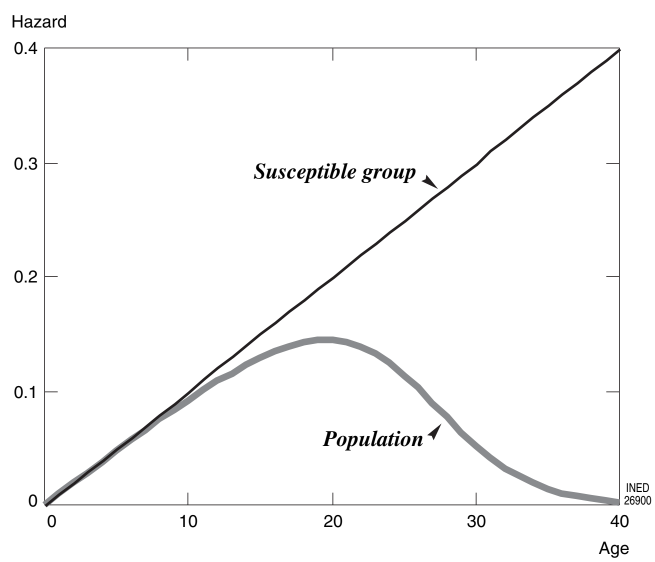

FIGURE 21–2 The population hazard may increase and then decline if the hazard rate for one group is increasing and the other group is immune. The hazard for the susceptible group is $\mu(x) = 0.01x$. It was assumed that 95% of the population is susceptible.

for the other, marriages weaken (despite the appearance of the curve for the entire cohort, there is no divorce hump).

4. Changing Frailty Models

As Box (1979) asserted, all models are wrong, but some models are useful. It is often useful to define an individual's frailty as fixed, at least after some age, and to classify individuals into groups depending on their frailty at that age. Alternatively, it may sometimes be useful to develop models in which an individual's frailty can change with time or age.

In one simple model of this kind, all individuals start out with frailty one. They suffer a hazard of death of $\mu_1(x)$ at age x. They also are subject to the hazard $\lambda(x)$ that their frailty will change from one to two, in which case their hazard of death changes to $\mu_2(x)$. The second state might be associated with some morbid event, such as having a heart attack or losing the ability to walk. Alternatively, the hazard of *death* could be the hazard of divorce and the event could be having a baby. Let $s_1(x)$ denote the proportion of the cohort that is alive with frailty one at age x and let $s_2(x)$ similarly denote the proportion of the cohort that is alive with frailty two at age x. In the simplest case when the three hazards functions are constant, it is not difficult to show that

$$s_1(x) = e^{-(\mu_1+\lambda)x} \quad \text{(Eq. 16a)}$$

and

$$s_1(x) = \frac{\lambda}{\mu_1+\lambda-\mu_2}\left(e^{-\mu_2 x} - e^{-(\mu_1+\lambda)x}\right) \quad \text{(Eq. 16b)}$$

The population hazard is given by

$$\bar{\mu}(x) = \frac{\lambda\mu^2 e^{(\mu_1+\lambda-\mu^2)x} + (\mu_1-\mu_2)(\mu_1+\lambda)}{\lambda e^{(\mu_1+\lambda-\mu_2)x} + (\mu_1-\mu_2)} \quad \text{(Eq. 17)}$$

At age zero, $\bar{\mu}(0) = \mu_1$ and as x approaches infinity, $\bar{\mu}(x) = \mu_2$ if $\mu_2 \leq \mu_1 + \lambda$ and $\bar{\mu}(x) = \mu_1 + \lambda$ otherwise.

Hervé Le Bras (1976) and Leonid Gavrilov and Nathalia Gavrilova (1991) proposed generalizations of this model. Instead of two states of frailty, suppose that frailty z can equal any nonnegative integer. Initially everyone has frailty zero. People with frailty z face a hazard of death of $\mu_o + z\mu$ as well as a hazard of $\lambda_o + z\lambda$ that their frailty will change to $z + 1$. Although μ_o, μ, λ_o and λ are constants and do not vary with age or time, the population hazard $\bar{\mu}(x)$ follows a logistic trajectory. Anatoli Yashin, James Vaupel, and Ivan Iachine (1994) show that this trajectory is identical to the trajectory obtained if frailty is fixed and gamma distributed and the baseline hazard is of the Gompertz form $\mu(x) = ae^{bs}$ with $\mu(x, z) = z\mu(x) + c$, where c is the constant Makeham term. Without ancillary information it is impossible to tell whether frailty is fixed or frailty is changing.

Instead of only taking on discrete values, frailty can be modeled to vary continuously. Vaupel, Yashin, and Kenneth Manton (1988), for instance, develop a changing-frailty model based on a stochastic differential equation. They apply the model to clarify the interaction of debilitation, recuperation, selection, and aging. The model yields various insights about lingering mortality consequences of disasters such as wars, famines, and epidemics that may weaken the survivors. A key result is that debilitation and selection are interdependent: debilitation that increases population heterogeneity will result in subsequent mortality selection; selection, by altering the distribution of frailty, will influence the impact of debilitating events. The basic equation of the model is

$$\mu(x,z) = \mu_o(x) + z(x)\mu_*(x) \quad \text{(Eq. 18)}$$

where $\mu_o(x)$ is the baseline hazard, $\mu_*(x)$ determines the additional hazard, and $z(x)$ is the frailty of the individual at age x as given by

$$z(x) = Y^2(x) \quad \text{(Eq. 19)}$$

where $Y(0)$ is normally distributed and

$$dY(x) = [a_o(x) + (a_1(x) - a_2(x))Y(x)]dx + b(x)dW(x) \quad \text{(Eq. 20)}$$

where W is a Wiener process with $W(0) = 0$. The functions a_o and a_1 represent the effects of debilitation whereas a_2 represents homeostatic healing and recuperation; the function b determines the importance of the Wiener process term.

5. Correlated-Frailty Models

Because of shared genes and a shared childhood environment, two twins may have similar frailties. More generally, relatives or people who live in the same environment may have similar frailties. As discussed by Vaupel (1990 and 1991), shared-frailty models can be used to analyze such situations, but a more appropriate and powerful approach involves the correlated-frailty models developed by Yashin and colleagues and explained in Yashin, Vaupel, and Iachine (1995) and Yashin and Iachine (1997).

A simple variant of this kind of model involves pairs of twins, with one twin having fixed frailty z_1 and the other twin having fixed frailty z_2 and with the hazard of mortality given by $\mu(x, z_i) = z_i\mu_o(x)$, $i = 1,2$. The correlation between the two frailties is modeled as follows. Let

$$z_1 = y_o + y_1 \quad \text{(Eq. 21a)}$$

and let

$$z_2 = y_o - y_2 \quad \text{(Eq. 21b)}$$

where the y_i, $i = 0,1,2$, are three independent random variables that are gamma distributed with the same scale parameter. The gamma distributions of y_1 and y_2 have the same shape parameter, but this parameter may differ for y_o. The frailties z_1 and z_2 are constrained to have a mean of one and they have the same variance σ^2. The values of σ^2 and ρ, the correlation coefficient between the two frailties, are simple functions of the scale and shape parameters.

As shown by Yashin, Vaupel, and Iachine (1995), the bivariate survival function for the population of twins is given by $\bar{s}$

$$\bar{s}(x_1,x_2) = \bar{s}(x_1)^{1-\rho}\,\bar{s}(x_2)^{1-\rho}(\,\bar{s}(x_1)^{-\sigma^2} + \bar{s}(x_2)^{-\sigma^2} - 1)^{-\rho/\sigma^2} \quad \text{(Eq. 22)}$$

Because the survival of adult twins is very similar to the survival of adult singletons, in studies of adult mortality the function $\bar{s}(x)$ can be taken from demographic life tables for the general population. In this case the bivariate survival function depends only on σ^2 and ρ; no assumptions have to be made about the shape of a baseline hazard function. Using Equation 22 values of σ^2 and ρ can be estimated using the kind of maximum-likelihood estimation described below. Then the baseline survival function can be calculated by rearranging Equation 6 as follows:

$$s(x) = \exp((1 - \bar{s}(x)^{-\sigma^2})/\sigma^2) \quad \text{(Eq. 23)}$$

and $\mu(x)$ can be calculated from Equation 1. Applying this model to survival data on Danish twins born between 1870 and 1900, Yashin and Iachine (1997) found that the baseline hazard of mortality increases faster than exponentially after age 30 even though the population hazard of mortality decelerates at advanced ages. That is, it is possible that the observed leveling off of mortality may be entirely accounted for by a level 2 explanation (compositional change due to mortality selection) and the actual trajectory of mortality for individuals may rise more rapidly than a Gompertz curve.

V. EMPIRICAL DATA

The survival or duration data used in fitting frailty models is often of the following form. There are n individuals in some cohort, with observed ages at death X_i, $i = 1, \ldots, n$. More generally, X_i stands for age at some event, such as marriage, or some duration, such as time from marriage to divorce. For simplicity, we will refer to X_i as age at death.

Age at death may not be known for all individuals: it may only be known that the individual survived at least until some age. These are called *right-censored observations*. They can arise if some individuals never "die" (e.g., some women never give birth, some people never marry, some married people never divorce). They can also arise if some individuals are still alive at the end of a study or if some individuals drop out of the study and are lost to follow-up.

It may also be the case that it is only known that individual i died between age x_1 and age x_2. And it may be the case that an individual is not followed from age zero but from some age x_o, so that the individual is only at risk of dying after age x_o. These are called *left-censored* or *left-truncated observations*.

Various covariates may be observed: We will let w_{ij} denote the value of the j-th covariate for individual i.

VI. METHODS OF PARAMETER ESTIMATION

Various methods may be used to fit frailty models to empirical survival or duration data. In an important article on deceleration in the age pattern of mortality at older ages, Shiro Horiuchi and John Wilmoth (1998) estimate the parameters of a Gompertz–Makeham model with period effects and unobserved frailty by a weighted-least-squares procedure. They carefully document the method they use, so their article is of pedagogic value as well as being of substantive interest.

It is more common, however, to use maximum-likelihood methods in analyses of survival or duration data in general and in fitting frailty models in particular. We recommend a textbook such as that by David Cox and David Oakes (1984) for discussion of this approach. Here we adumbrate a few points of particular relevance to the estimation of parameters of frailty models.

The likelihood of an observation X_i can be thought of as the probability of observing this value given a particular model with specific parameter values. More generally, the likelihood can be proportional to the probability instead of being equal to the probability, because any parameter values that maximize the probability of the data will also maximize any quantity that is proportional to the probability. Let $s_i(x)$ be the probability of surviving from age 0 to age x, for some individual with a vector of covariates w_i and with some unobserved frailty z. Then, if age at death X_i is observed and if the individual is followed from age zero, the likelihood of the observed age at death is $\mu_i(X_i)s_i(X_i)$. If it is only known that the individual survived at least to age X_i, the likelihood of this observation is $s_i(X_i)$. If it is known that the individual died between ages X_{1i} and X_{2i}, then the likelihood of this datum is $s(X_{1i}) - s(X_{2i})$. If the individual is first observed at age X_{1i} and then dies at age X_{2i}, then the likelihood is $\mu(X_{2i})s(X_{2i})/s(X_{1i})$.

It is customary in survival analysis to make calculations in terms of the logarithm of the likelihood, the log-likelihood, because the likelihood of a data set is often extremely small. Let $L(X_i)$ denote the log-likelihood of the observation. The log-likelihood of the entire data set is given by the sum of all the $L(X_i)$'s. The maximum-likelihood estimate of the parameter values in a model is the estimate that maximizes the likelihood or, equivalently, the log-likelihood of the data.

The effect of observed covariates on survival can be modeled in many ways. Because our focus here is on hidden heterogeneity and not on general methods of survival analysis, we restrict our attention to the simple case in which the covariates are fixed (rather than changing over time). Furthermore, we will assume that the impact of the covariates on an individual's hazard is given by $W_i\mu_i(x, z)$, where W_i is the net relative-risk imposed by the vector of observed covariates. Often in survival analyses, W_i is modeled by $W_i = e^{\sum_j b_j w_j}$, where the b_j's are coefficients that are estimated.

For ease and conciseness of exposition we will consider only the relative-risk frailty model with gamma-distributed frailty. For the relative-risk model (Equation 3b),

$$s_i(x) = s(x)^{W_i z} \qquad \text{(Eq. 24)}$$

where $s(x)$ is the baseline or standard survival function for individuals of frailty 1 and with an estimated relative-risk W_i of 1. In the special case of gamma-distributed frailty, it follows from formula (6) that

$$\bar{s}_i(x) = (1 - \sigma^2 W_i \ln s(x))^{-1/\sigma_2} \qquad \text{(Eq. 25)}$$

where $\bar{s}_i(x)$ is the probability that an individual with estimated relative-risk W_i will survive to age x and where σ^2 is the variance of frailty. The bar over the s indicates that $\bar{s}_i$ is an average: unobserved frailty z is removed from the formula by taking the expected value of s with respect to z. The corresponding value of $\bar{\mu}_i(x)$ can be calculated by Equation 1 and the log-likelihood $L(x)$ can then be calculated as indicated above.

A remaining issue is how to estimate the baseline survival function $s(x)$. There are two approaches to this. First, a parametric form can be assumed. For instance, it might be assumed that $s(x)$ [and $\mu(x)$] are of the Gompertz or Weibull form. Kenneth Manton, Eric Stallard, and James Vaupel (1986) provide an example of this kind of analysis.

Alternatively, $s(x)$ can be estimated nonparametrically. That is, values of $s(x)$ can be estimated for a sequence of ages over some age range without imposing any assumptions on the shape of the trajectory of $s(x)$. Several different methods of nonparametric estimation have recently been proposed and research in this area is rapidly developing. Here we sketch one method, to illustrate the general idea of nonparametric estimation.

Suppose that the survival data that are available for analysis are based on a large random survey of some population. Further suppose that survival in the population is known, perhaps from vital-statistics data. Let $\bar{\bar{s}}(x)$ be the survival curve for the population. As above, let $\bar{s}_i(x)$ be the survival function for the individual i in the survey. For a large random survey, the following equation might approximately hold:

$$\bar{\bar{s}}(x) = \sum_{i=1}^{n} s_i(x)/n \qquad \text{(Eq. 26)}$$

If so, the following method could be used. For the relative-risk gamma-frailty specification, Equation 25 can be substituted in Equation 26, yielding

$$\bar{\bar{s}}(x) = \sum_i (1 - \sigma^2 W_i \ln s(x))^{-1/\sigma^2} \Big/ n \qquad \text{(Eq. 27)}$$

For any specific set of estimated values for W_i and σ^2, one and only one value of $s(x)$ will satisfy this equation. Hence, σ^2 and the coefficients that determine W_i can be determined by maximum-likelihood estimation under the constraint that Equation 27 holds.

The theoretical and practical properties of this algorithm still need to be investigated. Many other estimation procedures that do not require parametric estimation of $s(x)$ are being developed and various imputation methods, EM algorithms, and other concepts might be used (see, e.g., Andersen, Borgan, Gill, and Keiding, 1993). The statistical estimation of frailty models is currently a hot topic of statistical research and the coming decade is likely to produce major advances in the development of powerful, practicable procedures.

CONCLUSION

The frailty models and parameter-estimation methods sketched above are not yet available as part of easy-to-use computer software packages. Several software packages, however, include convenient options for fitting other kinds of models to survival and duration data. In particular, David Cox (partial likelihood) regression can be readily applied to empirical observations. Why bother with frailty models when Cox regression can be used to estimate the coefficients of covariates in hazards models? There are three main reasons.

First, Cox regression yields coefficient estimates that tend to be biased toward zero. As epidemiologists have often observed, most risk factors that raise the chance of death appear to become less important with age or duration. The reason generally is that high-risk individuals who survive often have unobserved strengths or advantages, whereas many of the apparently low-risk individuals who survive may be relatively weak or unhealthy along unobserved dimensions. Consequently, at older ages or longer durations, the high-risk group differs in composition from the low-risk group: the high-risk group has lower unobserved frailty. If unobserved frailty is not included in the model, this effect will result in a convergence with age of the hazard functions for the two groups, as discussed by Vaupel *et al*. (1979) and Vaupel and Yashin (1985). The proportional-hazards assumption used in Cox regression does not allow for such convergence: The estimated relative risk is a measure of the average relative risk over the entire age range. The implication of this is that Cox regression tends to result in underestimates of risk factors: The estimates are biased toward zero. More generally, any method that ignores hidden heterogeneity will tend to underestimate risk factors at older ages or longer durations.

Second, frailty models permit estimation of underlying (or baseline) hazards (i.e., the hazards that govern the trajectory of risks at the individual level). It may be of interest, for instance, to know whether the underlying hazard is monotonically increasing even though the observed population hazard first rises and then declines. More generally, demographers are concerned about whether observed trajectories of demographic rates over age or duration can be explained by level 1 accounts or level 2 accounts. Does the trajectory observed for a population also hold for the individuals who comprise the population—or is the trajectory attributable to compositional change? Frailty models are designed to address this question.

Third, frailty models permit the use of ancillary vital statistics data in the analysis. For example, as briefly discussed above, it is possible to analyze detailed data on some subset of a population (e.g., twins or those who participate in a survey) together with the vital statistics data on the survival of the general population. The combination of detailed data on a subpopulation with survival data on the entire population leads to more accurate statistical estimates. This combination seems natural and highly appropriate for demographers.

CHAPTER

22

Mobility and Spatial Heterogeneity

DANIEL COURGEAU
Institut national d'études démographiques (INED), Paris, France

Up to Chapter 20 of this treatise, discussion has been concerned with the population of a country or region whose individual members possess the same patterns of behavior, with the same levels of mortality and fertility and with equal propensities to exit or enter the population. This assumption of population homogeneity, taken with the condition of independence between demographic phenomena, forms the basic premise of the traditional analytical approach to demographic processes (Henry, 1959).

As was seen in Chapter 21, the assumption of individuals' social and spatial homogeneity needs to be abandoned so that the heterogeneity of the populations under study can be included in the analysis. Later it will be seen that the assumption of independence between phenomena must also be abandoned (Chapter 23). We begin, however, by introducing individuals whose demographic behavior is dependent on their region of residence, and we observe the changes in their spatial distribution over time, produced by their mobility. Analysis needs to consider behavior patterns with respect to fertility, nuptiality and mortality for the territory under observation and the migration flows between its component regions.

I. CONCEPTS OF MOBILITY

Demographers have traditionally treated the events that make up their field of study as being located primarily in time while completely ignoring their spatial aspect.[1] This oversight has long been a handicap to the analysis of mobility, whose very definition is impossible without reference to space. Also, construe the space in question not as an immutable entity that is external to the population but as continuously produced and transformed through individual and collective activity, a contextual element being fundamental to human groups and social institutions. Linking these different social spaces is mobility—by the migrants exchanged between them but also by all manner of spatial flows that vary continuously over time (tourism, cross-boundary commuting, professional traveling, and so forth).

We can see from this why a definition of mobility cannot be based on the multiplicity of flows that by their nature are transient and ever changing. A clear definition can, however, be based on the social space in which this mobility occurs. In this case it can be said that the study of spatial mobility involves identifying the changes occurring over time in the relations between an individual or social group, and space (Courgeau, 1988). This space-focused definition expresses the basic principle behind the approach—individuals are constantly mobile, so the aim is to describe and analyze this mobility and its changes over time. This definition also avoids the search for a definitive and universally valid typology of migrations, which is nonexistent. Such a classification would

[1] The revival of interest in this aspect is recent, thanks in particular to developments in multilevel analysis (Courgeau and Baccaïni, 1997, 1998).

in effect fix the phenomenon in a rigid framework that would be unable to accommodate either the appearance of new forms of mobility or the disappearance of existing forms. The advantage of the approach as proposed lies precisely in permitting analysis of these new forms of mobility, which can take completely unexpected forms.[2]

However, the temporal dimension of mobility is also an important element and must be incorporated in analysis. It is particularly important for relating this mobility to other demographic or economic phenomena and for identifying the very close interdependencies that exist between the events in the individual's life course (Courgeau, 1985). Event history analysis (Chapter 23) is an effective tool for illustrating these interactions.

A definition along the lines indicated also allows integration of the various concepts of migration or spatial mobility into a systematic analytic framework. We will show how these concepts can be defined in such a way that they combine to form a consistent and nested conceptual structure.

1. Change of Residence

The notion of residence was introduced to provide a relatively straightforward way of determining the position of each individual in a particular country. As used in demography, the term individual residence means the place where the person lives, in the sense of *domicile*, denoting the place where a person is legally deemed to reside. The latter criterion must be sufficiently unambiguous for us to be able to attribute a single place of residence to each individual at a specified time. We will see later that definitional changes can hamper comparability over time, while definitional differences between countries are an obstacle to comparability in space.

Assuming these problems to have been resolved, at least for the members of a particular subpopulation, we can say that migration

> . . . involves a change in usual place of residence. The place left by the migrant is the place of origin or place of departure; the place to which the migrant goes is the place of destination or place of arrival.

If places of origin and places of destination are equated with actual places of residence, all migratory moves will be included: this concept enables international comparisons to be made, on condition that place of residence is defined in the same way in all countries.

[2] See in particular the new forms of mobility identified by Hervé Domenach and Michel Picouet (1987) and Ronald Skeldon (1990), in the developing countries, and more generally by Wilbur Zelinsky (1971).

Failing this, migration that occurs inside the regions that define the places will not be enumerated as such, thereby making comparison impossible, due to the differences in geographical divisions between different countries.

Also to be considered are the individuals and subpopulations for whom the concept of residence is either meaningless or problematic. A more detailed examination is required for these particular cases. Groups and individuals such as nomads and seminomads, sailors, and tramps, cannot be attributed a fixed place of residence, and so for them the concept of change of residence is irrelevant. These subpopulations must be clearly identified from the outset and alternative concepts employed.

In other cases it is defining a single place of residence that is problematic. For example, should soldiers in garrisons, patients in hospitals, boarders in schools, and so on, be treated as residing at these locations or at their personal place of residence? Such cases call for the adoption of classificatory criteria, which, although usually arbitrary, should if possible be kept constant over time so that comparisons can be made. This last condition is not always respected, creating discontinuities in statistical series. Thus in France until 1954 the usual place of residence of servicemen, school boarders, and so forth was where they lived on a more or less temporary basis. Since the 1962 census, for those who also possess a personal residence, it is this that is counted. By contrast, for prison inmates and individuals in communal accommodation (i.e., members of religious communities), the place of communal residence is used, whether or not they also have a personal residence.

Thus we can see that although the concept of residence is useful in census-type operations to determine the population of a particular place, it is less accurate when applied to the study of spatial heterogeneity, where movements of a more temporary nature are also important for an understanding of societal change. In these conditions new concepts have to be used.

2. Changes of Dwelling Unit

Given the impossibility of distinguishing clearly between temporary mobility and migration, one solution is to consider both forms of mobility simultaneously. The concept of dwelling or dwelling unit, defined as denoting housing accommodation appropriate for occupation by one household, appears preferable to that of residence, since even when parts of the population live in nonconventional housing—in tents or on boats, for example—the term *dwelling unit* is still comparable in meaning. This concept is much more flexible than that of residence and means that at any given time an individual can be associated with a specific dwelling. Nomadic or seminomadic populations can thus be tracked over time, because they are associated with a dwelling unit.

With the details of this concept made clear, it is straightforward to define migration as a change of dwelling. Such a definition both extends and encompasses the concept of change of residence. Criteria can be selected, which vary between countries and over time, with which to decide whether a change of dwelling is in fact also a change of residence. The population registers for Hungary, for example, record both migratory and temporary moves and show the latter to be twice as numerous as the former.

The dwelling unit concept is becoming essential for a correct analysis of spatial mobility. The developing countries, in particular, are witnessing a rapid growth of temporary migratory movements with a preeminent role in economic and other areas of national life. But in the industrialized countries too, new spatial structures are now emerging in which temporary mobility has an increasingly important role.

A further advantage of this concept is its formal equivalence with the concept of migration. In both cases an individual is tracked over his or her lifetime and at each point in time is associated with a single location, which may be a place of residence or a dwelling unit. Both types of mobility can thus be approached using similar methods of analysis.

3. Change of Life Space

If the identification of an individual with a specific place at a specific time is to be satisfactory it must give an effective summary of the spatial area within which he or she interacts. Although this was certainly the case in the past, notably for much of the rural population, the space in which individuals nowadays lead their lives is expanding greatly. Substituting the place of residence or dwelling unit for this space is no longer satisfactory and the definition must be enlarged to include a new dimension.

This dimension is provided by the life space concept, which encompasses all the places with which individuals interact at any given time. Included in this space, as well as the places they actually visit or stay in, are those to which they are relationally linked. To facilitate quantitative analysis, however, this space has to be limited to a smaller number of places that can be precisely defined.

In an initial simplified form, life space is the individual's spatial work-residence pattern. The commuting journeys thus defined can be studied in relation to the migratory moves made by individuals. It is interesting to note that although at certain times in the life course this may be two distinct places, as when people are economically active and do not work at home, it is the same place when people work at home or are retired. This new concept thus corresponds to a space whose dimensions can vary over time.

Other forms of life space could include holiday homes or the places of residence of an individual's family and friends. On condition that these different places and the individuals associated with them are specified sufficiently carefully, the life space can be made more complex yet remain quantifiable.

From a formal perspective, the life space concept differs significantly from the two previous concepts. It involves monitoring along spatial and temporal dimensions not one but a varying number of locations. A spread or extension may occur through the addition of new points of spatial attachment. An example of this is when individuals start employment yet retain all their existing points of attachment. Conversely, elimination of some existing points causes the life space to contract or shrink. This is frequently observed when a person retires. When some existing points are lost but new ones acquired, we could speak of a shift in the life space, such as accompanies a change of workplace, for example. Finally, this shift could become transplantation, in the case that contact is broken with all former points. This results in a complete change in the person's spatial implantation and the occupation of a new territory.

Collection and analysis of information on these life space changes requires innovative survey designs and new methods of measurement and investigation. Though still in its early stages this work is rich in potential for future research.

II. MEASUREMENT ISSUES

The concepts of mobility are thus much more numerous and complex than those associated with other demographic phenomena, and they also imply use of sharply contrasted measurement procedures. Each of these measurement procedures is in addition associated with a specific type of data source that must be reviewed at the same time.

III. MIGRATORY MOVES, REGISTERS, AND SURVEYS

The first approach considers all the migratory moves undertaken by an individual in the population being studied. Individuals are counted as many times as they move. Working from this standpoint, therefore, what is being counted is a number of events, whether these are changes of residence or of dwelling. This is the measure used in population registers or in prospective and retrospective surveys, already mentioned in Chapters 13 and 14.

The most satisfactory method for completeness of coverage is certainly that of population registers, when they are well maintained. Migratory moves are then recorded as and when they take place. Unfortunately, only a few countries, mainly in northern and Eastern Europe, operate and maintain correctly such a system of continuous registration. Furthermore, they are not especially reliable for measuring international migration, compared with migratory movements within national boundaries. They record only a limited amount of personal information, such as civil status, nationality, and occupation, which is unsuitable as a basis for very detailed analysis, compared with information collected by surveys. As operated in some countries, however, the registers record changes both of residence and of dwelling (Hungary and Poland, for example) and in some cases even changes in the life space, as measured by residence, dwelling and work place (Denmark), thus allowing a more detailed measurement of population mobility.

Prospective surveys record moves as they occur and yield high quality information when carried out in good conditions. Unfortunately, almost insurmountable problems arise with data collection when following up such a sample in the national territory and, to an even greater extent, abroad, because the sample is likely to become biased as a result of selective loss of individuals. People who have been through a difficult experience or who have made a migratory move without leaving an address at their place of origin form special subsamples of the population; they will either refuse to be reinterviewed for the survey or will be impossible to trace for the follow-up. Also, the long interval between initiating a survey and analyzing the results leads many investigators to prefer retrospective surveys. It is true that a good-quality analysis requires an observation period of at least 10 years and often longer.

Thus, investigators usually opt for a retrospective survey in which a sample of individuals are questioned on their past mobility. By selecting cohorts of a fairly advanced age at the time of the survey, information is obtained that relates to much of their lifetime. With this procedure the problem of sample attrition does not arise since all individuals are questioned on a single occasion. In addition, the investigator conducting the survey is able to analyze the results immediately, since the totality of retrospective information is collected. However, there can be serious memory recall problems given that individuals are required to remember events that may have occurred long ago and to date them as accurately as possible.

These recall problems were tested empirically with a retrospective survey conducted in Belgium, a country that also possesses a population register (Poulain *et al.*, 1991, 1992). Although the retrospectively collected information is of significantly poorer quality for migration compared with other demographic phenomena (marriage or birth of children), we were able to verify that the material errors in the retrospective collection did not generate large errors in the longitudinal analysis (Chapter 13) or event history analysis (Chapter 23) of these moves (Courgeau, 1991a, 1992). It seems that the errors introduce a random noise in the exact dating of events but do not create bias in the analysis results. Memory would thus appear to be reliable on the points that are crucial for the analysis.

Another source of bias in these surveys is the fact that interviewing is restricted to individuals who have survived up to the survey and who have not emigrated abroad definitively. The assumption has to be made that, for as long as they are in the territory being studied, their migration behavior is the same as those present at the time of the survey. The hypothesis is made that the sample is noninformative (Hoem, 1985) with respect to the behavior we wish to study. The validity of this hypothesis can be tested for countries that possess population registers. This verification has been undertaken for the study of other demographic phenomena (Lyberg, 1983), and the hypothesis does seem to be supported, but we are not aware of any studies that have attempted it for migratory movements.

Surveys, finally, provide information suitable for the study of life spaces, ranging from the simplest to the most complex. They allow us to show the changes that occur over the lifetimes of individuals and to relate these to their personal characteristics and to the characteristics of the sociospatial environment in which their lives are led.

1. Migrants, Latest Migration and Censuses

Exhaustive measurement of migration activity in the census, even if limited to the intercensal period, is impractical for reasons of cost. Consequently we have to make do with less detailed information, derived from just one or two questions, to provide a general view of population mobility.

If we compare the places of residence of individuals at the beginning and end of the period, we obtain the number of migrants when these two places are different. The focus in this approach is the individual, ignoring any intervening moves that may have occurred in the period and comparing only the origin and destination points. The period considered is usually of 1 or 5 years, producing annual or 5-year rates, respectively, for use in analysis. In some countries, such as France, the migration question in the census concerns the intercensal period. The reason for this is that knowing the populations of a region at two successive censuses, its natural increase over the period, number of internal and international immigrants, and number of internal emigrants, allows the level of international emigration can be deduced. Unfortunately, this estimation by comparison of two successive censuses usually generates a very large error term that makes the method unreliable (Baccaïni, 1999).

The *place of birth* question asked in most censuses can be used to measure what are known as lifetime migrants (i.e., whose place of birth was in a different administrative unit to their current residence). Their number is a useful general indicator of migration activity in countries with very low levels of mobility but is of limited interest for most modern countries where individuals undertake a great many migratory moves over their lifetime.

Another approach is to ask only about individuals' last residential migration and previous place of residence. With this we measure the number of latest migrations or more exactly the number of migrants by latest migration. In contrast to the single question on migrants, measurement of latest migrations precludes two analytical possibilities. First, whereas the number of migrants can be measured on any of a country's territorial subdivisions, by asking for the previous address in as much detail as possible the latest migrations in effect impose a particular migration-defining division. Reconstituting the numbers of migrants that would be observed using different subdivisions is thus impossible. Let us assume, for example, the latest migrations are measured between departments. If we wish to estimate the most recent migrations between communes, those whose most recent move was inside a department and who had previously made an interregional migration, will not be captured. Conversely, if we wish to estimate the most recent interregional migrants, those whose previous move was between departments in the same region will not be identified either. An additional drawback is that the most recent migration, the date of which will vary between individuals, cannot be used to make population projections with migration, as this requires the numbers to be measured over fixed 1- or 5-year periods.

For these reasons the questions on the latest migration, although often still included in censuses, should not be used. Measurement of migrants avoids these disadvantages and is strongly recommended.

IV. MOBILITY OVER TIME

In traditional longitudinal analysis of age-specific all-orders migration, the rates are calculated in exactly the same way as the age-specific emigration rates discussed in Chapters 13 and 14. These rates are seldom used, because they are not amenable to a simple modelling of migration flows. However, if mobility is analyzed by order of move and duration of residence, we obtain rates and probabilities that are much less volatile and easier to apply in modelling attempts. Modelling with a small number of parameters is in fact essential in the case of migration activity, given the complexity of the phenomenon and the large number of flows to be introduced, especially when working with a division into regions.

Let us see first of all how these rates and probabilities can be estimated, before applying them in the modelling process and comparing the numbers of migrants and migratory moves obtained with the various measurement methods.

1. Mobility by Order of Move and Duration of Residence

We proceed for first migrations in the same way as for first births. Data from retrospective surveys are unlike data drawn from prospective surveys and population registers because they do not include deaths. If we denote $M_x^{i,1}$ the number of first migratory moves observed between ages x and $(x+1)$ in the birth cohort i, and $P_x^{i,0}$ the nonmover population of age x, the migration probability mg of rank order 1 is written, when working with retrospective data:

$$mg_x^{i,1} = \frac{M_x^{i,1}}{P_x^{i,0}}$$

When working with prospective data the mortality of nonmovers between ages x and $(x + 1)$, $D_x^{i,0}$, has to be introduced, which gives the following migration probability:

$$mg_x^{i,1} = \frac{M_x^{i,1}}{P_x^{i,0} - 0.5D_x^{i,0}}$$

For higher than first-order migrations, numerous studies have established that it is much better to work on the duration of residence between successive moves rather than on the age of the individual. This is because with the latter the populations at risk obtained for the young ages are very small, resulting in rates or probabilities with substantial variance that are liable to lead to completely wrong estimations if used for distributions or survival functions. Such problems are avoided if we work on duration of residence, and the much more uniform curves that result can be used for a simple modelling of successive migrations.

In the case of migration of order n, we denote $M_t^{i,n}$ the number of migrations of order n occurring in an interval between t and $(t + 1)$ of the previous migration in cohort i, $P_t^{i,n-1}$ the population of individuals who have made $(n - 1)$ migrations and not yet made the next order migration, and $O_t^{i,n-1}$ the losses from observation affecting this population. The latter have to be included because we are working on the duration of residence since the last migration. The migration probability for rank order n is then written, if we have retrospective data:

$$mg_t^{i,n} = \frac{M_t^{i,n}}{P_t^{i,n-1} - 0.5O_t^{i,n-1}}$$

If we have prospective data, we need to introduce the deaths in the population of individuals having made a migratory move of rank order $(n - 1)$ at time t, $D_t^{i,n-1}$:

$$mg_t^{i,n} = \frac{M_t^{i,n}}{P_t^{i,n-1} - 0.5O_t^{i,n-1} - 0.5D_t^{i,n-1}}$$

The analysis can be further developed by calculating the probabilities by duration of residence and age at previous migration. To do this we obviously need to be able to work on large numbers or combine ages to form age groups.

For illustrative purposes let us examine migrations by the Norwegian 1948 birth cohort, followed from age 15.[3]

Figure 22–1*a* shows that first-order migration is clearly differentiated from higher order migrations.

The migration probabilities for rank order 1 rise to a maximum at age 23 whereupon they fall rapidly. In contrast, the migration probabilities for higher order moves are all very similar and follow the same pattern of a continuous sharp fall without reaching a maximum. It can also be noted that, at least for durations up to 6 years, the probabilities are higher the lower the migration rank order, although the differences are never great. If the age group in which the previous migration was made is also introduced, we obtain for rank orders of move 2, 3, and 4 the results in Figures 22–1*b*, *c*, and *d*. These show clearly that these probabilities depend on the age at the previous migration—the younger the age at this migration the higher the probabilities—but they are now almost independent of the order of move being considered. These results show that migrations of orders higher than one can be modelled using a small number of parameters.

2. Time-dependent Models

These sets of migration probabilities by order of move and duration of residence can be conveniently summarized by means of simple models. The various migration models encountered in the literature cannot be discussed in detail here and we will simply consider the most commonly used.

The oldest and most widely used formal model is certainly the so-called *mover–stayer* model (Blumen *et al.*, 1955). Its basic hypothesis is that only a fraction of a population that has made a previous migration is at risk of making a subsequent move. The first step in the modelling procedure is to disaggregate the population that has made a migration of order $n - 1$ into a subpopulation that will make no further move and, on the other hand, a subpopulation that will move again. For this second subpopulation the hypothesis is then made that the probability of making a new move is independent of the duration between the move of order n and move of order $n - 1$. If we assume that the proportion of potential migrants is K, the proportion of stayers at time t may be written as

$$S(t) = (1 - K) + K\exp(-\mu t)$$

where μ is the instantaneous migration hazard in the population of potential migrants. We verify that when $t \to \infty$ the proportion of stayers tends to $(1 - K)$, as predicted by the model. The curve representing the hazard rates of order higher than 1 does indeed have the same form as the curves in Figure 22–1.

The relatively constant scale of these parameters can be confirmed by working on the sample of women in the INED *Triple Biography* (3B) survey from which respondents under age 50 have been excluded. Table 22–1 gives the parameter estimate values of K for migrations of successive orders and involving changes of dwelling, commune, or department. The proportions of potential migrants for any given type of migration are seen to be virtually independent of migration rank order. However, this constant declines slightly as

[3] We would like to thank the Norwegian statistical services for allowing us to use the data files produced from their population registers and censuses.

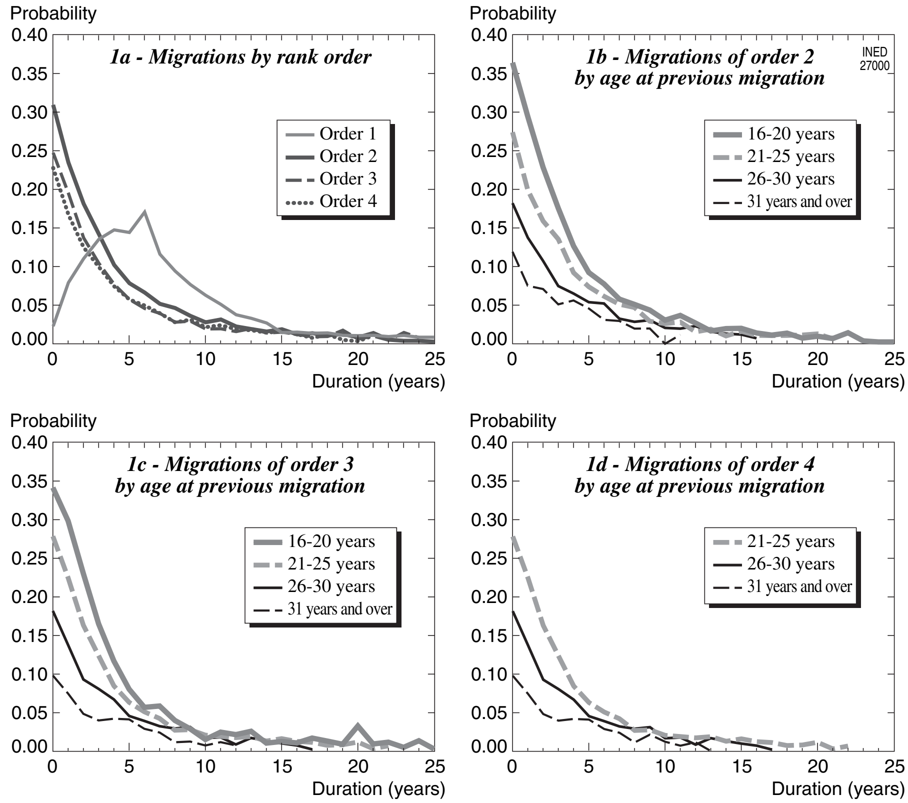

FIGURE 22–1 Migrations in the Norwegian 1948 birth cohort. (Source: Population Register of Norway).

TABLE 22–1 Probability of a Subsequent Residential Migration in France, for Successive Migrations and Different Types of Move

Change	Individuals aged 50 or over, %					No. observed
	*K*2	*K*3	*K*4	*K*5	*K*6	
Dwelling	0.89	0.86	0.87	0.91	0.84	1954
Commune	0.77	0.75	0.76	0.76	0.74	1610
Department	0.72	0.64	0.70	0.71	0.67	1028

we proceed from changes of dwelling to changes of commune and to changes of department.

Let us now consider changes of dwelling and see how parameters K and μ vary as a function of age at the previous migration and of the order of move. The results appear in Table 22–2.

This shows a slight decline in parameters K and μ as mean age at the previous migration rises. On the other hand, for a given age at the previous migration, these two parameters are only slightly dependent on order of move. This result is very similar to what we determined by empirical observation for the Norwegian migrations.

Modelling of successive migrations is also possible using the *Gompertz* model. This model postulates that the variation in the instantaneous hazard rate is proportional to the population at risk at a particular point in time. Under these conditions the proportion of stayers is written:

$$S(t) = (1 - K)^{1-\exp(-\mu t)}$$

where K again represents the proportion of individuals who will migrate, and μ is a parameter expressing this relationship between hazard rate change and population at risk (for more details see Courgeau and Lelièvre, 1989, 1992, 2001). When $t \to \infty$, we verify that the proportion of stayers tends to $1 - K$ as predicted by the model.

Ginsberg (1979) conducted a comparative assessment of these two main models with several others using data from the Population Register for Norway. From this it emerged that the fit obtained with these two types of model was on the whole equally good for all the flows under consideration (by age, marital status, income, region of origin, etc., representing 308 different flows) and considerably better than that obtained with the other distributional models (exponential, Weibull, log-normal, etc.). However, the Gompertz model is more flexible, because it allows both

TABLE 22–2 Parameters K and μ for Changes of Dwelling of Successive Orders, Pre-1931 Birth Cohort, France

Mean age at move of order $(n-1)$, x	K_2	μ_2	No. observed	K_3	μ_3	No. observed	K_4	μ_4	No. observed x
17.5	0.91	0.19	820	0.92	0.20	309	0.91	0.18	113
22.5	0.78	0.16	563	0.84	0.18	420	0.87	0.17	242
27.5	0.67	0.15	114	0.70	0.16	222	0.80	0.16	192

increasing and decreasing hazards, and can thus accommodate cases in which the flows follow distributions that are nonmonotonic decreasing.

3. Migrants and Migrations

We are now in a position to model the differences between measurements of migrations derived from population registers or surveys and census-based measurements of migratory flows. Such modelling is necessary because census data are often only available over periods of varying length, while for making comparisons across time and across countries it is preferable to work with results relating to flows and to annual migration rates.

The model we present here is in a simplified form, and while it can be made more realistic by adopting more complex hypotheses, this does not fundamentally modify the theoretical argument or the results.

The first assumption made by the model is that the instantaneous migration probability, p in the total population is time invariant. This hypothesis can be considered to be valid for a short period of time though it may well not hold over longer periods. Thus for the United States the probability remained at around 0.19 from the end of the World War II to the start of the 1970s, when it fell slightly to 0.17 in subsequent years. This shows that the hypothesis is satisfied for this country, and the same is true for many other countries (Long and Boertlein, 1976). The second assumption is that a mover–stayer model adequately describes the migrations observed in the country. As noted, this hypothesis is often verified correctly. In addition, parameters K and μ are assumed not to change as a function of order of move or of age at previous migration. This hypothesis is not fully verified for migration in France and Norway, but it can serve as a satisfactory first approximation of behavior. For ease of calculation the assumption is also made that the population does not change during the interval under consideration: It is equal to P.

Over a very short interval $(\theta, \theta + d\theta)$ this population will make $Ppd\theta$ migrations. Under the mover–stayer model, only a proportion of these movers will go on to make a new migration: $PpKd\theta$. Let us consider the distribution over time of these additional moves. During the time interval $(t, t + dt)$ these new migrations will satisfy the following formula:

$$\frac{d[M_n(t)]}{PpKd\theta - M_n(t)} = \mu dt$$

where $M_n(t)$ represents these new migrations occurring between θ and t. Integrating between θ and t, we obtain this number:

$$M_n(t) = PpKd\theta[1 - \exp(-\mu\{t-\theta\})]$$

By varying θ, between an initial time ($\theta = 0$) and a final time ($\theta = t$) we will have counted all the new migrations that occur in this period:

$$\int_{\theta=0}^{\theta=t} PpK[1-\exp(-\mu\{t-\theta\})]d\theta$$
$$= PpK\left[t - \frac{1}{\mu}(1-\exp\{-\mu t\})\right]$$

Lastly, if there are no return migrations, by calculating the difference between the total migrations that will be recorded during the period ($M(t) = Ppt$) and these multiple migrations, we obtain the number of migrants that would be given by a census at time t in the place of residence at the initial time:

$$m(t) = Pp\left[(1-K)t + \frac{K}{\mu}(1-\exp\{-\mu t\})\right]$$

Introduction of a geographical division into units such as communes and departments, for example, means that return migrations also have to be included. If we assume that these return migrations $r(t)$ form a constant proportion of the migrations of order higher than 1 that occur in a year, this hypothesis is written:

$$r(t) = l\sum_{i=2}^{\infty} m_i(t)$$

where $m_i(t)$ represents the migrations of order i that occur during the year t. This hypothesis is verified for France (Courgeau, 1973a, 1979) and allows us to write the number of migrants as:

$$m(t) = Pp\left[(1 - K(1+l))t + \frac{K(1+l)}{\mu}(1 - \exp\{-\mu t\})\right]$$

Applying this model to the data for the United States and France produces the parameter estimates reported in Table 22–3.

With these parameter estimates we can compare the main characteristics of migrations in the two countries. We note first that the instantaneous migration hazard p in the United States is almost twice what it is in France (0.183 compared with 0.104). This greater mobility is not associated with a smaller proportion of nonmovers, since in both the United States and France approximately 80% of individuals who have made a residential migration subsequently make another one. The essential difference, however, is the time that elapses before these new migrations occur. In the United States, nearly half the population at risk makes this new migration in the year following the previous migration, compared with less than one fifth in France.

A comparison can also be made between changes of dwelling and changes of county in the United States. These are characterized primarily by a much lower rate of intercounty mobility, whereas this time the proportions of nonmovers and the interval between moves are very similar in each case. It must be noted, however, that the data do not enable us to distinguish authentic nonmovers ($1 - K$) from return migrants l, since we can only estimate a coefficient that measures nonmovers corrected for returns, $K(1 + l)$. For changes of dwelling, the estimated parameter obviously relates only to nonmovers, because moves back to a previous dwelling are negligible. Figure 22–2 displays the curves observed for migrants, compared with the curves estimated by the model, for changes of dwelling and of county in the United States.

TABLE 22–3 Parameter Estimates of the Migrants–Migrations Model, United States and France

Coefficients	Change of dwelling		Change of county United States (1960–1970)
	United States (1960–1970)	France (1968–1970)	
μ	0.490	0.180	0.520
p	0.183	0.104	0.075
$K(1 + l)$	0.810	0.780	0.770

Comparaison des migrations internes en France et aux États-Unis, *Population*, vol. 37(6), p. 1184–1188 and Long, John F. and Boertlein, Celia G. 1981. *Using migration measures having different intervals*. Washington DC, US Bureau of the Census, 39 p. (Population Division working paper).

We note first the near-perfect match between the curves showing observed and estimated data. The corresponding migrations show the large size of the differences between migrants and migrations, of approximately 1:2, after 5 years.

This model can of course be made more realistic by introducing a variation over time in the probability of moving and dependencies between parameters K or μ and age at the previous migration. This involves no fundamental change to the formulas used.

V. MOBILITY, SPACE, AND SPATIAL MODELS

The next step in the analysis is to incorporate the spatial context in which these migrations occur. We define a territorial division into r regions between which flows of migrations or of migrants are observed. Let us begin by looking at the different rates and indices that can be defined to describe these flows.

1. Interregional Mobility Rates

Let us consider the totality of inflows and outflows affecting a particular region. The most favorable situation is when the analyst has data from population register or survey sources. For region i, we have already defined the annual age-specific emigration rates, x, e_x^i, and the rates for age groups of n years ${}_ne_x^i$ (see Chapter 13). We also explained that age-specific immigration rates are harder to define, since the population at risk is no longer

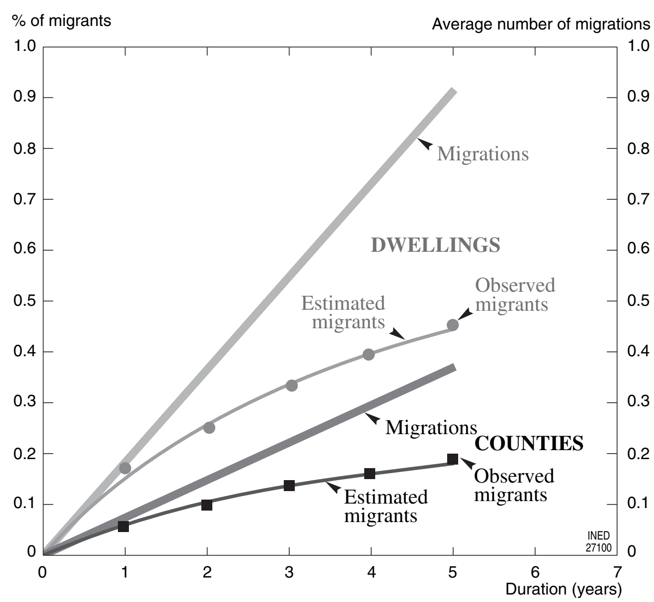

FIGURE 22–2 Proportions (%) of estimated and observed migrants and average number of migrations, United States).

that of region i but of the rest of the world. In this case the preferred solution is to use the same denominator as for the emigration rate, though by so doing we no longer have a conventional demographic rate.

The situation is more complex when census data are available for migrant numbers over a duration of n years. Calculation of a corresponding annual rate is now made impossible by the multiple moves and return migrations that occur during this period (Courgeau, 1973a, 1979). Thus all we can calculate is a *probability of emigrating* over n years, or *proportion of migrants*, by dividing this age-specific number by the population of individuals surviving at the census and who resided there at the start of period P_x^i:

$$_n\varepsilon_x^i = \frac{_nE_x^i}{P_x^i}$$

In this case, the proportion of immigrants will also use the same denominator, even although this term no longer represents the population at risk.

If we consider now the flows between two regions, two types of rates can be calculated. The first relates the number of migrations or migrants only to the average population of the area of origin, considered to be at risk. Thus the rate of emigration from i to j at age x can be written

$$e_x^{ij} = \frac{E_x^{ij}}{0.5(P_x^i + P_{x+1}^i)}$$

The second type of rate includes in addition the population of the area of destination. Numerous empirical studies have established that the flow depends as much on the population of the destination area as on that of the origin area (Courgeau, 1970; Poulain, 1981). We are then able to define an *index of migration intensity* between two regions, i and j, in the period (t, $t + n$), for migrants of age x at the start of the period, over n years:

$$mg_x^{ij} = \frac{E_x^{ij}}{P_x^i P_{x+n}^j}$$

This index can be interpreted as the probability that two individuals alive at the end of the period and selected at random, one from the population living in i at the start of the period, the other from the population living in j at the end of the period, will be identical (Courgeau, 1980). The effect on the migrants of the origin and destination populations is thus eliminated. It can be demonstrated that when two or more regions are combined, as origins or destinations, the intensity index is a mean, weighted by the products of the populations, of the intensity indices for each pairing. It follows that when the indices between each pairing are equal, the index for their combination will always take this shared value.

2. Spatial Models

For a country divided into r regions and a population containing y age groups, $yr(r-1)$ indices must be calculated in order to characterize all the flows affecting the individuals. It is not hard to see the advantage of condensing this information into a smaller number of summary indices with which to characterize mobility in the country in question. This can be done by means of explanatory models in which interregional distance—in its spatial and more sociological conceptualization—is introduced as a variable. This distance is known to be a deterrent to migration, a phenomenon related to the sharp reduction in relational networks that occurs as the distance between individuals increases. In the discussion that follows, we present only the most commonly used model (for a more comprehensive review of the other types of model in use see Courgeau, 1980).

Let us suppose that the distance between two regions i and j is d^{ij} and that the index of migration intensity between these two regions is mg_x^{ij}. A Pareto-type distribution can then be fitted to the set of flows observed:

$$mg_x^{ij} = \frac{k}{(d^{ij})^n}$$

where parameters k and n are estimated from the data. These models give a generally good account of the migration flows and yield coefficients of determination of between 0.8 and 0.9 (Poulain, 1981).

This kind of model can be used to describe the distribution of migrants across various divisions of the territory. Using different spatial units and running the model with different exponents, we have given a theoretical demonstration (Courgeau, 1973b) that there is a simple relation expressing the migration rate observed as a function of the number of units in the division used, r, which is equal to the ratio between the total population of the country and that of an average unit:

$$mg_r = K \log r = K(\log P - \log P_r)$$

Empirical verification of this law is straightforward for countries for which migration rates by various territorial divisions are available. Table 22–4 presents the results observed in Holland and France.

The annual migration rates in France were estimated using the migrants—migrations model presented above and are therefore fully comparable with the rates observed using the Dutch Population Register. The model is found to give a good fit for both

TABLE 22–4 Relation Between Migration Rate and Average Population of a Spatial Unit, Holland and France

Territorial division	Annual migration rate, %	No. spatial units	Parameter K
	Holland (1982)		
Dwelling	10.59	5,310,945	0.0159
Municipality	3.90	774	0.0156

Dutch and French data. The curves showing the percentages of migrants as a function of the logarithm of the average population of a spatial unit form straight lines almost parallel to each other (constant parameter K). Consequently, if a measure of residential migration was not available, good estimates could be made based on the other types of migrations.

This means that in the countries for which we possess no general measure of residential migration but only measures of mobility between various types of territorial units, a residential migration rate can be estimated that is suitable for comparison with other countries. The divisions for which data are available can also be used to check the validity of the model to ensure comparability. These models have been used to compare population mobility in the European countries (Rees and Kupiszewski, 1999).

VI. MULTISTATE MODELS

We again consider a country divided into r regions. The objective is to represent the probabilities of the various demographic events in matrix form, which we can use to project from the age-specific regional population at time t to that at time $(t + 1)$. This representation is much more complex than that considered in Chapter 20, which allowed only for mortality and fertility in a single population. Moreover, the matrices depend heavily on the hypotheses made about the migrations. In what follows we consider only the two main hypotheses.

1. Priority to Emigration Rates

For ease of exposition we will limit ourselves to a female population. Let us suppose that for each region $i(i = 1, \dots r)$ we know the survival probability between the age groups x and $x + 1$, p_x^i, and the number of girls born between t and $t + 1$ to a woman of age x at t, f_x^i. For the migration, we determine the probability of migrating from region i to region j, ε_x^{ij}. This probability will thus be calculated in relation to the population of the area of origin, like the proportions of emigrants presented earlier. To simplify the calculations we consider the female population, by year of age up to the limit age l and we assume that only one event can occur in the course of a single year.[4] Under these conditions we can project the population of age x of region i at t, $P_x^i(t)$, to its population of age $(x + 1)$ at $(t + 1)$:

$$P_{x+1}^i(t+1) = P_x^i(t)\left[p_x^i - \sum_{j\neq i}\varepsilon_x^{ij}\right] + \sum_{j\neq i}\varepsilon_x^{ji}P_x^j(t)$$

For the births in the course of the year we can write:

$$P_0^i(t+1) = \sum_{x=15}^{49} f_x^i P_x^i(t)$$

The set of probabilities can be represented in matrix form, M, while the age-specific populations of the regions are represented by a vector of $r(l + 1)$ elements, $P(t)$ and $P(t + 1)$, between which the following relation is verified

$$P(t+1) = MP(t)$$

This relation can be used to project the initial population, by making the assumption that matrix M remains constant over time, for example, or changes according to certain rules. We can show that when matrix M does not change, the population will tend towards a stable population structure. The first real element in this matrix tells us if the overall population will increase or decrease. The stable population structure will be reached in two stages: at the end of the first the populations of each region become stable; at the end of the second stability is reached in the regional age structure (Rogers, 1995).

It remains to estimate the probabilities, based on the annual emigration and mortality rates. At age x, for example, we will write the following matrix of the annual rates of emigration, e_x^{ij} and mortality (q_x^i)

[4] More realistic assumptions can easily be made, although presentation of the results then becomes more complex (Rogers, 1995).

$$M'(x) = \begin{bmatrix} \left(q_x^1 + \sum_{j\neq 1} e_x^{1j}\right) & -e_x^{21} & \cdots & -e_x^{n1} \\ -e_x^{12} & \left(q_x^2 + \sum_{j\neq 2} e_x^{2j}\right) & \cdots & -e_x^{n2} \\ \vdots & \vdots & \ddots & \vdots \\ -e_x^{1n} & -e_x^{2n} & \cdots & \left(q_x^n + \sum_{j\neq n} e_x^{nj}\right) \end{bmatrix}$$

It can be shown that the matrix of survival and emigration probabilities can be written:

$$M(x) = \left[I + \frac{1}{2}M'(x)\right]^{-1}\left[I - \frac{1}{2}M'(x)\right]$$

where I is the unity matrix, whose diagonal terms are equal to 1, and all the others zero (Willekens and Rogers, 1978; Rees, 1986). It is of course possible to work on 5-year periods and age groups.

2. Priority to Migration Intensities

The previous solution is not very satisfactory because it is based on emigration rates, whereas as was seen earlier, many studies have confirmed that relations between two regions are better represented by indices of intensity. Thus, if we now let mg_x^{ij} be the migration intensity between i and j, the previous relation between populations at t and $t + 1$, can be rewritten in the following form:

$$P_{x+1}^i(t+1) = P_x^i(t)\left[p_x^i - \sum_{j\neq i} mg_x^{ij}\ P_{x+1}^j(t+1)\right] + P_{x+1}^i(t+1)\sum_{j\neq i} mg_x^{ji}\ P_x^j(t)$$

To identify the populations for estimation more easily, this system of equations can be written in the form:

$$P_{x+1}^i(t+1)\left[1 - \sum_{j\neq i} mg_x^{ji}\ P_x^j(t)\right] + P_x^i(t)\sum_{j\neq i} mg_x^{ij}\ P_{x+1}^j(t+1) = p_x^i\ P_x^i(t)$$

We see in this case therefore that these equations can still be represented in matrix form, but that this matrix will depend on the populations at time t:

$$M[P(t)]\,P(t+1) = P(t)$$

If matrix $M[P(t)]$ possesses an inverse, we can write:

$$P(t+1) = (M[P(t)])^{-1}\ P(t)$$

We still have a relation with which to project from $P(t)$ to $P(t + 1)$, but it is no longer a linear relation. If for example this nonlinear relation is used to project the initial populations under the assumption that the migration intensity values remain constant over time, we no longer obtain a stable population (Courgeau, 1991b; Keilman, 1993). Instead, some populations may disappear, while others may follow a sustained cyclical or even *chaotic* course, albeit one that is fully specified because the model contains no random variable.

CONCLUSION

We have seen that measurement and analysis of population mobility is extremely complex. The phenomenon must be considered in its temporal as well as spatial dimensions if all its aspects are to be grasped. The demographic analysis of migrations has developed new methods to improve our understanding of these flows, while making use of techniques originating in economics and human geography (Courgeau, 1976).

As part of this, linear regression methods can be used to explain the aggregated flows with respect to the characteristics of the origin and destination areas. This involves a generalization of spatial models, in particular that of Pareto, by introducing physical and social distance but also variables such as the effect of unemployment, the percentage of old people, and more generally the economic, social and political attributes of the regions of origin and destination (Puig, 1981).

An alternative approach to migration involves working at the individual level and explaining migration behavior by means either of logistic models, which do not introduce time, or event history models, which do (Chapter 23). Differences in migration behavior are explained here with reference to characteristics related to the occupation, family, and so forth of the individuals to identify the personal motivations in these migrations and the effect of time on the process (Courgeau, 1985).

Last, there is an approach that attempts a synthesis of the two previous strategies by means of multilevel models (Chapter 24). These seek to explain individual characteristics by introducing personal but also aggregated characteristics, and differentiate the behaviors with regard to the regions under examination. These models are a rich analytical tool for the study of migrations, situating the individuals under consideration in a multi-dimensional context that is both geographical and social.

Demographic Event History Analysis

DANIEL COURGEAU AND EVA LELIÈVRE

Institut national d'études démographiques (INED), Paris, France

As was seen in Chapter 10, traditional longitudinal analysis examines the occurrence of a single demographic event, and that event alone, by eliminating the effect of all other phenomena that are treated as interfering events. This form of analysis was developed before large amounts of individual-level data became available through specific surveys and before major advances in probability theory and statistical techniques. Longitudinal analysis studies the phenomena of interest isolated in their *pure state* and uses primarily civil registration or population register data to calculate series of probabilities or rates by age or by durations between two successive transitions. Obviously, this approach is purely descriptive.

The growth of survey-taking in the 1980s (Groupe R. A. B., 1999) and developments in probability and statistical techniques (Cox, 1972; Kalbfleish and Prentice, 1980; Courgeau and Lelièvre, 1989, 1992, 2001; Andersen *et al*., 1993; Lelièvre and Bringé, 1998) equipped demographers to switch their attention from aggregate-level data (the numbers of individuals experiencing an event in a particular year) to individual-level data (an individual with certain characteristics experiences various events at different times and in different contexts over the length of his or her life course). The result is an explanatory approach that attempts to disentangle the mass of factors to identify the interdependencies between phenomena and assess the influence on behavior over time of individual characteristics.

Studying these complex individual histories or trajectories requires the elaboration of an analytical and methodologic framework that generalizes the ideas outlined in the previous paragraphs.

I. FROM LONGITUDINAL ANALYSIS TO EVENT HISTORY ANALYSIS

Traditional longitudinal analysis is based on a double postulate: The demographer studies the occurrence of a single event in a population that remains *homogeneous* for as long as that phenomenon is present and from which the effect of the interfering phenomena, considered to be *independent* of the phenomenon being studied is eliminated (Henry, 1959).

Satisfaction of these conditions is the prerequisite for calculating the conventional demographic rates and probabilities, which are taken to express the risk of experiencing the event in question assuming no losses from observation or interfering events. Chapter 9 showed that the results thus obtained need to be treated with a degree of skepticism. We will now go further and show that these postulates have to be changed if the behaviors are to be analyzed in their true complexity.

Let us begin by considering the condition of independence. Empirical observation and simple reasoning tell us that there is not usually independence between processes (Henry, 1959). It is, for example, reasonable to expect migration to a metropolitan area to alter the fertility behavior of a female migrant from a rural region.

Accordingly, we need to discard this hypothesis and introduce the effects of the other phenomena into the analysis, not by excluding the individuals who experience them as in the traditional analysis, but by assessing their influence on the processes being studied. Also note that when analysis is limited to a single event, the restrictive assumption of independence makes it impossible to study losses from observation due to competing events, as with cause-specific mortality, for example. Nor can we work on a subgroup of the population that can be entered by several different events (as in the case of direct entry to a population of manual workers at the end of schooling or indirect entry after a series of previous experiences in the workplace). It would be unfortunate to forgo these analyses simply because they imply a heterogeneity of the cohort under investigation.

Consider now the condition of homogeneity. It is obvious from the sheer diversity of individuals that no human group will be homogeneous (Henry, 1959). One way of dealing with this heterogeneity is to break down the population being studied into subgroups, so that the population in each can be considered as homogeneous. The resulting multistate table will have an ever-larger number of cells, each containing fewer individuals. Large random errors result, as was seen in Chapter 8, and we can never be certain that all the factors of heterogeneity have been taken into account. Decomposition into subgroups is therefore an unsatisfactory solution and another way must be found to incorporate heterogeneity.

A further restriction is that for a population to remain homogeneous *over time*, the assumption must be made that new members immediately acquire the same characteristics and adopt the same behavior as existing members. Concomitantly, the same applies to those who move out of this subpopulation and join another, whose behavior they are assumed to adopt, while losing all recollection of their past conditions. This amounts to making a Markovian assumption, whereby experience of the present state is totally independent of the individuals' history. Also, the individuals remaining in the subpopulation are assumed to have a behavior that evolves in the same way over time. This assumption again bears little relation to what is actually observed, since real-life individuals obviously do remember their past and this does influence their future behavior.

1. Changing Paradigm

These problems highlight the need for a new paradigm that will enable us to analyze interdependent processes affecting heterogeneous populations. This requires using a different unit of analysis—instead of the single isolated event that was considered previously, analysis now focuses on the entire individual life course, which is treated as a complex stochastic process. The following postulate can then be stated: The trajectory an individual follows over his or her lifetime moves through a succession of different states, and the position occupied at any given moment depends on the individual's life course to date, all that he or she has experienced or acquired, contextual constraints, and the working of personal choice (Courgeau and Lelièvre, 1996). With this change in perspective, the bases of event history analysis can be formulated in terms of individual processes.

The first point to note is that losses from observation (also known as *censored information*) are no longer problematic because the date of the survey or—if population registers are being used—of the study, is not linked in any way to the individual's life. The condition of independence between loss from observation and the events being studied is thus satisfied. The sampling is said to be noninformative, and these censored observations can be taken into account when estimating the hazard rates (Courgeau and Lelièvre, 1989, 1992, 2001). Selection bias can arise because only the individuals who survive and who are present when a retrospective survey is conducted can be questioned. Such bias can be measured using data from prospective surveys or population registers and varies depending on the population being studied. It should be adjusted for, whenever possible (Hoem, 1985). However, it can be assumed to be of limited importance if the event being studied does not occur in an elderly population or one subject to high levels of emigration.

This approach makes it possible to study the dependence between the processes under study and the other phenomena, which are now considered not as interfering events but as interactive events. In the next chapter we will see how this can be achieved by developing multistate event history models. When working on competing events, we can use cumulative transition intensities (sum over time of the hazard rates of experiencing the events being studied), which, contrary to survival probabilities, are suitable for valid comparison. They can be analyzed as approximately independent processes when the actual risks are dependent (Aalen, 1976).

Last, the heterogeneity of individuals must be introduced to improve our understanding of their behavior. Here we assume that behavior patterns are not innate but change over the life course in response to all that the person experiences and acquires with time. It is clear that traditional longitudinal analysis, whereby the initial population is broken down into more homogeneous subpopulations, offers no solution to this problem because it fails to allow for continuous change in this accumulated knowledge and experience. By contrast, the introduction of methods that generalize regression techniques offers a more satisfactory way of including these characteristics, which can then be considered in their time-dependent dimension.

Describing the full complexity of these behavior patterns calls for detailed observation of the different phenomena at work over the life of the individual. Traditional observation using data from civil registration, census, and survey sources is not adequate for this task; more sophisticated data-gathering tools are required to capture the multiple and interlinked chronologies of the different processes. Of these instruments, we prefer the life history survey, which assembles data on the events or *milestones* in the family, occupational, mobility histories that make up a person's life. These critical transitions enable us to identify the dynamic of the interacting processes through comparison of the various histories. Thus, a simple birth history does not constitute a life history account, because it does not include the other events that are related to it. In the same manner, a record of only the *high points* in an individual trajectory, even when it extends over several life domains, cannot form a basis for an event history analysis because it fails to observe the temporal continuity of each process.

Although realistic in scope, a data-collection operation that enables the subject to situate his or her history in the broader temporal context enhances reporting quality as regards consistency between the different calendars, by favoring a better general recall of events in different domains relative to each other (see Groupe R. A. B., 1999).

The event history techniques for handling the data raise highly complex statistical problems that have been overcome largely through advances in the theory of martingales, stochastic integration and counting processes (Anderson *et al.*, 1993). A detailed exposition of these methods is not possible here, but after outlining the basic principles and main results, we will show examples illustrating their application in different areas of demographic research.

II. STATISTICAL FORMALIZATION

An initial formalization, referred to as *nonparametric*, enables us to illustrate the interactions between phenomena. Imagine a population comprising n groups between which transitions occur over time. Let $T_{i,j}$ be the positive random variables corresponding to the times of these transitions. If we have $P_i(t)$ individuals in state i just before state t and if $M_{i,j}(t)$ transitions are observed between states i and j at time t, the instantaneous transition rate between these states can be defined in the following form (Johansen, 1983):

$$h_{i,j}(t) = \lim_{dt \to 0} \frac{P(T_{i,j} < t + dt \mid T_{i,j} \geq t)}{dt} = \frac{M_{i,j}(t)}{P_i(t)}$$

The corresponding cumulative transition intensity is then written:

$$H_{i,j}(t) = \int_0^t h_{i,j}(u)du = \sum_{\theta} \frac{M_{i,j}(\theta)}{P_i(\theta)}$$

These transition intensities (or hazards) can be estimated from observations and compared with each other.

Consider the relationship between family formation and urbanization (Courgeau 1987, 1989). The fertility of French women born between 1911 and 1935 is compared according to their residential migrations between metropolitan areas (Paris, Lyon, and Marseille) and less urbanized nonmetropolitan areas. After second births, migration to the metropolitan areas is accompanied by a sharp reduction in fertility—approximately one third—whereas out-migration from the metropolitan areas increases it to the same extent, multiplying the cumulative intensity by 1.4 or even 2. However, migration to metropolitan areas is by women whose fertility before the move was already as low as that prevailing in the urban areas, resulting in a *selection* process. Conversely, migration to the less urbanized regions attracts women whose fertility before moving was the same as that of other women in the metropolitan areas who did not move. In this instance the reduction of the migrants' fertility leads to a process of behavioral *adaptation*.

An additional finding is that the birth of successive children influences women's residential migration, which combined with the previous results produces a *reciprocal dependence*. The propensity to move to a metropolitan area is reduced after each successive birth, whereas the same births have the opposite effect on the migration risks of those leaving metropolitan areas.

Complex dependencies can be identified using this analysis. For example, one process may be observed to influence another whereas there is no effect operating in the other direction. In this case we speak of *unilateral dependence* or *local dependence*. For instance, if we observe the interactions between marriage and departure from farming of men originally employed in this sector, leaving farming is seen to produce a sharp rise in their chances of getting married, whereas marrying while still in farming does not affect their chances of changing employment. We might also observe a *total independence* between these events, in the case that neither has any influence on the other. However, this case is seldom encountered in practice, thus illustrating the need for an event history analysis.

Analysis of this type can be applied to more complex situations, involving trivariate and multivariate relationships, for example. Thus we could study the interaction between fertility and separation in different types of union (cohabitation or marriage) or the interaction between two events with multiple occurrences (fertility and residential migrations).

To develop the analysis further and examine the effect of multiple characteristics on more than one process, we have to adopt more restrictive assumptions about the behavior being studied, by use of parametric or semiparametric proportional hazard models, for example.

Consider an individual k who makes a transition from state i to state j at time t. The instantaneous hazard is expressed in the following general form, which is a generalization of the Cox model (1972):

$$h_{i,j}(t|Z_k(t)) = h^0_{i,j}(t)\exp(\beta_{i,j}Z_k(t))$$

where the first term is the instantaneous transition rate from state i to state j, at time t, under the standard conditions, $Z_k(t) = 0$. The second term of the equation incorporates the individual's characteristics, which may be time dependent, in the form of a column vector $Z_k(t)$ and a vector of $\beta_{i,j}$ parameters. When the individual characteristics are binary, this exponential expresses their proportional effect on the baseline hazard.

When $h^0_{i,j}(t)$ is considered as a function whose form is fully specified in advance, the model is described as *parametric*. Many possible functions can be used for this purpose (Pareto, Gompertz, Weibull, log-normal, etc.) depending on the phenomenon being investigated. Their parameters and the values of $\beta_{i,j}$ can be estimated by the maximum likelihood method. However, this formulation implies the selection of a function, which is not always fully adapted to the phenomenon being studied.

For this reason it is preferable to leave this baseline hazard in a non parametric form. The result is a *semi-parametric* model (Cox, 1972), whose parameters $\beta_{i,j}$ can be estimated using partial likelihood methods, which can then be used to estimate the baseline hazard rates $h^0_{i,j}(t)$.

For example, looking again at third births and the influence on them of residential migration to or from metropolitan areas, the effect of many different characteristics can be demonstrated. Thus the fact of having a farming father influences this birth: before migration the effect is to delay third births while after migration the effect disappears. Other variables are not affected by this migration. For example, the more siblings a women has, the more likely she is to have a third child herself, irrespective of whether she lives in a metropolitan area or not, or has moved or not. When all these effects have been incorporated, moving to metropolitan areas remains associated with a reduced chance of having a third child, whereas moving out of metropolitan areas continues to be associated with a raised fertility, thus confirming the persistence of what was observed when the characteristics were not introduced.

Because, as was seen in Chapter 21, we can never be sure that all the variables with an effect on the phenomena of interest have been introduced, it is important to know how this unobserved heterogeneity affects the estimated risks.

If this unobserved heterogeneity is independent of the characteristics introduced, Bretagnole and Huber-Carol (1988) have established that when a proportional hazards model is used the result is to underestimate the absolute value of the effect of these characteristics, whereas in a linear regression it has no effect on these parameters. This means that an effect that appeared significant will remain so when the initially nonobserved characteristics are introduced. Conversely, an effect which initially appeared not significant, may become significant when the previously unobserved characteristics are introduced.

When the explanatory factors, observed or not, are correlated with each other, the choice of characteristics to introduce into the model is of crucial importance. This can be illustrated by an example. When studying duration of residence at a particular dwelling, age is usually taken to be a characteristic strongly correlated with the risk of moving. But it is reasonable to think that this characteristic is itself linked to other characteristics with a more fundamental role in the migration process, such as the stage of the individual's family life at the start of residence, the tenure status of the present dwelling, and so on. Many such characteristics can be introduced, after age, using data from the *Triple Biography* survey conducted by INED (Courgeau, 1985). Not only does this greatly improve the performance of the model for explaining these durations of residence, but more important, the age effect decreases sharply and, for some of the cohorts observed, even disappears completely. Age thus appears merely a proxy variable, attributable to the fact that it is strongly correlated with the onset of critical transitions in the life course.

The proportional hazards model is merely one of several alternative models that can be used. Others include the linear and logistic models, models introducing time-varying estimated $\beta_{i,j}$ parameters and so forth (Gill, 1992). Some of these models present the advantage of dispensing with some of the earlier restrictions relating to unobserved heterogeneity.

In the case of a proportional hazards model it is important to verify with a nonparametric model whether the effect of the various risks considered separately does in fact have a multiplicative effect on the hazard rates.

III. APPLICATIONS OF THESE METHODS IN VARIOUS RESEARCH FIELDS

These techniques have been applied in many research fields, ranging from econometrics to biostatistics and epidemiology. In this section, we give an overview of their demographic applications in several demographic areas. The studies are categorized by their primary field of application, although it should be emphasized that their methodology addresses the interaction between several fields. Attention will be drawn to the originality of the results obtained with these methods.

1. Mortality

Mortality analysis was an important field of application in the early development of these methods, hence the name *survival analysis*, by which they are sometimes known. Since the original article by Cox (1972), the spread of these techniques in medical research has been reviewed (see, for example, Andersen, 1991). But their use outside of clinical trials and medical epidemiology has not developed to the same extent, particularly in demography. One reason for this concerns the type of data needed for their implementation. But we begin by looking at two examples of studies based on survey data.

Use of proportional hazards models to analyze the effects of childbearing on the occurrence of Hodgkin's disease (Kravdal and Hansen, 1996) is a perfect illustration of the most important use of this method for prognostic purposes. An earlier article by these authors, using a more conventional methodology, concluded that childbearing conferred a protective effect against Hodgkin disease. However, that protective effect is called into question in this article (Kravdal and Hansen, 1996) by the more relevant results obtained using survival models.

Guan Guo and Lawrence Grummer-Strawn (1993) analyze twin survival using data on multiple births from 26 Demographic and Health Surveys (DHS). This identifies the factors of vulnerability for twins and indicates a general increase in the effects of the variables measured for twins compared with those for other children. The model used is derived from the bivariate model and takes into account the dependence between the survival chances of the two categories of children. This is a major advantage of these models.

In contrast to traditional demographic mortality analysis, the two previous studies do not use civil registration data. That source supplies too few individual characteristics for it to be suitable for in-depth event history analysis. A linkage is sometimes possible with census data, which provide more detailed information. Thus several authors (Sahli *et al.*, 1995; Wunsch *et al.*, 1996) have studied mortality in relation to characteristics from three successive censuses linked with Norway's register of deaths. These analyses take the form of a series of logistic regressions on time-ordered sequences, without introducing duration. This procedure, while entirely legitimate and effective, differs from the event history family of models by not including duration, which is a fundamental dimension of these models. However, it will be seen shortly that duration can be introduced for the analysis of interval-censored life history information of this kind.

2. Fertility

Fertility analysis has produced numerous surveys suitable for event history analysis. In a review article, Adrian Raftery *et al.* (1996) give a critical appraisal of the methods used to analyze the World Fertility Survey (WFS) data. With the exception of descriptive analyses, using conventional tabular presentations of fertility rates and linear regression analyses in which the explanatory variable is the number of live births, the authors indicate that although these data give detailed, reproductive histories combined with calendars of contraceptive use they have seldom been subject to event history analysis. After outlining the practical difficulties involved in conducting such an analysis and the innovative nature of the indicators obtained, they present an analytical strategy for event history modelling of WFS data, with a view to increase the use of this strategy. Using the number of live births as a regression variable encounters a certain number of problems, which can only be resolved within the much more appropriate framework of event history analysis. The first problem concerns incomplete information due to censoring at the time of the survey, something that cannot be allowed for in a conventional regression analysis. The second problem relates to the impossibility of distinguishing cohort and period effects. Finally, if the influence of explanatory variables varies with parity, these effects are *diluted* in a conventional regression because individual variables cannot be modified according to exposure duration (i.e., cannot be time-dependent). The authors then apply the proposed procedure to WFS survey data for Iran, achieving results that could not be obtained with the other procedures.

In an article on extramarital fertility, Eva Lelièvre (1993) reviews the methodologic problems encountered in such a study and how they can be overcome by means of event history analysis. Particular attention is given to the question of the validity of analyses where the results are conditioned by knowledge of the future (i.e., by the outcome of the process being studied). In the case of extramarital fertility, the processing of the period of cohabitation is determinant. If, for the evaluation of fertility differentials, unions are distinguished by whether they lead to a marriage or not, the rates are in effect conditioned relative to the future. These difficulties are avoided with an event history analysis that allows for past events and introduces union transformations at the time they occur.

3. Union Formation and Dissolution

Many analysts have come to favor event history analysis for the study of divorce, because the introduction of time-dependent variables is necessary to grasp the nature of the mechanisms at work. This also makes it easier to distinguish between period, age, and cohort effects.

Michael Bracher *et al*. (1993) have carried out a systematic examination of hypotheses advanced to explain the risk of marriage dissolution in Australia, using a Cox model. In constructing their model, they consider successively the introduction of historic time (characterized by period and cohort aspects) and biographic time (age at marriage, age and duration of marital union), the relevant characteristics. It is clear that only event history methods (and the data for running them) are suitable for conducting such an analysis, which is applied to empirical data.

Working on the plentiful and very precise data from the Swedish Population Register, Hoem (1997) has called into question the effects of educational attainment on divorce and has shown (as is only possible with event history models) that these effects are time-variant. These findings run counter to the generally accepted hypothesis (in the English-speaking and Scandinavian countries) of a decrease in the risk of divorce as educational attainment increases. This hypothesis was already at odds with the opposite or nonexistent effect of educational attainment observed in other countries, and thus appears very questionable.

In his study on the place of children in the history of couples, Laurent Toulemon (1994), responding to an earlier critical comment by Adrian Raftery *et al.* (1996), proposes simple indicators, drawn from event history analysis, to present the variations in the risk of marriage breakdown by number of children and age of last child. This study concludes that increased risks of marri-age breakdown are partly independent of fertility behavior.

4. Internal Migration

The French *Echantillon Démographique Permanent* (Demographic Longitudinal Survey), which links civil registration and census data since 1968, makes possible a new approach to interval-censored event histories. In this data file, the residence of individuals is recorded only at the time of censuses and family events. The dates observed are therefore those before and after the migration event to be studied.

Two simplifying assumptions have to be made to use these interval-censored data. The first is that only one of the migrations being studied can occur between two observation times. The second is that the observation scheme is non informative, i.e. that observation of individual trajectories occurs independently of their progression, at random points in time. The first of these conditions determines the choice of observation, using both census and civil registration data, to obtain the optimum estimation. For the second condition, it can be seen that while it is fully satisfied by census observation, civil registration observation can be a source of bias, since there is no reason to expect migrations to be independent of family events.

The test conducted with data from the Triple Biography survey, which were artificially censored for this purpose (Courgeau and Najim, 1995, 1996), established that bias was not large when working on changes of residence. The estimates are similar with census or civil registration data, or with both together, although when civil registration data alone are used significant overestimation of the hazards occurs related to the interactions between migration and fertility. On the other hand, when working on changes of region, serious errors arise due to return migration. A semiparametric analysis of residential migration after marriage has been conducted using the EDP data (Courgeau *et al*., 1998).

5. Occupational Histories

In the field of the study of individuals' occupational histories, Daniel Courgeau (1993) has shown how event history analysis can answer a perennial research question. The problem is that of how do we *allow for the interactions between occupational and migratory events, by introducing a continuous time during which these events occur?* Whereas traditional methods cannot deal with this problem, the general framework of event history analysis is effective for identifying the nature of the interactions in question and the heterogeneity of the population under consideration.

This general framework is also effective for handling far more complex problems, such as the interaction between the professional and migration behavior of the members of a couple (Courgeau and Meron, 1995). These interactions can be modelled, taking into account the effect of the couples' characteristics, which can be time-dependent, to obtain information about the close links between its residential mobility, occupation, and family life. In this way we are able to relate the three main role domains in the life of a couple.

This brief review shows the scope of application of event history analysis and indicated its value as an explanatory tool in demography.

IV. FUTURE DEVELOPMENTS

The event history approach is now widely accepted in the social sciences, including in demography (Keilman, 1993). We must nonetheless resist the temptation to explain a behavior by reference only to individual-level characteristics. The danger then is of committing the atomistic fallacy, because the analysis ignores the broader context in which human behavior occurs. Individuals actually operate in multiple domains (family and occupational, for example) and are linked to a geographic context (resident of a neighborhood, originating from a region, etc.), all of which influence their behavior.

On the other hand, when working at a given level of aggregation, only the conventional demographic rates can be related to the aggregate-level characteristics of the regions being considered, such as the regions' emigration rates to their percentages of farmers, labor force participation rates, and so forth. The danger here is of committing what is known as the *ecological fallacy*, which occurs when inferences about individual-level behavior are drawn from aggregate-level results.

Thus, we must find a way of integrating these different levels of aggregation in the same event history analysis. An initial approach is to examine the effect of both individual and aggregate characteristics on individual behavior, with the possibility of introducing a specific effect for each region at any given level of aggregation. This leads to contextual and multilevel event history models (see Chapter 24).

A second approach involves the analysis of more complex groups, when it is no longer possible to consider the group as forming a single entity but as composed of interacting individuals. This means that instead of studying the interactions between the processes that affect an individual, we study the interactions between individual processes affecting members of a group (Lelièvre *et al*., 1997, 1998). This shift from individuals to their entourage (or *contact circle*), whether for the purpose of data gathering or analysis, implies rethinking the units used for longitudinal observation.

Whereas an individual can be tracked over his or her entire lifetime, the practical impossibility of defining a household in longitudinal terms (Keilman and Keyfitz, 1988) has led to development of the concept of entourage or *contact circle* (Lelièvre and Bonvalet, 1994). It is still the individual who is tracked, but linked with all the members of the various households to which he or she has ever belonged, plus other close but not necessarily co-resident family members.

One approach involves an event history analysis that treats such groups as a composite individual who can be described by both collective and individual characteristics. But the events studied will be mainly collective in nature (change of membership, place of residence, etc.), whereas individual characteristics and the interactions between members are considered only implicitly. In these conditions, the techniques of event history analysis of the group considered as an individual can indeed be applied, on condition the definition of the group and the events it experiences are carefully specified.

Modelling on these lines is not perfect, however, because it overlooks the fact that the process being studied is multivariate, with each of the group trajectories resulting from the interacting trajectories of its members. Since the life histories of the individual members of the group will no longer be independent, a specific modelling strategy has to be developed. This problem has been explored from a statistical angle and these models are currently being adapted for application to demographic processes (Lelièvre *et al*., 1997, 1998).

From the standpoint of data collection strategies, all the events of union and reproductive histories are already included in an individual life history survey, and if the varying position of the individual within his or her contact circle is defined using these dimensions, no additional information is required. If data collection also includes the residential histories of children/parents (direct descent) when the respondent does not live with them, information on the role of kinship in individual decisions becomes available. By working on factual data, such as the location or occupation of a certain number of close friends and relatives, the existence of an influence can be established when there is residential or social proximity. Last, the structure of the individual's network, that is, the nature of his or her contact circle will be known for the entire life course of the individual. A survey along those lines, the *Biographies et entourage* (Event Histories and Contact Circle) survey, was conducted by the Institut national d'études démographiques at the end of 2000. Analysis of the results from this survey will represent a major advance for event history analysis.

Individuals and Context in the Multilevel Approach to Behavioral Analysis

DANIEL COURGEAU

Institut national d'études démographiques (INED), Paris, France

Analysis of multistate data aggregated by socio-occupational group, geographic area, administrative unit, and so on, is based on the assumption that the behavior of individuals is homogeneous in each of these subpopulations. If these conditions hold, it is sufficient simply to use the conventional demographic measures and rates and identify the relations that exist between them. For example, a study might relate the emigration rates for the various regions of a country to the unemployment rates, percentages of farmers, and so forth observed in each region. But we must be careful not to infer that these relationships between aggregate-level values are also valid for the corresponding individual-level characteristics. That would be making the error of reasoning known as the *ecological fallacy*—a positive association between a region's emigration rate and the proportion of farmers in its population in fact tells us nothing about the migration probability of farmers, for whom the correlation may be negative. Aggregate-level models can also be constructed in which fertility, mortality and interregional migrations are introduced simultaneously (see Chapter 20 on *r*-level population models), under the additional assumption of independence between the phenomena being studied.

The hypothesis of homogeneity of behavior within each group becomes unnecessary if we work on individual-level data, because an individual's behavior can then be related to his or her personal characteristics (see the previous chapter on event history analysis, and Chapter 131 on causal models in the final volume of this treatise). In this case, the fact that an individual has moved out of a particular region will be related to factors such as being unemployed, being a farmer, and so on. However, the danger here is committing the *atomistic fallacy*, because the analysis ignores the context in which human behavior occurs. In the real world, this context influences individual behavior and it is a mistake to consider individuals in isolation from the constraints imposed by the groups and settings in which they belong.

What is needed, therefore, is an analysis that works at different levels of aggregation simultaneously but whose objective remains that of explaining individual behavior. The pitfall of the ecologic fallacy is thus avoided, because the aggregated characteristic is used to measure a construction that is different from its equivalent at the individual level. It is introduced not as a proxy variable but as a characteristic of the subpopulation that influences the behavior of an individual member of that group. At the same time, the atomistic fallacy ceases to be a problem once the analysis accounts properly for the context in which the individual lives.

I. INDIVIDUAL AND AGGREGATE MEASURES: CONTEXTUAL ANALYSIS

The behavior to be analyzed here is still individual but the explanatory variables can be both individual and aggregate. Let us begin by looking at the different types of aggregation that can be employed.

1. Types of Measures

For any aggregation level, we can simply add together the individual characteristics and estimate the percentages and averages. Examples are the percentage of farmers, the average starting salary in an occupation, and so on. More complex analytical procedures can also be applied. Thus, as well as average income, the product of this and the binary variable for whether the individual is a farmer could be introduced, which, as will be seen shortly, gives a better characterization of the interaction between individual- and aggregate-level characteristics, or the correlation between this income and household size.

Other characteristics for a given level of aggregation are more general by nature and do not apply at the individual level. Examples are the number of hospital beds in a particular region, or the number of classes in a school. But although these do not correspond to any individual characteristic, they can nonetheless be aggregated at other levels. Thus the number of hospital beds in a region is the sum of the number of beds in each department of the region.

Another class of characteristic is defined for a single level of aggregation and cannot be aggregated at higher levels. The political orientation of a commune, as defined by the party affiliation of its mayor, for example, cannot be aggregated with those of neighboring communes, which may cover a broad spectrum. This characteristic therefore cannot exist at the individual level, because the individual may have voted for another candidate, nor does it exist at the level of the department, because the different communes of the department are not usually all of the same political orientation. Nonetheless, it may influence the behavior of the individuals who live in the commune.

2. A Regression Model

Having specified the characteristics to be evaluated, we will now consider the analytic models that can be used to measure their impact. We begin with an extension of conventional estimation procedures, such as multiple linear regression or logistic regression. This extension is usually termed *contextual analysis*.

This model explains individual behavior by reference to both individual and aggregate characteristics. Let us first of all see how it is formulated in the case of a regression that introduces variables considered at different levels. The example used here is taken from the 1992 Demographic and Health Survey (DHS) of Morocco (Enquête Nationale sur la Population et la Santé, or ENPS-II), for the analysis of fertility determinants in a rural environment (Schoumaker and Tabutin, 1999). Individual fertility is measured by the DRAT (duration ratio), obtained by dividing the number of children each married woman has had by the theoretical number of children she would have had (adjusted for her age and length of union) in a regime of natural fertility. These data are organized in the 72 sampling clusters, which are treated as separate groups.

We write as $y_{i,j}$ the DRAT at the time of the survey of a woman i living in group j. This fertility will first be related to the fact of her husband being a farmer or not ($x_{i,j}$):

$$y_{i,j} = a_0 + a_1 x_{i,j} + e_{i,j} \qquad \text{(Eq. 1)}$$

where $e_{i,j}$ is an individual random term.

The estimated parameter values are reported in the first column of Table 24–1, with their standard error in brackets. According to this conventional regression model, women married to a farmer have a higher fertility than the others. But these parameters may differ depending on the groups and we can estimate them separately for each group j, with the following regression models:

$$y_{i,j} = a_{0j} + a_{1j} x_{i,j} + e_{i,j} \qquad \text{(Eq. 2)}$$

where $e_{i,j}$ is a group random term.

Figure 24–1A displays the results of this estimation. The great diversity in the parameters is clearly apparent, but no conclusion is possible, because most of the parameters a_{1j} are not significantly different from zero. The numbers observed in each group are too small on which to base a conclusion: The differences between the slopes may be the result of purely random error. The solution is to work on the entire population and introduce new characteristics: the percentage of women married to a farmer in cluster $j(x_{.,j})$ and its interaction with the fact of the husband being a farmer, thereby introducing an interaction between an individual and aggregate characteristic. The new model is written

$$y_{i,j} = a_0 + a_1 x_{i,j} + a_2 x_{.,j} + a_3 x_{i,j} x_{.,j} + \varepsilon_{i,j} \qquad \text{(Eq. 3)}$$

where $\varepsilon_{i,j}$ is an error term representing the effects of all the implicit or unobserved variables. This model can of course readily be extended to include additional explanatory variables that are considered to act simultaneously on the female fertility index. Parameter estimation is by the least squares method, with the usual assumptions made for the residuals (i.e., a normal distribution of expectation zero and a constant variance σ^2 for all values of the explanatory variables). Let us

TABLE 24–1 Comparison of results from contextual and multilevel models (rural Morocco, 1992)

Characteristics	Contextual models Estimation (standard error)		Multilevel models Estimation (standard error)	
Fixed				
Constant	0.786 (0.009)	0.749 (0.016)	0.800 (0.014)	0.751 (0.027)
Husband farmer	0.060 (0.013)	0.047 (0.033)	0.040 (0.014)	0.067 (0.036)
% husbands farmer		0.112 (0.040)		0.122 (0.059)
Interaction husband farmer * % husbands farmer		–0.028 (0.061)		–0.072 (0.067)
Random at group level				
σ^2_{u0} (Constant)			0.0084 (0.0024)	0.0076 (0.0024)
σ_{u01} (Covariance)			–0.0017 (0.0020)	–0.0014 (0.0019)
σ^2_{u1} (Husband farmer)			0.0003 (0.0024)	0.0001 (0.0023)
Random at individual level				
σ^2_{e0}	0.1090 (0.0031)	0.1085 (0.0031)	0.1022 (0.0030)	0.1022 (0.0030)
–2 (log-likelihood)	1,530.20	1,519.04	1,455.49	1,451.23

Sources: ENPS-II survey, Morocco, 1992; Schoumaker and Tabutin, 1999.

examine the interpretation of the parameter estimates in more detail.

Calculating the mean of all the observations of group j, gives the following relation, which is valid for each group considered separately:

$$y_{.,j} = a_0 + (a_1 + a_2)x_{.,j} + a_3x^2_{.,j} + \varepsilon_j \qquad \text{(Eq. 4)}$$

where ε_j is the mean error term for each group. We then see that the estimations of the mean values are not distributed randomly but lie along a parabola or a line, if a_3 is zero, when they are plotted as a function of $x_{.,j}$. Again for group j, we can now observe the position of the individuals in this group relative to the mean values that have just been calculated. By subtracting relations (3) and (4), we obtain the following expression:

$$y_{i,j} - y_{.,j} = (a_1 + a_3x_{.,j})(x_{i,j} - x_{.,j}) + \varepsilon_{i,j} - \varepsilon_j \qquad \text{(Eq. 5)}$$

which shows that in each group the estimations lie broadly on lines of slope $a_1 + a_3x_{.,j}$. We can easily verify that these lines pass through a fixed point if a_3 is not zero or that they are parallel to each other in the opposite case.

For the case examined here, the various parameter estimations are given in the second column of Table 24–1. We see first of all that the lines corresponding to each group are parallel to each other because parameter a_3 is not significantly different from zero: There is no interaction effect between individual fertility and that of the group. On the other hand, fertility is no longer identical regardless of group but is strongly differentiated: As the percentage of farmers among men in the group rises, so fertility increases. However, when this increase is allowed for, the relationship between fertility and the fact of the husband being a farmer is reduced by a quarter (coefficient of 0.047 instead of 0.060). Figure 24–1B displays these lines, which can be compared with the regressions calculated on each group separately (Figure 24–1A). From this we can see that while contextual analysis does take into account the different levels at which the groups are situated, it is less effective at explaining the variation in the slopes corresponding to the various groups.

As it stands, Equation 3 introduces only a single error term at the individual level, which means that the results for individuals in a group are analyzed as if they are independent. In addition, the effects of the aggregate characteristics have a predetermined form—quadratic or linear for the mean, and convergent or parallel lines for the group effect. To dispense with these restrictions, the next step is thus to introduce the random variables specific to each level of aggregation.

II. INTRODUCING GROUP EFFECTS: MULTILEVEL MODELS

It is reasonable to think that the result for an individual in a group may depend on the results obtained by the other individuals in the same group. Because they overlook this intragroup dependence, contextual models produce biased variance estimates for the contextual and individual effects, resulting in confidence intervals that are too narrow. This problem of intragroup dependence can be handled by introducing random effects into the previous contextual models. Let us examine this for the regression discussed in Equation 2.

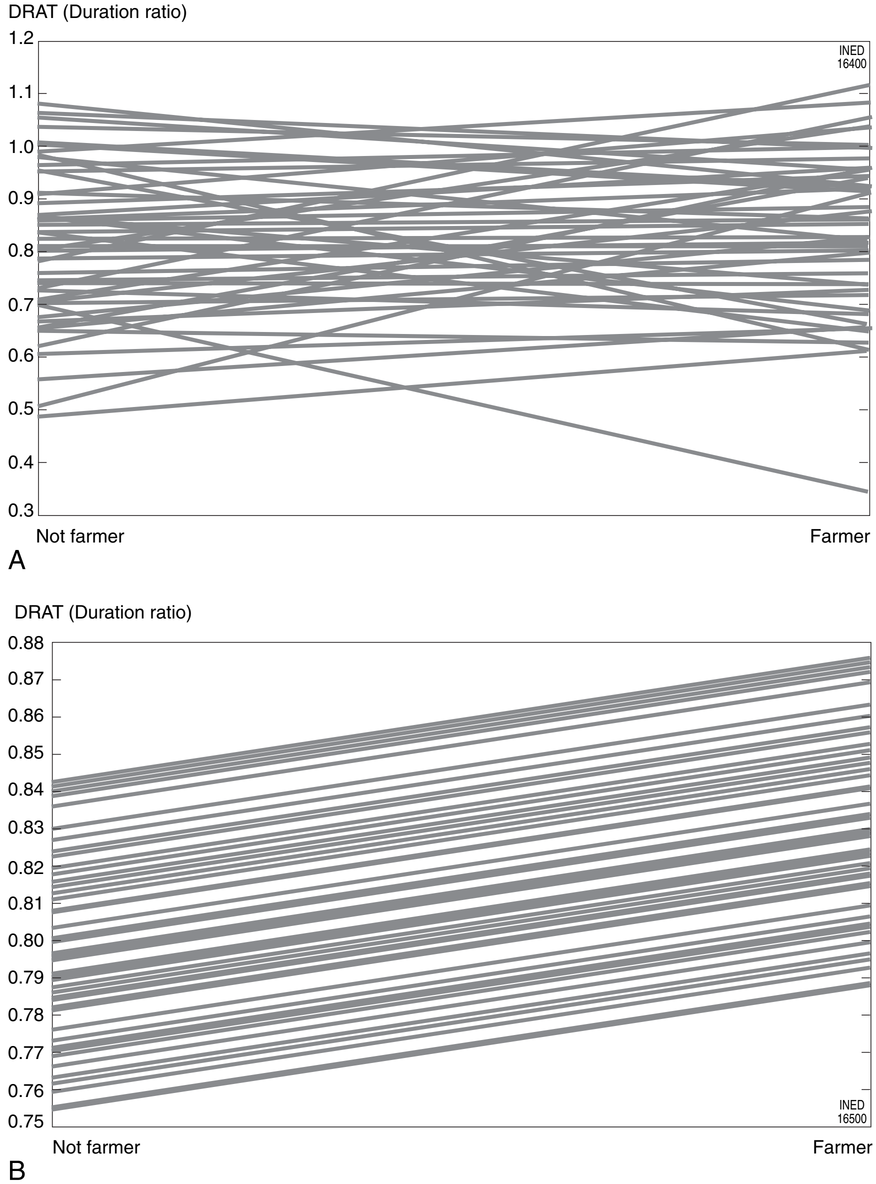

FIGURE 24–1 Fertility estimations by whether the husband is a farmer. **A:** Separate regression on each context. **B:** Contextual regression.

1. Reworking the Previous Regression Model

Because of the small number of individuals observed in each group, the regression parameters estimated earlier will be treated as a random sample from a larger set of parameters. This results in the parameters of Equation 2, a_{0j} and a_{1j}, becoming random variables at the level of the groups, for which we want to estimate the mean a_0 and a_1 and the variation around this mean. We can then write:

$$a_{0j} = a_0 + u_{0j},\ a_{1j} = a_1 + u_{1j} \qquad \text{(Eq. 6)}$$

where u_{0j}, u_{1j} and $e_{i,j}$ are random variables of expectation zero and with the following variances and covariances:

$$\begin{gathered}\mathrm{var}(u_{0j}) = \sigma^2_{u0},\ \mathrm{var}(u_{1j}) = \sigma^2_{u1},\\ \mathrm{cov}(u_{0j},u_{1j}) = \sigma_{u01}\end{gathered} \qquad \text{(Eq. 7)}$$

these three terms corresponding to the level of the groups, and $e_{i,j}$ (Equation 1) to the individual level. This model is fully *multilevel*. The parameters of such a model can be estimated using generalizations of the least squares method (Goldstein, 1995, Courgeau, 2004).

FIGURE 1 (*Continued*) **C:** Multilevel model. **D:** Multilevel model with all variables. Source: Schoumaker Bruno and Tabutin Dominique, 1999. Analyse multi-niveaux des déterminants de la fécondité. Problématique, modèles et applications au Maroc rural, *in:* UEPA-NSU (ed.), *La population africaine au 21e siècle*, vol. 1, p. 299–332. Dakar, UEPA, 630 p. (Proceedings of the Third African Population Conference, Durban).

Applying this model to the previous data gives the results set out in the third column of Table 24–1. The multilevel model, which introduces only the constant and the fact of the husband being a farmer, gives an effect for the latter characteristic very similar to that obtained with the contextual model that introduces all the other characteristics (0.040 compared with 0.047). This is because the introduction of the constant term in the random variables at the level of the groups confirms the effect of these groups on fertility, without the additional terms having to be introduced. Figure 24–1C shows the fertility predicted by this model, depending on whether or not the husband is a farmer. Although the results for the random variable corresponding to having a farmer husband are not significant, the strong negative correlation, close to –1, between the constant and the fact of having a farmer husband, is now reflected in the *fanning-in* configuration of the lines corresponding to each group—The higher the fertility of the nonfarmers, the greater the reduction in the slope of these lines. This result is not obtained with the contextual model, due to its overrestrictive specification—it is closer this time to the regression lines of Figure 24–1A. Also observed, as expected, is an increase in the standard errors of the fixed parameters, compared with the estimations from Equation 1.

The last column of Table 24–1 introduces the percentage of men who are farmers and the product from multiplying this with the fact that the individual is himself a farmer, again in a multilevel model. The variances of all the random terms are seen to decrease. This confirms that these aggregate characteristics account for part of the random terms at the group level as well as reducing the effect of the farmer husband. However, a significant effect is still associated with the random term corresponding to the constant. Figure 24–1D displays the results predicted by this model, which are very similar to what was obtained in Figure 1A, although some significant parameters from the multilevel model used are now also given.

We have discussed these results at length to demonstrate the utility of multilevel regression. This analysis must be continued with other characteristics, such as educational attainment, standard of living, and so forth of the wife or of her household to see whether this random effect persists and to show the effect of these variables on the fertility level being studied.

2. Analysis for Binary or Polytomous Data

Now let us look at how to construct, for example, a *multilevel logistic model*. For this purpose we use a practical example, drawn this time from the Norwegian population register.[1] We examine interregional migrations over a 2-year period (1980–1981) by women born in 1958 and resident in Norway in 1991.

Let us assume that we are working with the probability that a characteristic to be estimated, $y_{i,j}$, in this case, the fact of having migrated, is 1. Individual i is present in region j before migrating. We want to examine the relationship between this probability and an explanatory variable, $x_{i,j}$, which is assumed here to be binary. This probability, conditioned by the fact of the individual having the characteristic $x_{i,j}$, is written as follows:

$$P(y_{i,j} = 1|x_{i,j}) = p_{i,j} = [1 + \exp(-[a_0 + u_{0j} + (a_1 + u_{1j})x_{i,j}])]^{-1} \qquad \text{(Eq. 8)}$$

It follows that the answers $y_{i,j}$, are distributed according to a binomial distribution:

$$y_{i,j} \sim B(p_{i,j},1) \qquad \text{(Eq. 9)}$$

[1] We would like to thank the Norwegian statistical services for allowing us to use the data files produced from the Norwegian population registers and censuses.

In this case we have the following conditional variance:

$$\mathrm{var}(y_{i,j}|p_{i,j}) = p_{i,j}(1 - p_{i,j}) \qquad \text{(Eq. 10)}$$

The model then becomes a nonlinear model:

$$y_{i,j} = p_{i,j} + e_{i,j}z_{i,j}, \quad \text{where} \quad z_{i,j} = \sqrt{p_{i,j}(1-p_{i,j})}, \quad \text{and} \quad \sigma_e^2 = 1 \qquad \text{(Eq. 11)}$$

The individual level variance in this case is equal to unity, and we will work principally on the regional level variances and covariances.

In Table 24–2 we have estimated the parameters of the contextual logit and multilevel models, for studying the migration probabilities of the 19 Norwegian regions according to whether the women have at least one child before this migration.

The first contextual model yields a lower migration probability for women with at least one child (first column), close to that obtained for the fixed part of the multilevel model (column 3), although with a smaller variance for the first model. The random part of the multilevel model shows a variation by region and by whether or not the woman has at least one child. We show the joint influence of the fixed and random parameters at the regional level by calculating the logit functions for the probabilities of emigrating from region j, according to whether the woman is childless or not. The logit function of women without children, Π_{0j}, is simply the sum $a_0 + u_{0j}$; its between-region variance is equal to σ^2_{u0}. The logit function of women with children, Π_{1j}, is given by the sum $a_0 + a_1 + u_{0j} + u_{1j}$; so its between-region variance is equal to $\sigma^2_{u0} + 2\sigma_{u01} + \sigma^2_{u1}$.

The data in Table 24–2 can be used to calculate the between-region variance of women with at least one child (0.205), which is four times higher than that of women with no children (0.051). Figure 24–2 displays the values of Π_{0j} and Π_{1j}, corresponding to women with and without children, linked by a line for each region. These lines are characterized by a fan-shaped form, which is explained by the differences between the variances and by the positive correlation between the random variables, corresponding to women with and without children, close to unity (0.93).

When the aggregate characteristics are introduced, these are highly significant in the contextual model (column 2). Figure 24–3 presents the logits of the probability of migrating according to the regional percentage of women with children. This shows that the migration probabilities depend both on whether women have children and on the proportion of women with children living in the different regions. The higher this proportion, the more these probabilities are reduced by the fact of having children. A region's high

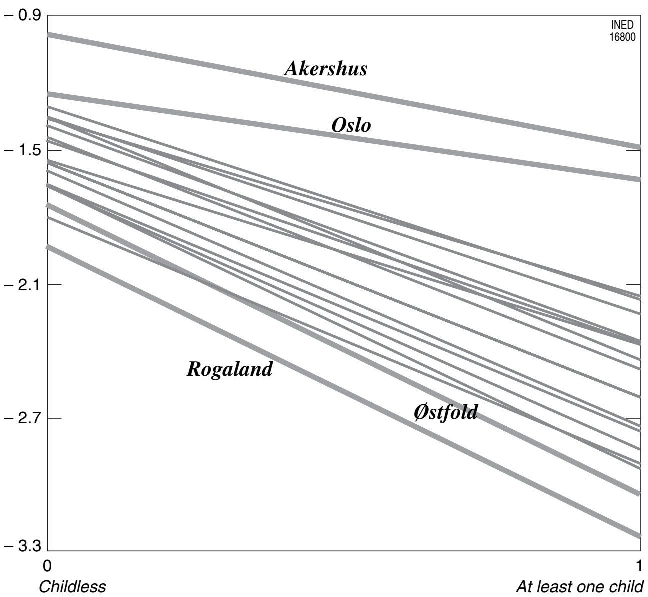

FIGURE 24–2 Logit model on Norwegian migrations: logit of the probability of migrating by number of children.

aggregate fertility is associated with a greater capacity to retain women with children.

These conclusions are completed by the multilevel model. Only the interaction effect between the individual and aggregate characteristic is significant on the fixed parameters, indicating as before that the higher the proportion of women with children in a region, the less likely these women are to migrate. At the same time, a reduction in variance is observed at the regional level for women with children (0.151 compared with 0.205), which confirms the effect of the aggregate variable. However, the regional effect for the constant is still significant and at the same level (0.05): this was not properly accounted for in the contextual model. Figure 24–3, which also displays the logits of

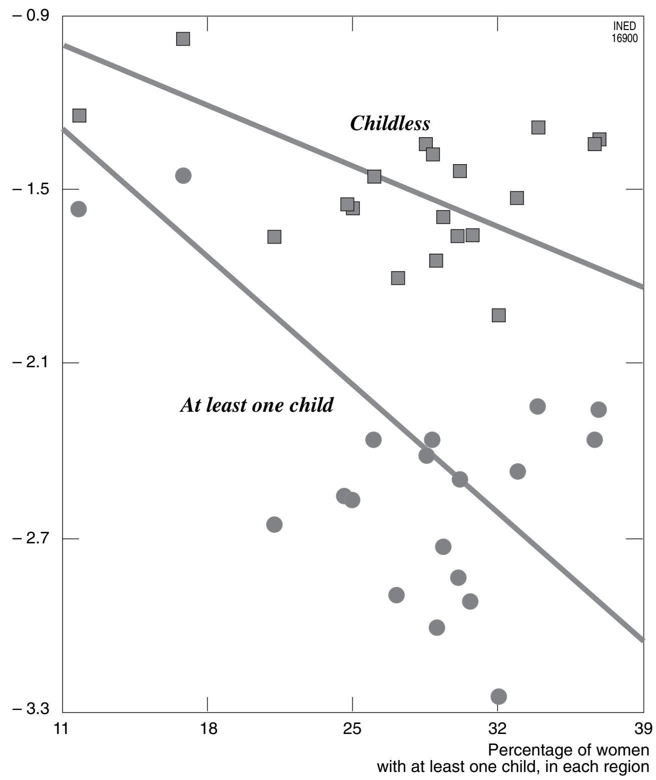

FIGURE 24–3 Logit model on Norwegian migrations: logit of the probability of migrating, relative to the percentage of women with at least one child.

the probability of migrating for each region as a function of the percentage of women with children, reveals a more complex situation than that obtained with the contextual logit regression: the points corresponding to the different regions are highly dispersed in relation to the regression lines plotted on the same diagram.

Various characteristics (marital status, labor market status, educational attainment, etc.) can of course be introduced, separately or simultaneously, to examine their impact on the probability of interregional migration. Their effects may differ from those we have identified by introducing the presence of children. Thus for men the fact of working in farming greatly reduces the probability of emigrating (Courgeau and Baccaïni, 1997). Conversely, it has no effect on the random variables at the regional level: In this case the lines, corresponding to those shown on Figure 24–2, will be parallel to each other. Introducing the percentage of farmers present in each region now produces two parallel lines that rise with this percentage: farmers have a much lower probability of migrating than other categories, but the higher the percentage of farmers in a particular region, the higher the probability of migrating for all categories. This result clearly illustrates the danger of inferring results for individuals from results obtained at a more aggregated level. Having a large number of farmers in a region results in a higher probability of migrating for all population categories, doubtless due to the increased scarcity of nonagricultural employment in such regions. However, this does not mean that farmers have a higher probability of emigrating than the other categories. Indeed, the opposite is observed.

Finally, such analyses can be extended to competing risk models in which individuals experience several types of events, such as death from a specific cause, emigration to different regions, and so forth. These models are a relatively straightforward generalization of the binomial model presented above and we will not discuss them in detail here.

3. Multilevel Event History Analysis

We now come to the most comprehensive analysis of behavior, which combines an event history approach (see Chapter 23 on *event history analysis*) and a multilevel analysis. Because individuals are followed throughout their occupancy of a given state, some of their own characteristics may change at certain points in time (they marry, change occupation, etc.) and the characteristics of the regions in which they live will be subject to continuous change over time (increase in the percentage of married people, changes in the percentages of occupational groups, etc.).

Conducting such an analysis calls for finely detailed survey data, of the kind obtained from retrospective designs, that record all the events in the life course of individuals. Population register data, even when linked to census data as in the Norwegian source used in the prior section, can be used to monitor only a small number of events. It is inadequate to sustain a full multilevel event history analysis. Also, for event history surveys to be usable they must be on large numbers. The data must be capable of revealing the differences between a large number of groups, geographic regions, and so forth.

To illustrate an analysis on these lines we will use data from the Youth and Careers survey conducted by INSEE on a sample of nearly 20,000 individuals. The event we examine is leaving home for the first time by young girls (9043). France has been divided into 19 regions.

The exposition uses a semiparametric model, also known as the Cox model. The objective of this model is to estimate an instantaneous hazard rate (in this case for leaving the parental home), at $t_{i,j}$, as a function of the column vector of the different characteristics $Z_{i,j}$ and the regions j in which the individual i lives. This hazard rate, $h(t_{i,j};Z_{i,j})$, can be written:

$$h(t_{i,j};Z_{i,j}) = h_0(t_{i,j})\exp(\beta_j Z_{i,j}) \qquad \text{(Eq. 12)}$$

In this case, some of the parameters for estimation of the row vector, β_j, will have a random part.

Let us suppose that the times at which a young woman leaves the parental home, or is lost to observation without yet having left, are time-ordered and that at each point in time we can determine the population exposed to the risk. At time $t_{i,j} = l$, the probability that a young woman i will leave her parents, conditioned by the population exposed to the risk and by a departure from the parental home occurring at this date, is equal to:

$$\frac{h_0(l)\exp(\beta_j Z_{i,j})}{\sum_{k\in R_i} h_0(l)\exp(\beta_j Z_{k,j})} \qquad (13)$$

where R_i is the complete population of individuals exposed to the risk at $t_{i,j} - 0$ in any group.

Cancelling out $h_0(l)$, which is in both numerator and denominator, we obtain a partial likelihood that no longer depends on this baseline hazard by multiplying these conditional probabilities at all the dates. What we have written here is a *multilevel event history model*.

So far we have assumed that a single event is observed at each point in time. In practice data tend to be more grouped and we observe $n_{i,j}$ departures from the parental home at date l. The parameters β_j can still be estimated by the maximum likelihood method. The values of $h_0(l)$ are then estimated using these values of $\hat{\beta}_j$. Estimation of the latter function can be simplified by fitting a polynomial distribution (Goldstein, 1995), thus giving in effect a parametric model. A third-degree function is used here.

The explanatory variables can be defined at any level of aggregation and can be considered time dependent. Those introduced here are the individual's birth cohort, whose effect is represented by a second-degree function; the number of brothers and sisters, up to a maximum of four; and the fact of the young woman being in employment before leaving the parental home, which is a time-dependent variable.

Table 24–3 presents the estimated parameter values depending on whether a simple or multilevel event history model is used. The fixed parameters are very similar in both cases. They indicate a slight fall in age at leaving the parental home, up to the cohorts born at the end of the 1950s, followed by a sharp increase, in parabolic form, of this age for subsequent cohorts. The more brothers and sisters there are, the earlier leaving the parental home occurs. Last, for the woman in employment, the probability of leaving the parental home is multiplied by 1.9 (exp [0.64]). The multilevel model shows that depending on the individual's region of residence there is substantial variation in the probabilities. Figure 24–4 shows how this multiplicative effect varies from region to region. The highly urbanized regions are those where leaving the parental home occurs latest (regions around Bordeaux, Marseille, Paris), whereas the opposite is observed in the rural regions (such as Brittany and Normandy). The cohort effect at the level of the random variables is not significant: The curves on Figure 24–4 are nearly all parallel to each other, even though they were estimated with this random effect.

The example given above is of course merely the initial stage of such an analysis. Many other characteristics will have an influence on the behavior of young people, including family and parental background, the economic, political and social conditions at the time of taking the decision, and a range of individual characteristics.

III. GENERALIZATION OF THE ANALYSIS

In the present exposition, we have deliberately restricted attention to relatively simple models, with the aim of illustrating the contribution that contextual and multilevel approaches can make to an exclusively individual approach. We will now indicate the extensions that can be given to these models.

So far we have considered hierarchical aggregation at a maximum of two levels: the individual and rural clusters; the individual and geographic regions. If we retain this *hierarchical classification* we can begin by considering a greater number of levels of aggregation. Thus the individual is a member of a household, which is resident in a neighborhood, which in turn is located in a town, and so forth. However, any other structure of classification can also be used. For example, pupils are grouped by classes, the classes are in schools, the schools may be public or private, and so forth. The

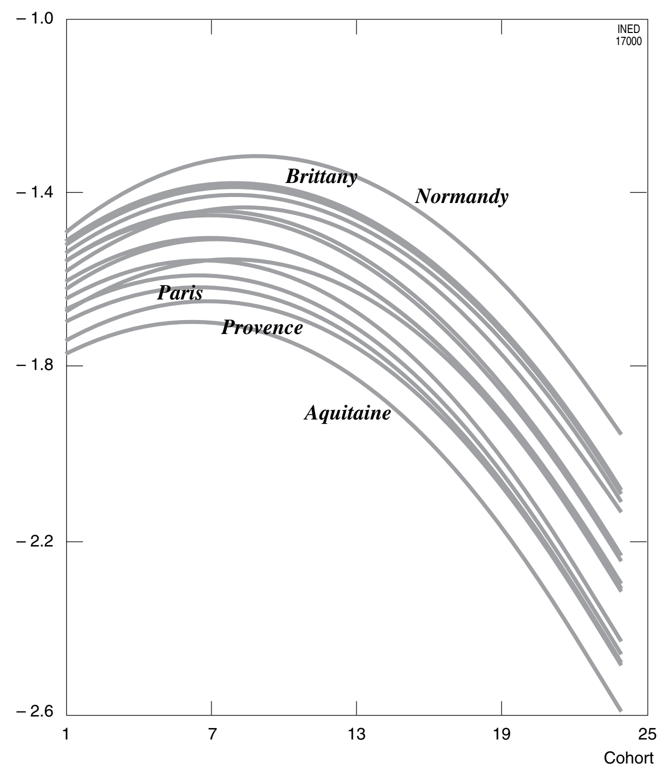

FIGURE 24–4 Logarithm of the probability of migrating by Region.

explanatory characteristics, individual or aggregate, will operate at these different levels, with the random variables specific to each. In each case, careful thought is required about how to interpret the action of a characteristic that operates at different levels of aggregation.

More complicated structures of classification can be realized, such as individuals resident in towns that are grouped by ascending size order but also by their role as centres of government, manufacturing, tourism, etc. The result here is a *cross-classification* in which towns are classified both by their size and by their function. The models presented earlier can be generalized to classifications like these (Goldstein, 1995; Courgeau, 2003).

It is of course possible to have data structures that are in part hierarchical and in part cross classified. For example, individuals can be classified by type of residential area (town centre, suburb, etc.) and type of workplace (industrial, commercial, etc.), which are themselves units in a hierarchical classification of departments and regions.

We can also try to dispense with the hypothesis that underlies the previous analyses, namely, that the groups have no structure. This hypothesis is untenable when working on small groups such as the family and the household. In this case we need to introduce a social structure for these groups, by distinguishing the behavior of parents from that of children and of other people living in the group, for example (Lelièvre *et al.*, 1997).

Looking still further ahead, there is also a need to advance beyond the individual approach used here, which explains behavior by characteristics measured at different levels of aggregation. The analysis must be extended to examine the elaboration and modes of operation of the various levels. How are these levels organized, and how is their action modified? For example, actions by isolated individuals in a given community may produce an awareness of problems and action to resolve them by those with influence at the community-wide level (new laws, acceptance of new forms of behavior, and so on). This could create new problems at both the societal and individual levels, for example.

In summary, multilevel analysis offers a solution to many problems encountered when demographic analysis is conducted at either the individual or a more aggregated level. It combines the different levels of aggregation in an entity that is more informative than when each level is considered separately. As such it enables us to assess the conjoint influences of individual and aggregated characteristics on demographic behavior. Further advances require its generalization to the study of the operation of the different levels of aggregation, thereby offering new insights into the nature of change in human societies in their full complexity.

SECTION

II

DETERMINANTS OF FERTILITY

Introduction

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

After population dynamics, considered in the first section of this treatise, the next three sections address a composite topic that we have split among two volumes purely to avoid ending up with a tome too voluminous and difficult to handle. Logically, the determinants of the three components of population dynamics—fertility, mortality, and migration—could have been considered together in a single section. This is because these three factors of population change and their trends depend on processes which may be very different but have the same rationale: Based on biologic preconditions specific to humankind, the propensities to procreate, migrate, and die are conditioned by an extremely complex set of variables, proximate or not, ecologic, geographic, economic, sociologic, political, cultural, philosophical, metaphysical, and so forth, which are time and space dependent. Through them, all populations at every moment of their history develop individual or collective faculties and behaviors that determine their dynamics. So, where Section I analyzed the internal mechanisms of these dynamics; measured fertility, mortality, and migration; and discussed the linkages between these three factors and the age–sex structure of population before taking them all into account in models that help us gain insight of the demographic impacts of a given process, the following three sections will attempt to show how the elements of these dynamics are shaped and change.

Because the task had to be divided between three sections, each section will be given over to one component of population change: fertility, mortality, and migration. This section considers fertility determinants.

Although recent developments in bioscience mean that human reproduction by cloning no longer lies entirely in the realms of science fiction, humans essentially remain sexual beings whose reproduction is possible only through the combination of male and female gametes. And what is a biologic necessity is also broadly true in sociologic terms: In most cases, gamete combination is preceded by the formation of a union, notwithstanding the rapid changes in the typology, and even the very nature, of unions in the past few decades.

One of the primary factors in human fertility therefore is union formation. In almost all societies, couples' union formation, lifestyle, and relations have been governed by social, ethical and religious rules that are often so strict that marriage was in many cases for long a precondition of fertility, nonmarital fertility being completely forbidden. That being so, the study of marriage should precede that of fertility, the latter being mainly composed of marital fertility in many societies. It is, admittedly, a foregone conclusion that rules are never applied to the letter, and nonmarital fertility may exist alongside marital fertility. But that is by definition illegitimate, since legitimate fertility can only take place within marriage. Demography, born in a highly puritanical Europe, for long had only these opprobrium-filled expressions to distinguish not only marital from nonmarital fertility, but also the issue of these two forms of fertility: legitimate births and illegitimate births. No longer so. Not only have demographers had to account for population dynamics where the distinction is more complex, less rigid, and less discriminatory, as in some African societies for example, but, in Europe itself, the picture has changed radically with the spread of nonmarital cohabitation and new patterns of union. The fact still remains that, whatever the form, the union of two individuals of opposite sexes is still in most cases a precondition of fertility. On a purely technical level, admittedly, nonsexual reproduction is now possible for a woman. But the overwhelming majority of such cases are couples seeking to overcome infecundity. A study of union formation, and an analysis of *nuptiality*, is therefore the necessary first step toward explaining fertility factors. That will be the focus of part one of this section.

But union formation is not the only precondition of fertility. The union so formed must be fecund and fertile. It must be biologically fecund (i.e., physiologically capable of conception). This means not only must neither the woman nor the man be infecund but also that the union they form must itself be fecund. Then, too, the ability to conceive must be transformable into a capability to give birth. That means the mother being able to carry her pregnancy to term and produce a live birth. Here again, biology plays an overriding role through the process of fetal development exposed to the risk of all causes of intrauterine mortality. Finally, it entails the woman—the union—being fertile (i.e., able to effectively manifest its fertility). Here, of course, far more than in other respects, individual and social behaviors also come into play. Sexual behaviors, contraception, and induced abortion are all proximate determinants of fertility. These interconnected proximate determinants of fecundity and fertility are examined in Part II.

However, before these proximate factors, sometimes called *intervening variables*, come into play there is a set of fundamental or nonproximate fertility determinants that stem from the economic, social, cultural, or ideologic context in which individuals and couples live. The complexity of these relations has led to the development of a constant flow of new explanatory models and theories of fertility trends. These will be considered in the third and final part of this section.

PART

I

A PRECONDITION TO FERTILITY

Union Formation

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Any self-respecting textbook on demographic analysis will deal with nuptiality on equal terms with fertility, mortality or migration. Rightly so, since marriage, like conception, childbirth, migration, or death is a major life event whose impact in a population merits the same demographic analysis as any other vital event. Rightly also on the grounds that, educationally speaking, nuptiality probably lends itself best to the most comprehensive explanation of the principles of analysis.

And yet, marriage was deliberately not considered in Section I of this treatise. It is true, as stated in the introduction to Section II that union formation is in most cases a precondition to fertility. However, it is only of several. Marriage *per se* has no direct influence on population size and development: Many marriages are celebrated in a given year, no new members will be added to the population if the newly formed unions are infecund or permanently infertile. The only difference is the exposure to the risk of conception and childbirth, assuming that out-of-wedlock fertility is lower than in-wedlock fertility. Consequently, marriage or, more generally, union formation had no place within the analysis of population dynamics as such, but should more appropriately be considered in connection with the factors of that element of the dynamic that it helps to determine: fertility.

The traditional approach focuses on the fertility differentiation that union formation creates between the individuals (especially women, since fertility is most often measured in relation to women). The first thing therefore is to measure nuptiality itself, which entails a breakdown between married and nonmarried couples, before measuring the fertility of married and nonmarried couples. This will give a breakdown of fertility into marital and nonmarital fertility, usable to gauge the influence of nuptiality patterns on fertility trends.

But no union is never-ending: Inherent within union formation is union dissolution. This means considering widowhood and, where relevant, divorce in the same way as nuptiality, which clearly complicates the model, especially as a dissolved union may be followed by a second, third, and other unions. Almost the first step, therefore, is to look at nuptiality by order of marriage. However, even that is not enough, for not only are there other forms of marriage beside monogamous marriage—not least polygamy, still very common in some societies—but the types of unions themselves, monogamous or otherwise, are increasingly varied, both in legal and social terms, and in terms of the effective commitment to a permanent union.

For that reason, no less than three chapters are given over to the measurement of nuptiality. Chapter 25, authored by Patrick Festy, gives an overview of the traditional analytical approach to union formation and dissolution, informed essentially by data from European countries. In Chapter 26, Philippe Antoine then explains how the biographic approach can inform that analysis, at the risk of somewhat begging the question of factors. Finally, in Chapter 27 the same author reviews the many forms that unions can take, referring to a case study of Africa.

Union formation and dissolution may be fertility factors, but also have their own determinants as the biographic analysis will have shown. Thérèse Locoh takes a more detailed look at these in Chapter 28.

Finally, in Chapter 29, Silvana Salvini and Antonio Santini look at measurements of marital and nonmarital fertility.

CHAPTER

25

Analysis of Couple Formation and Dissolution

PATRICK FESTY

Institut national d'études démographiques (INED), Paris, France

Strictly speaking, marriage is not a demographic event, for it does not contribute—as do births and deaths—to population replacement. Indeed, in several ways, it stands apart from the other topics of demographic study.

Marriage is an essential step in family formation and in childbearing. In technical terms, it is the first of the intermediate fertility variables (i.e., an essential factor in the exposure to the risk of birth). In other words, the likelihood of a couple having a child in the year ahead is usually very different depending on whether the partners are married or not. To treat married persons as a distinct category thus involves defining a group whose fertility behavior is more consistent than that of the total population.

However, married status is only an approximation of the intermediate variable that the demographer would like to define. It is a social status in which people are more likely to want children, or to agree to having children, than in the unmarried status. In Western societies, there has long been a desire for fertilizing intercourse to take place in marriage; fertility out of wedlock was stigmatized. But the frontier between the desirable and the nondesirable can shift. Today, in France, the married and the unmarried are not separated as sharply as before given society's ready acceptance that unmarried persons in stable partnerships should have children. The frontier now lies between (stable) couples and noncouples; the defining factor that marks the entry into family life—because it signifies an abrupt change in the risk of birth—is the formation of the couple, whether legalized by marriage or not.

The same pattern has long been observed in many non-Western societies as well. For example, in Latin America or in the Caribbean, marriage is only a formal and optional stage in a partner relationship, without significant impact on fertility. It has never been a major object of study for demographers. In such societies, as in Western countries today, the difficulty is to determine a marriage-equivalent event marking the entry into family life, whose frequency and other characteristics can be measured.

The privileged attention given to marriage is partly due to the existence of an easily available source that enables it to be identified and enumerated: the civil registration records. As this source is also the one that enables demographers to compile birth and death statistics, the study of marriage is typically linked to that of fertility and mortality. The source is, however, much older than civil registration and demographic studies, since the Catholic Church has long required baptisms, marriages, and burials to be recorded in parish registers. Better yet, marriage played a central role in the recording process, because the purpose was to make sure that the marriage was possible: The spouses had to be free—through widowhood—of any earlier marital ties, and had to prove they were not too closely related to marry.

As a result, France has a source dating back to the 17th century that captures the basic characteristics of marriages. By contrast, it is often hard to construct a life table spanning all ages of life for so remote a period. In the 19th century, France added a question on marital status to the census: The question—almost as old as modern censuses themselves—provides information that supplements the classic statistics and is based on principles discussed later.

However, marriage is not only a major element for understanding fertility that is well covered in current statistics. It is also a convenient educational tool for setting out the essential principles of classic analysis of demographic phenomena and addressing most of the difficulties encountered in the study of the main phenomena.

Marriage, like childbirth, is a repeatable event—or, as demographers say, a *renewable event*. However, unlike births, the repetition cannot occur unless another event has taken place: divorce or widowhood. Nuptiality is defined by all or part of the marriage-termination–remarriage sequence, which, as it unfolds, may become first marriage–divorce (or widowhood)–second marriage, and so forth.

Moreover, the stable union that is the relevant object of study in certain societies can take the legal form of marriage or be merely consensual. This option, offered to the partners when they begin to cohabit, is formally comparable to competing risks, which exposes an individual to death from cancer, cardiovascular disease, and so on.

Last, more than any other analysis, the study of marriage provides a tangible illustration of a fundamental difficulty in demographic measurement: How does one evaluate the sensitivity of the number of marriages to the number of males *and* females old enough to form partnerships? The same difficulty occurs in fertility studies and in all instances where the encounter of two persons is a prerequisite to the occurrence of an event.

I. PRINCIPLES OF COHORT ANALYSIS

As we have seen, nuptiality encompasses various events that can form a sequence. However, these successive events are governed by three common principles of analysis:

1. *The breakdown into successive events makes each of them unique* or, more precisely, nonrenewable in the life of a group: there is only one first marriage; a person can lose his or her partner only once, and so forth. To assess the importance of a phenomenon associated with these events, we must begin by measuring its frequency: What proportion of persons marries, at least a first time; what proportion of couples divorce; how many divorced women remarry; and so on.

   For each stage (first marriage, divorce, remarriage of divorcees, etc.) there is a frequency, and for each frequency there is a group in which we can measure it. Everyone can marry (a first time) but only married persons can divorce, and only divorced or widowed persons can remarry. The frequency of marriage will therefore be measured in the total population, that of divorce or widowhood in the group of married persons, and that of remarriage in the group of divorced or widowed persons.
2. *In each of these groups, a period of time must elapse* before we can determine the number of persons who have experienced a given event. The starting point of the period is identical to the date of formation of the group studied: the frequency of divorce will be measured 25 or 30 years after the marriage date, that of remarriage some 15 years after the divorce or widowhood, and so on. First marriage has no specific origin-event other than birth and no other specific duration than age.

   To characterize a nuptiality-related event—such as first marriage, divorce, or remarriage of divorcees—we determine not only its frequency but also its distribution in time. This distribution is often summed up by a baseline value such as mean duration. In the sequence of married-life events, each specific duration originates in the immediately preceding event. We therefore measure the mean duration of marriage at the time of divorce, the mean time since divorce at the remarriage of the divorcees, and so on. As the duration specific to first-marriage analysis is identical with age, we likewise compute a mean age at first marriage.

   Louis Henry (1966) summarizes these first two principles of analysis as follows: When event B cannot occur unless A has taken place, we define a cohort of persons having experienced event A in a given year and we measure, within this cohort, the proportion of persons who have subsequently experienced event B and the distribution of durations elapsed between A and B. The proportion is the quantum of phenomenon B, while the distribution is its tempo.
3. *Because time elapses between A and B, persons in group A may have left the group at the time when they would have liked to experience B*. In a birth cohort, persons who would have married at 25 are prevented from doing so by premature death or departure (emigration). The number of marriages taking place is inversely related to the number of

> deaths and migrations occurring in the cohort studied. It is not, therefore, a very satisfactory basis for measuring nuptiality *per se*. To arrive at that figure, we must determine how many marriages would have occurred at each age if there had been no mortality or migration until that age, that is in a *pure state* by analogy with the principles of chemical analysis that allow simple and pure elements to be isolated from mixtures.

The estimation of the number of marriages at a given age x absent earlier mortality or migration rests on the following hypothesis: Persons deceased or emigrated before age x would have had the same risk of marrying at age x as survivors present at that age. This hypothesis—known as the *independence hypothesis*—underlies the determination of quantum and tempo of demographic phenomena. In the area of nuptiality, it is applied to the measurement of first-marriage frequency as well as to the calculation of the mean duration of marriage at the time of divorce, and so on. We will examine its relevance and validity.

II. THE NUPTIALITY TABLE

Using the model of the probability of dying by sex and age, we can calculate a first-marriage probability by sex and age x, which measures the risk of contracting a first marriage in the interval x, $x + \Delta x$ for persons who have not yet been married at age x. If marriage is understood in the narrow sense of a legal marriage, these persons still have never-married status (if we are dealing with a first union, in a broader sense, the persons thus defined have always been free of any conjugal tie; we shall return to this issue). Let:

$$\Delta_x^{n_x} = M_c(x,x + \Delta x)/C_x.$$

At older ages, the number of single or never-marrieds C_x (C representing celibacy) is reduced not only by the number of first marriages M_c, but by the deaths and migrations of never-marrieds. If we compare the number of never-marrieds at age 50, C_{50}, with the number of never-marrieds at age 15, an age before which marriage is very rare in present western societies, the difference $C_{15} - C_{50}$ or the ratio C_{50}/C_{15} depends not only on nuptiality but also on the mortality and migration of never-marrieds.

To express the sole effect of nuptiality,[1] we compute a series c_x by combining, through multiplication, the probabilities of not marrying $(1 - \Delta_x^{n_x})$ at successive ages from C_{15} onward. For example, if the first-marriage probabilities have been calculated on annual intervals,[2] we have

$$c_{50} = C_{15}(1 - {}_1n_{15})(1 - {}_1n_{16}) \ldots (1 - {}_1n_{49}).$$

More generally, we can write:

$$c_x = C_{15}(1 - {}_1n_{15}) \ldots (1 - {}_1n_{x-1}).$$

$$c_{x+1} = C_{15}(1 - {}_1n_{15}) \ldots (1 - {}_1n_{x-1})\,(1 - {}_1n_x).$$

and therefore:

$$c_{x+1}/c_x = 1 - {}_1n_x.$$

$${}_1n_x = 1 - c_{x+1}/c_x = (c_x - c_{x+1})/c_x.$$

As the series c_x is reduced, from one age to the next, by the sole effect of nuptiality, the difference between c_x and c_{x+1} is due only to marriages of never-marrieds $m_c\,(x,x + 1)$. Hence:

$${}_1n_x = m_c(x,x + 1)/c_x = M_c(x,x + 1)/C_x.$$

The probability calculated on observation data (in a reality where the number of never-marrieds is determined by marriages, deaths, and migrations) is then incorporated into a nuptiality table, where only marriages reduce the number of never-marrieds. If, of 10,000 never-marrieds at age 15, there are 4000 remaining at age 30 who are still never-married, survivors, and present, there will be, perhaps, about 5000 persons of the same age in the nuptiality table—absent mortality and migration. The transition from age 30 to age 31, measured in reality on the 4000 survivors present, will then be applied to the 5000 never-marrieds in the table, under the implicit hypothesis that mortality and migration have not altered the representativeness of the 4000. This is known as the hypothesis of inde-

[1] Block capitals indicate real data, whereas lower-case letters represent data in the table.

[2] Marriages are not the only events occurring in the interval $\Delta\psi$: There are also deaths and migrations of never-marrieds. These last two events can prevent never-marrieds from marrying in the same interval. The number of never-marrieds exposed to the risk of marrying will be modified as a result. For example, if a never-married person dies during the interval, he or she is excluded from the risk for the remainder. The effect is negligible if the interval Δx is very short, and increases with the duration of the interval. If it becomes significant, we factor it in by making two simplifying hypotheses (see Chapter 8): (1) the deceased are excluded from the risk of marriage for the remaining half of the interval; (2) their risk of marriage is the same as that of the other never-marrieds.

The number of marriages is consequently reduced by $D_c(x,x + \Delta x) \times \frac{1}{2} \times {}_{\Delta x}n_x$.

Hence:

$$M_c(x,x + \Delta x) = C_x\,{}_{\Delta x}n_x - (D_c(x + \Delta x)_{\Delta x}n_x)/2$$

and

$${}_{\Delta x}n_x = M_c(x,x + \Delta x)/(C_x - D_c(x + \Delta x)/2)$$

Migrations of never-marrieds are similarly accounted for. The effects of emigration are comparable to those of mortality.

pendence between (1) the mortality and migration of never-marrieds and (2) the nuptiality of never-marrieds.[3]

We can thus construct a nuptiality table of never-marrieds, whose elements are comparable to those of a life table (i.e., at successive ages), three series, respectively, describing first-marriage probabilities, never-marrieds (taking $c_{15} = C_{15}$), and first marriages. With 1-year intervals between successive ages, we obtain:

Age	Probabilities	Never-marrieds	Marriages
15 y	${}_1n_{15}$	c_{15}	$m_c(15,16)$
16 y	${}_1n_{16}$	c_{16}	$m_c(16,17)$
17 y	${}_1n_{17}$	c_{17}	$m_c(17,18)$
—	—	—	—
x	${}_1n_x$	c_x	$m_c(x,x+1)$
$x+1$	${}_1n_{x+1}$	c_{x+1}	$m_c(x+1,x+2)$
—	—	—	—
49 y	${}_1n_{49}$	c_{49}	$m_c(49,50)$
50 y	${}_1n_{50}$	c_{50}	$m_c(50,51)$

$$c_{x+1} = c_x(1 - {}_1n_x).$$

$$c_x - c_{x+1} = m_c(x,x+1).$$

$${}_1n_x = m_c(x,x+1)/c_x.$$

As the number of marriages m_c generally becomes negligible after age 50, we admit that the ratio c_{50}/c_{15} measures the total proportion never-married. The mean age at first marriage is written:

$$\bar{x} = (15{,}5\ m_c(15{,}16) + \ldots + (x + 0{,}5)m_c(x,x+1) + \ldots + 49{,}\ 5m_c(49,\ 50))/(c_{15} - c_{50}).$$

III. PROXY MEASURES OF THE NUPTIALITY TABLE

Let us take, for simplicity's sake, a closed population (i.e., without migration). Its nuptiality table sets up a virtual universe that also lacks mortality. The number of never-marrieds accordingly moves from c_{15} to c_{50} as age rises, and the ratio c_{50}/c_{15} measures the resistance to nuptiality; it is equal to $1 - N_{50}$ with $1 - N_{50} = \prod_{15}^{49}(1 - {}_1n_x)$. In these same conditions of no mortality, the population, regardless of marital status, remains fixed: $p_{15} = p_{50}$. As the entire population is still never-married at age 15, c_{50}/c_{15} is equal to c_{50}/p_{50}.

In reality, never-marrieds aged 50 have resisted both nuptiality, and never-married mortality; and the population, regardless of marital status, has resisted mortality. Hence:

$$C_{50} = C_{15}\ (1 - N_{50})\ l_{c50}.$$

$$P_{50} = P_{15}l_{50}.$$

where l_{c50} denotes the probability of survival of never-marrieds between ages 15 and 50, and l_{50} the probability of survival of the total population between the same ages. This gives:

$$C_{50}/P_{50} = (C_{15}/P_{15})(1 - N_{50})\ (l_{c50}/l_{50}).$$

As the entire population is still never-married at age 15, $C_{15} = P_{15}$ and we can write:

$$C_{50}/P_{50} = (c_{50}/p_{50}) \times (l_{c50}/l_{50}).$$

The ratio C_{50}/P_{50}, easily calculable in a population census, is equal to the proportion never married in the nuptiality table—to within one factor that measures the difference in survival rates between never-marrieds and the total population. This factor is generally below unity, because never-marrieds have a lower survival rate than the total population.

In an open population, differential migration has a comparable effect. In some cases, its influence can greatly exceed that of the comparative survival of the two groups. Let us bear in mind, however, that the calculation of the proportion of never-marrieds in the total population of the same age in the censuses gives a proxy measure of the proportion never married. The proxy value is smaller than the actual value because of the excess mortality of never-marrieds. The absence of mortality, which characterizes nuptiality tables, also enables us to write:

$$m_c(x,x+1)/p_x = c_{15}(1 - N_x)_1n_x/p_{15} = (1 - N_x)_1n_x.$$

In reality, the equivalent computation on observed data gives:

$$M_c(x,x+1)/P_x = C_{15}(1 - N_x)\ l_{cx1}n_x/P_{15}l_x = (1 - N_x)_1n_x(l_{cx}/l_x).$$

Thus, the ratio of observed marriages of never-marrieds to the total population of the same age (i.e., *first-marriage frequency*; see Chapter 8) is equal to the marriages in the nuptiality table $[(1 - N_x)_1n_x]$, to within one factor. The latter expresses, as before, the difference in the survival rates of never-marrieds and of the

[3] In most cases, the independence hypothesis has little effect on the validity of nuptiality tables, given the modest numerical impact of mortality and migration among the never-married. In studying events other than the marriages of never-marrieds, we shall encounter situations where the outcome is different, and we shall examine the possible ways of dispensing with this simplistic but convenient hypothesis.

total population. The cumulated first-marriage frequencies, which are easy to compute from current civil-registration statistics and from estimates of the population by sex and age, therefore give a proxy measure of marriages in the nuptiality table. The measure is proxied by default in the frequent case where never-marrieds have a lower survival rate than the total population.

Some components of the nuptiality table—in particular the factors directly involved in the determination of the total proportion remaining single and of the mean age at first marriage—can be calculated on widely disseminated statistics. This gives considerable relevance to the construction of all or part of nuptiality tables.

IV. PERIOD MEASURES

The cohort measurements we have just made capture the age-by-age transition of a male or female cohort from never-married to married status. In Chapter 14, we saw that this type of process could also be described in a hypothetical (or synthetic) cohort on the basis of statistical information pertaining to a given year rather than to a birth cohort. The aim here is to construct a *period nuptiality table*. We begin by computing the first-marriage probabilities of never-marrieds ${}_1n_x$. Next, we combine them at successive ages to produce a series of never-marrieds c_x and a series of marriages $m_c(x,x+1)$. In this combination, we act *as if* the populations at successive ages were linked as closely as in the cohort analysis, whereas in fact they necessarily belong to distinct cohorts in a given year rather than to a single cohort.

The summary indices such as the proportion never married c_{50} or the mean age at first marriage, calculated from the marriages in table m_c, are generally interpreted as the quantum or the tempo of the nuptiality that would be recorded in a cohort if the period conditions persisted long into the future. The implicit hypothesis that makes the computation meaningful is not very different from the independence hypothesis on which cohort construction is based. For example, the probability at age 30 in 1995 is a fragment of the history of the generation born in 1965; its inclusion in the pseudo-history of the hypothetical cohort associated with the year 1995 supposes that the operation has a meaning, despite the fact that this pseudo-history before age 30 differs from the cohort's true history. We thus postulate that the fraction of never-marrieds who marry at a given age is independent of the number of never-marrieds who married before that age: each probability is cut off from its past.

The separation between the events or the risks of a year and the past of each cohort is so sharp that it is almost impossible to formalize the links between the period tables and the cohort tables or between the summary period indices and cohort indices derived from them (see Chapter 17). These links are easier to identify using other summary indices such as cumulated first-marriage frequencies.

We have seen that the first-marriage frequency is very nearly identical to the marriages in the nuptiality table of a cohort of never-marrieds. Their longitudinal combination enables us to construct a table. But we can also combine them at different ages in the same year, in which case we can compute total period indices: sum or mean age.

The ratio of the number of first marriages to the total population of the same sex and the same age—which defines first-marriage frequency—is of the same nature as the computation of the total fertility rate. The period sum of these values has the same relationship to the cohort sums as the sums of total period and cohort fertility rates studied by Nico Keilman (see Chapter 17). In particular, a fall in the age at first marriage in successive cohorts drives up the combined first-marriage frequency, whereas an increase in that age drags the frequency down. When the age at first marriage declines sharply, the upward pressure may actually drive the total period index over the 100% ceiling on cohort indices. The implausibility of such values is a reminder that period measures are only fictions, when it comes to expressing the frequency of behaviors. The lesson also deserves to be heeded in cases where the period index is low: Weak values do not necessarily signal a high never-married rate in cohorts measured in that period, but may be due to ever-later marriages in successive cohorts.[4]

1. Selected Illustrations

In Sweden, the number of marriages started declining before the late 1960s. The annual nuptiality index of never-married women, which was close to 100%, fell by one third in 4 years and has remained stable for more than 20 years at around 50% (Figure 25–1). What was once perceived as a reaction to the economic crisis

[4] Henri Leridon and Laurent Toulemon (1997) show, using the French example, that there are substantial discrepancies between series of total period indices based, respectively, on period nuptiality tables and cumulated first-marriage frequencies. They also measure the gaps between period indices and cohort indices, and show that they are narrower when one uses period tables than when one uses cumulated first-marriage frequencies. They conclude that period tables are a "better" approximation of cohort measures (but is that a sound validation criterion?).

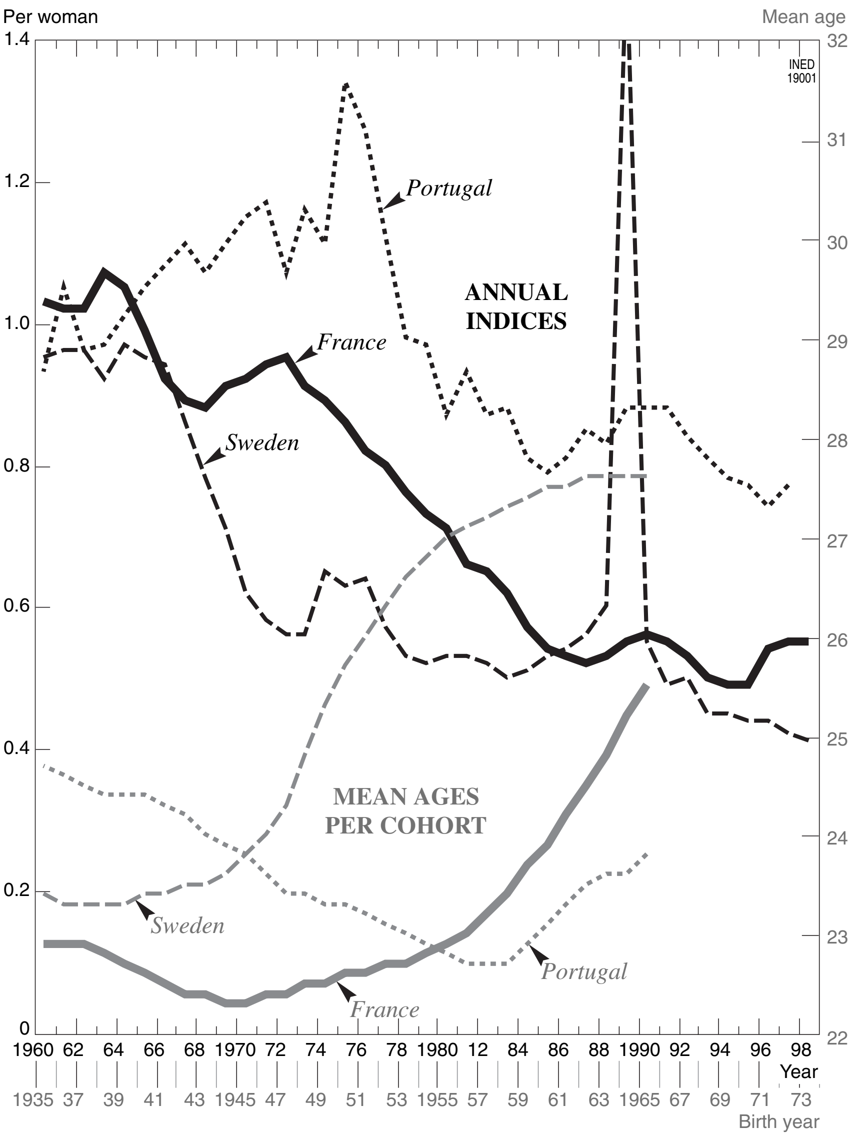

FIGURE 25–1 Annual nuptiality indices for never-married women and mean ages at first marriage by cohort.

or as a fashion has now become a long-term phenomenon. A sharply higher proportion of men and women will never marry—a rare occurrence in the past. The proportion of men and women born in the mid 1960s (i.e., still in their 30s at time of writing) who will not marry is estimated at about 40%, compared with less than 10% for men and women about 20 years older (Table 25–1 in Appendix).

There has been a parallel shift toward later marriage. Women born in the 1960s who marry do so on average at age 27.5 years, which is 4 years later than women born in the 1940s (Table 25–2 in Appendix).

One would have to go back more than 100 years to find such late ages at marriage in Swedish cohorts, when trans-Atlantic migration sharply disrupted the nuptiality of men and women who stayed behind. However, the proportions of never-married men and women have never been so high.

Marriage has declined across Western Europe. The pattern in the Nordic countries and France has been almost as spectacular as in Sweden. In France, the proportion of men and women who never marry has climbed to 30% in recent cohorts, and the age at marriage has risen to 26.5 years for women and 28.5 years for men. The trends in Finland and Norway are comparable. By contrast, the changes under way in southern Europe are distinctly mild: In Italy, for example, the proportion of never-married women born in the 1960s is still below 20%, and the rise in the age at marriage is modest; the extreme case—in total contrast to Sweden—is Portugal, where the very recent increase in age at first marriage has barely affected the cohorts already in their thirties (ODE, 1998).

In a shaded pattern running from the north of Europe to the south, the center (Germany, Austria, and Switzerland) holds a median position. Only France stands apart with a resolutely northern profile, which does not tally well with geography, but underscores the singularity of the marriage model developed in the past two decades.

V. DIVORCE TABLE

Like marriage formation, marriage termination can be analyzed by constructing a table. This enables demographers to identify—absent any other phenomenon that could conceal the risk of termination—the ultimate frequency of divorce and a summary index of its tempo. Some formal adjustments are required, however, before compiling a divorce table.

The impact of divorce is not so much on individuals as on couples. The unit taken into account is therefore the marriage, of which we monitor the duration or termination. The terminating events are of two types: separation of spouses or death of a spouse. The second event, in turn, can take two forms: widowhood of the husband or wife. For our purposes, we will use only the first distinction, without discriminating between terminations due to the death of the husband or wife.

Divorce is analyzed in terms of time elapsed since marriage. This method is consistent with a principle stated in prior sections: Divorce cannot occur except after marriage. Marriage is thus the origin-event that creates the population at risk.

The probability of divorce r_y is the ratio, at the duration $(y,y + \Delta y)$, of the number of divorces (D) $D(y,y + \Delta y)$ to the number of still-married couples Uy. Applying the same principle defined for nuptiality, we use the table to construct something that observation cannot measure—the pattern of extinction of a group of marriages, under the sole effect of divorce—whereas reality describes the combined effect of divorce (D) and widowhood (W). We thus replace the series Uy with the series u_y such that, with annual intervals between successive durations:

$$u_{y+1} = u_y(1 - {}_1r_y)$$

with:

$$_1r_y = D(y,y + 1)/U_y$$

and:

$$U_{y+1} = U_y - D(y,y + 1) - W(y,y + 1).$$

The hypothesis implicit in the combination of successive probabilities of not divorcing is that couples terminated early by widowhood would subsequently have been exposed to the same risks of divorce as the couples that have been preserved from mortality. It is the hypothesis of independence between the risks of widowhood and of divorce.

Using the table, we can determine a divorce quantum and measure it at 25 or 30 years of marriage: Beyond that duration, the number of new divorces becomes negligible. The table also enables us to measure the distribution of marriage durations up to divorce and to summarize them with a mean duration.

However, let us return to the initial choices that led us to group together newly formed couples and study the extinction of this group as it moves along the marriage-duration timeline. Why have we abandoned age as a time clock? First, we should discard the (genuine) objection that the marriage duration is common to both spouses, whereas age is not. Age is defined as that of the wife. As a result, we will refer to divorces of married women aged 20, 21, 22, and so forth. But between 20 and 21 years, for example, the group at risk is not only reduced by divorce and widowhood, it is also enlarged by newly married persons, who, at age 21 years, will not have the same behavior as the married persons who formed the initial group. This is known as the marriage-duration effect (i.e., same-aged women in marriages of different duration are not exposed to an identical risk of divorce). This violates the independence hypothesis, as an external event (marriage) modifies the change over time of the risk studied (divorce rate). The problem does not arise with a marriage cohort monitored from one duration to another, as the duration sequence does not introduce new unions.

Yet, the age issue is not eliminated. First, it would be wrong to pretend that age has no effect on the risk of divorce: At the same marriage durations, early-married women are more likely to divorce than later-married women. But the opposite is also true of the other risks of disunion, as these are linked to the death of one of the spouses (i.e., to mortality): At the same marriage durations, early-married women are less likely to die or lose their husbands than later-married women. Age at marriage therefore introduces a double heterogeneity: Between the risks of divorce *and* between the risks of other forms of termination. It also introduces a negative correlation between the two risks: when the divorce risk is high, the other risk is low, and vice versa. The combination of the heterogeneity and the correlation creates a dependence between the event studied (divorce) and the event that may prevent its occurrence (widowhood).

Let us assume, in an extreme simplification, that there are two ages at marriage of equal numeric importance; the divorce risk is high in the first and zero in the second, whereas the opposite is true for the widowhood risk. For all ages at marriage combined, we find medium-level risks of divorce and widowhood, and the death of a spouse seems to mask the divorce risk. In reality, widowhood does not prevent divorce at all because it occurs in a group where the probability of divorce is zero. The amalgamation of two different subpopulations creates a heterogeneity that contradicts the hypotheses needed for the analysis. Conversely, a good analysis requires a division into homogeneous groups, where the independence hypothesis is justified. For divorce and widowhood, the interaction is unlikely to be as strong as to bias conventional measurements, but we shall encounter a different situation later on.

Between divorce and widowhood, the interferences are so weak that we can often ignore them. As most marriages occur before age 35, and divorces are concentrated in the first 15 years of marriage, mortality is low at the time when divorces are most frequent. We can therefore safely omit widowhoods and simply calculate the ratio of divorces to initial marriages, at each marriage duration, in order to obtain a good estimate of divorces for the table and to deduce the table's other components.[5]

The statistics used to construct Table 3 in the Appendix have been analyzed using these methods. We have computed the ratio of divorces to the initial number of marriages in France at each marriage duration in the marriage cohort examined. *Disregarding the widowhood factor*, which we should have withdrawn from the denominator, the ratios are equal to the divorces of the divorce table. Their aggregation therefore measures the proportion of marriages terminated by divorce at the end of a marriage duration of over 40 years; the distribution of marriage durations at the time of divorce is summarized by a mean duration.

In 25 marriage cohorts (1946–1970), the increase in the ultimate proportion of terminated marriages has been spectacular, from 10% to almost 28%. The rise was moderate in the first 10 cohorts, then quickened: in the last 15, the ultimate proportion doubled. This trend is not confined to France, but is observed throughout Western Europe. It has been accompanied by changes in legislation. On January 1, 1976, France introduced a law liberalizing access to divorce by facilitating consensual procedures; it is doubtful, however, whether legislative reform is responsible for the rise in divorces.

In the cohorts studied, divorce remains a phenomenon very widely spread over time. The mean duration initially rose in cohorts affected later in life by the general change in behavior; it peaked at nearly 17 years in marriages contracted in around 1960, and then declined. The latter downtrend should gather speed in the post-1970 cohorts, in which there have been so many divorces in the first years of marriage that one can hardly believe they will be some day be as frequent as they used to be at the longer durations.

VI. WIDOWHOOD TABLE

The construction of a widowhood table obeys principles comparable to those used for divorce. Let us choose, as before, to study only terminations due to the death of *either* spouse. Divorce is the interfering event and marriage the origin-event that creates the population at risk. There are, however, some specific aspects of widowhood that prompt us to depart from the approach used for divorce when compiling the tables:

- The statistics by marriage duration of couples terminated by death are rarely produced. Yet they could be obtained simply by adding up the deceased married men and women at each duration. Moreover, it is surely easy to establish the marriage dates of the deceased, since one of the spouses almost always survives and is presumably the person who reports the death.
- Divorce prevents widowhood far more often than the opposite, as it occurs relatively early in marriage, whereas widowhood tends to occur late. We can therefore omit widowhood in a rough measure of divorce frequency, but the opposite is hardly possible.
- These constraints enhance the attractiveness of a classic, indirect, and convenient method of computation, which is to combine male and female life tables in order to produce a life table for couples. This is done by linking a cross-table of male and female ages at marriage x and y with the probabilities of survival of couples at successive marriage durations a:

$$(l^{M}_{x+a} \times l^{F}_{y+a} \div l^{M}_{x} \times l^{F}_{y})$$

- But this substitution method does have many imperfections:

[5] One must also consider the *interfering* role of migration, as it can be high at the ages when the risk of divorce is high as well. Emigration exerts an influence in the same direction as mortality and widowhood; immigration exerts an opposite influence. It should be noted, however, that the migration concerned is that of married persons, often far more modest than that of never-marrieds. We should also examine, on a case-by-case basis, whether divorces of migrant couples are pronounced in the couples' country of origin or in the country of destination.

- For a cohort computation, we need cohort life tables by sex, year of age, and year of birth. The available statistics are often far from offering such detail.
- We also need a measurement of the specific mortality of married men and women for each cohort—plus, of course, measurements differentiated by age at marriage, given the links between age at marriage and social group, which can influence mortality.
- Proxy measurements postulate a form of independence different from the hypothesis used until now in this chapter: the independence between the mortality of husbands and the mortality of wives. But, given the social homogamy of spouses, this independence is far from certain.

To these caveats we should add that widowhood plays a modest role in contemporary western societies, if nuptiality is viewed merely as an intermediate fertility variable, as it occurs in couples at ages and marriage durations where fertility has already been completed. But the situation is different if we take into account the sociological dimension of marriage. For example, it is commonly argued that the rise in divorces for marriages contracted after 1950 is linked to the extension of the potential duration of married life, consecutive to the increase in age at widowhood—although the latter trend cannot be adequately measured.

VII. REMARRIAGE

The principles of the remarriage analysis are modeled on those developed for divorce analysis. The duration to be measured is the time since marriage termination. However, we return to the individual—man or woman—as the unit of account. Death can prevent remarriage from occurring, and is thus a competing event. It is also very likely not be independent of remarriage, as early-widowed or early-divorced persons have a high probability of remarrying and a low probability of dying, while the opposite is true of their elders. But we simply need to introduce a distinction between widowers (or widows) and divorcees (of either sex) to restore the independence between death and remarriage, as the first group is, on average, far older than the second.

Moreover, the influence of mortality is all the more modest as remarriage generally occurs very soon after the termination of the earlier marriage, without leaving time for death to conceal the formation of new couples. Thus the ratio of the number of remarriages to the initial number of divorces or widowhoods at each marriage duration usually suffices to provide a good estimate of remarriages in a nuptiality table. This observation is even more valid if the data are gathered retrospectively through surveys of survivors. The figures obtained resemble the census proportions of never-marrieds mentioned earlier in our discussion of first marriages.

Thérèse Locoh and Marie-Paul Thiriat (1995) have used data of this type, compiled from surveys of women under 50 in Togo in 1988. The authors study the respondents' second marriages by introducing, as a time measure, the duration since divorce or the first husband's death. The 50-year age limit impairs the visibility of a phenomenon that occurs inevitably late, because it follows a first marriage and a termination. However, the age at first marriage is sufficiently young in Togo to give time for the termination to occur and to generate a population at risk of remarriage. It should be noted, however, that this population excludes terminations at older ages, whose number is surely not insignificant, especially for widowhood.

In Togo, second marriages are very frequent: 87% of divorced women and 76% of widows remarry. The difference between these two figures is probably due to the fact that divorces concern younger women than widowhood: the propensity to remarry generally declines with the age at marriage termination. In European societies, the frequencies are generally lower, most notably for widows, but the latter tend to be substantially older. New unions occur very soon in Togo, on average 1.8 years after divorce and 1.6 years after widowhood, which is much quicker that in France or its neighbors.

VIII. UNIONS AND MARRIAGE

For some years now in Western countries and for far longer in other societies, marriage has ceased to be the almost exclusive form of partner relationship. Different types of union are socially accepted and are just as likely to be adopted by couples who want to start living together. We shall not discuss here the potential diversity of these unions (with or without cohabitation, substitute for or prelude to marriage, etc.). We will simply examine the problems inherent in analyzing a situation in which marriage exists alongside other types of union. Solutions for these problems may be sought in two directions: aggregating all unions (marriages and other forms) and computing the total frequency of their formation or distinguishing between marriage and alternative forms and calculating the respective frequencies of either.

In the first case, as all forms of union are analyzed in the aggregate, their quantum is measured under the principles already developed for measuring the quantum of marriage alone. Accordingly, we classify unions by their rank in the life of male or female cohorts and we compile a first-union table similar to the first-marriage table, using probabilities by age (ratio of the number of first unions to the number of persons who have never lived in a partner relationship). To obtain a rough measure, we can calculate the following: (1) *first-union frequencies* (i.e., the ratio) at each age, of the number of first unions to the number of persons in the cohort, regardless of whether its members have already lived in a partner relationship or not (this is an equivalent of the unions in the first-union table); or (2) proportions of persons who have never lived in a partner relationship, (i.e., the ratio), at each age, of the number of these persons to the total size of the cohort, regardless of whether its members have already lived in a partner relationship or not (this is an equivalent of the frequency of life without spouse or companion in the first-union table).

The core difficulty lies not in the theoretical definition of these aggregates, but in collecting the statistics required to calculate them. By nature, unions without marriage go unrecorded in the administrative system and are not enumerated in the same way as events included in civil registration. Demographers usually resort to surveys of individuals to determine their marital life course and determine first-union formation retrospectively. The number of first unions at different ages and the population at risk are therefore calculated by aggregating individual data on survivors present at the time of the survey. As is always the case with retrospective observations, the statistics obtained are initially cleansed of the disruptive effects of mortality and migration; but we also need to make sure that the resulting selection in the composition of the respondent sample has not altered the representativeness of the sample relative to the population profile at the time the unions were formed.

A 1986 French survey was used to prepare a table of first-union formation for female cohorts born in 1938 and subsequent years. Table 25–4 in the Appendix shows the universality of partner relationships, whose frequency consistently approaches or exceeds 94%. By subtraction, the proportion of women never having lived with a husband or companion is thus under 6%. There is no perceptible change in the pattern over time. The first union occurs early, on average at age 22; the mean age declines slightly from one cohort to the next. These results deserve comparison with the frequency and tempo of first marriages in the same cohorts. In the oldest age group, the differences are modest: More than 92% of women born in 1938 to 1942 have married and more than 94% have lived in a partner relationship; the mean ages at first marriage and first union were 22.6 and 22.3 years, respectively. In an overwhelming majority of cases, therefore, first union and first marriage coincide. Fifteen cohorts later, the picture is different: Only 85% of women born in 1953 to 1957 have married and 97% have lived in a partner relationship; the mean age at first marriage is 22.7 years versus 21.5 years for the mean age at first union. Not all women who have lived in a partner relationship have married; first marriage does not coincide with first union, and often comes later. It is therefore well worth determining the form of the first union; we can always investigate later on the extent to which unions initially formed outside marriage were subsequently legalized.

We have already encountered a comparable problem in the analysis of terminations, where we distinguished between their two forms: divorce or death of a spouse. However, we eluded the issue, for example by stressing that divorce was rarely prevented by early death, as widowhood generally occurs at longer marriage durations, when the risk of divorce is low. We cannot apply this reasoning to the study of union forms, as the two alternative events (starting one's life in partnership with a marriage or a consensual union) can occur at the same ages. The difficulty is similar to the one encountered in measuring mortality by cause of death. Let us look at the options available:

1. We can always calculate the probabilities of a first partner relationship in marriage and the probabilities of a first consensual-union partnership for different ages. In a sufficiently short time interval, the probabilities will consist of the ratio of the number of events to the number of persons who have never yet lived in a partner relationship at the start of the interval. At the same age, the two probabilities are additive, given their common denominator. Their sum is a probability of first partner relationship, identical to the one computed earlier, for example in preparing Table 25–4 in the Appendix. We therefore obtain two series of probabilities and a sum-series; the difficulty is to combine the probabilities at successive ages.
2. The first solution consists in leaving the two series of probabilities together, preserving their additivity. We thus construct a double decrement table. From one age to the next, the number of persons never yet having lived in a partner relationship falls at the pace shown by the sum probability; in the interval, the number of new unions is distributed between marriage and consensual union in proportion to the

corresponding probabilities. The table therefore contains two branches—marriage and consensual union—and the size of each branch partly depends on the size of the other. For example, in the French female cohorts reported in Table 25–4 (Appendix), the distribution of first unions before age 36 between marriage and consensual union went from 87% to 13% for women born in 1938 to 1942 to 56.5% to 43.5% for women born in 1953 to 1957 (Thierry, 1993).

3. Can we move beyond that stage and supply a summary measure of the frequency of each form of union that is independent of the frequency of the other form? The answer is presumably negative, as it does not seem reasonable to postulate, for example, that the probability of a first consensual-union partnership, at age x, is not influenced by the number of marriages before age x. Absent independence, the combination at successive ages of the probabilities of a single series (first partner relationship in marriage or first partner relationship in consensual union) does not have the same significance as an intrinsic measure of the frequency of either type of union. It is preferable either to abandon this operation, or to try to comply with the independence condition.

Indeed, we saw that dependence resulted from the combination of two circumstances: in the group studied, the risk of either form of union differs between subgroups, and this heterogeneity is concurrent with a correlation between the two types of risk (either in subgroups where one is high and the other is low, and reciprocally; in subgroups where both are high; and in subgroups where both are low). We must therefore find a segmentation of the population into groups such that the heterogeneity or the correlation is eliminated in each. The same requirement exists when the aim is to obtain an intrinsic measure of surviving a given cause of death, *absent* the other causes (see Chapter 44). Such investigations are the focus of differential demography.

The same principles are at stake in the next step of the analysis when, once the union is formed, we examine its outcome. If the first union is not a marriage, it can be ended by two events: termination (generally through the partners' separation; far more rarely, under present circumstances in Europe, by the death of one of the partners) or legalization [i.e., the transformation of the consensual union into marriage]). The two outcomes are radically different. We cannot reasonably postulate, for example, that the probability of legalization computed for couples still united y years after their formation could have been equally valid for couples prematurely terminated through separation, *absent* such separations. This nonindependence leads us to calculate a double-decrement table for consensual-union terminations or seek to break up the cohort into more homogeneous subcohorts in an effort to create the statistical conditions for the independence of the separation and legalization risks.[6]

IX. NUPTIALITY AND FERTILITY

Nuptiality—in the broad sense, encompassing unions and marriage, formation and termination—has complex links with fertility. The simple notion that fertility is curbed by an abundance of never-marrieds and by late marriage applies only to populations with weak fertility control and strong social control over sex outside marriage. No Western country is in this situation any more. If the women who married earliest still have an above-average total number of children, it is no longer because of a greater *duration of exposure to risk* but because early marriage is associated with differences in sociocultural level, attitudes to the family, and contraceptive practices. Admittedly, some quasi-mechanical link may persist between age at marriage and age at childbearing. This is attested by the correlations between the two variables, measured between countries (early nuptiality and fertility in Central/Eastern Europe, late nuptiality and fertility in Western Europe) or across time (concomitant decrease in ages at marriage and at childbearing in Western Europe from 1950 to 1975, then reversal of the trend in the final quarter century). But the direction of the causalities is not established: Do people marry young *to have* children early or is childbearing delayed *because* marriage was postponed first?

This complexity is illustrated here with a few contemporary examples of the connections between unions, marriage, and fertility (Figure 25–2) and between divorce and the number of children.

1. The Place of Children in Marriage

In France, in the late 1960s, more than 60 of 100 children conceived by unmarried parents were born legitimate as a result of the fathers marrying the pregnant mothers. In addition, the other children, born illegitimate, did not all remain so: More than half of them were later legitimated by their parents' marriage. In all, more than 60% of the children conceived outside

[6] On all these issues, see the article by Xavier Thierry (1993) and the ensuing debate in *Population* (Courgeau and Lelièvre, 1994; Festy, 1994; Blayo 1995).

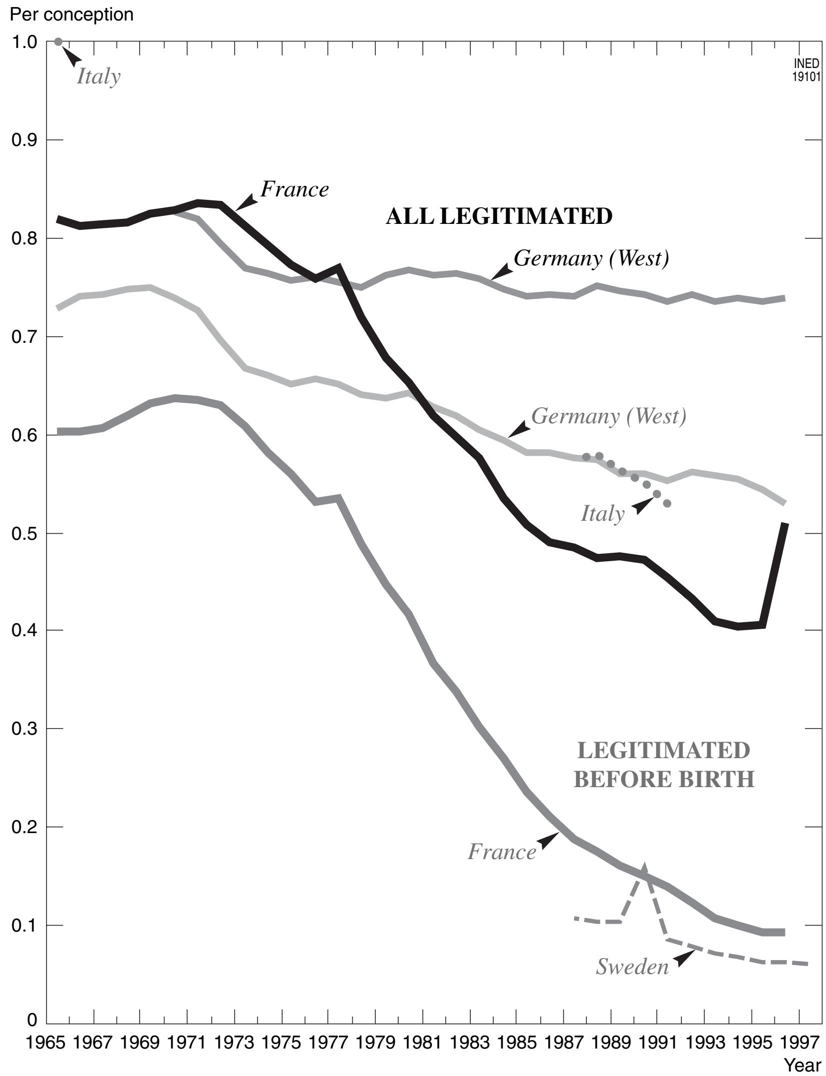

FIGURE 25–2 Proportion of legitimated conceptions outside marriage.

marriage were directly legitimated and 20% acquired legitimacy some time after birth through their parents' marriage—making a total of over 80%.

In the quarter century between the late 1960s and the mid 1990s, the number of children conceived outside marriage doubled, in France, from more than 150,000 to nearly 300,000 per year. But, in the same period, the number of unmarried women of child-bearing age doubled as well, from 3.8 million to 6.9 million. In other words, fertility outside marriage (measured at conception and not at childbirth) hardly varied in the interval. The increase in these births seems directly due to the fall in nuptiality, which swelled the never-married population without altering its fertility behavior.

By contrast, the fate of children conceived outside marriage has changed profoundly. Twenty-five years ago, nearly two thirds of them were legitimated by their parents' marriage even before childbirth; today, the proportion is less than one in 10. The desire to provide a robust legal framework to the birth of a child—a most eloquent indication of the importance assigned to marriage—has almost completely disappeared.

The future of children conceived *and born* outside marriage confirms this disaffection. Formerly, more than half of them would attend their parents' marriage and thus be legitimated (with a slight delay); today, the proportion has fallen to one third. In all, four in 10 children conceived outside marriage are raised in a marriage, one in 10 at childbirth and the three others a short while later (on average at 2 or 3 years old). The proportion in the late 1960s was more than eight in 10, of whom more than six at childbirth. The strong link that used to exist between the announcement of the birth of a child and the likelihood of the parents' marriage has been sharply weakened (Munoz-Pérez and Prioux, 2000).

This shift is, of course, largely due to the widespread acceptance of consensual union as an alternative partner relationship to marriage. An increasing number of children are conceived in these stable but nonformalized unions and, more and more often, the parents never marry. However,

> In unions of equal duration, unmarried couples are less fertile than married ones. From one cohort to the next, the relative fertility of cohabitants (in terms of conceptions) is [even] steadily declining, compared with married couples: if we set the conception rate for married couples to unity, the relative fertility of cohabitants, for a union of equal duration, is 0.75, 0.63, 0.50 and 0.39 for unions formed in ca. 1970, 1975, 1980, and 1985 respectively (Toulemon, 1994).

The proportion of couples who legitimate their pregnancies by marrying before the outcome has varied very widely from one country to another since the late 1960s, when it was high in almost every country, at around 60% or above. In northern Europe, including the United Kingdom, the proportion has fallen steeply—at least as much as in France—to 10% or even less; in Sweden, for example, only 4% of pregnancies outside marriage are legitimated by the parents before childbirth. In southern Europe, by contrast, the proportions have remained comparable to those of the 1960s; one example is Italy, where marriage still takes place in six pregnancies of 10. Between these two extremes, but close to the latter group, the countries of central Europe have recorded only a moderate decline in the nuptiality of pregnant women: in Germany (Western *Länder*) and Austria, more than half of all conceptions outside marriage are still legitimated before the completion of pregnancy. The case of Germany is all the more remarkable as, at the same time, the frequency of legitimations of born children has *increased* to well over 40%, versus barely 30% in the late 1970s. Today, three fourths of children conceived outside marriage in Germany are born in marriage or are legitimated shortly after birth. This has dramatically widened the gap with France in 25 years.

The dividing line in Europe separates the northwest from the southern and central parts, whereas the nuptiality trend isolated the south from the other countries. In fact, the differences in behavior toward children's status bear a greater resemblance to those that emerged during the decline in fertility in the past three decades than to the gaps that widened during the increase in age at marriage. Central Europe (in particular, Germany) and southern Europe (in particular, Italy) have recorded the sharpest falls in fertility, even as the decline in nuptiality was still moderate. In these countries, the attachment to marriage as the preferred framework for starting a family has blocked the rise in fertility outside of its traditional legitimate form. It has prevented the partial compensation of the decline in legitimate births by the rise in illegitimate ones—which has taken place more easily elsewhere, most notably in France.

2. On Divorce and Children

The relations between the presence of children in a couple and the risk of divorce are extremely complex and hard to unravel. The number of children is not the only determinant: the age of each, in particular the age of the youngest, also plays a role. Moreover, couples need time to have children and further time for the risk of divorce to show its effects. For France, the most eloquent results are the following (Toulemon, 1994):

- If we set the childless-couple divorce risk at unity for couples married in 1960 to 1979, the risk for a couple with child equals unity when the child reaches the age of four. From that age onward, the child's presence no longer makes a difference.
- Before the age of 4 years, the younger the child, the lesser the chances of divorce. The risk is 0.35 when the mother is still pregnant or when the child is in its first year, 0.55 when it is in its second year, and 0.75 thereafter.
- When there are several children, the risk remains below unity even when the youngest child reaches age 6, but the value is nearly 0.9 and the gap with childless couples is narrow. By contrast, the risk stays well below that level while the latest-born child is very young.
- After the birth of a child, the divorce risk therefore remains low, or even minimal, for a time. This *honeymoon* period is repeated with each pregnancy, but the number of children is not, in itself, a barrier to divorce: Once the youngest starts school, the difference with childless couples is very small. However, the childbearing period overlaps with the period of high separation risk consisting of the first years of marriage. The protection provided by the presence of very young children coincides with the period of highest divorce risk.

For all child ages combined, the presence of children lessens the risk of divorce in the first ten years of marriage by about 30%. The dissolution risk for unmarried couples with children is the same or slightly higher. By contrast, there is a large gap between the dissolution risks for the two types of union: it is five time as high for unmarried partners as for married couples, regardless of whether the couples in either category have children or not. The couple's status therefore seems to be a far more powerful differentiation factor than the presence and number of children.

We lack comparable studies for older periods that would confirm what more summary indicators suggest: the number of children no doubt provided more effective protection when the frequency of divorce was lower, i.e., in marriages contracted before 1960.

X. MALE AND FEMALE NUPTIALITY

We have measured first marriage and remarriage with reference to the male or female population. For example, we defined the proportion of men or women contracting a first marriage; the basic measure is a ratio between a number of marriages and a population at risk of marrying. But although the availability of men plays an essential role in the number of marriages of men of a given age, the availability of women is also an important factor. The *marriage market* is a convenient image to remind us that marriage results from an adjustment between male expectations and female expectations.

Initially, however, demographers' attention in this area focused not on nuptiality but on fertility. Births—like marriages—can be studied in relation to the male or female population (fathers or mothers): this yields a definition of male or female fertility (see Chapter 19). Now, it can be something of a shock to find that an identical number of births produces different rates, depending on whether it is measured against the male or female population of reproductive age. More specifically, it is astonishing to find population projections yielding different results depending on whether they are based on male fertility or female fertility rates, if both fertilities have been calculated from the same number of births. The initial priority is therefore to obtain fertility indices that avoid this inconsistency by taking both the male and female populations into account.

Transposed to nuptiality, the problem takes on a different form. It is not surprising that the male population marries more or less completely than the female population, as we can intuitively grasp that male nuptiality will be more intense than female nuptiality if there is a relative shortage of marriageable men, and less intense if there is a surplus. Nor is the frequency of these numeric imbalances surprising, given that men, on average, marry women from other cohorts—most likely of a different size than their own. In a population of, say, 100 men and 110 women, we expect that 90 first marriages between the two will leave 10 of 100 = 10% of never-married men and 20 of 110 = 18% of never-married women.

The surprise, therefore, lies not in the unequal frequency of female and male nuptiality, but in the size and nature of the inequality. Let us illustrate this with a concrete example borrowed from Louis Henry (1966). Human losses due to World War I created a deficit in a well-defined set of French male cohorts. This shortage predictably led to an intensification of male nuptiality in those cohorts and a decline in female nuptiality in the slightly more recent cohorts, given that men, on average, marry women who are younger than themselves. But:

1. In the cohorts most directly affected, the modulations in total marriage frequency remained well below what one would have expected using a simple computation as described above.
2. These modulations spread beyond the depleted cohorts (i.e., the phenomenon regained in scope part of what it lost in magnitude).
3. The repercussions are perceptible not only on the frequency of nuptiality, but also on age at marriage. In the depleted male cohorts, men married younger; in the female cohorts showing a *surplus*, women married later. The difference in age at marriage between men and women was therefore affected.

These three phenomena are closely linked. Men do not find their wives in a single, specific cohort, but in a range of cohorts. The range also varies with men's age at marriage. The reciprocal pattern applies to women. As a result, the deficit of one sex or the surplus of the other does not impact *one* cohort of the opposite sex, but a range of cohorts—hence a dilution of quantum effects. In addition, numeric imbalances initially alter the position and openness of the cohort range before causing an intensification or weakening of nuptiality: The excess women will wait longer to marry, and they will accept husbands with greater age differences.

From these observations, demographers have made various attempts to identify the male and female cohorts whose nuptiality would be influenced by numeric imbalances. The basic principle is to compare male and female cohort sizes allowing for the normal age gap between male and female marriage. The simplest measure is the ratio of the size of a male cohort to the size of a more recent female cohort, generally 2 to 5 years younger. This rough index is then improved in two ways. The first is to make allowance for the fact that matches occur not between two cohorts, but between two ranges of cohorts, whose definition may vary with successive ages at marriage. The second improvement reflects the fact that marriage is not only an adjustment between populations of marriageable males and females, but also a quest for a partner who displays (or does not display) certain characteristics (in particular, age characteristics); this may take time, as a fruitless search may lead an individual to stay in or leave the marriage market.[7]

These various attempts at measurement have one point in common. They seek to identify the cohorts whose nuptiality is liable to change because of the numeric inequality between men and women at risk of marriage. In the present state of research, demographers seem to have abandoned the notion of a single index that would take the male and female populations into account simultaneously and would therefore measure *pure two-sex nuptiality* (i.e., independent of any imbalances between men and women). We are not dealing here any longer (or we are not yet dealing) with the measurement of nuptiality; we are already involved in determining the factors that influence the quantum and tempo of marriage.

CONCLUSION

Demographers' interest in nuptiality, in all its forms, is due to the role played by the partner relationship in exposure to the risk of fertility. However, the measures described in this chapter do not aim to assess the quantitative incidence of a particular characteristic of marriage on childbearing. We have seen how to determine the quantum and tempo of nuptiality at its different stages (marriage or union formation; divorce, widowhood, or dissolution; remarriage or formation of a new union) without asking ourselves if the couples formed or dissolved were likely to have children.

Indeed, marriages and partner relationships are a major social phenomenon that deserves to be measured in itself—and is thus governed by the same principles of quantitative analysis as many other social phenomena. These principles are borrowed from the demographic methods for measuring mortality, fertility, and migration. The notion of risk (probabilities) and that of a table are shared with mortality; the breakdown of the marital sequence into stages has its equivalent, for fertility, in the succession of births in the same sibling group; the convergence between two populations at risk—which defines the marriage market—is closely related to the double influence of a population of origin and of a population of destination in the migration process. In fact, rather than an adaptation of tools specific to classic demographic phenomena, one should speak of mutual exchanges: the measurement of nuptiality has often produced innovations that have subsequently been taken up in the analysis of mortality, fertility, and migration.

This is because nuptiality, in fact, is not so much a marginal topic in a narrow demography concerned with the replacement of localized populations through natural and migration flows; rather, it lies at the heart of a broader demography, attentive to the characteristics of, and changes in, any population. The exchanges (transitions) between married and nonmarried populations are actually just a first example of this generalized approach, which also applies to transitions between economic activity and inactivity, employment and unemployment, good health and bad health, and so forth. This extension not only has the virtue of offering demography an infinite field of measurement and application. It also gives greater visibility to demography's ties with a diverse set of disciplines such as sociology, economics, and epidemiology.

Event-History Analysis of Nuptiality

An Application to Africa

PHILIPPE ANTOINE

Institut de récherche sur le développement (IRD), Dakar, Senegal

The study of nuptiality is relatively complex, as it concerns renewable events and events not always recorded statistically. Demographic studies on nuptiality rely either on cohort data, often from civil registration records (Chapter 25), or on cross-sectional observations, which allow only a partial and limited description of the phenomenon. Neither data source conveys the complexity of the marriage life cycle, a process that fits into an individual life course, itself shaped by the broad trends in the society to which the person belongs. The approach to nuptiality based on event-history methods (questionnaires and analytical procedures) yields an abundant harvest of results. Thanks to these methods, we can not only describe the evolution of a phenomenon, but also attempt to explain the change and isolate the demographic, economic, social, and even legislative factors involved (see Chapter 23). After addressing the inherent difficulties of tracking the marriage life cycle, we will discuss the collection and analysis of event-history data on nuptiality with the aid of African examples—in particular, a study carried out in Dakar (Senegal).

I. COMPLEXITY OF MARITAL STATUSES: FROM CONSENSUAL UNIONS TO POLYGAMY

The concepts and definitions of marriage used in the classical analyses of nuptiality focus on marriage recorded by administrative authorities (civil registration) or religious authorities (parish registers).[1] However, the data collected from these sources prove inadequate to describe the social reality of unions. Couple formation goes through several distinct phases: In Western countries, for example, an increasing number of couples begin with a consensual union; a proportion of them later officialize their partnerships, especially after the birth of children or for tax reasons. In France, prenuptial cohabitation rose sharply in a quarter century. Between 1960 and 1985, the proportion of unions starting with prenuptial cohabitation climbed from 10% to 43% for marriages before age 25 and from approximately 10% to 59% for those celebrated at age 25 or thereabouts[2] (Léridon and Villeneuve-Gokalp, 1994). These couples may eventually separate; later on, either spouse may enter into a new union, official or consensual, with another partner or remain single. Among the young, the variety of statuses is increasing—for example, cohabitation in one's parents' home, or intermittent cohabitation (Battagliola *et al.*, 1991). Only a survey of partner-relationship histories can describe the transitions between statuses. To illustrate the complexity of the marital life cycle, I will draw on African examples, which—in addition to the patterns mentioned above—frequently involve polygamy.

[1] In most European countries, religious marriage is on a steep downtrend (Dittgen, 1995); by contrast, consensual union is increasing sharply, and civil registration records now provide only a very incomplete picture of changes in nuptiality.

[2] These results were obtained from a specific cohort survey.

1. Stages in a Union

In Africa, marital life courses are made more complex by the fact that most marriages are not marked by a single event; they often require several compulsory stages before the spouses actually cohabit (van de Walle, 1968). In Bamako (Mali), for example, the first stage is typically engagement, which signifies that the parents of the wife-to-be accept the suitor as their daughter's future husband. We then need to distinguish between three types of marriage: religious, civil, and traditional. The three ceremonies are distinct and can be celebrated the same day or on different days, provided the religious marriage always precedes the traditional ceremony. Although the code stipulates that the civil marriage must be celebrated before the religious marriage, in practice the sequence matters little. The three marriages are rarely celebrated together, and one therefore observes lags between the ceremonies.[3] Cohabitation is sometimes allowed by the bride's family, which is empowered to lend its daughter as soon as the religious marriage has taken place. For a couple completing these stages at different dates, which will be regarded as the date of the marriage? Clearly, for the most religious, the most traditionalist or the most emancipated persons, the three celebrations will have different meanings (Djiré, 1993). Improvements in the distinction between legal, traditional, and religious marriage and in dating the start of cohabitation have been provided in some countries by the surveys executed under the World Fertility Survey (WFS) program. One example is the Côte d'Ivoire survey, in which the flexibility of questions on the type of union has made it possible to distinguish between the different forms of cohabitation (Brandon, 1991). In a recent survey on urban integration in Bamako, the authors have sought to pinpoint the marriage stages as precisely as possible (Ouédraogo and Piché, 1995).

The need to distinguish between union forms is, in itself, an indicator of the changes in marital behavior driven by the emergence of new practices that depart from traditional rules. These changes also require a better definition of the concept of divorce (formal dissolution of a formal marriage) or separation (informal dissolution of a formal or informal marriage). In Africa, the dissolution of unions is just as hard to track as their formation. Separation is not always final: In a customary marriage, families often attempt a reconciliation (Pison, 1986). Families may also intervene while divorce proceedings are under way. Typically, there is a rather long period between the end of cohabitation and the divorce ruling.[4] The question then arises: What should be regarded as the date of the divorce (Smith *et al.*, 1984)?

2. Changing Types of Union

A union changes over time: A consensual union may subsequently be confirmed by a civil or religious ceremony. In a recent study in Antananarivo, the capital of Madagascar, we have tabulated—with precise dates—the spectrum of union celebrations all the way from the absence of ceremony (consensual union) to marriage marked by a near-concomitant celebration of civil, customary, and religious marriage (Antoine *et al.*, 2000). Among women, we found a sharp increase in the proportion of nonformalized marriages (consensual union or *tokantrano maso*) or weakly formalized marriages (customary marriage or *vodiondry*) from one cohort to the next (Table 26–1). Purely religious marriage does not exist, and the proportion of unions starting with a religious ceremony has been falling steadily. In the aggregate, unions formalized at the town hall or (and) in a religious ceremony have fallen from 67.5% for the oldest cohort of our survey to 41.4% for the youngest. Thanks to event-history analysis, we can determine the outcome of unions at the end of a set period. We have specified an interval of ten years: by the end of the period about half of the informal unions had been formalized, while just under 20% had ended in separation (Table 26–2).

Marital mobility, in particular of men, poses another classification problem among ever-marrieds (Pison, 1986; Donadjé, 1991). In nuptiality studies, individuals

[3] In fact, the three celebrations are not always performed.

[4] In some cases, the separation is even harder to document because the spouses did not cohabit.

Marriage	517	222	0	0
Divorce	50	7	76	0
Widowhood	7	4	0	8

Source: IFAN-ORSTOM 1989 survey.

are usually classified as never married, married (monogamous or polygamous), divorced, and widowed. In fact, however, many changes can occur in the individual's life cycle after a first marriage: A widower or divorcee at a given date may formerly have been polygamous. Polygamy is largely measured from cross-sectional indices such as the proportion of polygamous men among married men, the proportion of women in polygamous union, the mean number of wives per married man, or the mean number of women per polygamous man (Donadjé, 1992; Klissou, 1995).

However, the ever-marrieds in each of the standard categories display different past nuptial characteristics and have not necessarily contracted the same number of marriages before ending up in the same marital category: Some bigamists, for example, are in their second marriage, whereas others have celebrated more than two marriages but have kept only two wives at the study date. One should take greater account of the distinction between marital events and period marital status. Different kinds of events can lead to the same marital status. Donadjé (1992), who has collected marital event histories, distinguishes between stable monogamous men who have been in a single union, unstable monogamous men who have been in more than one union, stable polygamous men who, after the second wife, have never returned to monogamy, and unstable polygamous men who have become monogamous again at least once in their lives. However, this typology is far from exhausting all the possible combinations if we include divorcee status. A few simple cross-classifications (Tables 26–3A through 26–3C) based on the Dakar survey (see subsequent sections) reveal this complexity. For example, we can see that a large share of divorcees (43%) are men who have several wives and are therefore still married after divorcing (Table 26–3A). Likewise, 30% of marriages entail a transition to polygamy. Although the shift to monogamy is the only marital transition for a bachelor, monogamous men move to polygamous status more often than to divorced status, whereas polygamous men may return to monogamy (Table 26–3B). On average, monogamous men experienced 1.32 marriages, 0.25 divorces, and an infinitesimal proportion of widowhoods at the time of the survey. Logically enough, polygamous men experienced more marriages (2.5 on average) and relatively fewer divorces (0.2) (Table 26–3C).

Most demographic studies make no allowance for the complexity of the sequence of these marital events.[5]

[5] Demographic and Health Surveys (DHSs), in particular in Togo, occasionally fill part of the gap by gathering information on birth history and marriage history—without, however, the possibility of linking these to the person's occupational or residential histories. Some event-history analyses have been conducted on this type of data. Thiriat (1998) shows, in Togo, that urbanization and schooling are the main factors in the increase in age at marriage and that there is a widening dissociation between sexuality and nuptiality.

TABLE 26–3B Period Marital Status by Previous Marital Status (Married Men Older than 35 Years, Dakar)

Previous marital status	Period marital status			
	Monogamous	Polygamous	Divorced	Widower
Bachelor	451	0	0	0

Changes in marital life captured in a dynamic approach must be integrated into the complete life cycle to assess the interaction between marital events and the change in the individual's economic and social status. Event-history surveys yield new information on the marital life cycles of men and women and on their socio-occupational histories. These data can provide a better understanding of the evolution and determinants of nuptiality, in connection with other events in the individual's life.

II. NUPTIALITY ANALYSIS AND EVENT-HISTORY ANALYSIS

The principle of the retrospective event history is to record the main events known to an individual from birth concerning his or her activity (including education), marital life (formation and dissolution of households), and residential life (mobility, *decohabitation*, access to home ownership). This information, known as *tri-biographical* (Courgeau and Lelièvre, 1989), can also be supplemented by birth history or any other information that can offer additional insights for the analysis of individual histories. The complete event history sheds greater light on the interrelationships between working career and marital life or between family life and dwelling changes. As a result, demographers no longer separate the analysis of marital events from the changes in an individual's living conditions. Several studies have been performed using this approach with the aid of event-history methods. For example, some recent work in North America has focused on the interference between women's working careers and their marriage outcomes (Hiedemann *et al.*, 1998; Neill and Le Bourdais, 1998; Le Bourdais, Neill, and Vachon, 2000). The aim is a better understanding of the demographic, economic, and social determinants of the formation and dissolution of unions, by viewing marital events against other dimensions of personal life. The purpose is less to measure the scale of a phenomenon than to identify the main factors that can promote it or not. Three concrete examples from a study carried out in Dakar will be used to describe the collection and analysis methods and highlight the value of measuring the influence of male working careers on marital dynamics.

1. Description of Dakar Survey

The main purpose of the Dakar study is to show the impact of worsening living conditions on demographic and social behavior. The IFAN-ORSTOM team in Dakar selected three dimensions: access to work, access to housing, and the formation of the household (through marital history and children's life courses). How do city dwellers manage to satisfy various needs—particularly jobs and housing—when they may not possess the same strengths and do not have the same demands?

The collection of *quantitative event histories* relies on the respondent's supply of an accurate time line of events experienced (GRAB, 1999). The problem is that few people memorize the dates of all the events they have experienced; by contrast, the sequence of family events is easily stored in memory. The Dakar survey (Antoine and Bocquier, 1999) used the AGEVEN (age-event) form to help respondents date the main events of their lives. Before starting to fill out the questionnaire, the interviewer asks the respondent to locate in time the main events of his or her family life, migration and residential life, and working career. The data are not collected in a preset order. As the interview progresses, events are recorded on a form showing a time scale (in calendar years) and the time lapsed since the event. This allows the events to be classified without too much difficulty.

From a representative sample of Dakar and its suburbs comprising more than 2100 households and 17,900 individuals,[6] we drew a subsample for the event-history survey. The individuals were selected according to a stratification by sex and age group (25–34 years, 35–44 years, and 45–59 years), so that we were able to interview an equal number of persons in each cohort. This was needed to minimize problems due to inadequate numbers that could arise when comparing cohorts. In the end, we collected 1557 event histories in Dakar in the last quarter of 1989.

2. From Questionnaire to Statistical Processing

Event-history collection requires a fairly long and complex questionnaire. The most practical solution seemed to be to gather the information by broad topic: activities, nuptiality, migrations, and so forth. For example, interviewers posed an identical series of questions on each union. At the end of the operation, we had series of event-history information on specific individuals. The transition from the questionnaire to computer files was a delicate process. In the Dakar survey, we had parallel series of migration histories, occupational histories in Dakar, urban residential histories, marital histories, and descent histories. For each topic we created a file in which the events concerning a single individual were dated and classified on a time line. For marital data, the main information was the date of entry into union, characteristics of the union and of the spouse, and the date of the end of the union, either by separation or death of the spouse. We therefore needed to prepare the marital file in such a way as to identify the date of each marital event (union formation or break up), and the successive marital statuses that each individual may have experienced. We then had to merge the marital file with the other files containing the other histories to obtain a single file with all the events experienced by the individual, in chronologic order. This computer task required specific procedures for data merger in time. They were tested in the Dakar survey and developed by Bocquier (1996) with the aid of the Stata software program, which seems particularly well suited to this type of study.

For a single individual, the file contains as many lines of information as status changes. We can therefore determine, at each point of the individual's life, his or her occupation, place of residence, marital status, children born—along with information on each event—and establish connections between the items. The events are dated and, for each period of the individual's life, we know the time spent in a given status, as shown in our example (Table 26–4A and 3B). Indeed, it is essential to arrive at a consistent collection of dates of transitions between life stages. The novel feature of event-history analysis is the possibility of determining time relationships between life events. It is therefore indispensable, when collecting the data, to locate the events in each dimension relative to the others (for example, marriage relative to employment, employment relative to access to housing, etc.). For this purpose, the accurate recording of the event sequence matters more than the precise dating of the events (to the day or to the month). In particular, the date-recording system should be capable of locating the relative positions of same-year events, even when the exact months are not known (Bocquier, 1996; GRAB, 1999).[7]

Table 26–4A summarizes the history of a man who has experienced four unions. The date of each marital event (marriage or divorce) is converted into a number of months elapsed since January 1, 1900. The man was first married in January 1968 (817 months after January 1, 1900). Thirty-eight months later (855 − 817), he divorced his first wife. He remarried shortly after (November, 1971) and a year later took another wife and became polygamous (December, 1972). In July of 1973, he divorced his first wife (first wife in his household at that date, but second union in his life). He remained monogamous for nearly 8 years until

[6] Random two-stage sample drawn from districts in the 1988 census covering the entire Dakar conurbation.

[7] For example, in Dakar, we have used a coding system for events occurring in the same year, but in months that have not been precisely determined. If three events occur in the same year, the first is coded 33, the second 66, and the third 88. Later, during computer processing, a fictitious month will be assigned to each event to preserve the order of occurrence.

TABLE 26–4A Marital Statuses Experienced by a Specific Male Individual Since His First Union

Spouse rank	Number of spouses	Marital event	Marital status	Date of start of period	Date of end of period
1	1	Marriage	Monogamous	817	855
1	0	Divorce	Divorced	855	863

October 1981. He then remained without wife for 10 months, and at the time of the survey (1080 = December 1989) he had been married again (for the fourth time) for more than 7 years (since August, 1982). The dating system is therefore very flexible and allows multiple analyses. For example, we can obtain the individual's age at each event. This man was born in 1947 (we arbitrarily assign him the month of July, or 571 months since 1900) and we can thus determine that he was 20 years old at his first marriage, 24 years old at his second, 25 years at his third, and 35 years at his fourth (ages in complete years).

But the example above does not exhaust the possibilities of this type of data file, which comprises a number of rows equal to the number of events. The principle is the same for each history and, in the case of the man we have just discussed, the file contains 21 rows for the 21 status changes since his first marriage. Table 26–4B recapitulates his marital status, neighborhoods of residence in Dakar, occupations, and number of children, as well as the mother's reference number. As we can see, a new row is created in the file with each status change. It includes the information from the previous row that has not changed and the updated information on the new event. The variables used in our example represent only a tiny fraction of the ones available in the file. Such a file makes it very easy to conduct complete event-history analyses covering an individual's entire life. Data and analysis of this kind make it possible to transcend cross-sectional analysis and take into account an individual's successive statuses. We can thus study marital history and occupational history, and factor in their reciprocal influences. Does marriage quicken women's entry into—or exit from—the labor market? Does divorce lead to new occupational statuses? These are just two of the many questions that can now be answered.

Preparing the data in this way may be fastidious, but it is a prerequisite for analysis. In particular, all the event histories must end on the same date (i.e., the survey date [1080]). Thanks to the time sequencing of events, we can move on to analyze the event histories themselves.

3. Fundamentals of Event-History Analysis: the Concepts of Population at Risk and Censoring

Once we have created the complete file, we can perform a number of analyses. Each specific analysis (entry into first union, end of union through divorce, remarriage after divorce, etc.) consists of measuring the time between a reference moment common to all the individuals and the date of the observed event or the date of exit from observation. This method chiefly demands a rigorous conceptualization of the issue studied. The population at risk, the event studied (the risk), and the competing risks that will cause the individual to exit from the observation must all be precisely defined. For example, if we study the transition from never-married status to first marriage for males in Dakar, the *population at risk* will comprise never-married men living in Dakar at age 18; the time interval will be measured from the 18-year anniversary date to the marriage date. A man arriving in Dakar after age 18 will not be included; a man leaving Dakar before his marriage will be included up to his departure date. This method of handling *censoring* makes it possible to take all event histories into account, even those of young cohorts observed up to the survey date (this is known as *right-censoring*). The procedure helps us to compute the regression coefficients. The diagram below shows a population at risk and the possible censoring events (Figure 26–1).

Using a similar approach, we can study male divorce (breakup of first union) or entry into polygamy. In both cases the population at risk is the same—men in first union—and the time examined runs from the date of the first union up to the date of the event defined as the risk. When the event studied is divorce, the censoring events are departure from

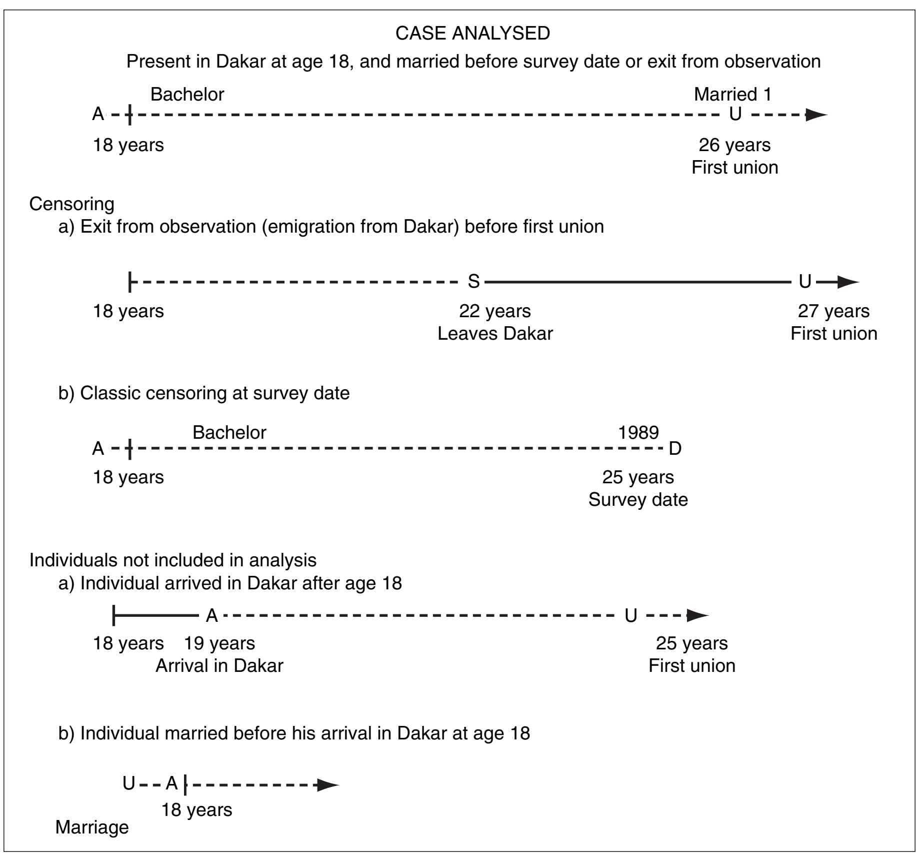

FIGURE 26–1 Population at risk: male bachelors living in Dakar at age 18. Risk: first union in Dakar.

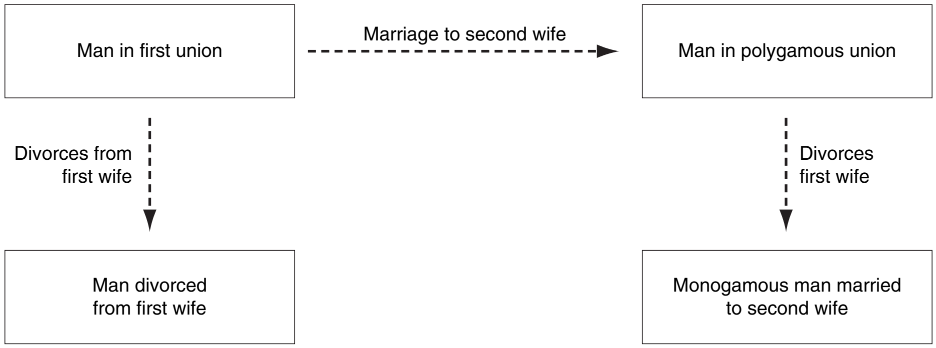

FIGURE 26–2 Diagram of possible statuses: transition from union with first wife to union with second wife (with or without divorce).

Dakar and widowhood. By contrast, entry into polygamous union is a variable that evolves over time and not a competing risk. Likewise, we can study entry into a polygamous union—but, in this case, divorce from the first wife constitutes censoring. The population at risk is that of men in first union, who may later be married to a second wife, either after divorcing the first or by becoming polygamous and later divorcing the first wife. The flowchart for this case is shown in Figure 26–2. Once the concepts used have been well defined, the causal analysis becomes easier.

4. The Semiparametric Cox Model: Introducing the Time Dimension into the Regression

Although event-history analysis emphasizes the time dimension, regression models omit it. We must therefore use methods that allow a combination of the time effect and the characteristics capable of explaining an event's occurrence. For example, we can study not only the time that elapses between the start of a union and its breakup in divorce, but also identify the factors that hasten the process.

Several methods and models are available (Courgeau and Lelièvre, 1989; Blossfeld, Hamerle, and Mayer, 1989; Trussell, Hankinson, and Tilton, 1992; Bocquier, 1996). Rather than give a catalogue of methods, it is more useful here to describe in detail some of the studies conducted with the aid of an event-history analysis method based on David Cox's semiparametric, proportional-hazards regression. Cox was the first to suggest combining regression analysis and the life-table principle (Cox, 1972; Cox, 1984).

The Cox model may be described as (1) taking account, by means of the regression, of the effect of explanatory variables in the life-table analysis or (2) the introduction of the time dimension into the regression. The advantages of one technique fill the gaps in the other. To solve the problem of duration and explanatory factors, the regression is performed not on the characteristic acquired by the individual at the end of his or her life, but on the characteristic acquired in each year of life up to the survey date. The reference status—required in the regression model—is not identical for the entire sample, but specific to each observation period. This series of probabilities makes it possible to define a baseline survival curve (for example, survival of never-married status if the analysis concerns first marriage), also called *baseline hazard function*: This is the model's nonparametric component. The regression model then computes the effect of explanatory variables on the annual risk of occurrence of the event. This is the model's parametric component, which is added to the nonparametric component to form a model known as semiparametric. A regression coefficient, measuring the variable's mean influence on the annual risk, is associated with each variable.

In a model of exit from never-married status, a variable that increases the risk of ending that status multiplies the basic risk by a quantity greater than unity; the converse is true of a variable that lessens the risk. For example, if the fact of being born between 1955 and 1964 rather than between 1930 and 1944 lowers the risk of marrying, the coefficient associated with the variable will be a number smaller than unity. If the value is 0.64, we will say that, all other things being equal, the modality concerned decreases the risk of marrying by 36% (or by just over one third). Alternatively, we can say that the modality divides the risk by 1.56, the reciprocal of the coefficient 0.64.

Time-dependent variables can be introduced into proportional-hazards models; in fact, that is one of the models' original features. The effect of independent variables whose value may vary during the observation is interpreted in the same manner as the effect of an independent variable with a constant value. A man who is successively an apprentice, a payroll employee in the informal sector, and unemployed contributes successively to the estimation of the risk of apprentices, of payroll employees in the informal sector, and of the unemployed. For interpretative purposes, this is the same as saying that the man is successively exposed to the risk change characteristic of apprentices, of informal-sector payroll employees, and of the unemployed.

III. FIRST MARRIAGE, DIVORCE, AND POLYGAMY IN DAKAR

The analyses presented in the following paragraphs are restricted to men aged 25 to 59 years (at the time of the survey) for the analysis of first marriage and to men aged 35 to 59 years for the analyses of divorce and polygamy. We have confined our sample to men as one of the problems in analyzing polygamy among women is the need for a complete record of husbands' marital histories. For each woman, we have information on all her unions and on the marital status of the husband at the time of the union, but we do not know the later changes in her husband's marital status (Does he have an additional wife? Has he divorced his previous wife?). This means we cannot monitor the dynamics of polygamy from data exclusively concerning women. With the latter data we can only study women's entry into union and try to establish, according to the husband's characteristic, if he was already in a union or not. We can also construct some simple indicators such as the proportion by age of women who begin their marital life in a polygamous union. In a more recent survey of the same type conducted by IFORD, some questions were introduced with the purpose of gathering the marital history of husband(s) from the wives (Kouamé *et al.*, 1999), but the results were not conclusive. Many women refused to give information on their co-wives (or rivals).

1. Explanatory Factors

Different explanatory factors, materialized by variables, are tested for each analysis. For the analysis of exit from never-married status, the following variables were selected.

- Birth cohorts are determined from dates of birth and reproduce the boundaries used in the sample stratification. The study focuses on the histories of three cohorts: men born between 1930 and 1944 (aged 45–59 years at the time of the survey), between 1945 and 1954 (aged 35–44 years at the time of the survey), and between 1955 and 1964 (aged 25–34 years at the time of the survey). The three cohorts experienced different economic conditions at the time of their entry into union, extending from Senegal's early independence years (1960s) to the slowdown of the 1970s and the crisis of the 1980s.
- The age at arrival in Dakar gives an idea of the migration history and allows a distinction between persons born in Dakar (the reference group) and the different types of migrants by age at arrival.
- The individual's ethnic group is that of the father, recorded by the survey. The largest and most urbanized ethnic group, the Wolof, is used as the reference.
- Islam is the dominant religion (95% of the population). We distinguish between the members of Muslim brotherhoods (reference), Muslims outside the brotherhoods, and Christians.
- The last grade attended serves as the indicator of education attainment. Five categories are used: no schooling; study at Koranic school for at least 7 years (without attending official school system); attendance in first grade (*cours préparatoire*) or second and third grades (*cours élémentaire*) (four years of schooling or less); fourth and fifth grades (*cours moyen*) or middle school (*collège*) (5–10 years of schooling); high school (*lycée*), technical education, or higher education. The reference group consists of men who have never attended school.
- Economic activity, residence status, and type of dwelling are independent variables that vary over time (i.e., the same person can experience different statuses during his or her lifetime).
- For *activity periods*, we distinguish between the following statuses: public-sector employee; private-sector employee; informal-sector employee; informal-sector self-employed; apprentice; student; unemployed.
- The *dwelling occupancy status* acts as an indicator of a certain degree of economic autonomy for individuals who are tenants or owners as against being housed by their parents or another relative.
- The *dwelling type* is an indicator of social differentiation, as a proxy for the social category of the household where the individual has lived in different stages of his life (Antoine *et al.*, 1995).

For the analysis of polygamy and divorce, we use only the two oldest cohorts. Some variables are identical to those used for the analysis of entry into first union: *age of arrival in Dakar, ethnic group* (of husband

and first wife), *religion*, *activity period*, and *dwelling occupancy status* with slightly different categories. A variable reflects the timing of the first union: *the man's age at first marriage*. These variables enable us to modulate cohort analysis by taking into account the variation in age at marriage, and to check whether polygamy or divorce vary as a function of later marriage.

Was the father polygamous (in the study on polygamy) or *was the father divorced* (in the study on divorce)? These two items tell us if family antecedents influence marital behavior. For polygamy, we can venture the hypothesis that the young man reproduces his father's marital behavior. *Kinship between spouses at first marriage* is also an indicator of marriages often arranged by the family. With this variable, we can test whether such unions are stabler. The questionnaire should have been more specific and should have been designed to establish whether the spouse was chosen or if the union was arranged. We can also advance the hypothesis that these unions, where the freedom of choice is low, can promote polygamy.

The last grade attended is used as a measure of *educational attainment*. Three levels are distinguished for the husband and for the first wife respectively: no schooling (reference category); elementary school; secondary school and higher. A hypothesis often put forward is that high educational attainment is the main inhibitor of polygamy.

In the analysis of divorce, the *arrival of the second wife* is taken into account from the date of the second marriage. The variable enables us to measure the effect of polygamy on a dissolution of the first union. In the case of divorce, we factor in the *number of children from the first marriage*.

2. First Marriage of Men in Dakar

In Dakar, we observe a sharp slowdown in the pace of entry into first union between the oldest and the youngest cohort (Antoine *et al*., 1995). Between the oldest cohort (1930–1944), with a median age at first marriage of 26 years, and the intermediate cohort (1945–1954), the gap in the median age at first union is two years. The gap widens further between the two youngest cohorts. The timing of first marriage has moved up five years to a foreseeable median age of 33 years for the 1955 to 1964 cohort. Despite such timing differences, marriage is by no means in jeopardy.

Table 26–5 reports the results of four analyses (Antoine *et al*., 1995; Antoine and Djiré, 1998). The first concerns all three cohorts combined; the other three analyses each concern one cohort, from the oldest to the youngest. The relative risk of entry into first marriage declines with cohort youth, but is not statistically significant (at the 5% limit) except for the youngest cohort. These youths are almost one half as likely as their elders to have entered into first union (0.64). Some individual characteristics promote a quicker entry into union, such as the fact of arriving in Dakar before the age of 12, or belonging to the Diola ethnic group. By contrast, males who stay in school beyond fifth grade, Muslims who do not belong to brotherhoods, and Christians marry later. But the strongest influence on the marriage rate is exerted by time-varying characteristics. For example, the fact of being in unemployment, in school, or in apprenticeship sharply slows the entry into first union, as is the fact of still living with one's parents or relatives. Crisis effects and cohort effect combine to make young cohorts marry later. But an analysis by cohort will provide a more detailed view.

The traditional marriage model still dominates the 1930 to 1944 cohort. Characteristics such as age of arrival in Dakar, ethnic group, religion or even educational attainment, activity status or residence status, and the dwelling category do not seem to influence first marriage (Table 26–5). Only apprenticeship seems to have some effect in reducing entry into first union. Marriage of men in this cohort seems virtually unaffected by economic factors. The marriages occurred between the end of French colonial rule and the late 1960s, which may be described as a period of relative expansion. There were fewer economic constraints, and household formation was a stage of the life cycle that did not depend significantly on economic well-being.

Some factors turn out to have a more discriminating effect on first marriage for the 1945–54 cohort. We observe sizable differences by religion. Muslims belonging to a brotherhood are the most prone to early marriage. They entered into first union twice as fast as Muslims outside the brotherhoods and eight times as fast as Christians. Those who have attended elementary or middle school are not significantly distinct from those with no schooling; only the young men with a high-school education or better marry at an older age. The latter display a rate of entry into union almost twice as slow as the members of their cohort who have never been to school. We find no meaningful difference between activity periods except for unemployment spells: The unemployed exhibit a marriage rate about five times as slow as that of the reference category (self-employed)—unlike their elders, who have almost never been out of work. It should be noted that unemployment has been a more powerful brake on marriage for this cohort than apprenticeship was for the preceding one. In the 1945 to 1954 cohort, employment and

housing constraints appear to emerge, already influencing entry into union.

More than for their elders, first marriage in the youngest cohort (1955–1964) has been more visibly subject to the effects of most of the characteristics specified, except for religion, which does not have the same hold as on the 1945 to 1954 cohort. Although the behavior of Christians does not differ significantly from that of Muslims belonging to brotherhoods, Muslims outside the brotherhoods have entered into union 2.5 times as slowly. Educational attainment is linked to lower entry into first union except for the men who have not gone beyond first grade or elementary school. The behavior of the latter category is largely explained by the activity period, and it is perhaps these young people who are most affected by unemployment.

Men in payroll employment show no perceptible difference in their rate of entry compared with self-employed men in the informal sector. For the 1955–1964 cohort, reaching majority and maturity in the 1980s was concomitant with greater tensions in the job market; as most of the men were seeking a first job, unemployment spells (as in the intermediate cohort group) and apprenticeship spells (as in the oldest cohorts) were the least conducive to early marriage. Apprentices were 2.5 times as slow to marry as self-employed men in the informal sector. But the differential was even wider in unemployment periods, where the risk of marrying was six times as small. Periods of residence in higher-quality dwellings (and hence of membership in better-off social categories) were not more propitious to an early first marriage, contrary to periods of residence in shanties, where the rate was 2.6 times the baseline. Middle-class marital behavior therefore seems to have been more affected by the economic crisis. The 1955 to 1964 cohort—for whom adolescence began with the 1970s recession that worsened in the 1980s—was the hardest hit in terms of family solidarity as well as on the individual level. Unemployment, the main consequence of the crisis, was a powerful brake to rapid entry into union.

3. Becoming Polygamous

In Dakar, the fact of having had a polygamous father quickens the entry into polygamous union, as if a section of Dakar society perpetuated a more traditional behavior (Table 26–6). Kinship with the first wife (synonymous with a family-arranged marriage) also fostered an earlier marriage to a second wife, confirming the hypothesis that when the husband has not chosen his wife himself, he will be quicker to marry another woman whom he may have met outside the family. By contrast, late marriage helps slow the entry into polygamous union. When the first wife's educational attainment reaches secondary school (or higher), the pace of entry into polygamy is halved: this corroborates the reluctance of educated women to accept the arrival of a second wife, or even their outright resistance to the idea. Christianity inhibits polygamy in Dakar. By contrast, the rate of entry into polygamous union seems unaffected by the age of arrival in the city, the husband's ethnic group, the first wife's ethnic group, the husband's educational attainment, or the husband's activity. As paradoxical as this may sound, Dakar is witnessing a diversification of polygamy patterns.

Urbanization does not spell the end of polygamy. It persists in Dakar, where it is vested with official, reli-

gious, and social legitimacy, and acts as a social and demographic regulator. It enjoys a popularity and a normality status that causes it to be perceived as commonplace—most notably by men, for whom it remains a privilege that they can claim, an ambition enabling them to flaunt their social success, a means of controlling and dominating women (Antoine and Nanitelamio, 1995; Antoine *et al.*, 1998).

4. Joblessness and Polygamy: the Main Causes of Divorce

The statistical analysis of event histories concerning divorce yields more contrasting results (Table 26–6). Several factors determine the pace of divorce. Kinship and the number of children slow a separation from the first wife; a preferential marriage is harder to break up, whereas it promotes polygamy. In contrast, economic precariousness favors divorce. Unemployment accelerates the risk of divorcing by a factor of more than three. The husband is supposed to meet household expenses; when his economic status deteriorates, the union is undermined. Failure to provide for one's wife is often cited as one of the main causes of divorce. The issue of economic precariousness and activity is, however, complex. In a study using a similar methodology on female nuptiality in Dakar, Bocquier and Nanitelamio (1991) have shown a higher risk of divorce among the youngest cohorts by comparison with the periods before the 1980s. They note that women's economic activity after marriage is the chief factor that increases the risk of divorce. Work means potential financial independence for the wife, giving her the capability of supporting herself and her children in the event of a divorce (McDonald, 1985; Burnham, 1987). For women who have worked before marriage and have left their jobs after marriage, the risk of divorce is smaller, corroborating the hypothesis of economic precariousness as a deterrent to divorce for women in that situation.

Men with a secondary-school education divorce twice as fast as men with no schooling. By contrast, better-educated women divorce more slowly than lesser-educated ones. A separate analysis (Antoine and Nanitelamio, 1996), cross-classifying the education attainments of the husband and his first wife, shows that too wide an education gap between spouses increases the risk of divorce. A husband with a secondary-school education or higher and an illiterate wife are three times as likely to divorce as a couple in which both spouses are illiterate. In contrast, the study finds no differences between the other education-attainment inequalities.

Gage-Brandon (1992), using an identical method (but without time-varying characteristics), shows that polygamy is an important factor in the instability of unions in Nigeria. For the study of divorce in Dakar, the polygamy episodes recorded in the marital event history have been factored in to test the hypothesis that the arrival of a second wife quickens the departure of the first. Entry into polygamous union indeed sharply accelerates the risk of the man's divorcing his first wife. The model incorporates only the sequence of events declared by respondents. However, our analytic template is close to true-life situations, as in many cases the first wife is placed before a *fait accompli*. Sometimes, she is not informed until the second marriage has already been celebrated. After this transition to polygamy, divorce may occur after a phase of observation and conflict. But the size of the coefficient (the risk of divorce is accelerated 3.7 times) shows that the situation often leads to divorce. Women are increasingly initiating divorce.

CONCLUSION

Event-history analysis makes it possible to evaluate interactions between events. For example, in Dakar, the cohort effect persists for the first marriage. Secondary schooling (and higher) slows marriage and accelerates divorce. But the main lesson of the analyses performed in Dakar is the major role of the job-market crisis on union formation or dissolution. Although the type of activity does not, in itself, influence the pace of marriage or that of divorce or emancipation, unemployment spells have a decisive effect. Unemployment sharply slows entry into union and hastens divorce. Educated men divorce more quickly than illiterate men, but residence in a high- or medium-level dwelling halves the probability of divorcing. Job insecurity hastens divorce, but material well-being slows it (Antoine and Djiré, 1998). When his economic position worsens, the husband can no longer meet the household's economic and financial liabilities for which he is responsible, and the union is in many cases at risk. In sum, the crisis-induced economic precariousness promotes divorce. Our analysis identifies few socioeconomic factors capable of explaining a differentiated behavior of males in regard to polygamy. Only a limited number of demographic mechanisms influence the phenomenon. The analysis of divorce shows a high risk of break-up of the first union after the arrival of a second wife.

Another valuable aspect of event-history analysis is the opportunities it offers for studying reciprocity. For example, we can analyze young people's residential autonomy as a function of access to employment or of marriage events. Tokindang (1995) has shown that, for Dakar's young generations, marriage and having a child are no longer—paradoxically—an incentive for couples to find dwellings of their own. Lack of work and lack of housing combine to slow marriage for young men, but marriage does not hasten access to an independent dwelling. A distinction is drawn between the formation of the couple and the formation of a new household.

The Complexities of Nuptiality

From Early Female Union to Male Polygamy in Africa

PHILIPPE ANTOINE

Institut de récherche sur le développement (IRD), Dakar, Senegal

Apart from its being less ostensible, in demographic terms, than mortality or fertility, nuptiality is a more delicate subject of study for two major reasons. The first is the ambiguity of the definition of marriage, which blends the legal and cultural concepts of the demographic event. The second is the renewability of marriage and especially the fact that it involves at least two statistical units (Tapinos, 1985) or even more in the case of polygamy. Despite its universality, demographers show little interest in the study of marriage and regard nuptiality as merely an intermediate fertility variable (Davis and Blake, 1956). However, nuptiality deserves more attention and is worthy of study in itself. The evolution of marital behavior reveals deep changes in society. The observation of marital change also sheds light on a society's preferred gender relationships (Hertrich and Locoh, 1999). A multifaceted phenomenon, nuptiality poses interesting analytical problems.

Sub-Saharan Africa offers a good example. Admittedly, in that part of the world, nuptiality-related issues have been partly masked by the need to produce relevant data for the study of trends in fertility, mortality, and spatial distribution of the population. However, experience demonstrates the necessity of paying special attention to marital change in order to understand the current transformations in African societies. In African cities, the present nuptiality transition is largely due to the enrollment of young girls in school but also to growing economic difficulties reflected in employment, housing, education, and other problem areas. The result is a weakening of the traditional social-management system in an urban setting.

The nuptiality transition concerns not just the age of entry into union, but the entire marital dynamics, including such factors as the change in the inter-spousal age gap, union terminations, and so on. A change in a single marriage-market parameter affects all behaviors. As we shall see, one of the preconditions for polygamy is a significant gap between men and women in the age at marriage. Later marriage among women, for example, will impact the overall marital dynamics that make polygamy possible.

I. NUPTIALITY IN AFRICA: DIVERSITY AND CHANGE

Marriage systems in Africa differ from one society to another. But some common features are found in these lineage-based societies: As a rule, unions concern lineage groups more than individuals. The asymmetry caused by the *loss of a woman* must be offset by what is known as *bridewealth*.[1] This compensation is usually more modest in matrilinear societies than in patrilin-

[1] Bertrand Lemennicier (1988) draws a bold parallel between bride wealth and pensions and alimony paid to wives in divorces in contemporary western societies. The author describes both kinds of payment as the price to pay for regaining freedom. "Paradoxically, it is the new wife who should indemnify the old one for the loss she causes by marrying the latter's ex-husband."

ear societies, where a larger set of belongings circulates between lineages (Dozon, 1986). Marriage is therefore treated primarily as a *family concern* and a *social concern* in which individuals play a passive role (Hertrich, 1996). Even if the system is relaxed, the marital processes are broadly complied with, both in the sub-Saharan rural area (Hertrich, 1996) and in cities with seemingly more liberal practices such as Douala, where marriage is still difficult without parental consent (Séraphin, 2000). Marriage thus leaves little room for the expression of feelings, which may even be viewed as a hindrance to family bargaining (Lallemand, 1985, quoted in Faizang and Journet, 1988). In Mali, for example, relations between men and women are built around two opposing and complementary poles: *furu* (marriage) and *kanu* (the love relationship) (Dumestre and Touré, 1998). Reconciling the two with the same spouse is often difficult: Studies show the development of strategies involving escape to avoid an imposed marriage, adulterous relationships, divorce followed by remarriage, and so on. Moreover, in an *arranged* marriage, incomprehension between spouses can be aggravated by their sometimes wide age gap (Tiemoko, 1999).

1. Marriage, Union, or Cohabitation? The Limits of Observation and Analysis

Before addressing nuptiality trends—and principally age at marriage—we should spell out the concept of union and give details of the measurement difficulties encountered. Most data-collection operations in Africa use marital categories that are identical to those of developed countries and are therefore barely relevant to African realities. Most African censuses include only a simple question on the marital status of respondents and, in some cases, a question on the number of wives (van de Walle, 1968). Absent specific data, the study of nuptiality is therefore dominated by the period approach. The task of defining the start of the union is often left to the respondent. Now, as seen earlier (Chapter 26), marriage or entry into union often involves several stages, and if we want to compare nuptiality data from different sources, we need to know how marriage is defined in each of the collection operations.

Thiriat (1999) clearly shows the difficulty of defining consensual unions and distinguishing them from premarital relationships. Changes in the type of union may accompany the rise in age at marriage. For example, in Antananarivo (Madagascar), the age of male exit from bachelorhood varies little from one generation to the next (approximately 25 years), but the first union increasingly begins as a consensual union: the percentage has risen from 32% of unions to 44%. Among women in the same city, not only has age at marriage risen from 20.8 years to 23.3 years in two decades, but the proportion of consensual unions has grown from 32% to 59%. The prevalence of consensual unions varies massively from one country to another. They comprise over half of total unions in Botswana (57%) and about 10% in Ghana, Nigeria, and Zambia. Their share is insignificant in Senegal (0.7%), and negligible in Kenya and Tanzania. There are sizable disparities even between countries that are geographically and culturally close such as Ghana (10%) and Togo (29%) (Thiriat, 1999). However, Étienne van de Walle (1996) observes that, apart from Togo, the surveys carried out in French-speaking countries mask the existence of consensual unions.

Beyond these definition problems there is also the issue of surveying practices in the field and the non-comparability of particular sources such as the Demographic and Health Surveys (DHSs) and censuses. Étienne van de Walle (1996) clearly demonstrates the limits of each of these sources: Censuses focus on formal unions, regardless of the type of cohabitation, whereas DHSs emphasize cohabitation regardless of the type of union.[2] Lastly, computation methods often differ from one operation to another. One of the methods most commonly used to calculate mean age at first union consists of determining a period index from a series of proportions of never-marrieds in different age groups, whether the data are derived from a census or a survey (Hajnal, 1953; Tabutin and Vallin, 1977). Another method relies on a direct computation from respondents' statements on their age at first marriage. The two methods yield significantly different results, owing to the calculation method, the memory effect, and the definitions used. Hajnal's method seems to overestimate age at first marriage, but some authors also believe the direct collection of age at first union encourages respondents to report a younger age at first marriage (Table 27–1). There is a wide discrepancy between the results of calculations based on the current status and those based on retrospective declarations.

Increasingly, demographers use as a nuptiality indicator the median age at first marriage, which gives the age at which half the women in a given cohort are married. This median age may or may not include women who will never marry. The difference is far from negligible in countries, such as Botswana, where a high proportion of women never marry (van de Walle, 1996). If we include all women, the median age

[2] DHSs are primarily concerned with the conception risk, rather than the form of the union.

TABLE 27–1 Mean Age at First Union According to Two Calculation Methods

Country	Mean age, years (Hajnal method)	Reported mean age, years
Benin (1989), men	28.0	25.5 (Men aged 35–44)
Togo (1988), women	20.3	18.4 (Women aged 30–39)

at first marriage is 26.2 years; if we include only ever-married women, the median age falls to 24.5 years. In countries where nearly all women marry, like Kenya, the two indicators converge (20.6 years and 20.5 years, respectively; van de Walle, 1996).

These methodologic issues call for prudence in drawing conclusions and commenting on changes in marital practices in Africa.

2. Increase in Age at First Marriage

In most parts of Africa, marriage is characterized by early first union among women and the near absence of never-marrieds among both men and women. The United Nations (1988) estimates that the proportion of never-married women at age 50 in Africa never exceeds 6%. In the early 1980s, the mean age at first marriage for women ranged between 17.7 years (Ethiopia) and 26.4 years (Botswana); only in a few countries did it exceed 21 years. If the proportion of never-married men never exceeded 10%, men's mean age at first marriage is far older than women's: It ranges from 25.5 years (Ethiopia, 1981) to 30.8 years (Botswana, 1981). Georgia Kaufmann *et al*. (1988) also find an increase in age at first marriage in most countries and for both sexes. First marriages occur at older ages in urban areas than in rural areas, and urban dwellers are entering into union increasingly late (Hertrich and Pilon, 1997).

The compilation of results of several recent DHSs confirms this pattern. We can compare the change in median age of entry into first union for two different cohorts: women aged 40 to 44 years and women aged 25 to 29 years at the time of the surveys (Figure 27–1). In most surveyed countries, the median age at first marriage in rural areas changes minimally from one cohort to the other (about half a year in 15 years, from approximately 17 years to 17.5 years), except in countries such as Liberia, Kenya, and Sudan, where the age at first union rises more sharply. In urban areas, the variation is greater (about 1.6 years): The age at marriage rises from just under 18 years to over 19.5 years. However, in some countries, the difference between cohorts remains minimal. This is the case in Burkina Faso, Togo, and Côte d'Ivoire. By contrast, the increase exceeds two years in Cameroon, and reaches almost 4 years in Rwanda, 5.6 years in Senegal, and 7.4 years in Sudan. In urban areas, the gap between countries is still modest for the 40- to 44-year-old cohort. The median age ranges from as low as 15.5 years in Niger (and similar values in neighboring sub-Saharan countries such as Chad) to 20.2 years in Kenya and 20.4 years in Madagascar. For the younger cohort aged 25 to 29 years, the gap is wider between countries like Chad (16.2 years) or neighboring sub-Saharan countries (Niger: 16.6 years) and countries such as Sudan (23.2 years), Senegal (23.3 years), and Rwanda (23.9 years). The shift in marital behavior is more pronounced in certain countries and the disparities between countries are growing.

This increase in the age at marriage in urban areas is confirmed in the countries for which multiple surveys are available (Figure 27–2). The comparison concerns the cohort of women aged 25 to 29 years at the time of the survey. In most countries, the median age at first marriage increases: This is the case in Cameroon between 1988 and 1994, in Mali between 1986 and 1996, in Niger between 1992 and 1998, and above all in Senegal between 1986 and 1997. Some countries (for example, Ghana) display virtually no measurable change; occasionally, as in Madagascar, the age of entry into first union decreases. Elsewhere, as in Senegal, the figures corroborate the sharp increase in age at first marriage of urban women[3] (from 18.8 years to 23.3 years in an 11-year period), in contrast with a minimal variation in rural areas (from 16.5 years to 17.7 in the same period). Young women's early entry into union—often presented as a major characteristic of nuptiality in Africa—seems to persist in rural areas, but is heavily challenged in urban ones.

Later first marriage of women is often attributed to a set of factors directly linked to urbanization: higher school enrollment for girls, participation of women in the labor force, particularly in the modern sector of the

[3] Interestingly, in a context of urbanization, increased school enrollment, and rising payroll employment, the age at marriage has moved in the opposite direction in France. Between 1821 and 1945, the mean age at marriage fell from 28.7 years to 25.2 years for men and from 26.1 years to 22.8 years for women (Segalen, 1981).

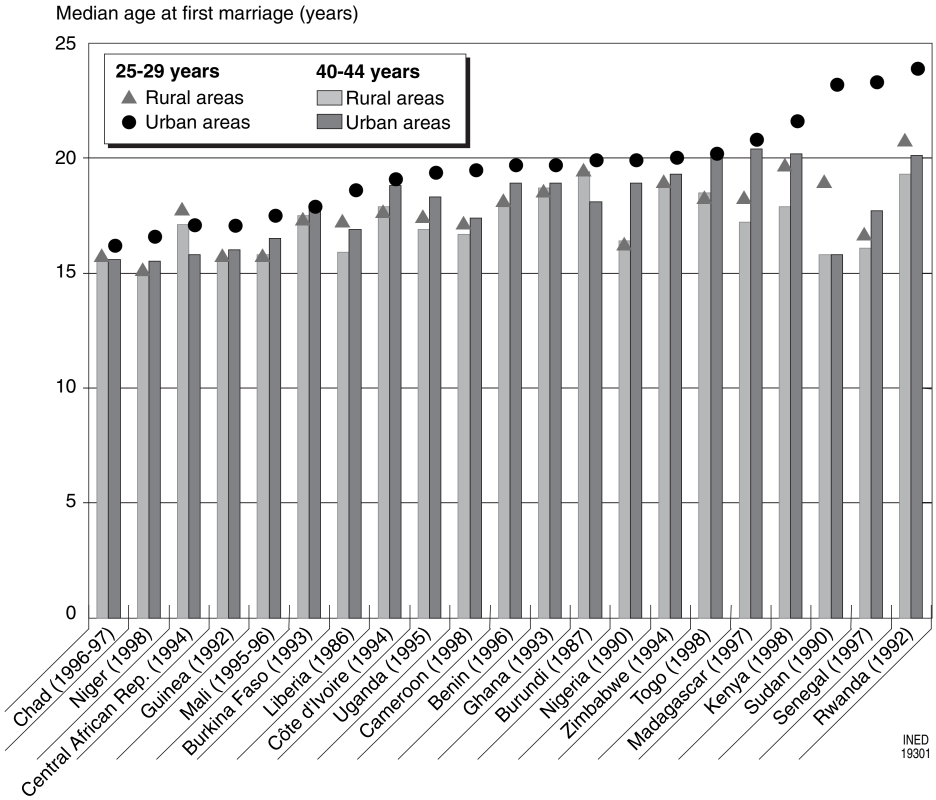

FIGURE 27–1 Change in median age at first marriage in urban area and rural area for two cohorts of women. The bars show median age at first marriage of women aged 40–44 at the time of the survey; the triangles and points are age at first marriage of women aged 25–29. Countries are ranked by median age at first marriage in rural areas for women aged 40–44. Source: Demographic and Health Survey data.

economy (Isiugo-Abanihe *et al.*, 1991), and the attendant difficulty of reconciling school or work outside the home with running a household. The adoption of new behaviors, new attitudes to intimate relationships before marriage, and new urban lifestyles are also major factors in women's postponement of first marriage (Lesthaeghe *et al.*, 1989). Nor should we overlook the existence of new legal rules on marriage and the family (in particular, the adoption of a family code), which offer women new rights.

There are very few similar results on the determinants of first marriage among men. The material difficulties facing most African urban males (i.e., problems of employment, housing, and bride wealth formation) are among the factors most often invoked to explain the increase in age at marriage among men (United Nations, 1988; Antoine and Nanitelamio, 1991; Donadjé, 1992; Djiré, 1993). This change in male nuptiality timing certainly accentuates the increase in age at first marriage among women.

The United Nations (1988) has developed a conceptual framework linking the timing and intensity of first marriage to socioeconomic and cultural factors via demographic factors, marriage standards, and individual factors. To perform their comparative analyses of nuptiality regimes in African ethnic groups, Ron Lesthaeghe *et al.* (1989) have used a theoretical anthropologic framework in which the main explanatory variables are degree of dependence of livelihood on agriculture and female labor, lineage organization, transfer of inheritance to women and endogamy, sociopolitical organization, castes and social stratification, and female education.

In the aggregate, the increase in age at first marriage is not confined to women. It also concerns men, and the wide age gap between spouses at first marriage—far from narrowing—tends to remain stable.[4] The age gap is particularly well correlated with the practice of

[4] One of the main social consequences of the age gap between spouses concerns widowhood. The age gap at marriage combined with a slightly longer life expectancy increases the duration of widowhood. The mean duration of widowhood estimated by Tiemoko (1999) varies from 7 years in Tunisia and Burundi to over 15 years in Côte d'Ivoire and Guinea, 17 years in Senegal, and 18.4 years in Mali.

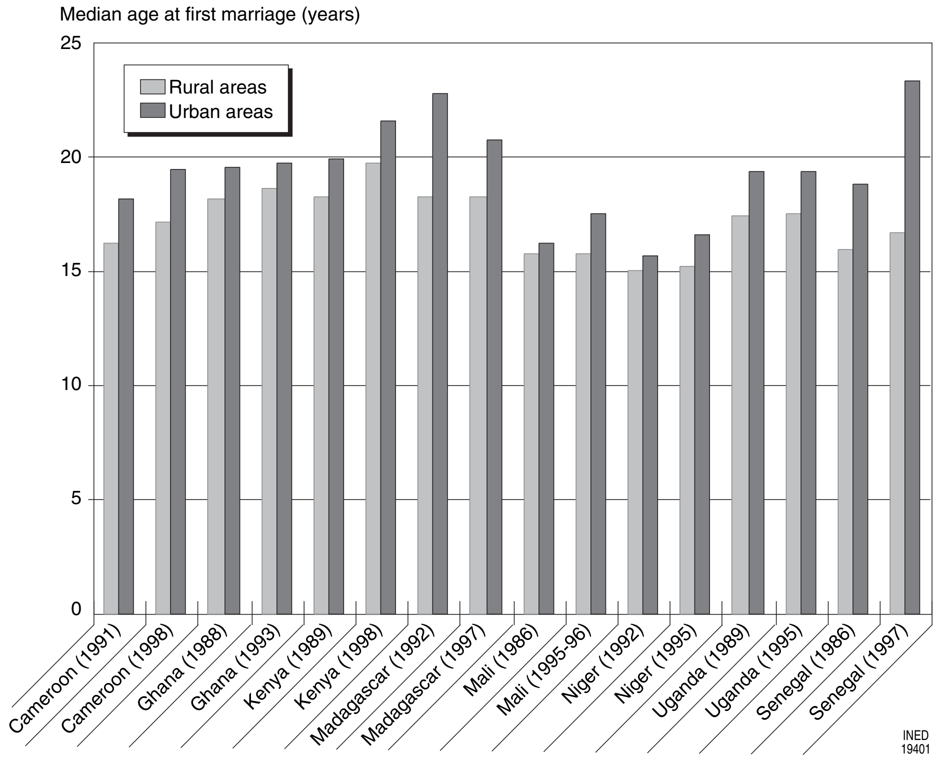

FIGURE 27–2 Comparison of change in median age at first marriage for women aged 25–29 between two surveys. Source: Based on data from Demographic and Health Survey.

polygamy and remarriage of women (Barbieri and Hertrich, 1999). The regions where women marry early and the age difference between spouses is greatest (over 9 years) coincide with those of high polygamy (chiefly West Africa). In Dakar, for example, women aged 20 to 24 years are on average 12 years younger than their spouses; the gap widens with the husband's age, particularly in the case of polygamy. Other studies confirm a progressive increase in age at first marriage and different marital behaviors in different neighborhoods of the same city (Antoine and Nanitelamio, 1991). In sub-Saharan urban areas, marriage, although delayed, remains the main concern of women in planning their future. Will women's later marriages alter the marriage market and undermine other marital practices such as polygamy? Is the African nuptiality transition driven by a tempo effect, with maximization of marriage by women still the rule? Thérèse Locoh (1988) notes that many factors combine to maximize marriage.

> Its frequency may or may not be rising, it may be inhibited for fairly long periods by the need to accumulate bride wealth (dowry), it may sometimes be hastened by the onset of pregnancy—but entry into union is a near-certain prospect for Africans. Never-married status is unacceptable and widow(er)hood or divorce without remarriage before a given age is condemned just as strongly in most countries.

The coexistence of these values with a divorce risk can surely point to favorable conditions for polygamy but doubtless cannot confirm the theory of a transition to monogamy.

II. DOES POLYGAMY STILL MATTER?

The term *polygamy* is often used as a synonym of *polygyny.* Polygyny is a form of marriage where the man has more than one wife at a time; the other form of polygamy, *polyandry*[5] (i.e., a woman with several husbands), is far rarer. Practiced in different periods in many societies, polygyny has never been the sole form of marriage in a society. As a rule, only rich and powerful men were or are able to support polygynous families; the majority of the population practiced

[5] Séraphin Ngondo A Pitshandenge (1996) describes an example of vanishing polyandry among the Bashilele of Zaire. Among Kotokoli (Togo) the practice of clan exogamy promotes relationships with official lovers in wives' native villages, all the more tolerated as the first husband is from another village and therefore resides elsewhere (Tchak, 1999).

monogamy.[6] This is not the case in several African countries where a large percentage of the population lives under a polygamous marital system. Although most married women may live in polygamous unions, polygamy invariably concerns only a minority of men in all the societies studied. Remember, however, that even in a polygamous society, a certain proportion of men and women will never enter into a polygamous union in their entire lives, but all members (more particularly, women) are exposed to the risk of living in this type of union.[7] In response to this threat, many women do not share their incomes with their husbands or may even incite their husbands to spend to thwart a new marriage. In a polygamous union, wariness toward husbands is compounded by wariness toward co-wives: The dependence and submissiveness of co-wives are aggravated by the rivalry and inequalities instituted between them (Hertrich and Locoh, 1999; Yana, 1997). The wife knows nothing about what goes on between her husband and his co-wife (or wives). Polygamy could be defined as a double (or even triple) monogamy: a serial monogamy for each wife (a few days a week) and concurrent monogamies for husbands (Fainzang and Journet, 1988).

Most attempts to explain polygamy are based on a ruralist perception of African societies, in the framework of a specific mode of production: a weakly mechanized subsistence economy, in which women play an important role as food producers. Polygamy in this context is viewed as cheap and profitable for the man (Boserup, 1970). This economic rationale is challenged by Jack Goody (1973), who points out that the highest polygamy rates are in West Africa whereas the highest proportion of women who farm is in East Africa. For Goody, the causes of polygamy are chiefly sexual and reproduction-related rather than economic and production-related. Polygamy allows the man to maximize his offspring. Polygamous union is a means of reconciling male sexuality with prohibitions such as *postpartum* abstinence. Polygamy is also a way to reconcile the group marital preferences and individual (and sentimental) preferences (Fainzang and Journet, 1988).

Other authors offer more political explanations; they emphasize the internal consistency of a marital system and a social organization in which power lies in the hands of elders (Meillassoux, 1975). Here, polygamy is regarded as a means of preserving the power of elders over juniors in societies where the access to women is controlled by elders. Abdoulaye Bara Diop (1985) sees several incentives to polygamy: It enables individuals to forge ties with several groups and confers a sociopolitical advantage. It provides an economic contribution, as the wife, by working or farming her personal fields, contributes to the upkeep of the household. Women sometimes seek this task-sharing, especially in rural areas: They may even propose a second wife to their husbands. Having children increases the household workforce and the prospects of being looked after by one's offspring in old age. Polygamy is also a factor of ostentation and prestige for privileged social categories.

Although Islam has consecrated polygamy in many African countries, it has never instituted it there. On the contrary, whereas traditional polygamy does not restrict the number of wives, Islam limits it to four. The Koran does not advocate polygamy, but restrains its practice: for example, the principle of strict equality between wives is a very difficult condition to meet.[8] Contrary to a widely held belief, polygamy is very rare in North African and Arab countries.[9] In Algeria, the proportion of polygamists among married men fell from 15% in 1886 to 1.5% in 1986 (Tabutin, 1974; Ajbilou, 1998). The percentage was about 3% in Egypt in the 1980s (Fargues, 1987), and 3.4% in Morocco in 1992 (Ajbilou, 1998). In these regions, the phenomenon is becoming less common if not disappearing altogether—for example in Tunisia, where polygamy has been abolished. When we look at the rather low polygamy rates in other Muslim countries such as Mauritania (where 18% of women live in polygynous unions[10]), and the high polygamy rates in some weakly Islamized countries such as Benin or Togo, one may question the true influence of Islam on polygamous behavior. In sub-Saharan Africa, Islam seems, if any-

[6] According to Jack Goody (1985), the Catholic Church had taken a stance on cohabitation as early as the fourth century, but he credits Pope Gregory VII (1073–1085) with the explicit condemnation of cohabitation and polygyny in Europe. The concubine was a member of the household and her children were entitled to the father's inheritance. The Church gradually abolished the traditional privileges of the concubine and her offspring.

[7] In many monogamous households the husband does not hesitate to threaten polygamy to ensure his wife's *docility* (Fainzang and Journet, 1988; Hertrich and Locoh, 1999).

[8] According to Ayatollah Mortadhâ Motahhary (n.d.), both Shiite and Sunni sources quote this *hadith* (narrative, utterance) of the prophet, "*Whoever has a two wives and does not treat them equally, by displaying an inclination [or preference] for one of them, will be treated on the Day of the Resurrection in such a manner that one side of his body will be dragged along the ground when he is taken to Hell*."

[9] As various authors point out (Fargues, 1986; Goody, 1985), polygamy in the Arab world seems to have primarily struck Western observers. In reality, however, polygamy was and still is practiced by only a small minority of the population in Middle Eastern countries.

[10] Fargues (1986) notes that polygamy in Mauritania concerns only a small proportion of Arab women: About 3% of married women there live in polygamous unions.

thing, to have channeled older traditional practices by legitimizing them.

Whatever its justifications, polygamy often enjoys legal status and recognition as a marital regime on a par with monogamy. Legislation in several countries allows spouses to choose between different marital regimes (Mali, Senegal, Togo). The abolition of polygamy elsewhere—as in Guinea (1962) or Côte d'Ivoire (1964)—has not eliminated it: 24% of married men in Côte d'Ivoire were polygamous in 1988 (Klissou 1995).

1. Demographic Conditions of Polygamy

The demographic mechanisms that make polygamy possible are relatively well identified (Pison, 1986; Pilon, 1991). Polygamy implies more married women than married men. But, contrary to a view still widely held—especially in Africa—polygamy is not due to a natural excess of women in the population, nor to an intake of women from neighboring societies, nor to a high percentage of never-married men. In fact the *excess of women* is the consequence of marital practices fostered by a specific demographic context: the two prerequisites for massive polygamy are a wide age gap at first marriage (with women marrying far earlier than men) and a young population pyramid. As men marry women 5 to 15 years younger than themselves, they have the impression of being in an unbalanced marriage market where women are more numerous. The age gap between spouses is far wider in a polygamous union than in a monogamous union (respectively, 14.5 years and 10.4 years in Mali and 11 and 7.6 years in Benin, for example) (Barbieri and Hertrich, 1999). Other factors abet the system: rapid and frequent remarriage of divorced or widowed women; a near-zero percentage of never-married women; a male mortality rate at older ages inducing widowhood for several women at once[11]; and a demographic growth that accentuates the imbalances between successive cohorts (Pison, 1986; Goldman and Pebley, 1989; Pilon, 1991).

Combined with specific kinship and marriage systems, these causes and demographic conditions of polygamy make it a key institution in the societies concerned—with multiple psychological, social, and economic implications. In societies where marriage remains urgent, competition between women is intensified by their relative excess in the marriage market. Some women who delay marriage too long run the risk of spinsterhood or of having to accept a first marriage with an already married man (Antoine and Nanitelamio, 1996). However, polygamy also implies marital competition between men of different cohorts (Clignet, 1997), as elders will lure women away from their juniors.

2. From East Africa to West Africa: Increasing Number of Polygamous Men

The practice of polygamy in sub-Saharan Africa displays major variations from one region or lineage system to another. The phenomenon is most prevalent in West Africa (the ratio M of married women to married men, adjusted for numeric imbalances due to migrations, generally exceeds 1.3), except among the nomadic populations of the Sahel (sub-Saharan savanna) and the Sahara (Lesthaeghe *et al*., 1989). The ratio is lower in Central and East Africa—where M exceeds 1.3 in few regions—and especially in Southern Africa, where M barely reaches 1.2. Moreover, polygamy is most widespread in patrilinear or bilinear societies.

For the preindependence period, van de Walle (1968) finds an incidence of polygamy among married men ranging from 17% in Congo (1956–1957) to 38% in Guinea (1954–1955). For the following period, according to Georgia Kaufmann *et al*. (1988), the proportion of married women living in polygamous union varied between 16.1% in Zaire[12] in 1975 and 51.8% in Senegal in 1976. Where data for different periods are available, the trend indicates a relative stability (Kaufmann *et al*., 1988). The high-polygamy zone is centered on West Africa, both in the coastal areas and the Sahel, where nearly one woman married in two lives in a polygamous union, even in urban areas. Polygamy is most frequent in Togo, Benin, and Burkina Faso, ahead of Senegal and Mali. In the countries bordering the Gulf of Guinea, in the same cultural area, polygamy is distinctly less common in the two English-speaking countries (Ghana and Nigeria) than in the neighboring French-speaking countries (Côte d'Ivoire, Togo, and Benin).

3. Polygamy Persists in Urban Areas

The DHS results show a disparity in polygamy levels between urban areas and rural areas (Figure 27–3). The low-polygamy zones lie in East and Southern Africa, where 11% to 31% of married women in rural areas live in polygamous unions, versus 7% to

[11] Levirate deserves special mention: This practice calls for a married man's widow(s) to be married by a younger brother or another relative of the deceased, who may already be married.

[12] Since renamed Democratic Republic of the Congo.

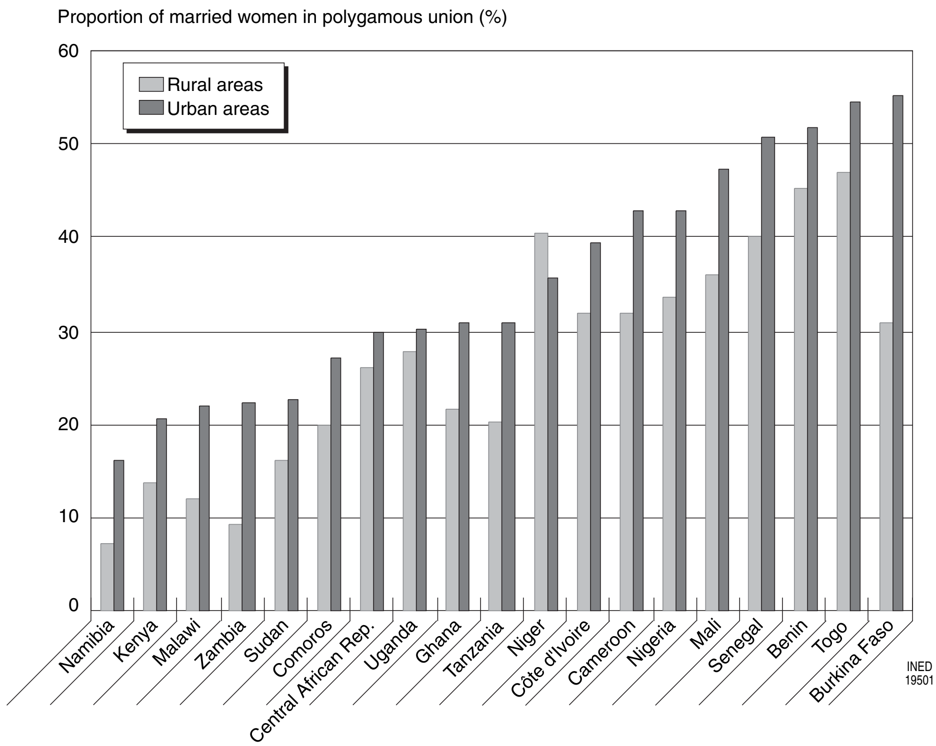

FIGURE 27–3 Proportion of married women in polygamous union in rural areas and urban areas. Source: Based on data from Demographic and Health Survey.

20% in cities and towns. Throughout sub-Saharan Africa, polygamy is far more prevalent in rural areas, most notably in southern Africa. The higher the frequency of polygamy in a country, the narrower the gaps between urban and rural areas. Only Niger exhibits a different profile: There, polygamy is more common in urban areas, where it is practiced in affluent social categories.

This overall analysis must, however, be complemented by examining the behavior of the younger generations, who—in principle—are the vectors of current change. Let us focus on the proportions of women in polygamous union among married women aged 20 to 24 years at the time of the DHS. In rural areas, we find the same evolution as described earlier for all women aged 15 to 49 in the aggregate. Polygamy increases from East to West, peaking at 45% of young women married to polygamous men in rural Burkina Faso and comparable proportions in rural Togo and Benin. By and large, the proportion of polygamous women is 25% lower in urban areas than in the countryside. A few countries, such as Burkina Faso and Zimbabwe, form an exception to the rule: There, the proportion of young rural women in polygamous union is one half that of the corresponding percentage in urban areas. Elsewhere—in Kenya, Togo, Ghana, Sudan, and Uganda—the proportions of young women living in polygamy in urban areas and rural areas are similar; in Niger and Burundi, the proportion in urban areas is actually higher.

In some countries, we have several observations from successive DHSs (Figure 27–4). These series show changes over time in a few cases only. The proportion of young women in polygamy decreases in Kenya, in rural Ghana, Mali, and to a substantial degree in Uganda, but the situation is unchanged (or displays a mild upward trend in urban polygamy) in Cameroon and Senegal.

Because of its structure and economic production system, the urban area—as well as the new ideals and lifestyles prevailing in it—should have had a constraining effect on polygamy (Gendreau and Gubry, 1988; Chojnaka, 1980). The media-propagated aspiration to Western lifestyles and family values could have entailed the gradual disappearance of polygamy in urban areas (Burnham, 1987; Clignet, 1987; Lesthaeghe *et al.*, 1989). As we have just seen, however, that has not happened: Urbanization does not appear to be an obstacle to polygamy. Polygamy can actually promote new distributions of activities in urban households. In Mali, for example, according to Marcoux (1997), women in polygamous households are more likely to engage in gainful activities, as they are freed from some domestic chores.

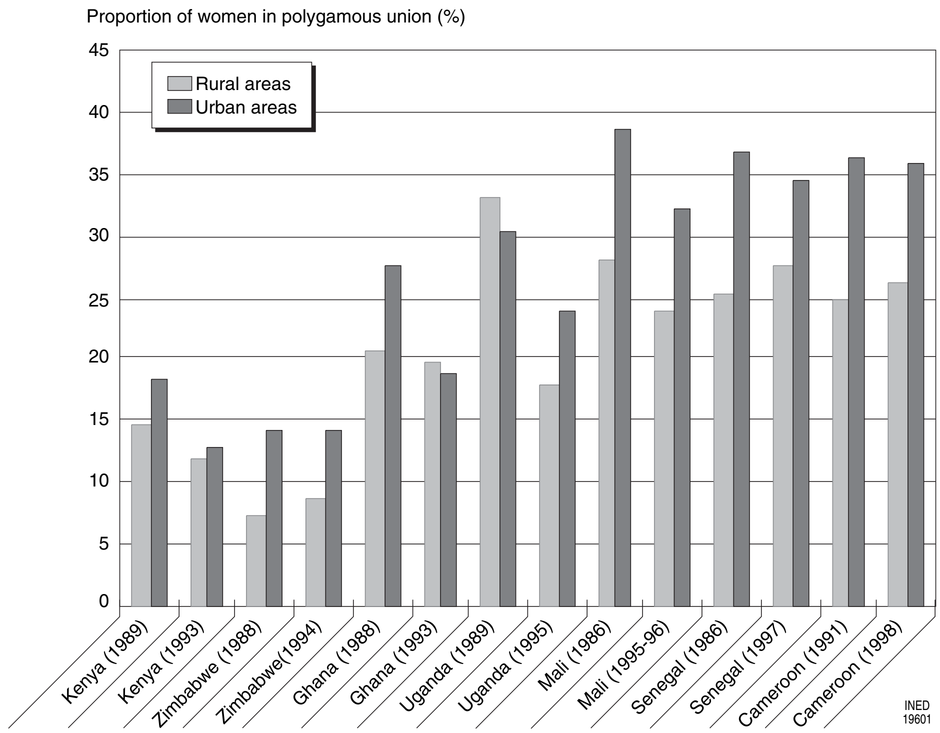

FIGURE 27–4 Proportion of women living in polygamous union among women aged 20–24 currently living in union. Source: Based on data from Demographic and Health Survey.

Back in the 1950s, Paul Mercier (1960) had observed the same phenomenon in Senegalese urban centers such as Dakar and Thiès: Urban life did not entail a rapid decrease in the polygamy rate. Mercier identified two phases in the urban evolution of the phenomenon:

> In a first phase, the influence of the rural tradition favorable to polygamy apparently remains intact, and would seem to be fully effective once individuals reach a certain income level.

In a second phase, aspirations to another lifestyle would appear to flourish and promote monogamy. The phases conducive or unfavorable to polygamy in an urban area overlap (Mercier, 1960). Luc Thore (1964), who is also very nuanced in his analyses of polygamy, stresses the complexity of the phenomenon, noting the coexistence of ambivalent attitudes: an opposition to polygamy on grounds of principle and an endorsement of the practice in actual behavior. Examining Zaire, Séraphin Ngondo A Pitshandenge (1992) notes that polygamy, hitherto characteristic of rural areas, has spread to several major cities, "The intrusion of polygamy in the urban area may be regarded as a revolutionary development" as it has occurred in spite of the structural hostility of the urban area (housing shortage, legal discrimination, respectability of monogamy, ban on polygamy by Judeo-Christian religions, etc.). The author suggests Zaire may be experiencing a ruralization of urban behaviors. He also ventures the hypothesis that (at least in central Africa) polygamy is more widespread among young generations less influenced by the colonial model.

At the individual level, research has found few discriminant socioeconomic characteristics of urban males in regard to polygamy. All social categories are concerned (Clignet, 1975 and 1987; Timæus and Reynar, 1998). Neither the husband's educational attainment, nor the fact of working in the modern sector of the economy, nor even ethnic-group identity seems to determine the practice of polygamy in African cities. In Dakar and Bamako, for example, most men are potentially polygamous (Antoine and Nanitelamio, 1996). Not all men become polygamous—about one in two will at some point in their lives—but no socioeconomic factor can enable us to predict who will become polygamous. However, the spells of nonemployment and economic precariousness sharply reduce entry into polygamous union in Dakar: The odds of becoming polygamous are divided by three (Antoine *et al.*, 1998). In Bamako, two socio-occupational categories are more likely to practice polygamy: small-business owners and self-employed men employing payroll workers, for example, "Two groups whose methods of accumulation and wealth creation are informed by the principles of a family-based economy" (Marcoux and Piché, 1998).

In sum, polygamy persists both in the countryside and in towns, and its dynamics deserve explanation.

4. The Demographic Perception of Polygamy

Most measures of polygamy are flawed to a certain extent as they basically rely on period data and therefore provide only a static, frozen image of the practice.[13] The demographic perception of polygamy is still strongly influenced by the male perspective. The intensity of the phenomenon, measured by the *average number of wives per polygamous husband*, generally varies between 2.0 and 2.5. The most prevalent form is bigamy, which concerns over 80% of polygamous men. The average number of wives per married man, usually ranging between 1.02 and 1.50, increases with age (Gendreau and Gubry, 1988). The *polygamy rate* commonly used gives the proportion of married men in polygamous union. This index is most often below 30%. On the women's side, however, the numbers tell a very different story: For example, whereas slightly over one third (35%) of married men in the Moba-Gurma ethnic group of northern Togo were polygamous in 1985, more than half (57%) of married women were living in polygamous unions (Pilon, 1991). An age breakdown of the data on the same population shows that, by age 25, more than half the women were living in polygamous unions; by age 50, the proportion had reached about 70%. Among men, the proportion of polygamists does not rise above half until age 50, reaching 60% or so. Obviously these figures may vary from one population to another, but without invalidating these gender differences, which reflect very different dynamics and life experiences.

Three indicators summarize the intensity of polygamy: the proportions of married women and men in polygamous union and the mean number of wives per polygamist. As an example, Table 27–2 reports these indicators for two cities: Bamako and Dakar.

These indicators vary over time, as illustrated in selected data on Dakar. Women aged 50 to 54 years had experienced, on average, 1.71 unions in 1955 (Service de la Statistique, 1962) and slightly under 1.63 in 1989

[13] For example, Pilon (1991) has determined that period indicators understate the intensity of polygamy by nearly 25% for the Lobi-Dagara of Burkina Faso and the Moba-Gourma of northern Togo—at all ages. Donadjé (1992) makes the same observation about Benin. According to him, the underestimation varies from 18% for men aged 20 to 54% for men aged 55, especially owing to the greater frequency of changes in marital status at older ages.

TABLE 27–2 Polygamy Indicators for Dakar and Bamako

Indicators	Dakar	Bamako
Proportion of married women in polygamous union (%)	66.3	64.2
Proportion of polygamists among married men (%)	28.1	25.1
Mean number of women per polygamist (at age 50)	2.2	2.4

Source: Antoine, Philippe, Djiré, Mamadou, and Nanitelamio, Jeanne, 1998. Au cœur des relations hommes-femmes: polygamie et divorce, in Philippe Antoine, Dieudonné Ouédraogo, and Victor Piché (eds), *Trois générations de citadins au Sahel*, p. 147–180. Paris, L'Harmattan, 281 p.

(Antoine, Djiré, and Nanitelamio, 1998). In 1989, 47% of Dakar women aged 50 to 54 were living in polygamous union. The proportion is highest in that age group, decreasing thereafter because of widowhood. Among men aged 55 to 59 years, the proportion of polygamists rose from about 30% in the 1955 census to 40% in the 1976 census and 45% in 1989. In 1955, men aged 60 years had experienced an average 2.6 marriages; by 1989, the number had fallen to 2.2; by contrast, at the same age, men in 1955 had an average of 1.45 wives, whereas in 1989 they had 1.70. This variation denotes a lesser marital mobility and perhaps a greater prevalence of polygamy in Dakar in recent years.

Another way to assess polygamy dynamics is to compare the mean number of marriages and the mean number of spouses for men and women. Within the same male and female cohorts aged over 45 at the time of the survey (i.e., the 1930–44 birth cohorts), we have examined two subpopulations: persons who have experienced at least one period of polygamous union in their lives and those who have stayed monogamous. The curves in Figure 27–5 show the mean number of marriages and the mean number of spouses at different ages. At age 15, no male is married whereas females have already experienced an average 0.34 marriages (about one young woman in three is already married). Through divorces and remarriages the number-of-marriages curve diverges from the number-of-spouses curve: At each age, individuals have experienced more marriages than they have had spouses. The gap is particularly wide for men who have been polygamous at some point in their lives. At age 50, they have experienced an average of 2.44 marriages, but have had an average of 1.96 wives—the reason being that some of these polygamists have reverted to monogamy. As the chart shows, male polygamy comes late (after 40) and is most often

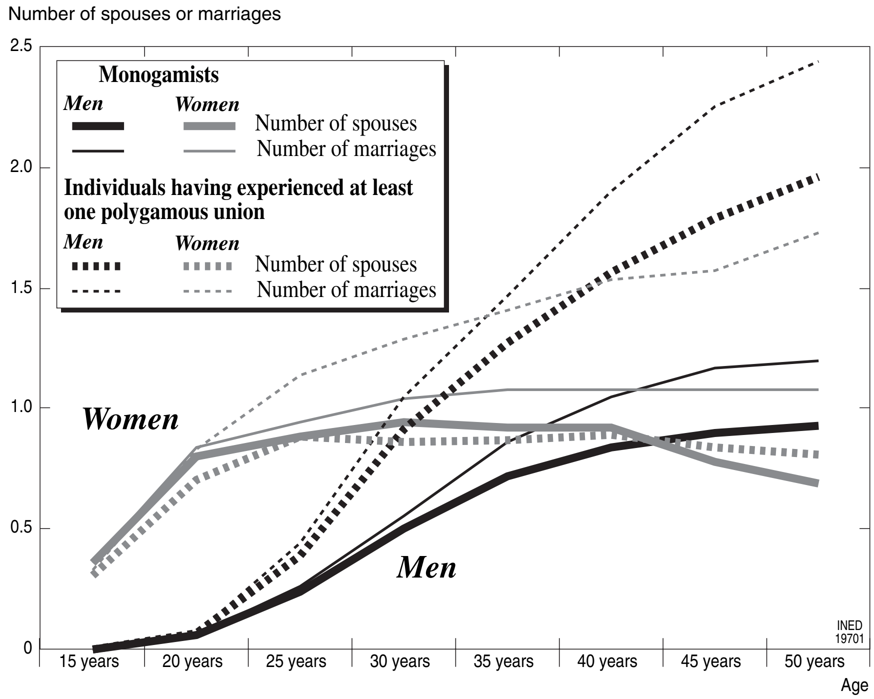

FIGURE 27–5 Comparison of number of unions and number of spouses by age for male and female 1930–1944 birth cohorts (Dakar, 1989). Source: Based on data from Dakar survey (IFAN-ORSTOM).

confined to bigamy. In the end, owing to divorce, men who are polygamous in the course of their lives fail to maximize the number of their wives. Polygamists, on average, have only 1.96 wives. Polygamy mainly accelerates the turnover of spouses. Among monogamists, the gap between the number of marriages and the number of spouses is smaller, suggesting a greater stability in monogamous unions than in polygamous ones.

We find a similar pattern on the female side. Women who have lived in a polygamous union at some time or other in their lives have had far more spouses than women who have remained monogamous (at 50 years, the number of marriages is 1.73 and 1.08, respectively). Monogamous women divorce far less often than women in polygamous unions.[14] By contrast, the number of spouses between ages 25 and 40 holds steady at around 0.9, indicating that at no age are all women married.

Marital status thus evolves throughout individual life courses; it is most notably subject to the random factor of mortality and dependent on the relationships between spouses. There is a considerable difference in the individual marital life courses of men and women: Although every polygamist was initially monogamous, a woman may shift directly from never-married status to polygamy by marrying an already married man. A man (or woman) in a monogamous union, widowed or divorced at time *t*, may have lived in a polygamous union beforehand. A fairer measure of polygamy should take this time dimension into account. Whereas a married, widowed, or divorced man will easily be able to remarry a never-married woman, the likelihood of a widowed or divorced woman entering into a new marriage with an already married man increases with her age. It is not uncommon for a woman to divorce her husband who has become polygamous and subsequently marry an already married man. These examples suggest the great complexity of these marital event histories and their specificity depending on whether we view them from the male or female perspective.

Figure 27–6 illustrates the example of two cohorts—one female, one male—of Dakar residents aged 45 to 59 years. The *marital dilemmas*, as Rémi Clignet (1997) puts it, differ for men and women. However, the situation seems more complex than he describes. According to him, the alternative for men is restricted to *an additional spouse or divorce*, whereas women have more options. Men, as well, have several possible choices, but men have greater control over the outcome than women, especially in the case of polygamy.

[14] Polygamy fosters divorce (see below); also, however, a divorced woman has hardly any choice other than to marry a polygamist.

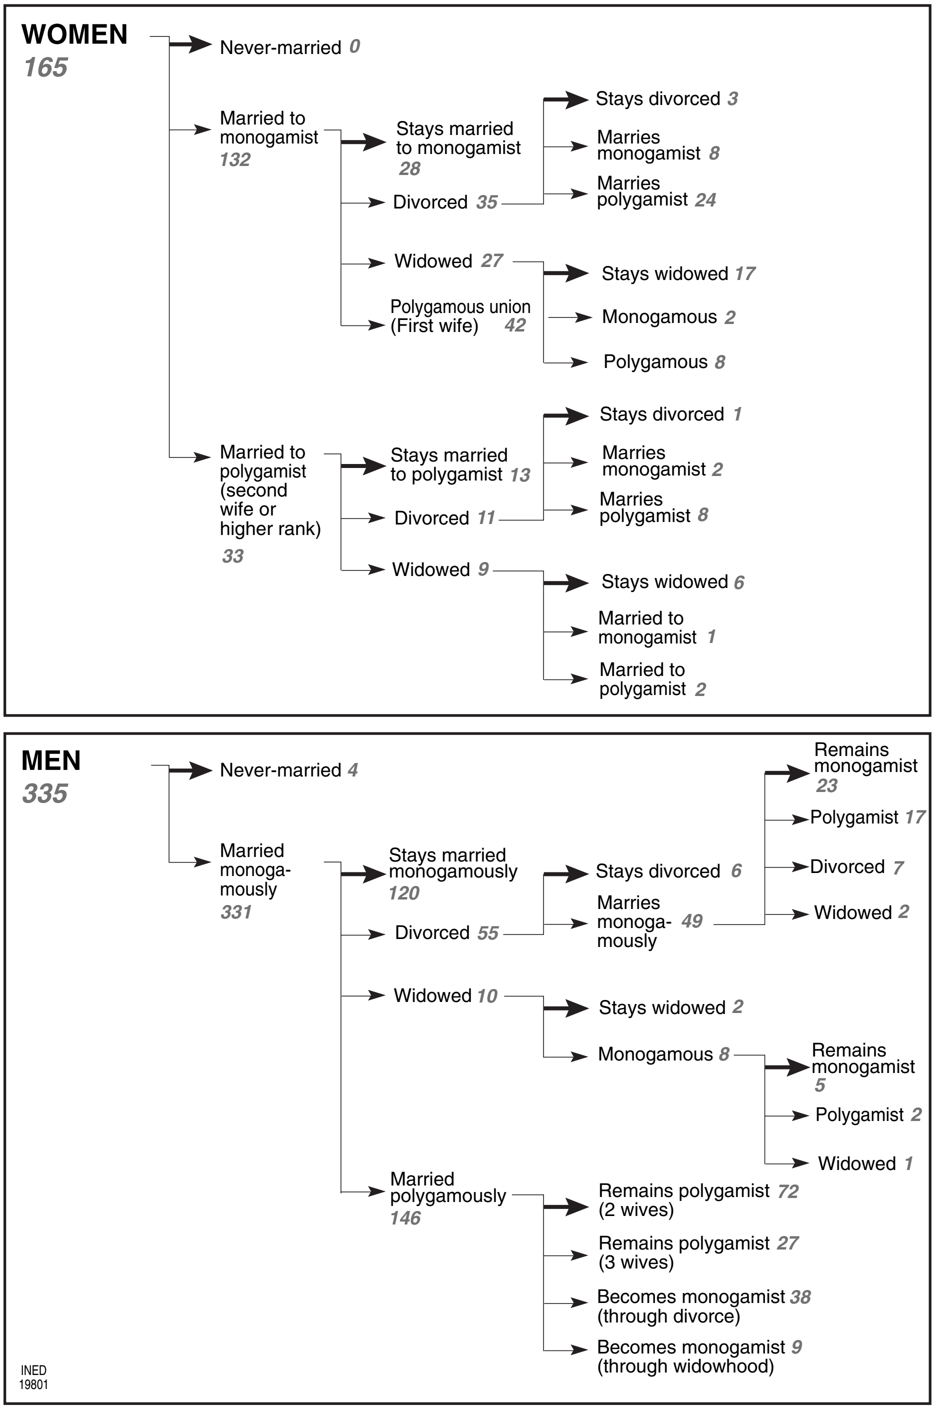

FIGURE 27–6 Female and male marital dilemmas (individuals aged 45–59). Source: Based on data from 1989 IFAN-ORSTOM event-history survey.

In Dakar, for men and women alike, divorce status is often only transitional. Among the 331 married men in the study (who are therefore monogamous at the start of their marital life courses), 165 have been polygamous at one time or other in their lives, and 166 have never been. Among the 165 women, at least 107 have been in a polygamous union at some point in their lives. However, that figure is understated: 35 divorcees and 27 widows began their marital life courses with monogamous unions, but we do not know if these subsequently became polygamous.[15] Women—partic-

[15] It is difficult to reconstruct the marital life courses of women's spouses from women's own accounts (see Chapter 26).

ularly divorcees—frequently remarry. Of the 46 divorcees in our sample, only four remained so; 42 remarried, of whom 32 joined a polygamous household. Divorce seems to be a form of resistance to forced polygamy, whereas remarriage leads to freely chosen polygamy.

5. Polygamy and Divorce

Regions with high polygamy are also characterized by more frequent dissolutions of unions, followed by rapid remarriages. However, the variations in union instability are still fairly underdocumented in Africa. The proportion of women who stay divorced is low in most countries. For example, in Burkina Faso—a country with a high polygamy rate—it varies between 1.8% at 20 to 24 years and 1% at 45 to 49 years. But despite this tiny proportion of women who stay divorced, nearly one in four women older than 35 years has already experienced several unions (DHS, Burkina Faso), a sign of rapid remarriage. As polygamy allows more frequent remarriage, it probably leads to a lower proportion of divorced women. In Ghana, by contrast, the proportion of female divorcees rises with age, from 5.2% at 20 to 24 years to 12.8% at 45 to 49 years (DHS, Ghana). The situation thus varies according to country, culture, legislation, and women's status.

We know nearly nothing about the changes in the frequency of divorce or about its determinants (Kaufmann *et al*., 1988). It is estimated that about 40% of women who marry before age 20 become widowed or divorced before age 50 (Lesthaeghe *et al*., 1989). Among women, the frequency of divorce and separation is higher in the first 10 years of marriage and especially at the youngest ages (Smith *et al*., 1984).[16] Union terminations are often concealed by rapid remarriages. As divorce undermines the alliances between families formed by the marriage, it is perceived as disruptive and hence treated as an event not to be talked about (Locoh and Thiriat, 1995). Remarriage becomes more difficult among women past childbearing age. Gainful employment is an important factor in divorce. It creates an opportunity for the woman to be financially independent. She can thus ensure her own livelihood and that of her children in the event of divorce (McDonald, 1985; Burnham, 1987). For women who have held a job before marriage and have ceased to do so after marriage, the risk of divorce is lower: Economic insecurity probably deters these women from divorcing. Divorce is sometimes a social-promotion strategy for women thanks to remarriage with a more affluent man. Independent of these material considerations, a woman who remarries gains more autonomy vis-à-vis her new husband (Dial, 1999).

The arrival of a second wife emerges as the main cause of divorce by the first wife in Dakar (see Chapter 26). Yet, according to some anthropologic studies, several factors may keep the first wife from divorcing. The first marriage often seals an alliance between families (Fainzang and Journet, 1988). Even if the arrival of a second wife is not a legitimate cause of divorce, first wives do seem to divorce more than second wives in urban polygamous unions. The first marriage is often a prescriptive marriage, which the woman sometimes experiences as an obligation from which she tries to free herself through divorce (Locoh and Thiriat, 1995).

A risk of divorcing or separating from the first or second wife may be deemed to exist from the very outset of polygamous union. There is a suitable method of analysis for measuring competing risks of this type: the Aalen estimator[17] (Trussell *et al*., 1992; Courgeau and Lelièvre, 1989). In the three cities studied (Bamako, Dakar, and Yaoundé) where event-history data is available for such analysis, the trend is always the same: divorce from a first wife occurs sooner than a divorce from a second wife (Figure 27–7). The survey does not make it possible to determine who initiates the divorce, but it is highly likely to be the wife: Faced with the *fait accompli* of the arrival of a second wife, the first will decide to leave her husband. Polygamy is not necessarily the main cause. Rather, divorce is triggered by unequal treatment or rivalry with the second wife.

6. Trends in the Phenomenon

The theory of modernization called for a fertility transition and a convergence toward the nuclear-family model. Within this rationale, many authors predicted a gradual disappearance of polygamy by the 1960s—in particular owing to urbanization, higher school enrollment, an opening to Western values, and so on. But the data available show that, overall, the institution continues to thrive. The links with urbanization, educational attainment, and socioeconomic status sometimes prove ambivalent—an ambivalence that would surely be accentuated by the inclusion of informal unions (mistresses, *deuxièmes bureaux*,[18] and

[16] In Senegal, the percentage of unions terminated in the five first years of marriage is as high as 17% (Smith *et al*. 1984).

[17] The interpretation chart for this estimator is constructed by comparing the slopes of the curves of instantaneous cumulative probabilities, which gives an idea of the intensity of each risk involved at any given moment.

[18] Literally, *second offices*, a euphemism for *outside wives* in French-speaking Africa.

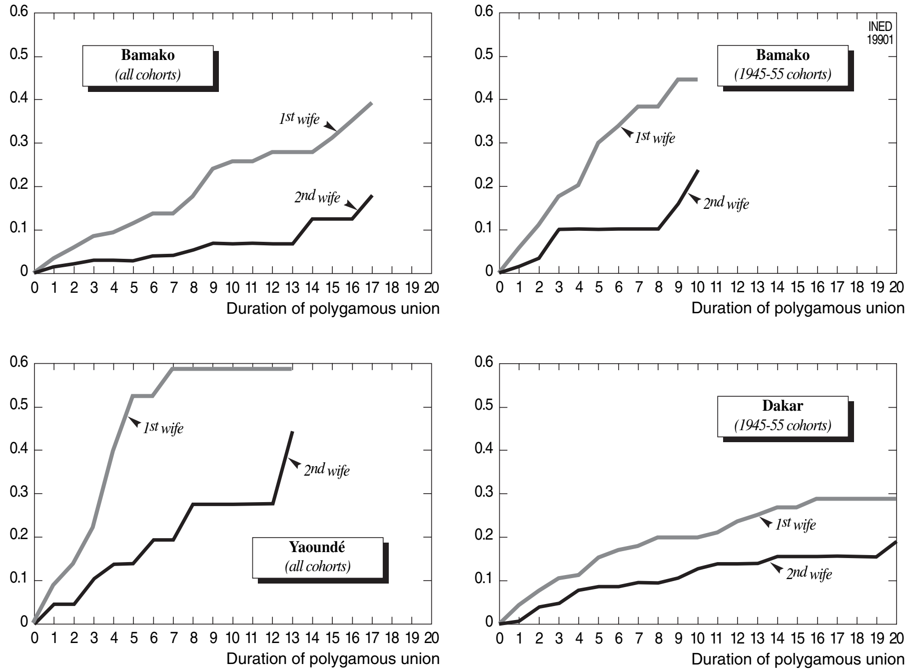

FIGURE 27–7 Divorce or separation from first or second wife by duration of polygamous union (in years). Source: Based on data from event-history surveys in Bamako, Dakar, and Yaoundé.

other arrangements) (Lacombe, 1983; Wa Karanja, 1987).

The World Fertility Survey (WFS) and DHSs give us several fairly reliable statistics for a number of countries. Figure 27–8 illustrates five countries where we can track the changing proportion of married women in polygamous unions. The sharpest fall is recorded in Kenya, the country with the lowest proportion of polygamists in the 1970s. The rate there fell by more than a third, from 29.5% in 1977 to 19.5% in 1993. In Ghana as well, polygamous unions have declined, albeit more slowly. In Côte d'Ivoire during the same period (1975–1994), the rate decreased by only 5 points, from 41.4% to 36.6%. In Mali and Senegal, no significant variation was measured (Antoine and Pilon, 1998).

The English-speaking countries are thus the ones where polygamy seems to be falling most steeply. However, this measure of polygamy masks certain changes. The indicator chosen concerns only married women. If we take into account all women aged 15 to 49 years regardless of their marital status (married or not) and if we calculate the proportion of polygamous women in that aggregate, the changes are more conspicuous. In Kenya, between 1977 and 1993, the ratio of women in polygamous unions to the total number of women aged 15 to 49 years fell from 21% to 11%. Even in a country such as Benin, where the ratio of women married to polygamists to all married women has varied very little since the 1960s (52% in 1961, 51% in 1992, and 49.6% in 1996), the proportion of women in polygamous unions fell from 43% to 34% of all women aged 15 to 49. Later marriage and divorce explain this decline in the frequency of polygamy when the ratio denominator consists of all women regardless of their marital status.

Polygamy plays an important role in the family strategies for controlling the married couple. When the spouses choose monogamy, they are subject to pressure from their family circle. Women—who have more reservations toward polygamy—often exhibit ambiguous attitudes and behaviors that reinforce this institution, particularly in the sub-Saharan countries. The deep change in population structure that will soon result from the decline in fertility will constitute the first major inhibitor of polygamy by curbing the present imbalance in the marriage market.

CONCLUSION

The decline in polygamy has been predicted by several anthropologic theories. By increasing the female age at marriage, education was supposed to contribute to the increase in the male population in the marriage market, entailing a shift in the numerical balance with adverse effects on polygamy.

In recent years, a number of changes have been taking place in African societies. In particular, worsen-

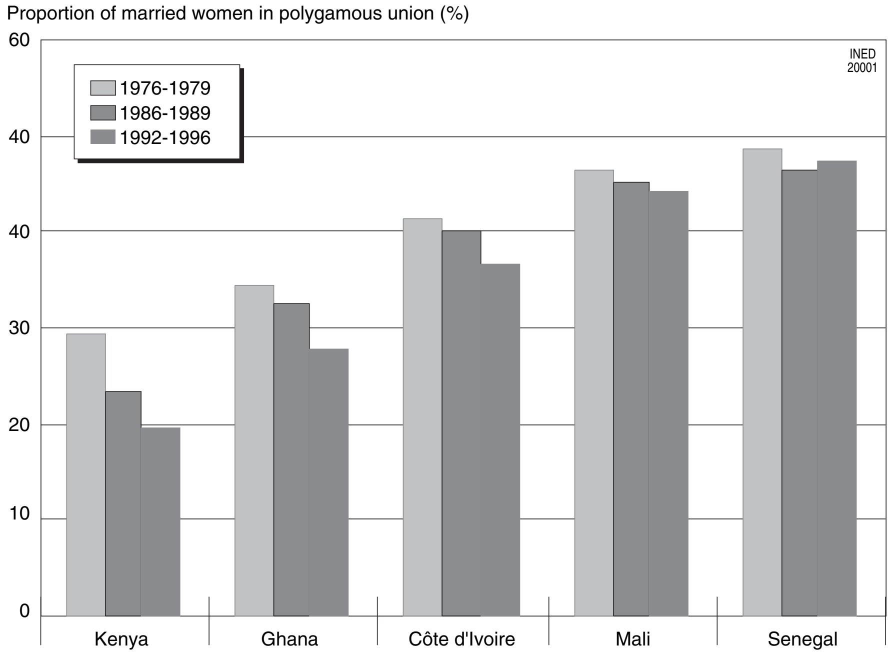

FIGURE 27–8 Proportion of married women in polygamous unions.

ing economic conditions have led to a sizable increase in age at first marriage and have made unions more vulnerable. The age gap between men and women at first marriage is shrinking in nearly all countries. The aspiration to large families has waned, and there are growing signs of a fertility transition in countries such as Kenya, Botswana, Senegal, and Côte d'Ivoire.

These significant changes in the levels of several nuptiality determinants may therefore entail either a shift in the prevalence of polygamy or a modification of other factors. If the age gap at marriage narrows, polygamy can survive only through an offsetting increase in the male never-married rate. On the other hand, an abandonment of polygamy would have tremendous implications for the organization and functioning of the societies concerned—starting with a challenge to the power of men over women, of elders over their juniors. As we can see, the present changes are bound to affect polygamy, but we still know little about the ways in which they will do so, in what time frame, and through what mechanisms.

Factors in Couple Formation

THÉRÈSE LOCOH

Institut national d'études démographiques (INED), Paris, France

In demographic terms, couple formation could be a very simple process. Barring accidental circumstances, all human populations comprise roughly the same number of males and females. Young boys and girls reach sexual maturity within few years of one another and—even if attraction to individuals of the same sex is a phenomenon encountered everywhere—most sexually mature young people are strongly attracted to their contemporaries of the opposite sex. Biology and demography combined could lead to the formation of couples most of whom would be fertile and would ensure the reproduction of the population. But this *plain tale* does not exist in any society. Quite to the contrary, couple formation is a process particularly subject to the formulation of social, religious, and customary norms that multiply the varieties of union to infinity. Bans and obligations restrict individual choices, creating distances between candidates to union and—depending on the circumstances—shortages and excesses of marriageable persons.

The central concern of all cultures is to control the formation of unions with the aim of demographic reproduction. Marriage is never treated as a straightforward sexual pact; it includes other major dimensions of social reality, most notably economic and religious. It establishes alliances between groups and defines the integration of the individual into the group by the recognition of his or her descent.

Whom can one marry? When can one marry? How can one marry? Who decides the answers to these questions? By the solutions it offers for them, each social group defines the marriage market, determines the stock of marriageable individuals (i.e., of those who have the most direct access to reproduction). The rules that will be adopted, valued, and handed down across the generations or challenged serve to control individual behavior and the attraction between the sexes—in sum, to manage alliances between groups and the formation of descents, the two basic activities of the social factory.

The conditions for access to marriage are defined by each society's culture, consensually accepted rules, and the degree of individual compliance with these rules. Religious beliefs, sex and marital education, the designation of the persons vested with authority over individuals' marriage choices, and the conditions defined for accessing a partner (sex, age, previous marital status, social or economic characteristics) are all ways of structuring the *marriage market*, which, in turn, will shape each society's specific marriage behavior.

I. NUPTIALITY, ALLIANCE, AND REPRODUCTION

In demography, the study of nuptiality is often essentially regarded as a facet of the study of fertility, because the conditions of couple formation in a society have obvious consequences on reproduction. Women's delayed entry into union, or even the exclusion of a portion of the adult population from the marriage market, may constitute the first form of birth control. This has been termed the *Malthusian transition* in a reference to Malthus, who invoked the *moral constraint* as a means of curbing population growth (Coale, 1974; Chesnais, 1986).

In Africa, where almost everyone marries, and where women marry extremely young, the increase in the age at marriage is beginning to have a tangible effect on the decline in urban fertility (Lesthaeghe, 1989; Pison *et al.*, 1995). The same pattern is found to some extent in Asia, where the increase in the age at marriage is playing a part in the fertility downtrend (Casterline, 1994; Smith, 1980). In Latin America, the recent fall in fertility appears to have little connection to a change in patterns of entry into union (Rosero-Brixby, 1990).

In all societies, however, the issue of couple formation goes beyond the concern over making sure that its members reproduce. In societies bearing witness to the oldest types of social organization, anthropologists have found that unions—whatever the form in which they are promoted—are not guided solely by the concern to ensure demographic reproduction; they are also designed to provide a group with opportunities for expansion through alliances with other groups, by *exchanging women* (Lévi-Strauss, 1958).

In postmodern societies, in a totally different context, ensuring offspring is now only one of several goals of partner relationships, whether involving marriage or not. There is no longer any need for the rigid set of rules formerly designed to ensure numerous offspring, and the freedom of each individual to enter into a union or not is considerable. The main priorities are personal attraction and satisfaction of the partners. In these societies, families have lost most of their control over unions, and social norms themselves may be ignored without incurring punishment. Tolerance grows as the stakes become more narrowly confined to the choices of individuals themselves. The sphere of social control tends to be limited to protecting the interests of children and to settling conflicts in this area. New modes of couple formation emerge, determining ever more diversified individual statuses and residential and family arrangements. Changes in nuptiality may therefore be determined by cultural changes more than by demographic rationales concerning reproduction.

Will the analysis of nuptiality become obsolete as nuptiality becomes distinct from fertility behavior? Demographic and Health Surveys (DHSs), for example, which are one of the major sources of demographic data for the developing countries, devote little attention to unions, except for current marital status. Yet the study of unions is a crucial area of demography, for at least three reasons. The first is that marriage arrangements are a decisive factor in fertility in many societies. The second is that unions play an important role in structuring exchanges of goods and services in a society, and therefore have unquestionable implications for adult residential arrangements, the care of children and dependent old people, and even the transmission of property. The third concerns the measurement of social change. The age of entry into union and the new forms of couples (consensual unions, unions without co-residence, homosexual unions, etc.) are a highly sensitive indicator of that change. In particular, the age of entry into union is strongly correlated with educational attainment, female autonomy, and access to payroll employment. The study of nuptiality is therefore a valuable means of assessing social change.[1]

1. Alliance by Marriage: a Principle at the Core of Social Life

In many societies, couple formation depends very little on individual decisions: The sexual and emotional attraction that draws young people to one another is strictly regulated and controlled by those who hold power in a society. Couple formation has always been under tight social control.

At the root of all social life lies the ban on incest, which, as Lévi-Strauss (1958) demonstrated, expresses the transition from the natural fact of consanguinity to the cultural fact of alliance: "The incest ban is not so much a rule that forbids marrying a mother, sister or daughter as a rule that obliges a mother, sister or daughter to be given to someone else."

It is merely the correlative of the obligation to exchange. As the archetype of exchange, marriage is central to kinship and social life.

Lévi-Strauss explains this starting from a simple observation: the contingencies of birth are such that each individual was very unlikely to find a suitable sexual partner in the small groups that initially constituted human societies. People therefore had to seek partners in another group. There were only two ways of doing this: war or exchange.

> People had to choose between isolated biological families juxtaposed like self-perpetuating closed units, overwhelmed by their fears, hatreds, and ignorance or—thanks to the incest ban—the systematic establishment of intermarriage chains, allowing the construction of an authentic human society on the artificial basis of affinity links, despite the isolating influence of consanguinity and even in opposition to that influence. (Lévi-Strauss, 1971b).

[1] For example, it is by analyzing the change in ages at first marriage, age gaps between spouses, and births out of wedlock that David Shorter has charted the emergence of the modern family in Europe in the 18th century (Shorter, 1975).

This explanation is perfectly illustrated by the reply of an Arapesh to Margaret Mead (1935), who asked him if men could marry their sisters:

> What, you would like to marry your sister? What is the matter with you anyway? Don't you want a brother-in-law? Don't you realize that if you marry another man's sister and another man marries your sister, you will have at least two brothers-in-law, while if you marry your own sister you will have none? With whom will you hunt, with whom will you garden, whom will you go to visit? M. Mead (1950, p. 68).

2. Prescribed Marriages and Forbidden Marriages

In the marriage legislation of industrial societies, the only bans concern parents and brothers and sisters. Marriages between cousins are legally possible. But, while Western societies have laid down only negative rules, others, on the contrary, in addition to banning marriage with certain groups, set positive rules for prescribing spouses. The most remarkable example is that of preferential marriage with cross cousins (an individual cannot marry parallel cousins—the children of the father's brothers or the mother's sisters—and must therefore marry, insofar as possible, a cross cousin, i.e., the children of the mother's brothers or the father's sisters).

In these societies with elementary structures studied by Lévi-Strauss (1971a), the principles of exchanging women apply between easily identified groups. The same is not the case in societies with complex structures. The length of reciprocity cycles is unassignable. A person renounces a close relative and thus acquires the right to take someone else's close relatives, but nothing guarantees that this right will be followed by effects. Reciprocity becomes a general principle here, not an immediately enforceable rule (Cuisenier, 1985). Many societies accordingly promote an endogamy that can be based on family (marriage between crossed or parallel cousins, depending on the society), lineage, or ethnicity. This approach is justified by the notion that a certain closeness between spouses makes it easier for the young bride to adapt to her new environment and facilitates the preservation of land and other possessions in the family group. At the opposite end, other societies, like those of northern India, prefer strict exogamy rules. Endogamy and exogamy create different statuses for the wife in the family she has married into. In societies practicing strict exogamy, the wife is more isolated in a family that is unrelated to her and treats her as an outsider. In a society where marriages are managed on endogamous principles, young wives remain in familiar territory.

In Africa, even absent strict endogamy or exogamy rules, marriages are typically determined by a complex game of gifts and counter-gifts; the elder kin know which families are likely to give one of their daughters and can be approached for the purpose. Preferential marriages between cousins are still common in Africa and the Arab countries. In Murdock's census (1969),[2] slightly over one third of the societies studied practice preferential marriage between cousins, 34% forbid it only between first cousins, and 28%, on the contrary, strictly forbid it between any cousins. The first type of marriage is more common in the societies of the Mediterranean rim, East Asia, and South America (Table 28–1).

3. Couples, Unions, Marriages: a Reality Hard to Measure Statistically

Unions are formed in a very complex range of ways that resist statistical observation and require localized anthropological studies: The mechanisms include prescriptions and bans, provisions and counter-provisions under rules recognized by a social group, alliances between families or decisions of two individuals. The demographic study of nuptiality has long relied on marriage statistics of the kind that exist in the developed countries, which is why statistical studies on couple formation have concentrated on formal marriage, registered by a religious or civil authority. However, the latter is only one of many partnership arrangements. Where the recording of vital statistics is not the rule, most unions, although fully recognized by society, are not registered. In such cases, the statistical analysis of marriages will draw on surveys where all unions described as marriages by the interviewees will be regarded as such.

Moreover, in industrial societies, a growing number of couples that do not formalize their living arrangements define their unions—on the contrary—as informal or *de facto*. These are sometimes called *unregistered unions*: They can be long-lasting and lead to the founding of a family. Civil marriage statistics cover only a portion of couples actually formed; new survey methods are also needed to track consensual unions, which are increasingly subsumed under the

[2] Murdock's atlas is a standardized compilation of information on 863 societies studied by anthropologists and ethnologists. The census offers a statistical picture of the diversity of cultural choices in regard to marriage arrangements. Of course the distributions shown apply to the populations of societies surveyed, not to the populations exhibiting each characteristic described. It is not a representative sample of current living arrangements but rather a description of the diversity of *life rules* conceived by human societies.

TABLE 28–1 Preferential Marriage between Cousins

Forms of marriage	Ethnographic regions[a]						
	HAS	C	E	I	N	S	Total
Preferential between cousins	34.3	58.9	64.4	29.3	17.3	63.0	37.5

confidential domain of private life without undergoing social approval or a legal registration, except in order to qualify for social benefits hitherto reserved for married couples. So great is the diversity of partner relationships that it is becoming ever more difficult to define a union.

The multilingual dictionary of demography (van de Walle and Henry, 1982) defines marriages as "unions between persons of opposite sexes which involve rights and obligations fixed by law or custom."

This definition is broad enough to include unions that are not recorded in writing, as still occur in many developing countries where unions are guaranteed solely through custom, but it excludes homosexual unions, for which some activist movements demand and sometimes obtain quasi-marriage ceremonies. Lastly, the definition does not include *de facto* unions, increasingly common in the developed countries, whose rights and obligations are not in any way set by law or custom; it does not even include unions assigned an intermediate status such as France's *civil solidarity pact* (*pacte civil de solidarité* [PACS]).

Nevertheless, all societies seek to control couple formation and promulgate norms for entry into union—even the societies that accept the fact that an ever greater number of individuals do not comply with the norms. The latter concern the conditions required for entering into marriage or a partner relationship, the partners that an individual may (or must) marry, their characteristics (age, earlier marital status), and their number (in polygamous societies). Marriages also differ according to the authorities through which they are recognized (religious bodies, families, representative of a community authority, the state, etc.).

4. Legal, Religious, Customary, and Consensual Unions

Control over sexuality and the formation of families, and obligations toward children, have always been major areas of expression of rules, often based on religious beliefs. In nearly all societies, unions—whether determined by families or individuals—are marked by ceremonies that attest to their recognition by the community. The recognizing entity varies from one group to another. It may require religious rites whose symbolism reflects the principles that must govern the spouses' behavior; these rites are intended to signal the union's recognition by a designated representative of a religious community. In Muslim countries, marriage is pronounced by an imam except when the prevailing legislation also allows the civil authority to pronounce marriages (in Tunisia, for example). With the secularization of social life, civil authorities are increasingly in charge of registering and recognizing unions. But in many African societies, recognition may simply consist in an agreement between the representatives of two lineage groups with or without the presence of the traditional chief. The union is no less recognized, however, if the groom's family has presented the required bride wealth to the bride's family.

In Europe, some countries recognize only civil marriage; religious marriage, being a matter of private choice, can be celebrated only after a civil marriage (France, Belgium). Other countries, such as those of Northern Europe and Italy, recognize either civil marriages or religious marriages. The choice of ceremony will depend on the beliefs of each or the desired resonance of the ceremony (Dittgen 1994). With the secularization of societies, the civil authorities have gradually taken over from religious authorities as marriage registrars. Religious precepts nevertheless remain crucial determinants of marriage behavior, and sometimes the religious ceremonies are socially more significant than the civil marriages.

Civil marriage includes the registration of the marriage decision by an official of the State (as a rule, spousal consent is the mandatory expression of the decision) and a public reminder of the principles accepted by the community, principles that the spouses undertake to respect in their life together. Civil marriage assumes certain prior conditions have been met, most notably the minimum age requirement and the earlier marital status of candidates to marriage (not already married, except in the event of a polygynous union). The minimum age for young girls is almost always lower than the one required for young men. These principles mostly apply to the couple's residential arrangements and to child-raising, but they can also define other issues. In African civil marriages, the groom commonly states whether he intends to live in monogamy or polygamy.

The registration of a union in the civil records makes it a marriage recognized by society and gives access to potential family entitlements such as State allowances and tax benefits. It defines certain rights and duties of spouses in the marriage. Noncompliance with the norms of married life may constitute a motive for dissolution of the union; this too will be recorded, enabling either spouse to remarry.

Religious marriages are governed by specific norms that can strengthen or dilute the norms spelled out by civil society.[3] They are based on a set of prescriptions concerning not only residence and child-raising but also sex before and in marriage, as well as the proper attitudes of the spouses toward each other. They thus play an important role in determining the prescribed gender roles in married life.

Catholicism, for example, defines a strict framework for sexual activity and starting a family. Intercourse is allowed only in marriage. Marriage is based on the principle of indissolubility, except through the death of one of the spouses. As a result, divorced persons cannot remarry. Marriage is regarded as the bond of a stable and autonomous family. Spouses must consent freely to marriage; "this is why a man leaves his father and mother," as stated in the Bible (Matthew 19-5). Marriage transmits values of strict control over sexuality and is predicated on a stable union in a family cell built around the conjugal core. Last, a high value is attached to celibacy vows (priests still cannot marry). This set of rules significantly narrows the population on the marriage market at a given moment. The Catholic model of marriage has been of major importance throughout Europe. It strongly influenced the behavior of candidates to marriage in all countries of Catholic tradition until the late 1950s. However, current trends show the lessening sway of the Church. In France, 90% of marriages registered in the civil records were also celebrated in church in 1950; today, formal marriages are declining and disaffection toward religious marriage is gaining, since only 65% of civil marriages[4] are now also celebrated in church (Dittgen, 1991).

In parts of the developing world, most marriages are *customary* (or *common-law*) *marriages* since formal registration is not widely practiced and the use of civil records is very limited. Customary marriages differ from one social, religious, and ethnic group to another. They can be validated by the presence of an authority recognized by the community but are often simply a family matter. When two families have struck an agreement and the exchanges of goods and services (symbolic or not) have taken place, the marriage is celebrated with varying degrees of publicity and recognized by the community. The payment of bride wealth or a dowry is often a key step in the process leading to the union. In the event of a separation, a customary village authority may be asked to determine the compensations due to the family that deems to have suffered from the breach of what the community regards as a contract.

In the transition countries, where the practice of civil marriage is gradually spreading, common-law marriage nevertheless endures, and family consent is sought if the initiative for the union comes from the future spouses themselves.

When no civil, religious, or customary marriage is involved, the unions are known as *consensual* or *visiting unions*. They are very common in Latin America, accounting for nearly 50% of unions in certain countries of Central America and the Caribbean. They are also fairly unstable, which suggests that many of them may be trial marriages (Rosero-Bixby, 1990). They differ from the noncohabiting unions found in Africa, which are unions recognized by society under the rules of polygyny (Locoh, 1994; Oppong, 1992).

The recent spread of consensual unions in Europe has been very rapid. In the early 1970s, when the

[3] Christian marriage has, for example, insisted since the Middle Ages on the need for the free consent of spouses. This represents a break with the patriarchal principle, then prevailing, that required children to obey parental decisions (Leridon, 1991).

[4] Estimated percentage of marriages of never-divorced individuals, the only marriages allowed by the Catholic Church.

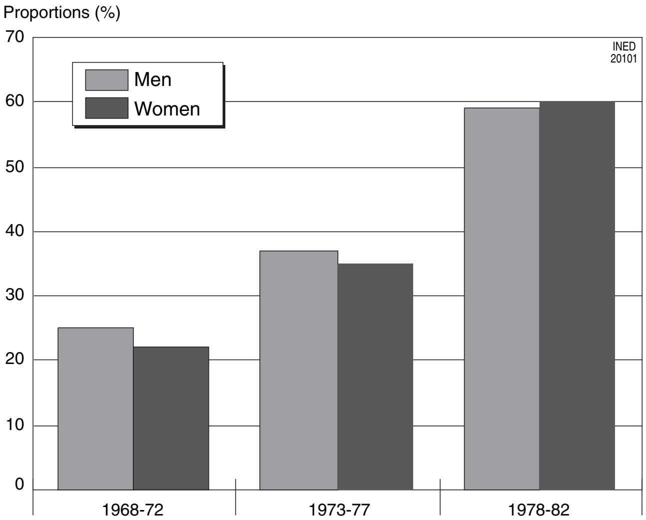

FIGURE 28–1 Proportions of men and women whose unions have begun outside marriage. Source: LERIDON Henri and VILLENEUVE-GOKALP Catherine, 1994. *Constance et inconstances de la famille: biographies familiales des couples et des enfants*. Paris, INED, PUF, 341 p. (Travaux et documents, Cahier no. 134).

phenomenon emerged, it was described as juvenile cohabitation. We now know that it was not a temporary living arrangement for young couples but a radical change of behavior that leads a growing number of adults to form partner relationships without necessarily marrying (Leridon and Gokalp, 1994) (Figure 28–1).

5. Marriages between Women

Anthropologists have noted marriages between women in several societies, for example in northern Benin and among the Nuer of Sudan. These marriages are entered into by infertile women to ensure that they will have descendants notwithstanding. A woman can marry a young woman and pay the bride wealth that seals the union. The children fathered by the husband with *his young wife* will be recognized as the descendants of the woman who has paid the bride wealth, not of the husband.

6. Homosexual Unions

Reported in several cultures as episodes of the youth life cycle (Badinter, 1992), homosexual relations are an abiding category of human behavior. In a recent survey on sexual behavior in France, for example, 4% of men reported having had a homosexual relationship at least once in their life. Similar figures (between 5% and 7%) are advanced for England and the United States (Messiah and Mouret-Fourme, 1993). With the concern over reproduction having given way to the satisfaction of partners as the main goal of couple formation, homosexual couples have acquired legitimacy, and the ideal of respect for individual rights has inevitably led to the recognition of their rights. The dramatic experience of the AIDS epidemic in homosexual communities has focused attention on the specific problems of gay couples and on the possibility of institutionalizing solidarity bonds comparable to those that exist for heterosexual couples in which a partner is mourned. In some countries, homosexual couples are entitled to official certificates of cohabiting partnership, which give them reciprocal rights. Religious ceremonies are also organized by some churches that recognize these unions (in the United States, for example; Collins, 1988). However, this recent tolerance must not hide the fact that, in many countries, homosexual unions are punished by harsh legislation, sometimes extending to deprivation of freedom.

Whatever the authority that sets the rules of marriage, or more generally of union, the rules mainly concern the age of access to sex and marriage, the control over spousal choice, the choice between monogamy and polygamy, partnership arrangements, and access to divorce. These five areas are of direct interest to the demographer as they determine at any given point in time the number of *marriageable* persons, and therefore whether the marriage market will function in harmony or in conflict. More broadly, they also define the balance of power between men and women, between young and old, and hence the decision-making capabilities of each player in regard to fertility.

II. AGE OF ACCESS TO SEX AND AGE AT MARRIAGE

1. Age at Puberty and Age at Marriage

The conditions of access to sex, to couple formation, and to parental responsibility shape an individual's entire adult life. Young girls in particular, when they enter this area before reaching physiologic maturity, run risks that can compromise their health, or even their later fertility. The same is true of their psychological maturity, which, if inadequate, will make the young woman dependent on her spouse or family-by-marriage. Indeed, most societies endorse the notion that men should demonstrate some maturity before marrying, even though the same societies extol early marriage for young girls.

When unions are subject to legal requirements, one of the conditions is a legal minimum age for marriage. As a rule, it reflects a concern of a physiological nature regarding the future spouses' capacity to engage in sexual activity; in principle, it is higher than the age at puberty. A United Nations survey (United Nations, 1988) showed that the statutory minimum age ranges from 14 years in some Latin American countries to 22 years in China for men and from 12 to 20 years for women in the same countries. The minimum ages are highest in Europe and lowest in Latin America. In the developing countries, the setting of a legal minimum age is a fairly recent concern. For girls, in particular, puberty was often the criterion that determined marriageable status. For young men, initiation rites were and still are arranged. They endow young males with the status of adult, a prerequisite for marrying. The notion that a young person needs to reach sexual or psychological maturity is a fairly widespread but not universal rule. In India, where child marriages are practiced, a little girl may be socially married very young but she does not go to live with her husband until she reaches puberty, after a new ceremony (United Nations, 1988). In Africa, customary marriage still prevails, and the legislation newly promulgated by central governments is not always enforced. Some social groups allow pre-pubescent girls to marry because, it is argued, they will thus adjust to their family-by-marriage as early as childhood, or because they have been promised as a consequence of matrimonial reciprocity relationships between two lineage or clan groups. The marriage is not consummated until puberty. This was also the case in China before Mao, where marriages arranged in childhood were a means of ensuring a low-cost marriage for a son.

> Since males often needed to pay a bride price and most of the wedding expenses, a son often needed for his family to accumulate enough resources for him to get married. The waiting period tended to be especially long for males in poor families and ones with many brothers. The widely documented practice of "little sister-in-law" (i.e., adopting and raising a future daughter-in-law to avoid the high costs of a son's marriage) is just one of the social practices arising from these economic realities. (Feng and Tuma, 1993)

Access to marital life is undeniably far more dependent on social factors than on physiological-maturity factors, as shown in Table 28–2, which reports the results available on the link between young girls' age at puberty and age at marriage (Udry and Cliquet, 1982). The link is obvious in some social environments and very weak in others. The connection is fairly strong among U.S. African Americans, in Pakistan, and in the Malaysian population; by contrast, in the Belgian sample and among young girls of Chinese descent living in Malaysia, it is weak or even nonexistent. Even more interestingly, the variations in the age at marriage are wider, for a given age at puberty, between the societies sampled than they are by age at puberty in the same cultural group. Among young girls who have had their first period at age 12, the age at marriage varies from 15.2 in Pakistan to 21.1 among Malaysian Chinese; in contrast, the maximum difference in age at marriage by age at puberty observed in Pakistan is smaller (from 15.2 to 19.7 on average). In individual terms, early puberty is correlated with early marriage. But the relationship is reversed at the collective level. The developed societies are the ones with the youngest mean age at puberty and the oldest mean age at marriage. The influence of age at sexual maturity on the age at first marriage or the age at first intercourse differs according to whether the society encourages early marriage or not. If early marriage is encouraged, the age at puberty is an important determinant of age at marriage. In the opposite case, social control over sexuality and reproduction is exercised and plays the leading role.

Some developing countries are in a transition phase where the improvement in living conditions leads to

earlier puberty and to an increase in the age at marriage—to allow schooling or work experience before entry into union. In Thailand, for example, a survey has shown that 60% of urban-dwelling young girls enrolled in school have had their periods before age 13 versus only 11% among those living in a rural area (Muangman, 1979, cited in Udry and Cliquet, 1982). For the first group, there follows a length of time—not experienced by earlier generations—in which they have reached sexual maturity but are not in a partner relationship. If they have not had access to contraception information and resources, they will be at increased risk of unwanted pregnancy, births out of wedlock, and possibly abortions. This is often the case in Africa and in many disadvantaged communities in the developing countries.

2. Tolerance of Premarital and Extramarital Sex

Some societies are fairly permissive about sex for unmarried young people others are repressive and strictly control access to sexuality. In China, marriage is the ceremony that gives access to sexual relations. The same is true in Christian populations, for which the religious ceremony of marriage is normally a prerequisite to intercourse and designates the only authorized sexual partner. In some societies, marriage ceremonies include the exposure of blood-stained bed linen as proof of the bride's virginity. In India, family honor is at stake in the preservation of the virginity of marriageable daughters. For this purpose, the inhabitants resort to *purdah* (reclusion of young girls) and a high segregation of female and male activities.

In African societies, family and social controls are totally focused on marriage. Young people marry partners designated by the elders, not chosen by themselves. This rigid control of marriage can go hand in hand with a moderate degree of sexual freedom for youth. Many African societies regard prenuptial births as normal, proving the young woman's fertility. In Kenya in 1989, for example, 41% of females aged 15–49 had had a child or been pregnant before marriage. In a rural Islamized population of Senegal, thought to disapprove of births outside marriage, these accounted for 20% of registered births between 1983 and 1991 (Delaunay, 1994).

Judging from Murdock's atlas (Table 28–3), the premarital-sex ban is not the most widespread norm. Premarital sex is heavily punished in one-fourth of the societies observed; 10% of the societies punish it when it results in pregnancy; 21% ban it in theory but punish it lightly; 7% of societies have adopted the practice of early marriage for women to avoid their having sex outside marriage, whereas one third of the societies are permissive in this respect. The greatest tolerance toward premarital sex is found in Africa (45%) and the Pacific Islands (49%); the heaviest disapproval is shown in the societies of the Europe and Mediterranean rim group (50%).

The most recent observations from the DHSs show that African societies remain the most tolerant of premarital sex. The highest frequency of premarital sex is found in sub-Saharan Africa (except Mali and Burundi). By contrast, the two Asian countries for which data are available, Indonesia and Thailand, show a broad coincidence between first intercourse and marriage. Latin America and the Caribbean are

also relatively permissive societies, most notably Peru and Colombia (Table 28–4).

Shorter (1977) has shown that, in post-Renaissance Europe, premarital births have signaled the decline in social control of sexual activity and the emergence of more independent behavior among youth. In Africa, where the concept of marriage is very different, the tolerance of premarital sex must be interpreted otherwise.

3. Access to Sex and Access to Contraception

When the gap widens between age at puberty and age at first childbirth, one generally finds greater social control over access of young people to sex by means of bans and moral or religious rules. The population policies adopted in high-fertility countries typically add the increase in age at marriage to the arsenal of fertility-curbing measures. However, in the first stages of the fertility transition, one often observes both the increase in the age at marriage and a rise in extramarital births. For young people, the access to contraception—seldom facilitated in these societies—and the easing of social control on sex that usually goes with schooling, urban life, and access to nonfamily jobs initially translates into a greater number of out-of-marriage pregnancies.

By contrast, in the developed countries, such control is gradually replaced by access to contraception—but this does not mean that young people do not begin their sexual activity as soon as they reach sexual maturity. Along with greater sexual freedom, there has been a downward trend in the age at first intercourse and a higher frequency of its occurrence outside marriage.

The 1991 to 1992 survey on the analysis of French sexual behavior, for example, indicated a fall in the age at first intercourse—in moderate proportions for men, far more sharply for women, in the previous forty years. The age fell from 18.4 years for men born between 1922 and 1941 to 17.2 years for males born in 1972 to 1973. For women, the age fell from 21.3 to 18.1 years. Increasingly early sexual experience has coincided with a convergence between female and male ages at first intercourse. The gap has narrowed from 3 years in the older generations to less than 1 year today. General access to contraception is one of the important factors behind this change, but so is the changing status of women, in particular their growing autonomy in the workplace (Bozon, 1993).

4. Factors in Age at Marriage

While parental or social-group control of access to sex is exercised differently from one culture to another, the difference is even greater as regards access to marriage—a quintessential social act—and especially as regards age at marriage. Control often has divergent effects for the two sexes. Many societies encourage early marriage for girls so they can have children as soon as they are physically capable of doing so. By contrast, it is not uncommon for young men's access to marriage to be delayed, either to make them undergo initiation rites, or to accumulate bride wealth. This is the case in Africa, where gaps in the age at marriage are, as a result, particularly wide. Appendix 28–1 reports a set of data on age at marriage[5] by sex in different regions of the world and for two successive dates. The figures reveal three basic phenomena:

1. All over the world, *men enter into union on average later than women*. Their mean age at first marriage varies between about 24 years (Guatemala, China, Iran, and Turkey, for example) and 30 years (Sweden, Norway, and Switzerland). The earliest marriages take place in West Asia, China, and South Asia; the latest, in Europe and in West Africa. For women, the mean age at first marriage exhibits a wider spread of values, from about 18 years (Burkina Faso, in particular) to 30 years (Sweden). By and large, women marry earliest in sub-Saharan Africa, where the mean age rarely exceeds 20 years. Next comes West Asia (the Near Eastern countries) where women marry at a mean age of 21. Women marry latest in Northern and Western Europe. Very recently, however, the age at first marriage has risen steeply in North Africa.[6]
2. The smallest *age gaps* are found in Europe and North America (one year in Ireland, two years in several European countries, Canada, and the United States) but also in some Asian countries, notably China (1.9 years in 1987) and Thailand. The other countries of Asia, Latin America, North Africa, and Eastern Europe display differences in mean age at marriage ranging between 2.5 and 5 years. The widest gaps are in West Africa—for example, 10 years in Mali and Senegal. Their role in polygyny is well known. In societies where individual choice ranks second to family choice, the age gap between spouses is often wide, increasing women's dependence.
3. Age at marriage is trending up in most countries. The spread of education and nonfamily employment are the essential factors in the easing of controls on unions. When the young partners have personal sources of income, they are freer to take the decision to marry, but as a rule they will take it later.

In Europe, the loosening of the family grip formerly translated into a fall in the age at first marriage (Shorter, 1975): for women, it used to be about 25 years, but in developing countries where people marry far earlier, youth emancipation through schooling or access to nonfamily jobs almost invariably drives up the age at marriage. The decrease in male age at first marriage in China—owing to laws banning arranged marriages and dowries—is an exception in the contemporary world. But this trend has gone with a decline in early marriage. The percentage of men married before age 20 has fallen from 35% in the 1900 to 1925 cohorts to 6% in the cohorts born in 1960 to 1964. For women, the proportions have shrunk from 70% to 20%, respectively.

Most of today's industrial societies no longer encourage early marriage. Advances in female education, the very high integration of women into the labor market, and the widespread use of contraception have all combined to delay first marriage. Moreover, pressures on the young to marry legally are now weak in some societies where the custom of consensual unions is deep-rooted or in those where the free decision of individuals is such a strong value that parents no longer feel they have a right to control their children's choices.

At the individual level, all the developing countries exhibit a rise in the age at marriage (or at union, in countries where marriages are not officially recorded) as a function of the number of years of education. Delayed entry into union for educated women is particularly in evidence among the most highly educated women of sub-Saharan Africa. Between illiterate women and those who have at least 10 years of schooling, the difference in median age at first marriage is 4 years in Kenya, Togo, Liberia and Zimbabwe, and 6 years in Senegal and Uganda (United Nations, 1995).

[5] The data have been calculated using Hajnal's method (1953) from the proportions of single persons observed in censuses or surveys. In some societies, consensual unions may be reported as marriages in surveys.

[6] It now stands at 27 years in Tunisia (Bensalem and Locoh, 2001) and 28 years in Algeria (Ouadah and Vallin, 2000a and 2000b).

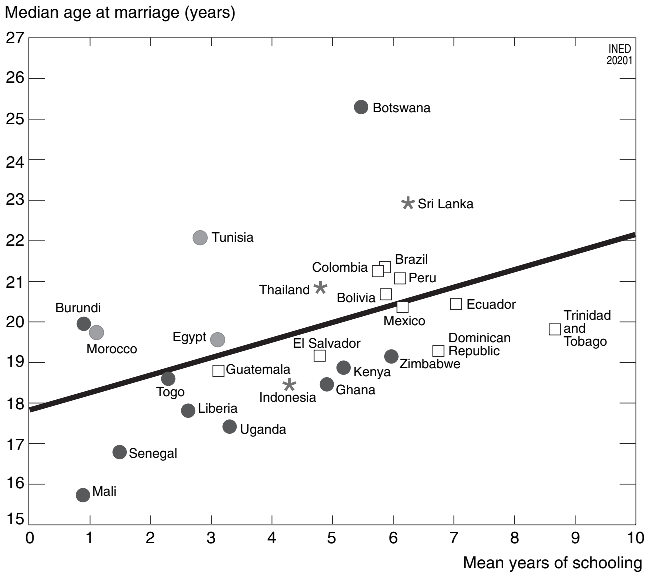

FIGURE 28–2 Median age of women at marriage, by mean years of schooling. Source: United Nations, 1995. *Women's education and fertility behaviour: recent evidence from the DHS*. New York, United Nations, Department for Economic and Social Information and Policy Analysis, 113 p.

Figure 28–2 plots the correlation at the collective level. Here, the link is less obvious, as countries with comparable educational levels may have fairly different median ages at marriage due to the influence of other cultural factors concerning marriage behavior.

Some countries have made the increase in age at marriage one of the components of their fertility-control policy. In particular, China introduced coercive measures in the 1960s. Coale (1989) estimates at 60 million the number of births avoided in the 1970s by the increase in age at marriage. Since 1980, controls on that age have eased again, and the age at marriage for both sexes has fallen by about two years. This reflects young people's desire to marry earlier than would have been allowed during the harshest period of enforcement of the late-marriage policy (Feng and Tuma, 1993). One of the most visible trends in the change in marriage patterns in China is the convergence of male and female behavior. As men have married younger and women later, the age gaps have narrowed. The age gap between spouses or partners tends to fall with the autonomization of women and their growing access to education and employment—and, more generally, when they attain the same empowerment over their own lives as men.

5. Can One Escape Marriage?

The proportions of men and women married (or in union) at age 50 reported in Appendix 28–1 show that marriage is the common lot of the overwhelming majority of adults. In a great many societies, only physical incapacities are an obstacle to marriage. However, some religions attach value to consecrated celibacy—for example, Catholicism, which makes celibacy mandatory for priests and nuns.

There are also situations of imbalance between the number of marriageable men and women that can entail unwanted adult celibacy. This has occurred in the French countryside, where the excess of female migration flows over male migration flows toward urban communities has sharply driven up male celibacy rates in the past thirty years (Courgeau and Lelièvre, 1986). More generally, the phenomenon arises in all social environments where sex-differentiated migrations create imbalances in the marriageable population. Such imbalances are also observed after devastating wars in which most casualties are male. This can lead the excess female population to adjust its behavior in order to escape celibacy (Henry, 1966). Last, economic crises can exclude certain population categories from access to marriage owing to a lack of resources for starting a household. Farm laborers of the Crofting Counties in Scotland between 1850 and 1900 had never-married rates of up to 30% (Anderson and Morse, 1993).

The probability of never marrying depends on cultural factors—social pressure in favor of marriage, values respectively assigned to celibacy and marriage, financial requirements for the future spouses, and so forth—but also demographic factors that determine the size of the marriageable male and female populations. These numbers, as well, are influenced by cultural factors. A temporary or permanent ban on access to the marriage market for specific categories (determined by age, marital status, or social condition) increases the risk of a numerical imbalance. If, instead, ever-married men and divorcees are allowed to become candidates to marriage again, the marriage market will regain flexibility.

In Figure 28–3, we have plotted the mean age at first marriage against the proportion of ever-married 50-year-olds for a selection of countries. We can clearly identify two distinct nuptiality regimes: Europe and North America differ from the other continents by a higher celibacy rate and older ages at marriage, for men and women alike. Again, the data concern cohorts aged 50 in 1980 or thereabouts. Indeed, if the marriage behaviors currently observed in Europe and North America endure, the proportion of never-marrieds is likely to rise substantially in the years ahead. The nuptiality rates in industrialized countries show a clear disaffection for marriage since 1970 (see Table 28–5). If the present behavior continues, we might see birth

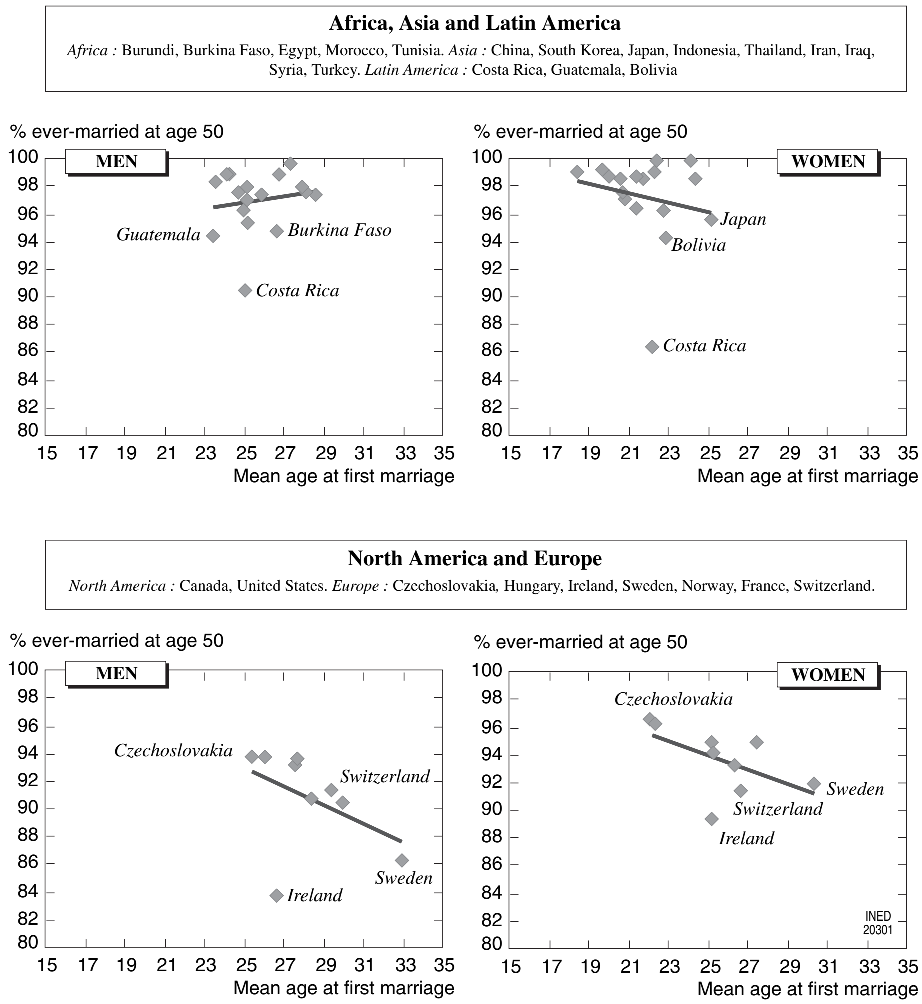

FIGURE 28–3 Correlations between mean age at first marriage and proportion ever-married at age 50 (Demographic and Health Survey, 1980–1990), by sex. Source: see table in appendix.

cohorts where one-third or even one-half of adults would never marry. However, they would have experienced one or more periods of partner relationships. What has changed is the type of relationship and its duration. Statistics will need to be based on a new definition of celibacy.

III. COUPLE FORMATION AND THE CHOICE OF PARTNER: FROM SOCIAL CONTROL TO PERSONAL DECISION

1. Dowry and Bride Wealth: How to Create Shortages to Control a Marriage Market

The need to accumulate goods in order to secure a partner is one of the crucial mechanisms for controlling access to marriage and the choice of partner. By requiring candidates to marriage to provide resources, the community decision-makers wield a powerful mechanism for regulating access to the marriage market. There are two contrasting methods: dowry, which is transmitted by the young girl's family to that of the future husband, and bride wealth, offered by takers of women to givers of women. Curiously, they have parallel effects on the marriage market by creating—via the socially accepted norm—shortages of either sex that do not exist in purely demographic terms. It is interesting to compare two matrimonial exchange systems: dowry in India and bride wealth in sub-Saharan societies. Both rely on the age difference between spouses.

In India, dowry has been subject to inflation for the past forty years or so (Rao, 1993). Some scholars have attributed this to a phenomenon known as Sanskritization (i.e., the poor imitating the behavior of the ruling classes, the Brahmans). Caldwell *et al.* (1983) have advanced the alternative hypothesis of a

Source: Monnier Alain and Guilbert-Lantoine Catherine de, 1994. La conjoncture démographique: l'Europe et les pays développés d'outre-mer, *Population*, vol. 49(4–5), p. 1107–1128.

dual demographic constraint. First, rapid population growth and the sharply increasing frequency of a wide age gap between spouses creates a relative shortage of marriageable young men. Second, Indian society advocates early marriage of young girls; for a family, housing an unmarried woman aged over 20 is a particularly heavy burden given the few work opportunities for women and the disapproval of what is seen as late female celibacy.

These mechanisms create a *husband hunt*, with dowry as one of the stakes. The excess of marriageable women incites families to make ever higher offers to young men's families. The numerical-imbalance constraint (Caldwell *et al.*, 1983) inevitably leads to market adjustments, as the social pressure is so strong that all girls must eventually marry and succeed in doing so.

In a study of the states of Maharashtra and Andra Pradesh, Rao (1993) has observed a significant increase in dowries along with a generalization of marriage. The 1981 census found that the vast majority of women over 20 in these Indian states were married. However, adjustments have taken place. First, the female age at marriage has risen sharply (from 15.57 years in 1931 to 19.86 years in 1981), and faster than that of men (from 23.6 years to 25.5 years in the same interval): This has narrowed the age gap between spouses from 8 years to 5.6 years. One could have imagined other adjustments via divorce and the *recycling* of men in new marriages or polygyny. But this region of southern India practices neither polygyny nor divorce (only 1% of Indians of either sex are divorced). In the end, the adjustments were confined to the gap in ages at marriage, but the social pressures accompanying the shift have driven up dowries.

This example clearly shows the extent to which culture—by playing a role in setting norms for age at marriage and by institutionalizing differences between young women and young men—perpetuates numerical imbalances in situations where a balance could be achieved. It is interesting to compare India's situation with that of the countries of sub-Saharan Africa. There as well, age-at-marriage norms create numeric imbalances but through a different mechanism and with entirely different matrimonial consequences than those observed in southern India.

In Africa, the age gap between marriageable males and females ranges from 3 to 10 years depending on the society (see table in appendix). In these societies, marriageable young men belong to older age groups and are thus fewer in number than the young girls entering the marriage market. Despite the resulting deficit, African societies practice bride wealth (i.e., a transfer of wealth from the men's families to the women's families), contrary to the Indian custom. The reason is that the goal of men in African societies is to have access to several women, as polygyny is a positive value. The *surplus* of young marriageable women allows this type of marriage. *Bride wealth* also acts as a regulator in polygynous marriage systems. By requiring the accumulation of livestock, money or time working in the fields belonging to the lineage whose daughter is being courted, the system fixes a waiting period for marriageable young men and puts them in competition against older men, who are candidates to a new union and are probably more likely to assemble the bride wealth. The accumulation of bride wealth is often handled by the family members rather than by the young man himself: this also introduces a form of control by elders on the sexuality of the young. By and large, the elders are competing with young bachelors for the favors of marriageable young girls.

2. Family Systems and Marriage Decisions

The importance of family systems in understanding the patterns of couple formation stems from the fact that marriage forms the context in which families are established and grow. If the family is the birthplace of society, marriage is the birthplace of the family (United Nations, 1988). To analyze the different modes of family intervention in marriage decisions, we can distinguish—for simplicity's sake—between extended families and nuclear families.

In societies with a strong seniority-based hierarchy where the family authority is the structuring principle and the *extended family* is the most common living arrangement—as in many African societies—couple formation is an integral part of family, lineage, or clan strategies. In these societies, couple formation is driven by two basic motives: the desire to preserve and develop alliances and the need to manage each family group's reproduction as efficiently as possible. Alliance and descent are the core concerns of these societies. Marriage candidates' personal choices count for little, and the satisfaction of spouses in a quality conjugal relationship—beyond the necessary peace that must reign in a good marriage—is not the prime concern of match-makers. What matters is a family group's decision in conformity with consensual rules. These include control over sexual activity, the choice of partner, the type of bride wealth and bride wealth compensation to be exchanged by the families, and age at marriage. The stricter the rules, the greater the intervention of families in spousal choice. For example, in the Bwa country (Mali):

> Because of the inclusion of marriages in alliance strategies determined by community issues, and the recognized authority of family members in the formation of unions, couples neither form nor define themselves in terms of a plan developed and shared by the two partners. On the contrary, husband and wife each preserve their specific family identity, and very often they exhibit individual characteristics that do not promote any convergence (for example, a significant age gap). (Hertrich, 1994, p. 5).

The kinship group must preserve control of its members and thus maintain its capacity to manage its survival. Control by the extended family covers three aspects of the marriage: timeliness of the marriage, age at marriage, and choice of partner. The timeliness of the marriage is usually very high in these societies, where extended families are the most widespread system, and individuals are under pressure of different kinds not to remain single. The organization of domestic life in extended-family societies favors early marriage for girls, most notably in order to achieve reproduction goals, which require high fertility. When new couples join a family group of residence and contribute to a family production unit, there is no reason to delay marriages. The domestic group that hosts the new family cell will benefit from the young woman's labor, as it is almost always the woman who joins the husband's group. The greater the family involvement in the marriage processes, the younger the age at marriage, at least for girls, and the lesser the say of the future spouses in decisions concerning them. Because of the production and social-exchange objectives prevailing in extended families, spousal choice is heavily constrained by the family group. Under the authority of its elders, the group will enforce compliance with norms concerning exchange, endogamy, and exogamy. Until the 1950s, marriages in China were still governed by similar norms:

> Early and universal marriage has been a central feature of the Chinese cultural tradition. This tradition stipulates not only that both males and females should marry in order to have a complete life, but also that they should marry at early ages, normally between 16 and 18 for females and slightly older for males. The function of marriage was primarily to fulfill the collective goal of continuation and expansion of the family system by way of forming new reproductive unions, rather than to satisfy the individuals involved in the process. Therefore, until very recently, marriages were usually arranged by elder members of the clan, and not by the individuals themselves. (Feng and Tuma, 1993).

Advances in education and the extension of employment outside the family substantially loosened the grip of the traditional Chinese marriage model in the twentieth century. The State has also banned arranged marriages, required the free consent of spouses for their marriage, and introduced late-marriage policies.

In other transition societies, the monetarization of the economy brings a greater freedom of spousal choice by reducing the share of domestic production. Sometimes, parents are merely consulted about the choice made by their children—a modified form of the old patriarchal controls (Domingo and King, 1992). Table 28–6 compares the influence of parents in their daughters' spousal choices in two south Asian

TABLE 28–6 Mean Age at Marriage (Years) and Role of Parents in Daughter's Spousal Choice

Indicator	Pakistan			Thailand		
	Rural	Urban poor	Urban middle-class	Rural	Urban poor	Urban middle-class
Mean age at first marriage	17.2	18.2	20.1	21.9	20.1	22.5
Proportion (%) of women married as a result of the following						
Decision by parents	98.7	90.5	78.7	11.1	11.5	13.5
Decision by parents with daughter's approval	1.3	7.8	17.4	17.9	7.9	11.8
Decision by daughter with parents' approval	0.0	1.0	1.6	14.6	11.4	17.4

countries: Pakistan and Thailand. In Pakistan, parental decisions still play an important role in young girls' marriages; in Thailand, as in many countries in transition toward monetarized economies, marriage behavior is evolving. In the most affluent strata of Thai society, where women marry at 22.5 years (a fairly high age), slightly over half the women (57.4%) have chosen their spouses freely, 17% have submitted their choice to parental approval, and one fourth have accepted the husbands chosen by their parents. By contrast, women in rural Pakistan—who marry, on average, at 17.2 years—never choose their husbands.

In nuclear families, whose rise has been facilitated by industrialization and urban living arrangements, parental intervention in spousal choice is less frequent. The interests of *nuclear* parents differ from those of extended families. True, they want their children to enter into prestigious marriages that will procure gains in status or property; they also seek a degree of geographic, religious or social endogamy in the marriage. But the young betrothed will establish their own cell. Their labor will therefore not be monopolized by their family group but, conversely, they will have to ensure the livelihood of their new family cell. In these societies, early marriage loses its justification and family pressures on marriage are weaker than in patriarchal societies. Moreover, the young usually acquire some autonomy, and parents have fewer means to force them to make choices against their will.

3. Endogamy and Homogamy: Individual Choice and Influence of the Social Environment

The closer one moves toward societies that value individual satisfaction, the more the couple-formation criteria reflect the partners' aspirations and the less the decision is shaped by social norms and pressures from the family circle.

> We are no longer dealing with groups that exchange their members, nor with families forming alliances, but with free and equal individuals deciding to unite in order to build their happiness together—and just as free to terminate their union later on, if it does not bring them the expected satisfactions. (Girard, 1981).

Yet, even in societies where individuals freely choose their spouses or partners, that liberty is conditional. Beyond their romantic quality, spontaneous attractions—and even *love at first sight*—are largely influenced by social conditioning, which shapes adolescent and adult preferences as early as childhood. Studies on social homogamy have shown that, even in industrialized countries, people continue to choose their spouses in *marriage markets* bounded by specific economic or social criteria. Doctors' sons have never really stopped marrying doctors' daughters, even though unions are slightly more imaginative than in the past and society is more tolerant toward what used to be called *mismatches* (Girard, 1981).

Endogamy is defined by the fact of choosing a partner in a group. Unions are called endogamous on the basis of precise characteristics. We can speak of ethnic, cultural, religious, geographic, and family endogamy. The most commonly studied family endogamy consists in marrying one's relative or a member of one's lineage group. This practice was inexorably eroded by the rise of migration (Fargues, 1986) and geographic mobility in the twentieth century and is certainly a factor that has hastened the transformation of marriage in many societies with endogamous preference. But society always locks the liberty of candidates to marriage in a wide variety of determinisms.

Geographic, social, and cultural endogamy is manifest in all societies. While losing some ground to more unpredictable unions because of geographic, social, and cultural mobility, it is clearly visible in most surveys.

Vicinity continues to play a major role in marriage choices. Despite migration flows, marriages are often still determined by ethnic, cultural, and regional preferences. Community and residential networks foster encounters between candidates to marriage and make others unlikely. Spousal choice is more open in today's urban societies than in older rural societies or in the present-day rural societies of developing countries, but traces of formerly prevailing conditions persist. In a survey of France of the 1970s, Alain Girard has observed (1981) that there was still

> a one-in-five chance that husband and wife came from the same village, a one-in-two chance of their being born in the same urban district, and a three-in-four chance that they came from the same département.

In societies whose members are free to choose their spouses, endogamy has given way to homogamy, which consists in marrying someone who resembles you. Homogamy can involve the family's social origin but also, increasingly often, common personal characteristics. In industrialized countries, cultural homogamy measured by educational attainment tends to prevail over social and economic homogamy. In France, the analysis of a 1989 labor-force survey showed education to be a more influential criterion than social origin in spousal choice. For a growing number of couples, being united through cultural homogamy is a means of accepting a degree of social heterogamy (Forste and Chauvel, 1995).

Cultural or social homogamy goes beyond the mere fact of marrying one's kindred spirit because he or she is closer, because one can meet him or her more easily, and because one is being encouraged by one's contact circle to form a union with a partner who is, in some sense, *familiar*. François de Singly (1987) ventures the hypothesis that the marriage market, like the labor market, is a space where individuals are recognized for their social value. He analyzes homogamy in the following terms:

> Homogamous unions are formed not out of respect for a social norm but on the basis of each partner's well-controlled interests [. . .] Heterogamous unions signal a strategic success for one of the two partners, since one of the two has apparently or actually succeeded in exchanging a value greater than his or her own. (p. 189)

Homogamy can also concern age. In advanced societies—including in China, where the break with traditional marriage has been strongly encouraged by the Communist regime—the age difference between spouses is narrowing. Traditional societies have hitherto been characterized by strong age heterogamy. Grooms are older than brides, sometimes much older. This type of heterogamy introduces a distance between spouses that has a powerful impact on their married life. It has a specific function in the workings of marriage systems where heavy female subordination is the rule. Dowry and bride wealth help perpetuate this wide age gap between husbands and wives in some societies. The gap has not vanished in advanced societies, where it is a survival from the days when people thought it normal that age gives the man additional authority over his wife.

IV. LIFE AND DEATH OF UNIONS

1. Monogamy, Polygamy, Polyandry: One Partner or More?

Monogamy, the union of one woman and one man, is the governing principle for all legal unions in the industrialized countries. Under the historical influence of the Christian concept of marriage, the industrialized countries have developed legislation consistent with the founding principle of the nuclear family, which—at least in theory—promotes an egalitarian relationship between spouses and makes reciprocal fidelity the cornerstone of exchanges between spouses. Yet monogamy can very well go hand in hand with a blatant inequality between spouses. The situation of European women until a recent period is proof of this. Bourgeois women in the nineteenth century had a lifelong status of minors, and, in certain countries, the financial independence of married women did not become reality until the 1950s.[7]

While monogamy is currently the most widespread form of union, this apparently has not always been the case in societies observed by ethnographers. Murdock's atlas (1969) indicates that the number of societies accepting polygamy far exceeds the number of societies advocating monogamy. Polygamy, in the strict sense, denotes the marriage of an individual with several persons of opposite sex. It includes polygyny (one man married to several women) and polyandry (one woman married to several men). Polygyny is by far the more common variant. Polyandry is extremely rare. It is observed in only a handful of societies (the Toda in India, the Bahini in East Africa, a few Eskimo tribes, and most conspicuously in Tibet, in the form of

[7] Conversely, polygyny, which is radically inegalitarian, is sometimes more conducive to the autonomy of both spouses.

fraternal polyandry). A closer analysis of polyandric practices shows that they typically result from a demographic imbalance due to girl infanticide. Societies incapable of ensuring their offspring's livelihood would appear to have practiced female infanticide as a means of controlling population growth—hence an imbalance between sexes leading to polyandry (Eskimos, Toda in India).

Polygyny is most common in Africa, particularly south of the Sahara (see Chapter 27). Contrary to what is sometimes believed, it predates the establishment of Islam. Everywhere else it is either heavily restricted or outlawed. In Muslim countries it is allowed but under strict conditions of equal treatment of wives, whose number is limited to four. In fact, polygyny is declining (between 1% and 11% in the countries of the Near and Middle East). In China, it was practiced by allowing concubines alongside the legitimate wife, but was abolished after the establishment of the Communist regime (Goode, 1963). In the developed countries, it survives informally and residually in a few religious groups, such as the Mormons.

Polygyny in sub-Saharan Africa is relatively stable. So far, it has also survived in the transitional urban environments, despite the introduction of modern, less favorable legislation and, in certain countries, the influence of Christian religions (Donadjè, 1992). Polygyny is a source of economic enrichment for the husband, either directly, through the appropriation of the wife's economic activity, or indirectly by taking advantage of the services of the children to whom the women will give birth. Polygyny is most common in the sub-Saharan African countries where women are most involved in agricultural production (Lesthaeghe, 1989). It also exists in Muslim countries, but Islam limits it to four co-wives. Most of the civil codes recently adopted in Africa restrict polygyny to two co-wives (Ngondo a Pitshandenge, 1994).

A large proportion of African women live in polygynous households: between one woman in three and one woman in two, depending on the country (Table 28–7). However, the new male cohorts hit by the economic crisis enter the marriage market at an older age and may find it difficult to access polygyny (Antoine *et al.*, 1995).

Marriage norms in these societies promote an age gap between spouses with the aim of creating a numerical imbalance between marriageable men and women. The age difference also increases the likelihood of widowhood among women and hence a contingent of newly *marriageable* women, sometimes systematically remarried in accordance with the practice of the *levirate* (see subsequent section on remarriage).

TABLE 28–7 Percentage of Women Living in Polygamy in Africa (1976–1987)

Countries	Percentage of women in polygamous union
Benin (1981–1982)	36.5
Cameroon (1978)	42.9
Côte d'Ivoire (1980–1981)	41.4
Ghana (1979)	34.4
Kenya (1977)	29.5
Liberia (1986)	38.0
Mali (1976)	46.3
Morocco (1987)	5.1
Mauritania (1981)	14.8
Rwanda (1983)	18.4
Senegal (1978)	48.5
Sudan (1979)	16.8
Zaire (1982–1984)	32.1

Source: United Nations, 1990. *Patterns of first marriage: timing and prevalence*. New York, United Nations, 327 p.

As long as the marriageable young agree to play by the rules—early marriage for women, late marriage for men, and the need to accumulate bride wealth—there is room for polygyny, despite the demographic equilibrium between the sexes! And, apparently, these rules are still well entrenched in African societies: the gap in the age at marriage remains stable, even in urban and schooled populations, and so does polygyny.

Polygyny is often justified by the desire to have many children in a context of high mortality. One of the reasons cited for polygyny is *postpartum* abstinence to preserve the health of the newborn child. In reproductive terms, polygyny has two effects that need to be separated. At the individual level, it has sometimes been argued that this type of marriage had a negative effect on the fertility of wives (Bean and Mineau, 1986). The effect is negligible when the wives' marriage-order effects can be controlled (Pison, 1986). At the collective level, polygyny has an undoubtedly positive effect on the fertility of the population by promoting a highly fluid marriage market. Every married man theoretically remains a candidate to marriage; as a result, all women can easily find themselves in a state of union and exposed to the risk of conception throughout their childbearing period—outside of *postpartum* abstinence periods—provided they accept life in a polygynous household.

2. Residential Arrangements and Partner Relationships

In couple formation, societies regulate not only access to union and the choice of partner. They often intervene in residential arrangements and in the spouses' married life.

The cohabitation of couples of different birth cohorts is still fairly frequent in traditional societies. This leaves room for controlling the life of couples, curbs their intimacy, and restricts their latitude to take decisions as an independent family unit. Typically, residence is patrilocal or virilocal. The wife will thus have the status of guest at best and of stranger at worst.

With modernization, residence is no longer necessarily determined by family considerations, but rather by economic constraints. In some cases, cohorts are forced to live together by the difficulty of finding accommodation for a new family cell. In Algeria, the present housing crisis is leading to a very pronounced delay in marriage and to unwanted situations where young couples are living with their parents.

Residential problem never before encountered are beginning to appear in the industrialized countries, where both spouses work but in different locales. This has prompted the invention of part-time conjugal living arrangements and, in some cases, dual-residence couples.

Polygyny, as well, gives rise to multiresidence households. In cities, *polygyny without co-residence* often replaces traditional polygyny (Locoh, 1994). Each woman has her own residence, and the husband goes from one to another. In traditional polygyny, one also finds forms of residential independence, with each wife assigned a hut of her own. The family authorities in the compound can thus exercise effective control over *postpartum* abstinence:

> Some sexual freedom among the unmarried youth is countenanced in many societies, but sexual relations of married couples tend to be carefully managed and scrutinized by senior kin, with the result that for many years of married life the majority of women are sexually inactive. (Oppong, 1992, p. 79).

3. Divorce and Remarriage

In the industrialized countries, the secularization of marriage, rising life expectancy, the reduction in the number of children desired, and the changing aspirations of men and women have combined to make divorce one of the possible and now accepted exits from marriage (Roussel, 1989). Legislation has gradually been aligned with social practice by making divorce more consensual and less disruptive for the ex-spouses.

Let us take the case of France. The divorce rate has risen from only 12% in the 1955 marriage cohort to 24% in the 1968 to 1970 cohorts, and will very probably reach 30% in the 1980–82 cohorts. The frequency of divorce has thus already doubled. From 1968 to 1980, with the swift spread of cohabitation, the frequency of divorce continued to rise, but at a slower pace. In fact, we are dealing here with two aspects of the same phenomenon: the decline in *marriage as institution*: "People are ever less convinced of the need for marriage (hence the fall in nuptiality) or of the need to preserve it when difficulties arise (hence the frequency of divorce)" (Leridon and Gokalp, 1994).

To different degrees and at different speeds, the phenomenon is affecting all European countries (Table 28–8). Italy seems to endure as a bastion of indissoluble marriage, but divorce was not legalized there until 1971. Likewise, Greece and Poland still report modest divorce rates. But in all the other countries of Europe and North America for which data are available, the period indicators show that, on present trends, between one-third and one-half of marriages will end in divorce. The highest proportion is found in the United States (55% in 1985).

Today, couples can form and break up several times in a life cycle. An increasing number of adults will experiment with multiple conjugal careers. Divorces and terminations of informal unions put candidates to marriage back in the running. This makes the marriage market—and, more generally, the partner-relationship market—more fluid in countries where the only conceivable form of couple is monogamous. A greater frequency of divorce increases the number of candidates to a union (official or not) at any given time, especially as fertility is no longer the cornerstone of marriage.

TABLE 28–8 Total Divorce Rate (Divorces per 100 Marriages)

Countries	1970	1980	1990
Austria	18.2	26.2	32.8
Belgium	9.6	20.8	31.0
Denmark	25.1	39.3	42.8
France	12.0	22.2	32.1
Norway	13.4	25.1	42.9
Netherlands	11.0	25.7	28.1
England-Wales	16.2	39.3	42.5
Sweden	23.4	42.2	44.1
Greece	5.0	10.0	12.0
Italy	5.0	3.2	8.0
Bulgaria	14.8	18.5	17.0
Poland	14.6	13.6	15.0
Canada	18.6	32.8	38.3
United States[a]	42.3	58.9	54.8

[a] For United States, last column shows 1985 data.

Source: Monnier Alain and Guilbert-Lantoine Catherine de, 1994. La conjoncture démographique: l'Europe et les pays développés d'outre-mer, *Population*, vol. 49(4–5), p. 1107–1128.

Divorce allows remarriage and therefore a conjugal mobility that some have described as *serial polygamy*. However, these successive monogamies have virtually nothing in common with African-style polygynous unions. The nature of relationships between partners, the impact on the fertility of couples, and the effects on the *marriage market* are radically different.

In the developing countries, many marriages are customary and not recorded by a civil or religious authority. Divorces, *a fortiori*, are even less often decided in court and recorded, so the scale of the phenomenon is harder to assess. In India, divorce seems practically nonexistent (Rao, 1993). In Africa, on the other hand, it is frequent but in the vast majority of cases it results in a *de facto* separation without judicial proceedings. In Togo, for example, by the age of 50, one woman in three has seen her first union terminated by a separation—quickly followed, in most cases, by remarriage (Locoh, 1985). In African societies where fertility remains the chief motive for couple formation, infertility is a major cause of divorce or remarriage for the husband. And after a separation, divorce or widowhood, women almost always remarry or are remarried, especially if they are still capable of bearing children. The practice of *levirate*—the remarriage of a widow with a brother or close relative of the deceased husband—illustrates this concern with fertility.

4. Widowhood

With the rise in life expectancy, the probability of a termination of the union through widowhood has decreased, leaving room for an increase in divorce. Widowhood obviously depends primarily on mortality but it is also determined by two factors of a more cultural nature: the difference in mortality between the sexes and the age gap between spouses. Where the age gap is wide, women are more likely to be widowed. In many societies, widowhood is an unenviable status. The extreme example is *suttee*, the cremation of a widow on her husband's funeral pyre, a practice now banned but formerly honored in India. In Africa, widowhood ceremonies are the occasion for rites involving violence toward the widows, who may also be remarried under levirate rules. While the practice is supposed to protect widows by placing them under the responsibility of their new husbands, in reality it only aggravates their dependency.

OVERVIEW AND CONCLUSION

The widening separation between marriage and maternity is a clearcut trend in most developed countries, although Southern Europe still exhibits fairly low rates of births outside marriage by comparison with Northern Europe. In North America, the proportion of out-of-wedlock births rose from about one in 10 in 1970 to one in four in 1990. In France, births outside marriage were six times as frequent in 1990 as in 1970 (Monnier and Guibert-Lantoine, 1994). Youth cohabitation is no longer a prelude to marriage; if a birth does take place it is usually desired and does not necessarily lead the partners to the mayor or priest. The *traditional* purpose of couple formation—that of begetting children and raising them together—has ceased to monopolize the conjugal universe in societies where falling mortality has made the task of reproduction less imperative. Behavioral norms are less constraining, and not all adults regard family and children as indispensable. Some claim the right to have children without necessarily forming a couple to raise them; others form couples without fertility plans. The satisfaction of partners can become the sole aim of couple formation. In the developing countries, by contrast, prenuptial births are increasing even though nuptiality remains intense and the proportion of never-marrieds is still very small (Antoine and Nanitélamio, 1991).

Couplehood and the Status of Men and Women

Couple formation plays a decisive role in determining the statuses of men and women. Age gaps, the origins of each partner, the involvement of their families and social groups, the values defining their couple (stability, precariousness, indissolubility), and the goals it embodies—all these factors reflect the status assigned by society to an individual as an adult member and potential parent; they can also influence that status, first within the couple, but also in society. These factors accordingly shape not only the partners' fertility decisions, but their entire family life and social life.

Under the influence of the human-rights ideal and feminist movements, modern legislation in the industrialized countries is increasingly aimed at ensuring equal rights and duties for men and women in marriage. The structure of the couple—formerly based on a hierarchic principle that subjected the wife to her husband's authority—has been rebuilt on a more egalitarian foundation. The implementation of sexual equality in marriage may take one of two forms: (1) recognizing for each partner, and more specifically for the woman, independence and freedom in the conduct of certain activities (choice of occupation, etc.); and (2) making both spouses jointly responsible and providing for the common exercise of their powers (joint liability for household debts, joint management of the family dwelling, and so on). In certain countries, estate law has gradually been adapted to the new concept of inter-spousal relationships.

This radical revision trend is producing different effects in countries that have recently introduced modern legislation. Much remains to be done in many countries as regards adapting the existing laws, but even more so as regards daily practice. All cultures, in varying degrees, rely on traditions of strong male dominance. The Cairo Conference on Population (1994) and the Beijing Conference on Women (1995) powerfully underscored the importance of striving toward equality between men and women and particularly toward the respect of women's rights in public life and private life.

The facets of marriage that societies seek to influence—age norms, partner-choice norms, and remarriage norms—govern couple formation in each period of the societies' history. Amid the maze of demographic, economic, and social determinants, what is the place of the individual, of his or her choices and inclinations? It is a subtle alchemy that succeeds in extracting the nectar of passion from so many combined determinants. And yet it exists: All societies have their tales of passionate love, their *Thousand and One Nights*, their *Romeo and Juliet*—which stand out precisely as an antidote to the constraints imposed by society, as an assertion of liberty, often for a fleeting but intense moment in the lives of individuals.

Marital and Nonmarital Fertility

SILVANA SALVINI AND ANTONIO SANTINI

Dipartimento di Statistiche, Università degli Studi di Firenze, Florence, Italy

At both the phenomenologic and methodologic levels, demography evolves in step with the behaviors of the populations it studies. When a particular phenomenon or some of the variant forms of a given process become an important factor in population change, they enter demography's field of study, not by virtue of their intrinsic characteristics, but because of the historic emergence of new behaviors. To corroborate this obvious fact, we need not even refer to the extreme situations described by Bourgeois-Pichat (1987), who contrasts the populations of the Paleolithic and those of the 21st century. Marriage and marital fertility are two emblematic examples.

Marriage is in no way a natural prerequisite for reproduction[1]; strictly speaking, a marital union, legally authorized or recognized, is not a demographic event. Nevertheless, from the outset, demography has been interested in the characteristics of marriage and has paid special attention to the distinction between procreation in marriage and outside marriage. The reasons for this are well known: Marriage—by nature a rite of passage, a legal contract, and an instrument of social organization—enters the field of demography because of the reproductive function assigned to it by nearly all societies. Since time immemorial, all the European cultures (or cultures of European origin) have been dominated by a *Malinowskian legitimacy principle*, whereby reproductive functions were entrusted by society only to married couples and denied to the never-married. Being vested with such functions, marriage plays a key role in fertility and thus becomes a fundamental demographic event for population dynamics. But if these functions change or cease in the course of social evolution—which is what has been happening in the Western world for a quarter century—the phenomenologic (and methodologic) framework defined in a previous age may become obsolete. The new behaviors designate new objects of study and require new methodologies.

We therefore cannot generalize the role of marriage and the effects of nuptiality—its *quantum* or *intensity*, the proportion of persons who marry, and its *tempo*, the age at which people marry—on fertility. We cannot analyze marital fertility without considering the historic context in which the populations studied live. Nor can we understand, out of context, how marriage can effectively become the focus of the observation and measurement of the reproductive process.

In historic terms, we must accordingly distinguish at least three different demographic regimes. Within each one, we need to examine the specific relationships between marriage and fertility and determine the most suitable approaches for analyzing them. The three regimes are (1) the *ancien regime*, (2) the phase long referred to as the *demographic transition* and today renamed *first demographic transition* in contrast to (3) the following phase, still in progress, which many already call the *second transition* (see also, on this topic, Chapters 37, 38, and 39).

[1] The debate on the demographic nature of the marriage event has been intense, especially in the late 1960s. This can be seen from the report on session 6.4 of the 1969 IUSSP Congress in London (Galan Vivas, 1969).

I. THE ANCIEN REGIME

We need not dwell at length here on a historic period that has been comprehensively examined by historic demographers and has made a powerful contribution to the analysis of population dynamics (Livi Bacci, 1989). Our discussion will be confined to the aspects directly connected to the topics of this chapter.

The demographic *ancien regime* was essentially characterized by high mortality and, in consequence, a high frequency of widowhood: In fact, (early) death played a comparable role with respect to marriage as divorce does today. However, even more important, it was a regime where fertility was not controlled and where illegitimate fertility was a demographically marginal phenomenon. Absent voluntary action to curb fertility according to the number of children already born (an absence that Louis Henry regards as the fundamental characteristic of *natural fertility*), the role of marriage is central. Marriage is not only the mandatory locus of reproduction, but a restraining factor with decisive direct effects on fertility. It is thus one of the determinants—along with mortality—of population dynamics: The larger the proportion of never-married women and the older the mean age at marriage of women, the lower the mean number of children per woman. In other words, the reproductive process is regulated by the proportions of never-marrieds, the frequency of remarriages, and age at marriage. As Dupâquier emphasizes (1972), marriage was the basic self-regulatory mechanism of traditional populations.

If there is no voluntary control of fertility, we can say that the reproductive events in a couple are independent of its will: What matters is the woman's *marital status*, her *age*, and her *age at marriage*. A reading of the reproductive process as the result of events willed by the couple is consequently of little use in analyzing and understanding the phenomenon. For an identical age at marriage and an identical mortality, the union duration is the same and the completed fertility tends to be the same: In marriage, the age-specific variations in fertility depend solely on biologic factors. Figure 29–1, reproduced from one of Henry's most famous historic studies (1958), is a well-known confirmation of this.

For the reasons just described, the sequence of births in the married couple is not the prime focus of the analysis of fertility of traditional populations. Also, marital fertility is generally difficult to measure and describe—even more so in successive marriages, unless we use simulations. Yet the historic information on marital-status–specific fertility is, curiously, more common and significant than the information on the

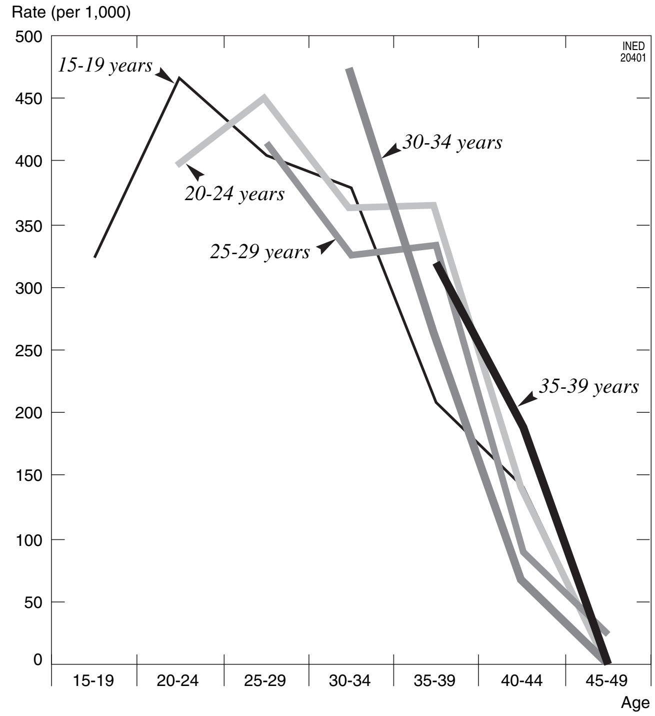

FIGURE 29–1 Legitimate fertility rates by age at marriage in a traditional population (Crulai, a parish in Normandy) (source: Louis Henry, 1958. *La population de Crulai paroisse normande*. Paris, INED and PUF, 270 p. Travaux et Documents series, *Cahier* no. 33).

population, even if it concerns very small demographic groups. This is strictly due to information availability: If the data on demographic characteristics and events are not systematically and periodically collected by official agencies, we will know very little indeed about a population's reproduction level and, in any event, the heuristic potential of official data is always constrained by their having been gathered for *nonscientific purposes*. Yet, thanks to the reconstitution of families (Henry, 1985) from the records of marriages, baptisms, and burials kept by the parishes—which are small communities—demographers have been able to document the reproductive history of couples with great precision. For *cohorts of marriages* celebrated in the same time interval (typically a decade or so), and distinguishing subcohorts by wife's age group at marriage, Henry (1972) has suggested using indicators of the following type:

$$f_x = \frac{\sum_y f_x^y \cdot \bar{F}_x^y}{\sum_y \bar{F}_x^y}$$

where

$$f_x^y = \frac{LB_x^y}{\bar{F}_x^y}$$

and where, for each age group at marriage ($y,y+a$), legitimate births (LB) are divided by the number of women-years ($\bar{F}$) effectively exposed to the maternity risk in the age group ($x,x+a$) (Del Panta, 1997).[2]

II. DEMOGRAPHIC TRANSITION

The change known as *demographic transition* in populations living in the area of European civilization was characterized by a sharp and fairly rapid fall in mortality, which became a general phenomenon by the mid 19th century. Its initial, direct effect was on fertility: By reducing widowhood, it promoted stable unions, made second marriages less frequent, and hence increased the duration of exposure to the fertility risk.

However, whereas marriage remained the cornerstone of family formation, birth control gradually spread across social strata and marital fertility decreased in the second half of the century—within the framework of the *European model* (Hajnal, 1965) and in step with its dissemination. In a cultural context where marriage remains the sole means of accessing reproduction, where fertility outside marriage remains socially stigmatized, and where the proportion of *illegitimate* births therefore persists at very low levels (with exceptions such as Portugal), marital status endures as a crucial factor in procreation. The spread of a Malthusian mentality and the concomitant rise of a new behavior in the population thus give the marriage-reproduction relationship a different content from that specific to the *ancien regime*. The study of the relationship therefore demands new analytic approaches.

The central link between completed fertility and age at marriage loses much of its significance. A growing number of couples want to form a family with one or two children—a goal that can be easily reached in the first years of marriage. This makes age at marriage secondary: Even the couples formed at a relatively old age will be able to satisfy their desire for children. Fairly soon after marriage, most couples behave, voluntarily, as if they were sterile. Figure 29–2 clearly shows this new reality.

[2] Even in the case of aggregate data (i.e., not obtained from a family reconstitution with personalized data), population fertility is measured more accurately by (1) exploiting the data on legitimate births through indicators derived from an adaptation to historic data of the method for analyzing legitimate fertility by year of marriage of the spouses, introduced in the 1930s by Corrado Gini (1932), or (2) establishing the ratio of this type of event to denominators that incorporate the change in marriage frequency over a given number of years prior to the period studied. However, as we can see, both of these are *period* (i.e., cross-sectional) measurement techniques.

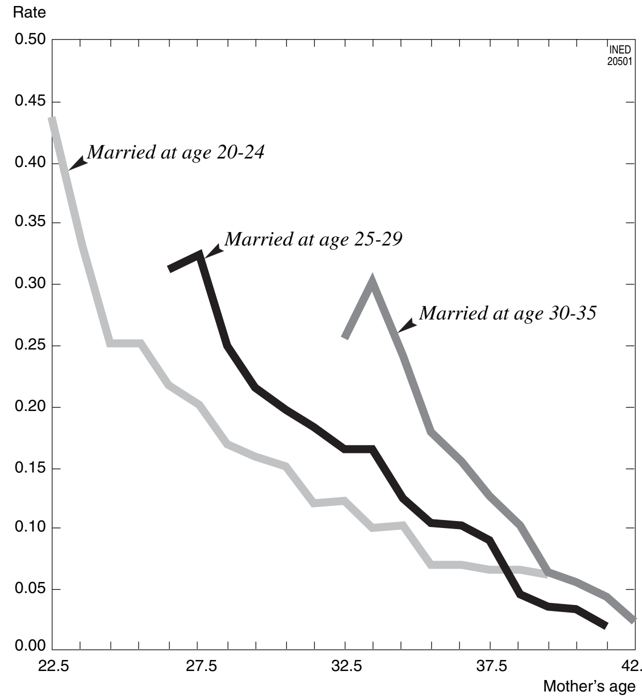

FIGURE 29–2 Age-group-specific legitimate fertility rates in a post-transition population (source: David V. Glass and Eugene Grebenik, 1954. *The trend and pattern of fertility in Great Britain, Part II*. London, HMSO, 692 p.).

In a controlled-fertility regime, reproduction is chiefly linked to marriage duration for all couples. Duration is merely the difference between the two effective determinants of legitimate fertility: age at marriage and the wife's current age. Duration has become a fundamental factor in behavior and obliges demographers (or gives them the opportunity) to replace the wife by the union itself as the reference unit for studying the reproductive process. In fact, one of the basic principles of demographic analysis is to link each demographic event experienced by an individual to the event that necessarily preceded it and determines its occurrence. The *origin-event* of a legitimate birth is marriage and, within marriage, time is effectively expressed by the duration elapsed since the event. As we saw, this measure of time was already implicitly present in traditional populations. However, in the new context shaped by the desire and ability of couples to control their fertility, it is destined to play a major role.

For each subcohort defined by the combination of year of couple formation and age of wife at marriage, we can assess the influence of marriage duration on fertility from three distinct angles. First, as the marriage duration increases, the proportion of couples who, with age, become physiologically sterile rises,

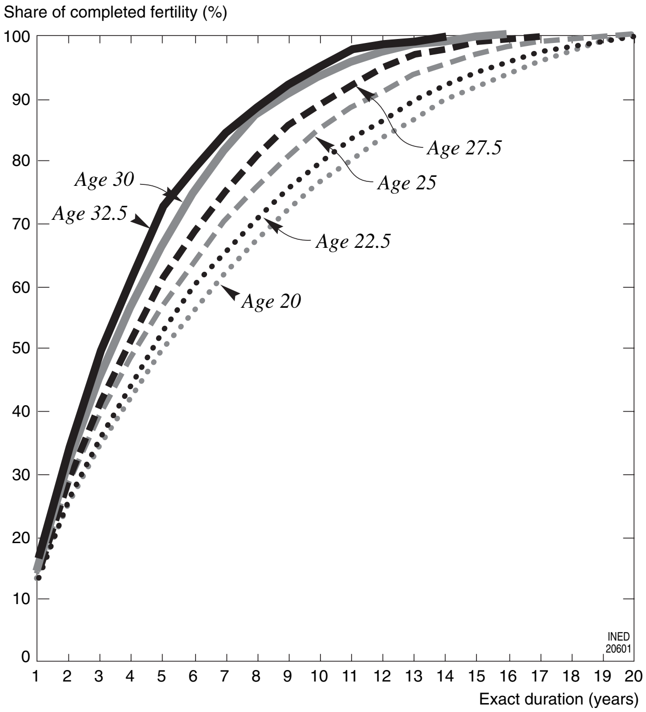

FIGURE 29–3 Family formation by age-group at marriage (source: G David V. Glass and Eugene Grebenik, 1954. *The trend and pattern of fertility in Great Britain,Part II*. London, HMSO, 692 p.).

because the wife's age increases with marriage duration. Second, and more important, marriage duration also determines the proportion of voluntarily infertile couples. Third, marriage duration, in itself, can also be a fertility-reducing factor if, over time, the couple tires of intercourse and thus reduces its frequency (Henry, 1953).

Henry (1953) argues that the marriage-duration factor, while operating with other factors, can be examined separately. This allows a relatively simple but, in fact, comprehensive analysis of fertility: The link between aging and marriage duration is a functional link that nothing can sever. The relationship between marriage duration and voluntary infertility is typical of post-transition populations where couples control their births; apparently, it prevails over the three effects describe (as shown in Figure 29–3).[3] We should bear in mind, however, that this relationship merely reflects the strict correlation between marriage duration and the number of children already born. In other words, in modern populations where couples curtail their fertility, an increase in marriage duration produces a rise in the proportion of couples who have reached their family-size goal and then remain voluntarily infertile or minimally fertile. Thus, in reality, these proportions increase not so much because of the marriage duration but because of the number of children already born. As the desired number is reached in each household, it is ultimately that number that becomes the main factor in procreative behavior.

Moreover, absent events that would force couples to interrupt their family formation or their partner relationship in a lasting manner, there is a close relationship between completed fertility and marriage duration, and it seems useless to explicitly introduce the number of children already born. In these conditions, the age-at-marriage/marriage-duration combination seems largely adequate to resolve a number of issues (Henry, 1953). However, the influence of the number of children already born on procreative behavior or, more specifically, on the definition of family strategies to reach the desired family size is sufficiently strong to require the explicit introduction of this factor into the analysis.[4]

III. FOUNDATIONS OF MARITAL-FERTILITY ANALYSIS

The spread and consolidation of birth control in Western societies has spawned a new methodology and stimulated a growing number of studies that describe the procreative process as a function of the woman's marital status and of her marital-event history.[5] However, the cohort approach to *legitimate fertility* (which would be more aptly described today as *marital fertility*)—based on the adoption of the marriage cohort as the unit of study—did not emerge and gain acceptance in demography until the 1950s. In that same period, national statistical institutes became increasingly involved in collecting demographic data extending beyond purely administrative needs,

[3] In fact, we can add a fourth: the time elapsed since the previous birth. This plays a role both for Malthusian couples wishing to space their births and for other couples because of the duration of pregnancy and postpartum amenorrhea.

[4] In this connection, it must be recalled that one of the most classic fertility measures in which birth order is taken into account—parity progression ratios, which measure the probability of an increase in family size—was introduced by Louis Henry and Norman Ryder in their study of marriage fertility, although it was later extended to that of overall fertility.

[5] Besides the studies published between the two World Wars in which demographers tried to take account of marital status to measure reproductivity (then a topical issue), we should also recall the studies by Jean Bourgeois-Pichat (see, for example, 1950) aimed at producing total fertility indicators based on marriage duration and age at marriage.

whereas theoretical inquiries led to the first attempts at cohort analysis[6]: One of the leading figures here was John Hajnal, who worked on the results of the large-scale fertility survey carried out with the 1946 British census (Hajnal, 1950); the two other protagonists were Louis Henry (1953) and Norman B. Ryder (1956), who, without coordinating their efforts, simultaneously set forth the principles of methods that have become well known and remain in widespread use.

As Henry explicitly argued, the analysis of marriage fertility is—for the reasons recalled earlier—the most suitable means for studying the reproductive behavior of populations that largely practice contraception but where a vast majority of births are *legitimate*. Although this is true, there are many practical difficulties involved in such an approach. The application of rigorous analytic techniques is chiefly dependent on—and often restricted by—the kind of information available. The resulting set of problems depends, in turn, on the type of observations available. In particular, they depend on whether the data are gathered by means of continuous observation (i.e., of the kind used to compile vital statistics) or by means of retrospective observation (i.e., of the sort used to compile most of the results from censuses, initially, and from *ad hoc* surveys subsequently).

What classical analysis is invariably asked to provide is a correct solution to the following basic problem: "Absent an intrusive event such as death, divorce or migration, what would be the mean number of children by marriage and how, in these same conditions, would the children's births be distributed by marriage duration?"

1. Continuous Observation

The general rule (Henry, 1972) according to which the description of a process should be tied to its origin-event implies that the reference cohort should be a couple cohort (i.e., the set of couples formed during a given period).[7] Within the cohort, the process will unfold as a function of marriage duration. Completed fertility is primarily determined by this duration. However, the ratio of fertility to marriage duration is far more rigid that the ratio of the wife's age to fertility. In consequence, the latter ratio cannot be overlooked, as it represents a heterogeneity factor for the structure of the observation unit. We can take it into account by creating subgroups (subcohorts) based on the wife's age at marriage. This requirement has obvious consequences on the event-classification criteria (for which we need to know three time variables simultaneously: year of marriage, marriage duration, and mother's age at marriage) and on the determination of person-years effectively lived in each duration interval by the cohort members. Birth classifications that meet these needs exist for a few European countries—France, for example, from 1946—at least for limited or recent periods of time.[8] In general, however, official statistics do not provide an update on current marriage duration after, for example, a divorce, separation, widowhood, or migration. For each marriage cohort formed in T with wives aged y, the measure of fertility at marriage duration x—called *legitimate-birth frequency*, is generally obtained from the ratio of events (LB) not to marriage-years ($\overline{M}^y_{T,x}$) of the interval of duration x, expressed by:

$$f^y_{T,x} = \frac{LB^y_{T,x}}{\overline{M}^y_{T,x}}$$

but to the initial number of marriages ($M^y_{T,0}$), whatever the duration examined:

$$f^y_{T,x} = \frac{LB^y_{T,x}}{M^y_{T,0}}$$

This has obvious consequences on the process quantum: Mean fertility—obtained, of course, by summing the rates—is routinely underestimated, unless the entrances of married persons exceed deaths and exits. There are also consequences, albeit less visible, on the tempo of marriage fertility, as measured by the mean index of the distribution of duration-specific rates. Naturally, beyond the approximations due to the denominator of duration-specific rates, the overall quantum and tempo indices will not express the marriage cohort's propensities unless the behaviors of arriving or departing couples are identical to those of the initial population.

[6] Actually, the first studies on marriage fertility date from the early 1930s, when some national statistical institutes, such as Italy's (Gini, 1932), began compiling and publishing statistics on legitimate births by parents year of marriage (or by marriage duration). These were, however, period analyses rather than cohort analyses.

[7] According to Ryder, studying fertility in marriage cohorts is also a way to skirt the issue of the difference between male and female fertility functions. By choosing marriage as the origin-event, since the duration is the same for both partners, we arrive at a reconciliation within one marriage cohort of two fertilities—male and female—with very different quantum and tempo characteristics.

[8] Very often, legitimate births are classified according to a single time criterion, such as year of marriage or marriage duration. Sometimes, a second criterion is used: the mother's age at marriage. In these cases, current statistics do not allow the computation of rates assignable to specific cohorts or covering correct durations (Santini, 1974; Calot, 1984; Prioux, 1991).

2. Retrospective Observations

As a rule, the analyses that rely on data gathered in retrospective surveys or from responses to census-schedule questions on reproductive history do not allow a reconstitution of marriage cohorts. However, to study female fertility, we usually have the wives' dates of birth and marriage, as well as the dates of birth of their children—or, at least, of their live-born children. We can thus construct female cohorts by year of birth and year of marriage, classify them by age at marriage, and locate the births of children on this double time scale.

Even with this type of observation, demographers studying legitimate fertility more commonly use marriage-duration–specific rates than age-specific rates, at least for contemporary populations. Hence the terminologic analogy: The term *marriage fertility*—obviously more suitable to continuous observation—still prevails in retrospective observation.

In principle we should subdivide the cohorts of married women by age at marriage and calculate separate marriage-duration–specific rates of legitimate fertility for married women in the successive 5-year age groups. Since the units examined are those still living and present at the survey or census date, consistently with the formulation given by Wunsch in Chapter 12, the rates (or *legitimate-birth frequencies*) should take the form:

$$f_{x,x+a}^{y,y+a} = \frac{LB_{x,x+a}^{y,y+a}}{Fm_u^y} \quad \text{or} \quad f_u^{y,y+a} = \sum_{x=0}^{u-a} \frac{LB_{x,x+a}^{y,y+a}}{Fm_u^y}$$

where, as before, y is the age at marriage, x the marriage duration to date of birth, u the marriage duration at the survey date, and *Fm* the number of married women.

The mean number sought for is the sum of births in marriage at each duration, in the absence of death, divorce, and migration, again subject to compliance with the *independence* hypothesis (and, implicitly, the *continuity* hypothesis). Since all the unions survive at time of survey, the age-at-marriage distribution stays the same: At any given moment, it is identical to the one observed at the time of the survey and—in keeping with the basic hypotheses—to the distribution prevailing at the time of cohort formation.

In determining the marriage-fertility quantum, we cannot disregard the composition of subcohorts by age at marriage. Unions with older wives are more rapidly terminated by death. After, say, 10 years, they are proportionally less numerous than the others, barring fortuitous compensations through divorce or migration; however, these unions are also the least fertile, so that the fertility of unions surviving after 10 years is higher than the fertility of all unions in the cohort, absent mortality.

To calculate the overall fertility, we therefore need to know the marriage-duration–specific fertility rates for different ages or age groups at marriage and combine them as they would be if the proportions of ages at marriage had remained unchanged. The error committed by performing a lump-sum computation—without distinguishing between the subcohorts of ages at marriage—is tolerable. But if we start excluding the marriages in which the wife is over 50 years, if the mortality at reproductive ages is fairly low and if the breaks in married life due to separation and migration are rare, then the study of the influence of the age at marriage on fertility is sufficiently relevant to make it worth renouncing, in practice, a purely methodologic simplification.

IV. POSTTRANSITION SOCIETIES

Since the late 1960s, the Western world has experienced major changes in collective behavior, concerning not only reproduction (end of the baby boom and lasting fall in total fertility rate well below the level needed for cohort replacement; van de Kaa, 1994) but the entire system of family formation and development. Of all these changes in the past 30 years, none has captured the attention of demographers and alarmed officials more than the drastic slump in fertility. This is not only because of the incredibly low levels reached, but also because of the differences in the pace of the trend across Europe. In particular, the Mediterranean countries, which initially lagged, have seen a violent plunge in their fertility after 1975—to well below the rates in central and northern Europe. But the transformations in marriage systems are no less important and decisive for the process we are seeking to estimate here; more generally, the crucial factors are the demographic behaviors governing the formation and stability of partner relationships and, consequently, family formation.

The changes have been sufficiently important to be taken as evidence, by some specialists, of a *second demographic transition* (van de Kaa, 1994). This new evolutionary phase, they claim, signals a radical break with the previous regime, even if, in some national contexts, the succession of birth cohorts does not display a genuine discontinuity (Santini, 1995). From 1970 to 1985, nuptiality has declined substantially. According to projections for relatively recent cohorts (born in 1960 and after), the proportion never married may reach nearly 50% in some countries, particularly of northern Europe (Roussel, 1987). Overall, the

Western world is heading toward a situation where one third of each cohort may remain outside marriage, at least in legal terms.

These fewer and later marriages are also more fragile. Around the 1960s, divorces occasionally peaked at 10% of marriages. More recently (2001), the period indicators have very often reached values near 40%; in northern Europe (Austria, Belgium, Finland, The Netherlands, England and Wales, Sweden, Denmark), that level has been far exceeded. In central–northern Europe, the ultimate proportion of divorced couples in the cohorts of marriages celebrated in recent decades will probably not be under 30%[9]—although that will in no way imply a recovery via second marriages. Moreover, although the phenomenon is hard to quantify, it is certain that a growing number of marriages are effectively terminated even if the break is not legally recognized: in other words, the evidence suggests more *de facto* separations than official divorces.

However, the difference with what we have called the *first transition* is even greater. The trend in *de jure* unions has been matched by profound changes in *de facto* unions. The decline in *legitimate nuptiality* has been broadly offset by the increase in consensual unions. This phenomenon is most visible among the under-30s. It has taken on considerable importance in some areas such as Scandinavia—most notably Sweden and Denmark, where, before anywhere else in Europe, nearly all marriages have been preceded by a fairly long cohabitation. But the model has spread widely across western Europe, except in the southern countries. There, couple formation is still mostly governed by traditional rules, although it will likely follow the path taken by the rest of the continent—with some local adjustments. In several countries, including France and Switzerland, half the cohorts of married people have cohabited before marriage.

Not all cohabitations, however, can be described as prenuptial union. Among young people and divorcees, there has been a gradual increase in unions that do not seem aimed at marriage. We are dealing no longer with *engagement* periods or trial marriages, but with true *marriages without certificates*. These unions—like some prenuptial cohabitations, in fact—no longer exclude the birth of children. As a result, fertility outside marriage has grown at an unprecedented pace since the 1980s. Once upon a time, fewer than 10% of births were *illegitimate*; the percentage was often much smaller, as in Italy and Spain. Today, the proportion now easily reaches or exceeds 20%—as in, for example, France, England and Wales, and the United States.[10] In Scandinavia, it ranges as high as 50%. Since the mid 1980s, many of these characteristics have consolidated and we are witnessing new changes, such as the upturn in fertility above age 30 and, in some countries, a halt in the decline in fertility among the young, either because the levels reached are extremely low, or because of a rise in teenage fertility. In certain countries, the upswing in fertility rates among the over-30s has led to a mild increase in total period fertility.

True, this summary may give an oversimplified image of a complex evolution, which is highly diversified in space and time, and extraordinarily important. As with the first demographic transition, some heterogeneity factors are emerging that may outweigh the common aspects, as different populations are following different paths. However, there are some basic shared characteristics. The first fertility transition was matched by a rise in individual autonomy, which has led to the rejection of religious bans on contraception; but the manifestation of this disagreement has remained totally private and the first transition was, as a result, very silent. By contrast, the second transition is driven by a far more vocal demand for even greater individual autonomy—in radical opposition to all forms of external institutional authority (Lesthaeghe, 1992; Lesthaeghe and Moors, 1991; Simons, 1994). Such is the context in which the form of unions is changing: fewer and fewer marriages, more and more consensual unions, a near-rejection of any official link that could institutionalize a sentimental attachment. The generalization of these new family structures is still confined to specific countries and large urban areas, and to the demographically most modern social strata (De Sandre *et al*., 1999). Apart from the recent plunge in their fertility, the Mediterranean countries, for example (particularly Italy and Spain), have not (yet) experienced a full-scale inversion of the trends in the complex phenomena that shape family formation (Lesthaeghe, 1992; Santini, 1995; De Sandre *et al*., 1997).

V. NEW FAMILY STRUCTURES AND THE MEASUREMENT OF FERTILITY: THE PROBLEM OF HETEROGENEITY

These changes in demographic behavior have revolutionized the analysis of marriage fertility. A few

[9] Nor should we overlook the fact that the tempo has changed: Today, couples divorce much sooner after marriage than in the past.

[10] In 1994, half of all pregnancies in the United States took place outside marriage. Half of these out-of-wedlock pregnancies ended in birth (54%) (Darroch *et al*., 1999). In 2001, the proportion in France, Norway, Denmark and Sweden exceeded 40% of all births (UNECE, see the Web site www.unece.org/stat/scriptsdb/variables.asp).

features need to be highlighted in order to properly understand the obstacles presented by the new demographic regime to measuring the phenomenon, whether from continuous observations or, for different and more complex reasons, from retrospective information.

First, we must stress that the disinstitutionalization of marriage has led to a proliferation of *de facto* situations at the expense of *de jure* situations; this applies both to the formation of couples living maritally and to the stability of unions, legitimate or not.

Second, despite variations in time and space in the dissemination of the new cultural and moral principles (variations already mentioned repeatedly), it seems hard to argue that the Western world still enforces the legitimacy principle (in the Malinowskian sense referred to at the start of the chapter) whereby the social right to have children is confined to marriage. Legal marriage is no longer, in practice, the exclusive locus of reproduction.[11] The measurement of marital fertility therefore loses its significance—not only in the countries where the proportion of births outside marriage is already very high, but also in more traditional societies where, in any event, the social stigma of illegitimate fertility has been drastically attenuated, if not totally dispelled.

Third, if the demographic reference unit for the reproductive process is no longer legal marriage alone, but encompasses all forms of heterosexual union, we must reckon with the fact that each of these unions seldom constitutes a reproductive history in its own right any longer; ever more often, it is merely one of several partnership sequences in an individual's fertility history.

The consequences are immediate and very clear for the analysis of continuous-observation data. These are extracted from declarations made to administrative agencies empowered to keep track of a *legal obligation* for individuals to report acts formally recognized by prevailing law. We cannot, therefore, use such data as the basis for defining a cohort of unions or monitoring it over time. Let us assume we wanted to restrict our attention to a conventional marriage cohort—despite the high probability of selecting different fertility behaviors among individuals who choose to marry versus all couples in the aggregate. We would still need to measure the fertility rate on the basis of the cohort's initial size in the denominator at each duration, despite the obstacles that are augmented and aggravated by the growing fragility of marriages—in *de jure* and *de facto* terms.

[11] This, of course, would also imply a reappraisal of the demographic role of nuptiality.

Because *de facto* unions can be determined only by questioning the couples directly, the reconstitution of the reproductive path—now linked to the woman's partnerships rather than to the woman alone—calls for survey-based observation. The spread of the new couple-formation patterns has given rise, since the late 1970s, to large-scale retrospective surveys. These are the only data sources enabling demographers to compile information on unions not regulated by legislative provisions and on *reconstituted* families or stepfamilies (Villeneuve-Gokalp, 1990). However, even in a retrospective observation framework, there is no shortage of problems involved in measuring a phenomenon as complex as the fertility of these undocumented unions.

The alternative cohabitation forms can be described according to the event that follows entry into union—marriage, birth, separation—and the union duration up to the event (Villeneuve-Gokalp, 1990). First, cohabitation can be regarded as a transitional arrangement that precedes but does not replace marriage. In this case, children will not be born until after the union is legalized. If the union is short-lived, it will be merely a prelude to marriage; if it has lasted longer, it may constitute a trial marriage. Alternatively, cohabitation may begin without any plan to continue it in marriage and without any commitment. It may end swiftly in separation, in which case it is only an ephemeral situation. But, equally well, it may endure long enough to form a lasting (stable) union, even without a special event such as marriage or birth (Munoz-Perez and Prioux, 1999a, 1999b). Last, the partnership may take the form of what is generally known as a consensual union (in French, *union libre*): A lasting cohabitation in which the partners live as husband and wife. Not only is their union stable but it acts as a locus for motherhood and fatherhood, without the legal ties of marriage. This is a new type of family, an additional kind of marital-event history.

However, the classification gets complicated when we consider the possibilities of entering into successive unions, legal or not, with different partners. The propensity to have children then becomes a composite function of the entry into first union, the precariousness or stability of the cohabitation (does it turn into marriage or not?), its duration, the propensity to form a new union after a separation, and so on.

In sum, these new family structures require—before any fertility measurement—an analysis of the heterogeneity of subgroups resulting from union terminations, the variety of union forms (marriage, cohabitation, etc.), and sequences of successive unions.

We are now measuring family formation not in a single marriage, but in a succession of partnerships with different legal statuses. Accordingly, what issues do we need to address in the retrospective survey to achieve a satisfactory measure?

For the sake of rigor and completeness, the analysis must obviously concern a cohort of individuals who have already formed a union at least once and have thus been able to express their fertility. The variability factors—the source of the group's heterogeneity—are numerous. In measuring the fertility of a consensual union, we must therefore simultaneously take into account exits due to termination of the union by marriage or by death, migration, and so forth. This requires a highly detailed classification into subgroups. For example, we will need to calculate fertility rates for specific union durations and marriage durations (as the case may be)—allowing for union terminations and competing events—by duration until the event; alternatively, we must use methods based on a dynamic analysis of individual data similar to the *life cycle* approach. We will briefly discuss event-history analysis in the subsequent sections. To simplify the presentation of measurements based on aggregate data, we can describe several typical situations, each reflecting a single aspect of an increasingly complex reality (Festy and Prioux, 1989).

1. Fertility in the Event of a Marriage Termination

For simplicity's sake, let us consider the measurement of marital fertility with frequent divorces. As seen earlier, continuous observation gives us virtually no data on marriages surviving at different durations. When we compute legitimate-birth frequencies, the denominator therefore consists of the initial number of marriages, which—if divorces and separations are deemed negligible—offer a correct proxy for the fertility quantum. The rising instability of marriages, however, makes this estimation somewhat irrelevant, obliging us to turn to survey data. Thanks to the retrospective data on ever-marrieds, we can make allowance, within a marriage cohort, for the duration elapsed since the marriage by aggregating the surviving marriages and unions terminated by divorce or separation. In such conditions, given the high propensity to separation and divorce, should we calculate the marriage-duration–specific rate by (a) setting the denominator to the decreasing numbers due to the exit of some couples from the cohort of ever-marrieds surviving at the time of the survey (regarded as the initial population) or (b) using a constant number of married persons, in keeping with the standard method described in Post-transition Societies, disregarding marriage terminations occurring since the start of the process?

Approach A assumes the truth of the independence hypothesis (and, of course, that of the continuity hypothesis). This holds that terminated couples—who have left the observation field—would have behaved, had they stayed together, in the same way as the couples still together: the implication is that fertility is not selective with respect to exits from the cohort. Approach B requires the additional hypothesis that marital fertility does not differ according to whether the couples break up before the potential end of the process or—on the contrary—stay together until the end of the reproductive period. The first hypothesis, of course, is totally unverifiable. But, if the survey data are sufficiently detailed, we can observe possible differences in behavior.

The importance of these issues is naturally increasing with the rise in divorces, which entails an ever greater number of premature marriage terminations. Special care should be taken to classify the respondents who, in the survey, have described themselves as separated or divorced by year of marriage and by marriage duration at the union-termination date. For each marriage cohort, we will thus construct subcohorts by duration at the time of separation and calculate (retrospectively) marriage-duration–specific fertility rates. By comparing the duration-specific rates for the two subgroups, we will be able to see whether a difference exists between stable marriages and interrupted marriages: this hypothesis turns out to be plausible, for example, for French cohorts in the 1960 to 1969 period (Festy and Prioux, 1989).

2. Marital Fertility versus Consensual-Union Fertility

Earlier, we stressed the growing numeric and social importance of cohabitation. Our main purpose was to remind the reader that in measuring total fertility we need to abandon the classical distinction between *legitimate* or marital fertility and *illegitimate* or nonmarital fertility when the spread of alternative forms of unions ceases to be negligible. We could, however, restore some meaning to the concept of illegitimate fertility (with no moral connotation, of course, but only as a label denoting an exceptional situation) by confining it to births occurring in these unions, which we previously described as *ephemeral* in contrast to stable unions. The term *illegitimate* would therefore be restricted to specific population groups such as teenagers (incidentally, we will see in the following paragraphs that the fertility of very young girls poses other measurement problems). By contrast, under these definitions, births occurring in stable unions where partners live as if they were married are in no way illegitimate and could usefully serve to compute *union fertility* as distinct from *marriage fertility*.

At this stage, the correct measurement of fertility in and outside legal marriage raises two types of questions: For a given union duration, does the propensity to have a child differ according to the type of union and des the transition between the two statuses entail a change in reproductive behavior? Both questions are relevant to the issue of measuring the fertility quantum of unions, taking into consideration the fact that some informal unions turn into legal ones. Would cohabiting couples who decide to marry have behaved, for the same duration, in the same manner as couples who do not? One could, in a sense, regard marriage as an additional intrusive event, but it would certainly be wrong to apply the independence hypothesis to marriage, because—by definition—*de facto* union and marriage are competing and dependent events (Thierry, 1993). Conversely, we may well ask whether a synthetic indicator of the marital fertility quantum is still correct when the group of marriages to which it applies is determined, at least in part, by the legalization of prenuptial cohabitations. Here as well, we are dealing with a heterogeneous group of marriages, and our analysis must rely on the classification of subgroups by union duration at the time of legalization. Fertility should therefore be measured for different subgroups, with a distinction between the period before the celebration of marriage and the period after; the measurement should thus be based on the rates by union duration at the legalization date and by marriage duration. This will enable us to determine whether the marriage event produces a behavioral discontinuity.

The French survey of female cohorts born between 1917 and 1964 yields two further observations: (a) There seem to be no differences in legalized-union fertility by union duration at the legitimation date but (b) the fertility of nonlegitimated unions is distinctly lower.

The study on French consensual unions that have turned into marriages after 5 years shows (on a common time axis) a bimodal tempo, with a first peak at the start of cohabitation and a second after legalization. We can thus conclude that fertility is not the consequence of union formation but—on the contrary—a cause; likewise, some of the legalizations are prompted by a pregnancy. The distinction between consensual union and marriage loses its relevance as regards the propensity for childbearing, and we can study duration-specific union fertility ignoring marital status: The quantum index obtained (by summing consensualunion periods and marriage periods) plays the same role as the overall fertility rate with respect to the legitimate-fertility and illegitimate-fertility rates.

However, we should continue to give separate treatment to the group of unions that do not turn into marriage. For this category, the behavioral heterogeneity reflected in the diversity of union forms is in itself a heterogeneity factor in the propensity for childbearing.

3. Fertility of Successive Unions

The increasing instability of marriage and the high probability of consensual-union termination have produced a growing number of stepfamilies or *reconstituted families* (i.e., unions above order one, whose origin-event is the end of a previous union). As a rule, later unions have a lower fertility than first unions because the new couples have already had children from the earlier union.

One way to simplify measurement problems would be to regard the total duration in union (regardless of union order) as a time axis on which to compute the fertility rate. This would be tantamount to assuming a continuum between the end of the previous union and the start of the following one, as if the partners in the new couple tended to complete the family formation begun in the preceding union. Obviously, this hypothesis obliges us to ignore the periods of nonunion (i.e., of nonexposure to risk).

We have already emphasized, in our discussion of retrospective surveys, that there is no basic difference in reproductive behavior, for an identical union duration, between the subgroups of couples who are still together at the end of the process and those who separate instead. Once again, however, we need to check the heterogeneity of the subgroups by union duration at the termination of the first union: For a given total union duration, there must be no significant differences in behavior between these subgroups, or between them and the unions that have never broken up. Absent such differences, the new couple's fertility would take up—so to speak—where the fertility of the previous union had left off. We could thus measure fertility by complete duration of successive unions as if they formed a single union. But, if we rely once again on the retrospective analysis of the fertility of French cohorts, the facts do not seem to fit that assumption (Festy and Prioux, 1989). When we compare the duration-specific rate for stable couples and the rate for separated couples, and then reformat the rate for the hypothetical durations of the unions if they had not been terminated, we find a sharp discontinuity: the new unions are far more fertile than the first ones. In sum, to obtain a measurement of the phenomenon that can be correctly interpreted, it is better to control for the heterogeneity by keeping the two subgroups apart in the analysis.

VI. EVENT-HISTORY ANALYSIS AND FERTILITY IN MULTIPLE UNIONS

The analysis of aggregated survey data leads us to examine special groups of unions but, as we have been able to observe, this forces us to make simplifying hypotheses. In the reconstruction of a cohort's typical event history through a retrospective survey, the interviewees are the set of *present and surviving* members of the original cohort. The population thus remains constant throughout the observation; it never deviates, numerically, from the initial population due to losses caused by negative events or gains caused by positive events. The hypothesis of *independence* between competing risks of events that do not alter the population size guarantees the relevance of quantum measurements. The respondents, however, must not constitute a biased sample of the initial set. In other words, the persons who have left the cohort before the survey must have the same propensity to experience the event studied as the *present and surviving* respondents. To ensure that the indicators calculated on data obtained from retrospective observations correspond to the raw figures, as in the continuous-observation method, the independence between the competing phenomena and the event studied must be documented before the occurrence of the event itself and must persist after it (Thierry, 1993; Salvini and Santini, 1999). The problem becomes complicated if the event studied, which changes the status of cohort members, is in competition not only with the intrusive events but also with other events leading to the same status change (Thierry, 1993). When we want to keep the different outcomes separate, the independence hypothesis is rarely tenable. A preferable alternative is to replace it—where the phenomenon studied allows—by a *complementarity* hypothesis. This holds that the events examined, rather than *interfering* with one another, flow from a prior decision. That is precisely the case with cohabitation and marriage: The complementarity hypothesis assumes that

> Each individual made a final and deliberate choice between the two forms of union and thus joined one of two distinct groups: those who have opted for cohabitation or those who have preferred marriage (Festy, 1986; p. 343).

To measure the fertility of these different forms of union, it therefore becomes essential to divide the cohorts into subgroups. We can thus check for heterogeneity according to distinct duration criteria for each type of union. This can quickly lead to an over-fragmentation of the cohort studied, without necessarily ensuring the explicit inclusion of all the heterogeneity components.

The availability of individual biographical data thanks to retrospective observation and the techniques of *event-history analysis* allow a treatment of initial or acquired heterogeneity (Salvini and Santini, 1999). In other words, individual fertility paths can be analyzed in parallel with marital event histories in order to measure the conditional risks of each status. The assessment of the risk of experiencing a given event rests on an examination of dependencies between events. For simplicity's sake, let us confine the discussion to two processes (union and fertility). The dependencies will be measured via the observed effect on the distribution of the first event when the second occurs and, subsequently, the changes in the distribution of the second event when the first occurs.

Using risk functions, we can compute summary quantum and tempo indicators with no need to assume independence and continuity between phenomena (Courgeau and Lelièvre, 1994 and 1996; Festy, 1994; Blayo, 1995). To measure the quantum of the phenomenon, event-history analysis relies on the computation of *cumulative risks* (i.e., the sum, over time, of the instantaneous risks of experiencing the different events in interaction). Unlike survival functions, this indicator allows us to regard the processes as independent even when the risks are dependent (Andersen *et al*., 1992; Courgeau and Lelièvre, 1996).

VII. FERTILITY OUTSIDE MARRIAGE AND ADOLESCENT FEMALE FERTILITY

It is generally admitted that births outside marriage have long been a minor phenomenon in population dynamics and for the understanding of the reproductive process.

Let us go back to the *ancien regime* societies described earlier. We can distinguish three long periods in the evolution of fertility outside marriage (or illegitimate fertility, even though the two concepts should not be strictly equated without a rigorous definition or cultural precautions[12]: Laslett *et al*., 1980). As

[12] The historic literature on illegitimacy is considerable, but the tone of the studies on the subject generally depends on the prevailing behavioral ethics. Before laicization—in the 18th, 19th, and early 20th centuries—the frequency of illegitimate births was actually regarded as a symbol of the moral condition of society: the increase in births outside marriage, as a sign of decadent morals; its reduction, as a sign of victory over moral decline by authorities and the clergy (Shorter *et al*., 1980). A more objective vision was introduced with the birth of the social sciences: Kingsley Davis (1939a and 1939b) authored the works that, in a sense, inaugurated the specifically sociologic era of illegitimacy studies. The adoption of ethical impartiality or neutrality toward the illegitimate child status sig-

far back as the data available on this issue go (i.e., from the 16th century to the first half of the 18th century), illegitimate births represented a tiny minority of total births, from 1% to 4% at most. It is in the second half of the 18th century that we find a gradual increase in the phenomenon, across most of Europe, up to a peak in the 1850s to 1880s. The following period saw a sharp down swing: By the eve of World War II, illegitimate births in most European countries had returned to very low levels, well below the 19th century values (Shorter *et al*., 1971).

In the 1950s, however, the number started trending up again, but the phenomenon did not become significant until the 1980s. This period witnessed the gradual increase in the number of nonlegalized unions among the young and divorcees. In their aims and their stability, such unions assumed the characteristics of full-fledged *marriages without certificate*. The fact that these unions do not exclude the birth of children accounts for the sharp rise in fertility outside marriage. Before this radical shift in family structures in European societies, fewer than 10% of births were *illegitimate*.[13]

Today, births outside marriage have risen to and even exceed 30% in a number of places including France, England and Wales, and the United States; in Scandinavia, they account for nearly half of total births. In Italy, the proportion is far lower, albeit constantly expanding: Births outside marriage, which represented under 7% of the total until the 1990s, rose to 9.7% by 2001 (Council of Europe, 2002). In sum, fertility outside marriage has become, in some cases, the rule rather than the exception, making *illegitimacy* a totally improper designation for these children living in families whose characteristics are comparable to those based on a legal marriage. Indeed, even in the past, other historic vicissitudes of the social, legal, or political environment make it necessary to provide a precise description of the context and an adequate definition, more relevant to the period and the culture—under pain of producing meaningless results (Laslett *et al*., 1980).

We have already discussed the problems of documenting and measuring fertility created by these new forms of union, but we thought it would be useful to elaborate here on the very specific issue of teenage pregnancies. These generally occur outside of a stable union and often cause trauma. Not until the 1960s to 1970s did teenagers become interested in fertility outside marriage—a phenomenon that, in some groups, is threatening to become a social ill.

From this standpoint, the reproductive behavior of female adolescents is of special interest. There has been much research on the social effects of teenage fertility, and the political sensitivity to the issue has prompted *ad hoc* surveys, since motherhood before age 19 is seen—in demographically advanced societies—as a behavior liable to disturb teenage girls maturing process, their future occupational performances, and, ultimately, their well-being and quality of life (Montgomery and Casterline, 1996).

This growing interest is closely linked to the fact that, in recent years, the phenomenon has been dramatically amplified in many countries (Foster and Hoffman, 1996; Hollander, 1996). According to the latest United Nations data, the fertility rate at age 15 to 19 varies from a low of 3.7% in Japan (but we also find fairly low values in Mediterranean Europe) to a peak of 59.2% in the United States (Singh and Darroch, 1999; Darroch *et al*., 1999).[14] The other Anglo-Saxon countries display rates ranging from 28.6% in the United Kingdom to 33.6% in New Zealand.

In the Western world, the problem is rather new. Before the recent changes in the *second demographic transition*, only a few Western countries had high teenage fertility rates linked to high levels of illegitimate fertility. As we have seen, during this process, the concept of illegitimacy seems to have lost its meaning and substance because of the rising number of births outside marriage, occurring in stable unions. Illegitimacy is therefore concentrated in the youngest age groups, and often has a disruptive effect on personal and family relationships. This gives a greater relevance to the study of illegitimacy, including its measurement.

Like the rates at other fertile ages, the data cited above are computed in terms of birth frequency (Darroch *et al*., 1999) or by dividing the number of births to girls aged 15 to 19 years by the number of

naled a break with the past—although reproduction outside marriage long continued to be treated as a deviant behavior (Shorter *et al*., 1980). The evolution of public morality on this issue reflects changing attitudes toward marriage: the change in the frequency of illegitimate births seems to reveal the erosion of marriage and other family institutions.

[13] Except in the entirely atypical case of Portugal, where, for different reasons, the proportion has been much higher in the past: From 12% in 1928, it rose to 17% in 1937, before declining steadily since (Livi Bacci, 1971).

[14] In 1992, 112 pregnancies per 1000 girls aged 15–19 years were observed; 61% ended in birth, 36% in intentional abortion. The fertility rate of this age group rose by nearly 12 points between 1987 and 1991 (Henshaw, 1997). The teenage birth rate dropped 5% in 2002, to 43.0 births per 1000 females aged 15–19 years, another historic low. This rate has fallen 30% since 1991 (61.8). Rates declined for teenagers of all ages; the rate for the youngest teenagers, aged 10–14 years, declined to 0.7 per 1000, exactly half the rate reported for 1994 (http://www.cdc.gov/nchs/data/nvsr/nvsr52/nvsr52_10.pdf).

young women in that age group. We disregard the conceptual and methodologic problems specific to the measurement of teenage fertility—problems that, once again, are chiefly due to the heterogeneity of situations. From a biologic (sexual maturity) and behavioral (sexual intercourse) standpoint, teenage girls form an extremely diverse aggregate. The process of change and the high variability within the group raise technical issues that are not simple to resolve. This provides an at least partial explanation of why sometimes, despite the wealth of social analyses, the literature on the statistical tracking and processing of female-adolescent fertility data is truly scarce. Similarly to the problems mentioned earlier concerning the other ages of reproductive life, the distinction between legitimate and illegitimate teenage fertility is even more fraught with imprecision and misleading appearances, particularly because of those who—not so long ago—spoke of *reparatory marriage*, namely, marriage not as the locus of reproduction, but as its effect. In dealing with this issue, it is crucial to remember the tremendous importance not only of the changing legislation on minimum age at marriage but also of the regulations on access of female minors to effective contraception methods and legal abortion (Livi Bacci and Ventisette, 1980). More than at other ages, heterogeneity concerns both individual factors (biologic, for example) and contextual factors (legal norms, among others).

Consequently, we should stress that—despite their widespread use—the conventional measures (legitimate and illegitimate fertility rates) are not entirely satisfactory for teenagers, because we cannot easily identify the population at risk of conception and childbearing. Unlike with other age groups, it is essential to the analysis that two preconditions be met: The young girl must be sexually mature, and she must have intercourse. Naturally, the retrospective surveys that allow an analysis of the variability of risk exposure for this age group are rarely available. Without such information, no meaningful comparison between populations is possible: the differences observed using classic age-specific rates may largely reflect the differences in the proportions of teenage girls actually at risk of pregnancy.

II

BIOLOGIC AND SOCIAL FACTORS OF FERTILITY IN INDIVIDUALS AND COUPLES

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

The formation of some kind of union is a near prerequisite to fertility, but not the only one. The union so formed must also be fertile. There are biologic conditions to this related to fecundity and its converse, infecundity, as well as behavioral requirements: sexual intercourse and ways of influencing the outcomes—contraception and abortion.

Following the overview given by Henri Leridon of these biologic and social factors of fertility as they relate to the individual and the couple in Chapter 30, five further chapters will consider in turn each factor of the various elements that determine human fertility.

In Chapter 31, Henri Leridon considers the factors of fecundability—the probability of conception during a menstrual cycle—and those of the nonsusceptible period (i.e., the period in which conception is impossible because the woman is either pregnant or subject to postpartum infecundability). The former is the result of positive fertility behaviour in a fecund period, the latter sets the schedule of fertility in line with the tempo dictated by both biology (period of gestation) and behaviors (duration of breast-feeding).

Clearly, however, the process of pregnancy can be interrupted before a live birth is produced, thereby reducing effective fertility. In Chapter 32, Catherine Gourbin gives a descriptive survey of the factors of noninduced-abortion–related fetal mortality. Likewise, in Chapter 33, Henri Leridon addresses the causes and solutions to the other biologic fertility-limiting factor: infecundity.

Summarizing the effects of these proximate determinants of fertility not expressly controlled by individuals or couples, the same author reviews the levels and models of so-called *natural* fertility in Chapter 34.

Finally, in Chapter 35, Gianpiero Dalla Zuanna considers the factors of induced abortion, whereas in Chapter 36, Michel Bozon assesses the role of context-specific sexual behaviors.

CHAPTER

30

Biologic and Social Factors of Fertility

An Overview

HENRI LERIDON

Institut national d'études démographiques (INED), Paris, France

I. FERTILITY AND FECUNDITY: THE VOCABULARY

The terms *fertility*, *fecundity*, and *sterility* are widely used not just by demographers but also by health professionals and the general public. Yet they are often a source of confusion, because except within the small world of professional demographers, this vocabulary is far from being precisely defined. Indeed, the same terms are used with completely opposite meanings by different people and linguistic conventions often change between different languages.

The most straightforward task for the demographer when observing a group of individuals and, on occasion, a particular individual (or a couple), is to *count the events that occur in a given period of time*—live births, still births, spontaneous and induced abortions. Thus we say that a couple *has been fertile* in the first 5 years of its marriage if at least one live birth is recorded during this period; in the opposite case (no birth) we say that the couple has *remained infertile* over the same period, which, however, has no implications for its future fertility. For a group of individuals, the *fertility rate* over a fixed interval of time expresses the ratio of the number of live births to the total (mean) membership of the group exposed to the risk. What we are concerned with here, therefore, are measures of *results* that can be, and actually are, observed.

The term *fecund*, on the other hand, attaches to a concept of *capacity.* It would apply, for example, to a woman whose physiologic condition was such that she could conceive if exposed to unprotected intercourse. The opposite of fecund is *infecund* or *sterile.* This concept appears to have obvious relevance for individuals and couples but it is of mainly theoretical value, because although we can sometimes know for certain that a particular man or woman is incapable of procreating (because of a clinically diagnosed pathology), in most cases the fecundity or sterility of individuals or couples is impossible to determine at the individual level. At the aggregate level, however, the concept remains of interest. If we first measure the fecundity of a group of people and then analyze the differences in this fecundity by various sociodemographic characteristics (beginning with age), a probable fecundity can be deduced that is valid at the individual level for each person with these characteristics.

Another important distinction that must be made is between capacity *for fertilization* (for a man, to fertilize; for a woman, to be fertilized) and capacity *for procreation*, meaning (for the woman) being able to carry a pregnancy to term and produce a live-born child. Civil registration statistics usually record only live births (i.e., the products of procreation and [at most] still births). Demographic surveys, by contrast, often contain questions about pregnancies that have terminated with either spontaneous abortion (miscarriage) or induced abortion.

Table 30–1 summarizes the terminology that follows from the preceding comments. The table incorporates the terms whose usage has already been codified in

TABLE 30–1 Conventional Terms and Definitions for Fertility, Fecundity, and Sterility

Event	Concept	
	Capacity (at a point in time)[a]	Result (over a given time period)[b]
Fertilization (conception, whatever the ultimate outcome)	**Fecundable**: capable of being fertilized, of conceiving (M, capable of fertilizing) Ant.: **Infecundable**	Who has conceived, who has been fertilized (M, who has fertilized) ***Ant.:*** who has not conceived (e.g., nulligravida: who has never conceived)
Fertilization followed by intrauterine death	Fecundable, but infecund (or pseudo sterile)	Partially fertile
Procreation (live birth)	**Fecund**: capable of procreating (a live-born child) ***Ant.*: infecund, sterile**	**Fertile**: who has actually procreated (e.g., primiparous, multiparous: who already has one or more children) ***Ant.*: infertile** (e.g., nulliparous: who has never procreated)

M, equivalent for men (the concepts are defined in the table primarily for women); ***Ant.***, antonym; e.g., example (particular case).

[a] More precisely: in the course of one menstrual cycle, which forms the indivisible unit of time (because the risk in fact varies from day to day in the cycle).

[b] The period can be defined between two dates, two birthdays, or two marriage durations. It is also possible to use the whole of the reproductive period before a particular age (e.g., *previously, or already, fertile*) or after this age (e.g., *subsequently, or permanently, infertile*).

specialist publications (Pressat, 1979; IUSSP, 1981), gives indications on their usage, and introduces some additional terms to maintain overall consistency.

Observed infertility, whether temporary or permanent, can be voluntary or involuntary. *Involuntary infertility*, assuming exposure to the risk of conception, can result from sterility of one or other member of the couple (inability to conceive or to carry a pregnancy to term); *voluntary infertility* can result from use of contraceptive methods or a recourse to induced abortion.

Infertility (retrospective) is said to be *primary* when there has been no live birth since the start of the reproductive period and *secondary* when there has been at least one birth.

It can be noted that among demographers the convention is that *fecundability* measures the capacity to conceive for *nonsterile* couples. This is the probability of conceiving in the course of a normal menstrual cycle, in relation to the frequency and distribution of coitus over the cycle. We shall return to this concept later, but it is relevant to note here that it can be applied to all conceptions or only to those that result in a live birth. A distinction is made between the following:

- *Effective* fecundability, which is limited to conceptions that terminate in a live birth;
- *Apparent* fecundability, which also includes any nonproductive pregnancies the woman has been aware of and that she can report in a medical interview or a survey;
- *Recognizable* fecundability, which includes all the conceptions that are detectable using existing techniques (in practice, a pregnancy has to have lasted at least two weeks from conception);
- *Total* (or physiologic) fecundability, which includes all successful fertilizations.

The Limits of the Reproductive Period

The limits of the reproductive period in females are clearly defined by puberty and menopause, which in physiologic terms correspond to the onset and the end of ovulation. This in turn prompts the question of how to identify these stages satisfactorily.

In the case of *puberty*, the appearance of the first menses is a fairly reliable indicator, even though the early menstrual cycles are frequently irregular and sometimes anovular. Table 30–2 gathers data from tables published by Wood (1994), many of them in fact taken from Eveleth and Tanner (1976) and Becker (1993). These make clear the diversity of past and present situations, with just a few significant results being selected in each case.

For European or European-origin populations and even for those of Latin America, the results indicate a median of 13 years. The age range broadens (at its upper end) for Asian and African populations: In rural regions the medians can rise to 15 and 16 years and even to 17 or 18 years for groups living in more specific ecosystems (highland regions, in particular). This amount of variation is not surprising because the relatively low ages at puberty observed in developed countries are known to be the product of a fairly recent trend. The median age in the Scandinavian countries

TABLE 30–2 Median Age at First Menses (Menarche)

was approximately 17 years in the mid 19th century compared with 13 years at present (Eveleth and Tanner, 1976). The general change in living conditions, and in particular the sustained improvement in nutrition, is responsible for this rapid decline, which has coincided with the demographic transition and industrialization.

The data concerning *menopause* are less reliable for at least three reasons. First, the process is more continuous—cessation of menses is often gradual, and a minimum duration of amenorrhea must be defined to conclude that menopause has occurred (usually 1 year, although if spotting is taken into account the estimation can become difficult). Second, in the countries not operating an official registration system, adults approaching age 50 years do not always know their exact age. Third, in the industrialized countries the menopause is increasingly influenced by hormone replacement therapies and surgery to the reproductive organs, with the result that for many women, going through menopause is no longer a natural process. Even more than with puberty, therefore, caution is in order when interpreting the data in Table 30–3.

The median age of menopause appears to lie between 50 and 51 years in industrialized countries. Elsewhere the range is wider, with some values close to those of the first group (49–50 years) whereas others are significantly lower, falling to 43 and 44 years according to some sources, notably in Asia; values of around 46 years seem to be confirmed by the Demographic and Health Surveys (DHSs) recently conducted in the various states of India (International Institute for Population Science, 1995). This time there is no evidence of any large change in age at menopause over time, as could have caused the values for the populations of the developed countries to rise from below 45 years to over 50 years. In view of the difficulties described above in this section, a *cautious* conclusion is that the median ages observed in some developing countries may well be appreciably lower (by several years) than those in the most developed countries, perhaps, again, related to nutritional conditions. Age at natural menopause seems not to vary significantly in the latter countries, the only known differentiating factor being smoking, which can reduce age at spontaneous menopause by 1 or 2 years (Willet *et al.*, 1983).

From the data available for the industrialized countries, we can estimate that 10% to 15% of women (not receiving treatment for perimenopausal conditions) experience menopause before 45 years, around 50% before 50 years, and 90% to 95% before 55 years; 75% to 80% reach the menopause between 45 and 55 years. Figure 30–1 summarizes this progression with age.

Turning now to men, the physical signs of puberty are less directly linked to onset of reproductive capacity (start of spermatogenesis), making this stage much harder to observe. There are, however, grounds for

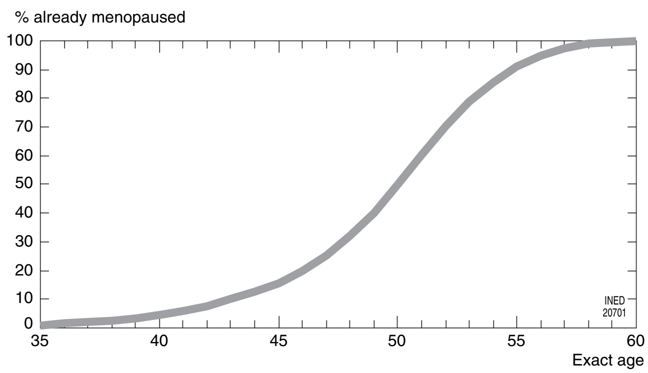

FIGURE 30–1 Estimated percentage of women who have reached (natural) menopause, by age (industrialized countries). Source: Adapted from Stanford *et al.*, 1987.

thinking that it occurs at a similar age to female puberty (La Rochebrochard, 1999). The main difference concerns the cessation of reproductive capacity, which is much more gradual in men than in women—fecundity declines slowly and surely from 30 or 40 years but we do not know at what age it gets close to zero. This upper age limit is clearly much higher than 50 years, but the small number of observations at high ages (of men still seeking to fertilize nonsterile women), related notably to loss of sex-drive, makes it hard to describe accurately the end of the period of male fecundity (La Rochebrochard, 2000). Analysis thus has to be based on the length of the *female* reproductive period, while bearing in mind that at all ages a couple's fecundity depends on both the man and the woman.

II. FROM ONE BIRTH TO THE NEXT: THE COMPONENTS OF BIRTH INTERVALS

Between two successive births, a woman passes through a number of clearly distinct physiologic stages. Ovulation does not resume immediately at the end of a pregnancy. The delay is approximately 2 months without breast-feeding and considerably longer in the presence of breast-feeding, especially when this is the infant's main source of food. It will be seen later that the duration of postpartum amenorrhea is as follows (approximate estimates):

4 months for a woman who breast-feeds for 6 months
6 months if the woman breast-feeds for 12 months
10 to 12 months if the woman breast-feeds for 18 months
14 to 16 months if the woman breast-feeds for 24 months

After resumption of ovulation, the woman can again conceive although the risk of doing so is far from 100% each month. This probability, termed *fecundability*, varies between couples but is on average situated between 20% and 30% in the high fertility ages, for an ordinary monthly frequency and distribution of coitus. This gives a mean waiting time to conception of approximately 5 to 8 months, in addition to the duration of amenorrhea.

Two live births can be separated by one or several conceptions that lead to miscarriages, as a result of *intrauterine mortality*, thus lengthening somewhat the apparent time to conception.

Finally, the interval ends with the 9 months of *gestation*, the average duration for a pregnancy terminating in a live birth (Figure 30–2).

In the context of premodern Europe, for example, the typical duration of an interval between live births would have ranged from 10 + 5 + 9 = 24 months to 16 + 8 + 9 = 33 months, depending on the assumptions made about fecundability and breast-feeding, findings that are fully consistent with the available observations on interval durations in this type of traditional society. It can also be noted here that stopping breast-feeding completely has the immediate effect of shortening considerably the interval between two births, unless it is compensated for by contraceptive (or abortive) practices: without breast-feeding, the mean completed family size from a marriage made at age 20 and still intact at age 50 would be over 12 children!

The diagram in Figure 30–2 summarizes the process, which is also illustrated by Figure 30–3. On the latter have been plotted the mean interval between two births in a population of rural Senegal (Sine Saloum) around 1965, by age at death or age at weaning of the infant born at the start of the interval: weaning or, *a fortiori*, death have the consequence of marking the end of the anovulatory period associated with breast-feeding (we will see in subsequent sections of this chapter that it ends, in fact, significantly earlier). When the infant dies or is weaned (because of inadequate maternal milk supply) in the first month, the

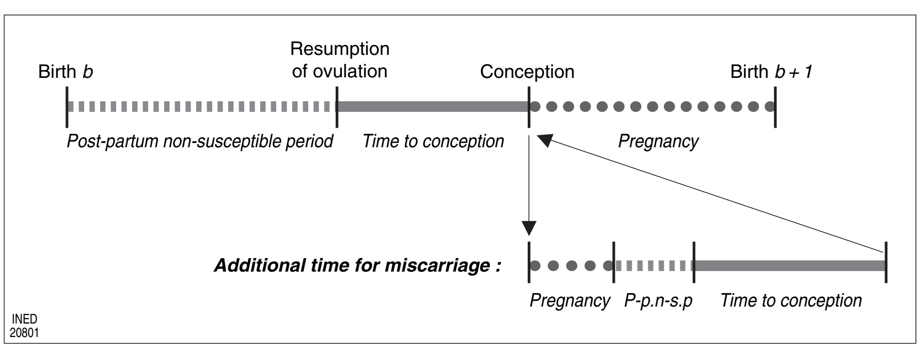

FIGURE 30–2 Decomposition of interval between two live births.

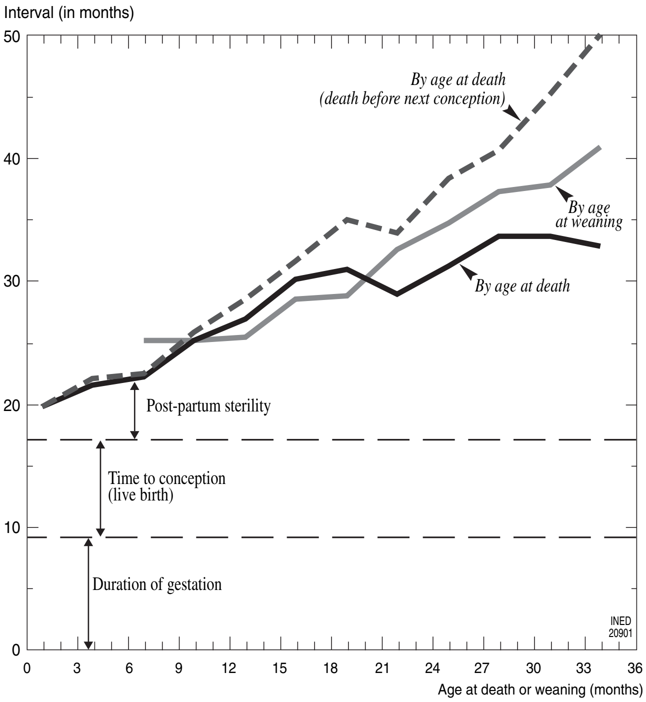

FIGURE 30–3 Mean birth intervals, by age at weaning or age at death of the first of two children (Senegal). Source: CANTRELLE PIERRE and LERIDON HENRI, 1971. Breast-feeding, child mortality and fertility in a rural zone of Senegal, *Population Studies*, vol. 25(3), p. 505–533.

interval until the next birth is around 19 months, representing 9 months' gestation, 8 months time to conception (including the time lost due to a possible miscarriage), and 2 months of postpartum sterility. There is no reason for the first two components to change with age at weaning, so it is the duration of breast-feeding (which in this population can last up to 3 years) that explains the lengthening of the interval, up to 40 months for a weaning that takes place at 3 years. The effect is slightly smaller when we consider age at death, if this takes place after 2 years: In this case, weaning may have preceded death by several months.

III. THE MENSTRUAL CYCLE AS A UNIT FOR MEASUREMENT OF TIME

Research by Ogino and Knaus in 1925 to 1930 established that fertilization is possible only during a short period in the middle of the menstrual cycle, around the point of ovulation. The precise length of this fecund period cannot be known because of the difficulty of determining the exact time of ovulation. Empirical studies such as those by Barrett and Marshall (1969) have shown that the probability of conception was significantly different from zero for 6 days, mostly before the date of ovulation *J* and with a maximum at day *J*-2. But this fecund period can be lengthened artificially by uncertainties in identification of the date of ovulation, which is detected here by variations in body temperature. However, more recent research based on biologic tests for the detection of ovulation confirms that the fecund period lasts 6 to 7 days (Wilcox *et al.*, 1998).

This heterogeneity of fecundity within the cycle means that this cycle must be taken as the minimum unit of time for the study of fertility, and therefore we need to know its duration. This seems to be between 26 and 30 days (Matsumoto, 1964) but the existence of appreciably longer cycles increases the mean duration to approximately 30 days. Consequently for the purpose of fertility studies, it is legitimate to equate menstrual cycle with calendar month and thus count 12 cycles per year. The duration of the cycles varies between women (ranging from 10 to 45 days) as well as between cycles and by age for the same woman. It also has to be noted that use of hormonal contraception establishes a strict 28-day cycle: In this case it is essential to count 13 cycles in the year.

A point to remember is that not all cycles are ovulatory. Anovulation is common at the beginning of the reproductive period (and may be responsible for the phenomenon of *adolescent sterility* described by Montagu in 1946), and again in the second half of this period; we will return to this point in our discussion of age-related change in sterility. The frequency of anovular cycles in women aged 20 to 35 years varies between 5% and 15% depending on the author.

IV. FECUNDABILITY

In practice, the concept of fecundability is only meaningful in statistical terms. For any given couple, the time required to conceive is measured by the number of cycles during which they have had unprotected intercourse. A satisfactory estimation of individual fecundability would require the test to be repeated many times, yet each couple wants to have only a small number of children. It is by combining the experiences of a certain number of couples that we are able to calculate the (monthly) rates of conception, at least for the conceptions that result in recognizable (and recognized) pregnancies. However, to do this we have to be certain that all the couples are indeed exposed to the risk of conception at the start of the period, a situation that is actually not very common. In traditional, noncontracepting populations, at any given time a large proportion of women will be in the nonsusceptible period (i.e., unable to conceive) because of a pregnancy already under way or the subsequent anovular period (that breast-feeding practices may extend to 1 year or more, as we have seen). In this case, the only favorable circumstance for the risk of conception is marriage, if it is accepted that this coincides approximately with the start of regular sexual relations for the couple.

That last assumption is unlikely to hold true for the low-fertility populations of the developed countries. Here, specific observations have to be made to determine the dates at which contraception was discontinued and the length of time that was then necessary for conception to occur.

The two types of observations lead to the following results:

a. Effective fecundability (rate of conception measured in live births) usually has an average value between 0.2 and 0.3 (20% to 30%);
b. The probability of conception decreases progressively, month on month, after the ninth month, revealing the heterogeneity of the cohorts being studied with respect to the risk of conception (Table 30–4).

A beta distribution function has proved extremely practical for representing the distribution of fecundability between couples. As well as enabling us to define a large variety of distributions with just two parameters, the beta law provides a simple yet effective tool for analyzing the progressive selection process of the less fecund couples. For if the parameters of the initial distribution are a and b, the fecundability of the couples who have not conceived after n months of exposure to the risk is also distributed according to a beta distribution with parameters a and $b + n$: Thus we immediately know all the characteristics of this new distribution and, in particular, the mean fecundability, which is equal to $a/(a + b + n)$.

So, for example, if the mean fecundability of the group is 0.25, with $a = 2.75$ and $b = 8.25$, after 1 year without conception (12 months) the fecundability of the residual group is only $0.12 = a/(a + b + 12)$ (Figure 30–4); but 71% of them will manage to conceive in the following 12 months. Even after 2 years without conception, when the residual fecundability has fallen to 0.08, the probability of conceiving in the next year exceeds 57%.

This approach can be used to clarify certain clinical practice problems. The first concerns the detection of so-called sterile couples, a category that is generally taken to include all couples who have still not conceived after trying for 12 months. This definition has the effect of grouping together—unfortunately in unknown proportions—couples who are pathologically sterile and couples who are merely subfecund, although for the latter, the probability of conception in the absence of any treatment is far from nil.

This clearly needs to be taken into account when estimating the effectiveness of an infertility treatment. If treatment is given uniquely to couples who are 100% sterile, any conception that results can be attributed to the treatment; if not, we must try to ascertain whether

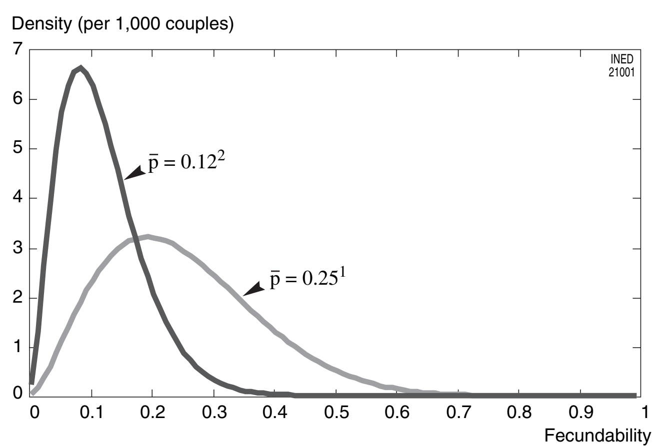

FIGURE 30–4 Distribution of fecundability by a beta function ($a = 2.75$ and $b = 8.25$).

[1]For all couples: mean fecundability $\bar{p} = 0.25$

[2]For hypofertile couples (no conception during the first 12 months): $\bar{p} = 0.12$

the result is better than would have been obtained without any treatment and this comparison can produce unexpected results.

In addition, the new techniques of *assisted reproduction* require us to rethink some aspects of the problem. For example, IVF (*in vitro* fertilization) specialists have adopted the concept of a *natural fecundability* in the order of 0.25, and on this basis conclude that when their *success rate from oocyte transfer* reaches 25% they are doing as well as nature. However, this reasoning neglects the fact that transfer involves the following stages:

- Hormonal stimulation of ovulation, intended to ensure that conditions for ovulation are normal, or even better than normal, because several eggs are usually collected;
- Attempted fertilization at the optimal point in the cycle and of several eggs at once;
- Transfer of several fertilized eggs to increase the chances of at least one developing.

These conditions are far removed from the average situation of ordinary couples, who experience merely one ovulation per cycle and who do not necessarily have intercourse at the *best* moment in that cycle. Furthermore, Barrett and Marshall (1969) and Schwartz, MacDonald and Heuchel (1980) determined that if intercourse takes place once a day throughout the fecund period, the chance of obtaining a *recognizable conception* can be as high as (or exceed) 50% per cycle. This is the type of figure that should be used when comparing the success rate per treatment cycle of AID (artificial insemination by donor) or of IVF, with allowance made for the pregnancies that do not run to term.

V. DURATION OF PREGNANCY

For live births, the duration of pregnancy traditionally seemed to vary little (on average) between different populations. A precise distribution of gestation durations was produced by Hammes and Treolar (1970) for almost 200,000 single births registered in California in 1966. Table 30–5 shows this distribution after conversion of the *conventional durations* (counted from the first day of the last menstrual period) to *actual durations* (counted from the day of ovulation) by the simple procedure of subtracting 2 weeks. The right-hand section of the table gives the distribution in calendar months (of 30.4 days), which is useful for some applications.

The mean duration of gestation is 265 days (38 weeks) when counted from the probable day of ovulation (or 279 days from the start of the last menstrual cycle). The median is also close to 38 weeks, whereas

TABLE 30–5 Distribution of Pregnancy Durations (Live Births) (Duration Calculated from Theoretical Day of Ovulation)

Completed weeks x	%	Cumulative % from 0 to x (inclusive)	Completed days	Completed months: y	%	Cumulative % from 0 to y (inclusive)

the mode is between 38 and 39, thus giving proof of skewness in the distribution.

This distribution has certainly been modified by improved medical care for premature babies in the countries with the most advanced health facilities. Because the scale of changes is closely dependent on the introduction and effectiveness of these new practices, we prefer to retain the Hammes and Treolar (1970) distribution as reference standard.

For pregnancies that do not end in live births it is hard to give a standard distribution. Because declaration of these pregnancies is not usually compulsory, we have to rely on information obtained in surveys. The result is then dependent on the proportion of early miscarriages that women report (see Chapter 32 for a comprehensive discussion of intrauterine mortality). For practical purposes, a mean of approximately 3 months can be used.

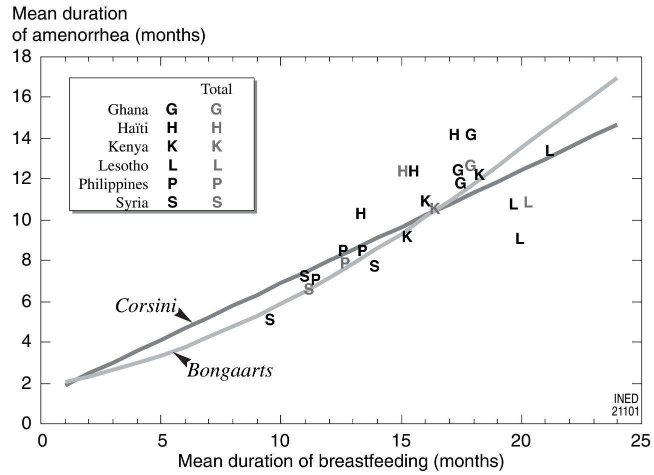

FIGURE 30–5 Relationship between mean durations of breast-feeding and amenorrhea (World Fertility Surveys and standard distributions). Source: Leridon and Ferry, 1985.

VI. THE POSTPARTUM NONSUSCEPTIBLE PERIOD

Birth is followed by a period in which the risk of conception is zero, a situation that in traditional demographic regimes contributes to a significant spacing of births, even when this outcome is not consciously sought. Although breast-feeding, by temporarily inhibiting ovulation, has long been known to be the main factor responsible for this phenomenon, the debate has suffered from two confusions. First, the relationship between the duration of breast-feeding and the duration of postpartum sterility is purely *statistical*—when working at the individual level, the second duration cannot be predicted from the first, and in most cases ovulation resumes before the infant has been weaned. Second, anthropologic data have established the existence in some populations of taboos on sexual intercourse for a period following birth. Only at the end of the 1970s did analysis of data from the World Fertility Survey (WFS) program make it possible to demonstrate the usually secondary role of sexual prohibitions compared with breast-feeding. We return to this point below.

The effect of breast-feeding has been proved in several ways. The indirect data provided by studies of historic demography (which have related the length of the interval between two births to the age at death of the first child, as represented by one of the curves on Figure 30–3), have been confirmed by data from surveys containing direct questions on the duration of breast-feeding. Furthermore, the workings of the biologic mechanism involved are now understood. Secretion of a specific hormone, prolactin, which begins during, and continues after, pregnancy, is responsible for maternal milk production and (perhaps not exclusively) for suppressing release of other hormones (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]), thereby preventing the resumption of ovulation.

The most obvious sign of the resumption of ovulation is the return of menstruation (the end of amenorrhea, or the *return of menses*). In point of fact, this is merely an approximate indicator, since the cycle preceding the first menses is sometimes though not always ovulatory. On average, however, the approximation is adequate. Figure 30–5 shows the possible relationships between the mean duration of breast-feeding and postpartum amenorrhea: These data provided the basis for the plausible estimates given earlier (6 months of amenorrhea for 1 year of breast-feeding, 14–16 months for 2 years). The larger data output from the DHS surveys will enable further refinement of this relationship. We are concerned here with *total* durations of breast-feeding: It is important to appreciate that during much (indeed usually most) of this period, the infant is not nourished exclusively on mother's milk. But the effect of breast-feeding on postpartum sterility is diminished when feeds are less frequent and of shorter duration. This is the reason, at least in part, for the fairly weak correlation between total duration of breast-feeding and duration of amenorrhea.

The duration of postpartum sexual *abstinence*, as noted, seldom exceeds the duration of amenorrhea and thus *a fortiori* the duration of breast-feeding. But the impact on the effective duration of sterility is not necessarily negligible, since we cannot here reason on mean figures—each individual case where the first

TABLE 30–6 Mean Durations of Breast-feeding, Amenorrhea, Sexual Abstinence and Postpartum Sterility (Months), in Selected Countries (World Fertility Survey)

Country	Breast-feeding	Amenorrhea	Abstinence	Nonsusceptible period

Source: Leridon and Ferry, 1985.

duration exceeds the second contributes a little to increasing the overall mean duration of sterility. Table 30–6 shows this clearly for various countries, based on the WFS. In this case too, the more plentiful data from the DHS will allow us to confirm this analysis.

The Factors of Fecundability and the Nonsusceptible Period

HENRI LERIDON

Institut national d'études démographiques (INED), Paris, France

The various biologic parameters of reproduction were presented in the last chapter, along with some components of their spatial and temporal variability. In this chapter we examine the possible causes of these variations, including those resulting from sexual behavior and contraceptive practices.

I. AGES AT MENARCHE AND AT MENOPAUSE

In most of the developed countries, the median age *at menarche* (for girls) is between 13 and 14 years. Although the data published by Tanner in 1962 describing the rapid decline in age at first menstruation during the 20th century have been criticized (Tanner inferred a reduction of 4 months per decade), the general trend is not disputed. Most available data point to a limit being reached around 12.5 to 13 years, although such a limit is not suggested by other data, notably for France (Ducros and Pasquet, 1978; de La Rochebrochard, 1999).

This secular decline has often been attributed to improved nutrition among infants and adolescents. The hypothesis, which cannot be verified directly, appeared to be supported by the idea that the onset of ovarian function is triggered when the proportion of body fat rises beyond a certain threshold in the course of a young girl's growth (Frisch and Revelle, 1970). Other elements, such as the cessation of menstruation in women whose body mass had fallen for some reason or another or in populations subjected to extremes of undernutrition or stress further strengthened this hypothesis. It has been largely discredited, however, by subsequent research. For example, growth of *skeletal mass* has been shown to be a much better predictor of puberty (Ellison, 1982), so much so that the body fat increase is now thought to be more a consequence of ovarian function onset than one of its causes (Wood, 1994). The possibility remains, however, that nutrition contributes to ovarian functioning in general and to onset of menarche in particular.

Differences between individuals remain, of course. The French data analyzed by de La Rochebrochard (1999) show an age distribution at first menses ranging from 9 to 18 years, although the ages between 11 and 14 years account for around 90% of cases.

The distribution of age *at menopause* is considerably more dispersed. The four most frequent years together account for only 40% to 50% of cases. On either side of the modal value, which is usually situated around 50 years, the distribution extends up to approximately 55 years in one direction and down to 35 to 40 years in the other (although cases of earlier menopause do occur) (see Chapter 33 and Treolar, 1974). The reasons for these interindividual variations are poorly understood. The only clearly documented factor is smoking, which is thought to bring forward age at menopause by between 1 and 2 years. For any individual woman, no correlation has been found between age at menarche and age at menopause (Treolar, 1974). Genetic factors may be implicated in the differences between individuals and in the mean values for different populations.

The predominant influence affecting age at menopause, however, is the development of treatments for perimenopausal conditions, which can substantially delay the onset of menopause, so much so that it becomes almost unobservable. However, because these are hormonal treatments that *also* have a contraceptive role, it does not follow that they extend the woman's fertile period, the risks of conception being extremely limited or even nonexistent.

II. FECUNDABILITY

We saw in the previous chapter that fecundability varies between couples and that a distribution of fecundability can be constructed from the distribution of the waiting times to conception. Figure 30–4 in the previous chapter showed that for a mean fecundability of 0.25, the individual values could range between 0 and approximately 0.6. A fecundability of 0.5 gives a mean time to conception of 2 months, whereas for a fecundability of 0.1 it reaches 10 months. Couples are thus very unequal in regard to the risk of conception—what are the main factors responsible for these differences?

For a particular couple, fecundability represents a combination of dimensions that are *biologic* (the respective physiologic capabilities of the man and the woman)[1] and *behavioral* (the frequency of sexual intercourse and its distribution within the menstrual cycle). Most of these results were obtained from populations in which contraceptive practice can be assumed to be negligible, especially at the start of marriage. For newly married couples, we can also assume a sexual activity of at least average level, in the absence of any direct information about the sexual behavior of these populations. In the next section we give some results from contemporary surveys on the sexual activity of couples.

Mathematic models have been constructed that describe the evolution of fecundability with the *woman's age*, by neutralizing the effect of coital frequency. In practice the assumption is made that intercourse takes place within each cycle at least once during the fertile period (i.e., at the point of ovulation). Under these hypotheses and for premenopausal women, Wood and Weinstein (1988) estimate total fecundability (the probability of conceiving regardless

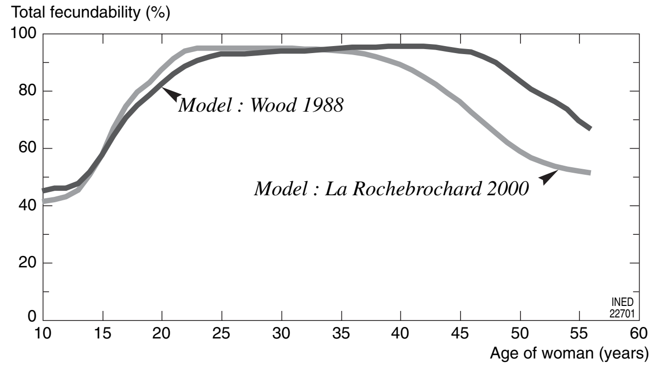

FIGURE 31–1 Age-specific total fecundability (women), per cycle of exposure to risk of conception (woman and man not yet sterile, cycle with sexual intercourse at point of ovulation) Source: La Rochebrochard Élise de, 2000. *Modélisation de la baisse de la fertilité avec l'âge de la femme et l'âge de l'homme* Paris, Université Pierre et Marie Curie, 438 p. (biomathematics thesis); Figure 9.4.

of the outcome of the conception) at close to 0.95 between 25 and 45 years; de La Rochebrochard (2000), who takes into account the reduced risk of ovulation in the years leading up to menopause, finds that fecundability actually starts to decrease between 35 and 40 years (Figure 31–1).

Turning from *total* fecundability to *recognizable* fecundability, we note that the latter is calculated by including intrauterine mortality occurring before a pregnancy is detectable by delayed menstrual period or a pregnancy test (i.e., in the first 2 weeks of gestation). Mortality in these first 2 weeks is particularly hard to observe and often it is necessary to use indirect methods. Working again on the assumption that sexual intercourse occurred at least once during the fertile period, the estimates proposed for recognizable fecundability were in the order of 0.3 to 0.4 (Leridon, 1977). More recently, de La Rochebrochard (2000) has suggested a value not exceeding 0.24 (between 25 and 35 years), which in terms of live births would give an *effective* fecundability not exceeding 0.21 at the most propitious ages (Figure 31–2): This is a low value compared with those obtained by direct demographic observations, which are approximately 0.25 (Leridon, 1977).

If age is a determinant of fecundability, this is because certain biologic parameters vary with age—the frequency of anovular cycles, the mean length and variance of menstrual cycles, the fertilizing quality of sperm, the risk of genetic defects in the embryo, and so forth. These same factors could also explain the differences between individuals. Any exceptionally long waiting time to conception should alert to the possibility of ovulatory difficulties, spermatic abnormalities, or problems in coitus. These causes are analyzed

[1] Forms of incompatibility may also exist between the aptitudes of the two partners that result in the sterility of a couple in which the man and the woman are nonetheless fertile individually.

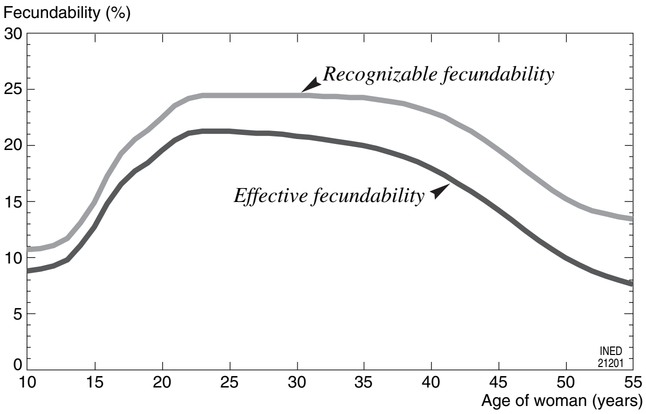

FIGURE 31–2 Recognizable fecundability and effective fecundability, by age of woman, per cycle of exposure to risk of conception (woman and man not yet sterile, cycle with sexual intercourse at point of ovulation). Source: La Rochebrochard Élise de, 2000. *Modélisation de la baisse de la fertilité avec l'âge de la femme et l'âge de l'homme* Paris, Université Pierre et Marie Curie, 438 p. (biomathematics thesis); Figure 9.14.

in the Chapter 33, since in practice it is not possible to know beforehand whether a couple seeking help for infertility is totally sterile or merely subfecund.

III. FREQUENCY OF SEXUAL INTERCOURSE

A comparison of results from surveys carried out in nine European countries in the early 1990s showed little between-country variation in the reported mean frequency of intercourse: In all countries, the weekly mean (for men and women in couples, aged between 18 and 50–75 years depending on the survey) is between 1.7 and 2.1, equivalent to 6.8–8.4 acts of coitus per 4-week period[2] (Sandfort *et al.*, 1998). The contrasts are greater in the developing countries. According to World Health Organization (WHO) surveys conducted at the same time, the mean frequency reported by women in couples (15–49 years) for the previous month ranged between 1.5 and 5.7 in six African countries and between 2.5 and 7.6 in five countries of Asia and Latin America (Caraël, 1995). Not only are the between-country disparities large but the mean values are significantly lower than those for the developed countries—an important reason is that a large proportion of the women interviewed (between 34% and 58% of the Africans) reported having had no intercourse with their husband in the previous month. This behavior can be attributed to numerous factors, including polygamy and widespread recourse to prostitutes, the existence of periods when intercourse is discouraged or proscribed (pregnancy, postpartum abstinence related to breast-feeding, terminal abstinence at the end of reproductive life), and economically motivated periods of separation.

Frequency of intercourse usually declines with age (for people living in couples), but the important variable in fact seems to be length of union, at least in the union's early years (Udry, 1979; Leridon, 1993). In the French Analyse des Comportements Sexuels en France (ACSF) survey (Leridon, 1973), people aged 25 to 34 years and living as a couple reported a mean frequency of intercourse over the past 4 weeks of 14.6 when the couple had existed for less than 6 months, 11.7 when this duration was between 6 months and 1 year, and 9.6 for durations between 10 and 14 years (Figure 31–3). The most significant decline thus occurs during the first 12 months. The age-specific data indicate that the age effect is apparent primarily after 50 years (for women): Thus, it has only a weak influence on the risk of conception during the reproductive period.

Naturally, allowance must also be made for reporting problems, which can distort comparisons between populations. Generally speaking, people questioned on this subject tend to give answers that are biased in the direction of normative considerations, corresponding to behavior in periods of full activity and overlooking the existence of periods when sexual activity has been reduced for various reasons (health problems, pressure of work, etc.).

IV. BREAST-FEEDING

As was seen in the previous chapter, breast-feeding is important in lengthening birth intervals. Without any effective substitute for the infant's nourishment, breast milk is essential for its survival—the death of the mother or a new conception too soon would endanger the life of the infant. Multiple births are a definite additional handicap. A study in Senegal (Cantrelle and Leridon, 1971) reported mortality levels over the first 3 months four times higher for twins than for other children and more than twice as high in the first year (for a more complete analysis, see Pison, 1989).

Breast milk production is dependent on the peptide hormone prolactin, which also has a role in inhibiting ovulation after delivery. Prolactin levels and milk yield depend in turn on the suckling stimulus—it has been established that more frequent suckling delays the resumption of ovulation and is therefore an important factor in variations in the duration of postpartum

[2] In practice, the question was usually asked for the 4 previous weeks.

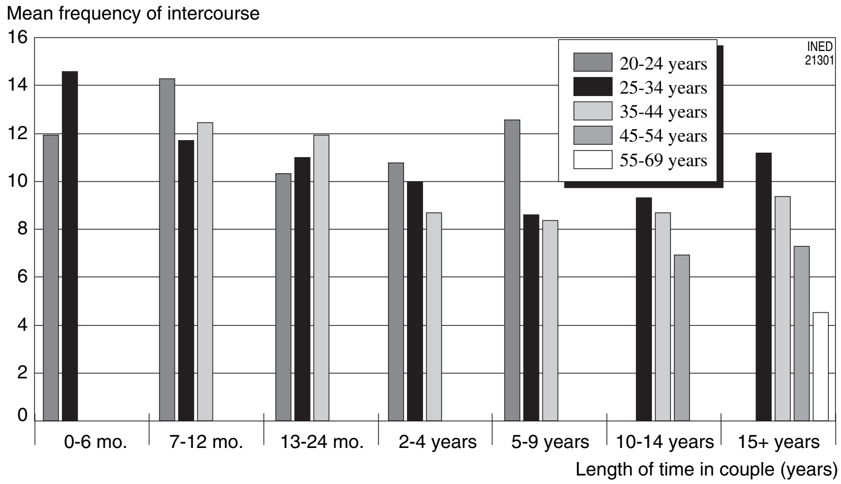

FIGURE 31–3 Mean frequency of intercourse over previous 4 weeks by age and length of time in couple: France, ACSF survey (men and women 1-year sexually active). Source: Leridon Henri, 1993. amenorrhea between women and between populations (Konner and Worthman, 1980). Table 31–1 presents an example of the observed relationship between suckling frequency and duration of postpartum amenorrhea (note that although the return of menses is not an absolute marker for the resumption of ovulation, the *mean* durations of amenorrhea and of anovulation are similar).

In this sample of rural women in Java, the total duration of suckling varies in a ratio of one to two between the four groups (formed for the purposes of the analysis), and this is associated with a difference of almost one to two in the median duration of amenorrhea. For this reason alone the birth interval increases by 9 months between the first and fourth groups. Thus it is clear that the correspondence between *mean duration of breast-feeding* and *mean duration of amenorrhea*, as described in the previous chapter, can only be approximate.

One reason for a low suckling frequency is that the infant has begun to receive supplementary food. Studies that take account of whether breast-feeding is partial or full have in fact shown the risks of resumption of ovulation and of conception to be significant even when breast-feeding is only partial, before the child has been fully weaned (see for example John *et al.*, 1987).

All these ingredients contribute to the existence of large differences in breast-feeding durations between populations, as can be seen from Table 31–2. Table 31–2 shows results for developing countries from two large-scale international programs—the World Fertility Survey (WFS), conducted for the most part between 1974 and 1981, and the Demographic and Health Survey (DHS), for which the data presented here concern the years from 1986 to 1997. Large disparities are observed, because the mean duration of breast-feeding varies from 5 months in Costa Rica to 29 months in Bangladesh. When data from both sources exist for a country, they show that breast-feeding practice has not decreased across the periods (the trend appears rather to be one of increase).

The subsequent columns of Table 31–2 confirm (as was seen in the previous chapter) that the mean durations of amenorrhea are always shorter than those of breast-feeding; they range from 5 months (Brazil) to

TABLE 31–2 Mean Durations of Breast-feeding, Amenorrhea, Postpartum Abstinence and Postpartum Sterility (World Fertility Survey and Demographic and Health Survey)

about 17 months (Rwanda). The effective duration of the *postpartum nonsusceptible period*, which refers to the period of zero fecundability following a birth, depends on the length of breast-feeding, but also, in some situations, on the duration of sexual abstinence after the birth of a child. When this duration is clearly shorter than that of the amenorrhea, it has little impact on the mean duration of postpartum sterility; in some cases, however, as in Burkina Faso and Namibia, it helps to extend it significantly.

V. CONTRACEPTION

The effective risk of conception at any point in time also depends, once we abandon the natural fertility framework, on couples' behavior in respect of contraception. The *effectiveness of contraception* is defined as the complement to 1 of the ratio between the *residual fecundability* p_r (with contraception) and the *natural fecundability* p_n:

$$E = 1 - \frac{p_r}{p_n} \qquad \text{(Eq. 1)}$$

The value of E is often expressed as a percentage. Thus, a method that is 99% effective reduces the risk p_n to 1% of its initial value.

1. Measurement of Contraceptive Failure Rate (Homogeneous Situation)

As defined above, contraceptive effectiveness measures the *reduction in risk* (of conception) induced by use of a contraceptive method; this measurement is thus independent of the amount of exposure to the risk without any contraception. The failure rate, by contrast, uses the number of *pregnancies that actually occur* in a given period—so it is in fact a fertility rate. It can also be calculated just for the periods of exposure to the risk of conception (the case of the Pearl index), thus modifying its nature considerably.

From the definition given above, it follows that:

1. The actual number of conceptions will depend both on E and on p_n. For example, if $p_n = 0.3$, a method with a 90% effectiveness will leave a risk of conception of 0.03 (or 3%) per month;
2. The notion of contraceptive effectiveness applies to a well-defined unit of time, that of fecundability—the month (or the menstrual cycle), and excludes any other;
3. Over a longer period, such as the year, the monthly risks are combined, so that an apparently high effectiveness (like 90%) will have left a nonnegligible number of conceptions by the end of 12 or 24 months (respectively, 31% and 48% in the selected example).

TABLE 31–3 Monthly Distribution of Conceptions (per 1000 Women). Homogeneous Case: Monthly Probability of 30% or Monthly Probability of 3% (Contraceptive Method 90% Effective)

Month	At 30% risk		At 3% risk	
	Not yet conceived	Conceiving in the month	Not yet conceived	Conceiving in the month
1	1000	300	1000	30
2	700	210	970	29
3	490	147	941	28
4	343	103	913	27
5	240	72	886	27
6	168	50	859	26
7	118	36	833	25
8	82	25	808	24
9	57	17	784	24
10	40	12	760	23
11	28	8	737	22
12	20	6	715	21
13	14		694	
Total		986		306

Thus, in our example, a method that is 90% effective gives 3% conceptions per month and 31% at the end of 1 year (Table 31–3). The complement to 100 of E (10%) has no particular significance in terms of failure rate and hence it is incorrect to assert, as unfortunately often happens, that when a method with a 90% efficacy is used by 100 women, 10 will become pregnant within a year.

Now let us examine in more detail what is involved here. For a group of N couples, observed during a certain number of months after adopting a particular contraceptive method, let

C_i be the number of conceptions during month i,
N_I be the number of women still in observation during month i,
S_i be the number of women at risk of conception during month i,

We note that N_i decreases progressively due to the women lost to follow up, and that S_i also decreases for the same reason but primarily as and when the women conceive and thus enter the nonsusceptible period.

The percentage of women conceiving during the n *first months* (if no woman has had the time to conceive more than once) will be

$$T_n = \frac{\text{Total number of conceptions}}{\text{Mean number of women under observation}} \times 100 = \frac{\sum_{i=1}^{n} C_i}{\sum_{i=1}^{n} N_i} \times 100\, n \qquad \text{(Eq. 2)}$$

If all the women are still under observation after n months, Equation 2 reduces to

$$T_n = \frac{\sum C_i}{N} \times 100 \qquad \text{(Eq. 3)}$$

If none of the conceptions is wanted, T_n *represents a contraceptive failure rate*, calculated for period n. In the case where exits from observation during period n are significant, using Equation 3 instead of Equation 2 will result in under-estimating the true failure rate.

Can we define a relationship between T and E? In the homogeneous case and again taking account of only one conception per woman, the procedure is straightforward. The monthly number of conceptions (C_i) is obtained by multiplying the number of women at risk (S_i) by the risk of conception (residual fecundability p_r):

$$C_i = S_i p_r = S_i p_n (100 - E)/100$$

if E is expressed in percentage terms. If the number of women under observation (N) stays constant during the observation period, the number of women still at risk (i.e. who have not yet conceived) at the start of month i is simple to calculate:

$$S_i = N(1 - p_r)^{i-1}$$

The formula for summing the terms of a geometric progression then gives:

$$\sum_{i=1}^{n} C_i = P_r N \sum (1 - p_r)^{i-1} = N\left[1 - (1 - p_r)^n\right]$$

and Equation 3 becomes:

$$T_n = 100\left[1 - (1 - p_r)^n\right] \qquad \text{(Eq. 4)}$$

which establishes a relationship between the rate of conception T and the residual fecundability (and hence also the contraceptive effectiveness E).

Let us again use the elements in Table 31–3:

- When there is no contraception, Equation 3 gives as rate of conception for the first year:

$$T = \frac{986}{1000} \times 100 = 98.6\%$$

- With a contraceptive that is 90% effective the rate will be:

$$T = \frac{306}{1000} \times 100 = 30.6\%$$

- We can check that an identical rate is obtained with Equation 4:

$$T = 100\,[1 - (1 - 0.3)^{12}] = 98.6\%$$

and

$$T = 100\,[1 - (1 - 0.03)^{12}] = 30.6\%$$

But the same is not true for the heterogeneous case, i.e. when there is couple-to-couple variation in natural fecundability or (to an even greater degree) in contraceptive effectiveness. For in this case *the couples with the highest risk conceive soonest* so that the mean risk of those who have not yet conceived after month i decreases. We will give an example of this with the Pearl index.

2. The Pearl Index

In the 1930s, Pearl (1932) proposed a method for calculating *a rate of conception that takes into account only the periods of exposure to the risk.* Once conception has occurred, the woman is in effect protected against any new conception, for a period at least as long as the pregnancy and sometimes appreciably longer. Paradoxically, therefore, a conception actually helps to reduce the rate of conception observed over period n as a whole. In the Pearl index, the denominator is formed by the sum of the S_i, rather than the N_i:

$$R_n = \frac{\text{Total number of conceptions}}{\text{Number of months of exposure to conception}} \times 1200 = \frac{\sum_{i=1}^{n} C_i}{\sum_{i=1}^{n} S_i} \times 1200 \qquad \text{(Eq. 5)}$$

This is a rate of conception, expressed for an annual period (per 100 women-years). The first point to note is that the *maximum theoretical value of this index is not 100 but 1200.* Assume that each woman conceives at each ovulation ($p = 1$): In these conditions the number of conceptions C_i would always be equal to S_i and R would be equal to 1200. In practice, p is not equal to 1. As we have seen, when no contraception is being used, it is between 0.2 and 0.3. In the homogeneous case, we can check that:

$$R = 1200\ p$$

i.e. that the rate of conception is given directly by p (apart from the coefficient 1200), as in fact results from the definition of R.

With $p = 0.3$, R is 360, and with $p = 0.15$ (a 50% level of effectiveness of the contraception), R still has a value of 180. In a situation of heterogeneity, the R values corresponding to identical values for mean fecundability would be even higher.

The relation $R = 1200\ p$ is only valid in conditions of homogeneity, except for an observation limited to a single cycle; in this case, under conditions of heterogeneity, we still have:

$$R_1 = 1200\ \bar{p}$$

Beyond a single cycle, the relation no longer holds, because of the progressive selection that operates, since it is the most fecund women who conceive soonest. Table 31–4 gives an example of the effects of this selection, taken from an American survey. Calculated over the first 12 months, the index R was 36%; over the first 24 months, less than 30%; and after 4 years, 26%.

This dependence of R on the length of observation is a drawback if we wish to compare two separate surveys that use different lengths of observation. For this reason *it is imperative* always to mention the exact length of the observation and to compare only values that are calculated over the same period (preferably 12 months).

Assuming we have a distribution of p_r we can try to establish a relation between R and E using an *empirical* approach. In accord with the conclusion of the previous paragraph, the relation must be calculated for an observation period of a specific length. This was the approach used by Henry. Table 31–5 shows the relations he established between values of R_{12} (12 months) and E.

TABLE 31–4 Effect of Length of Observation on the Pearl Index (R)[a]

Length of observation	R (per 100 women-years)
1 month	42.4
6 months	37.1
12 months	35.7
18 months	30.8
24 months	29.4
36 months	27.3
48 months	26.2

Source: Charles F. Westoff, Robert G. Potter, Philip C. Sagi, and Elliot G. Mishler, 1961. *Family growth in metropolitan America*. Princeton, Princeton University Press, 433 p.

The relation becomes looser as E decreases and the number of conceptions rises, but it is clear enough for the usual range of effectiveness E (90%–100%).

As long as the probability of conceiving in 12 months remains low, which in practice means levels of effectiveness of at least 95%, the proportion of women who conceive in 12 months (T_{12}) is very close to R_{12}. The number of women exposed to the risk (S_i) decreases only very slowly and Equations 2 and 3 differ little in the case of $n = 12$. It is therefore correct, in this case *and in this case only*, to interpret the Pearl index as the proportion of women who conceive in 12 months. We saw earlier that this would not be true for higher values of risk of conception.

Even in this case, however, it must be noted that the effectiveness of the method used is not equal to the complement at 100 of the failure rate. If, for example, we obtain a Pearl index value of 4 (per 100 women-years), it would be incorrect to conclude that the method has an effectiveness of 96%—according to Table 31–5, its effectiveness is in fact 99%.

3. Fertility Rates, Failure Rates and Fecundability

Mention can be made of a final specificity of the indices T and R—they refer to a cohort of women, characterized by the fact of *all being exposed to the risk of conceiving* (even if this risk is low) *at the start of observation*. This is what distinguishes them from conventional fertility rates, in which the number of births (or conceptions) is divided by *all* the women of a given age, whether they are exposed to the risk or not.

The distribution of conceptions, as presented in Table 31–3 for example, is equally uninformative as to the value of the conventional fertility rate, and, vice versa, knowing this fertility rate is of no help in evaluating fecundability. The fertility rate (number of

TABLE 31–5 Relation between the Pearl Index calculated for 12 months (R_{12}) and effectiveness of contraception (E)

Louis Henry, 1968. Essai de calcul de l'efficacité de la contraception, *Population*, vol. 23(2), p. 265–278.

births or conceptions per 1000 women under observation during one year) is in fact determined by several parameters:

- Fecundability, which determines the time necessary to conceive;
- The duration of gestation and of the postpartum nonsusceptible period during which the woman is unable to conceive. This nonsusceptible period is short when the woman does not breast-feed (approximately 6 weeks) but can last up to a year when she breast-feeds for 2 years (as observed in many African and Asian societies);
- Fetal mortality, which is responsible for further lengthening the interval between live births.

If we set aside sterility (i.e., take into account only women who are still fertile) the fertility rate is equal to the reciprocal of the interbirth interval. This result is consistent with what we would expect intuitively—a birth every 2 years is the same as a fertility rate of 0.5 (or 500 per 1000).

Let us examine a simple case in which we will disregard fetal mortality and assume that all the women have the same fecundability p and the same nonsusceptible period m. The interval between two births will be equal to the sum of the waiting time to conception and the nonsusceptible period (including in the latter the length of gestation), that is:

$$I = \frac{1}{p} + m$$

The fertility rate (annual) of women who are still fertile will be, when I is expressed in months:

$$F = \frac{12}{I}$$

Table 31–6 shows that even in this simplified case the values of the indices T (conception rate for first 12 months), R (Pearl index), F (fertility rate) and $1 - E$ are all different.

4. Other Problems

We have already identified a difficulty in the measurement of the contraceptive failure rate—namely that this measurement (even when we express it in annual terms) depends on the length of observation. A distinction also has to be made between the *theoretical* effectiveness and the *clinical* effectiveness (or *use* -effectiveness) of any one method. The former is evaluated in ideal laboratory conditions of use and assuming full compliance with instructions. The latter is measured under more realistic conditions for a real population whose members are not of above average motivation or education. The difference between these measurements is likely to be greater the more demanding the method is to use. This is why the effectiveness of the same method when used by two separate populations can depend in large part on the cultural distance between these two samples. The temperature method, for example, when practiced correctly by a population of highly motivated couples can be as effective—if not more so—as the pill used carelessly or half-heartedly. This is why it is important in a data collection to be completely rigorous and not to exclude a failure by blaming it on the carelessness of the subject. It is clear that if all failures are excluded, as tended to be done in the early evaluation studies of the pill and the intrauterine device (IUD), an effectiveness of 100% will always be obtained.

More recently, a third notion has been introduced: that of *extended use-effectiveness*, to take into account the contraceptive failures occurring after the discontinuation of a method that has been not well tolerated. This amounts to incorporating another dimension of contraception, namely its *acceptability.* What, after all, is

TABLE 31–6 Calculation of the Different Indices in Two Simple Cases[a]

Index	Monthly risk of conception:	
	$p = 0.25$ (without contraception)	$p = 0.0125$ (contraception with 95% effectiveness)

the value of a method that is completely effective if it cannot be tolerated for longer than two or three months? And what else could explain that women requesting abortion are often found to be former pill users, if it is not the low tolerance for this type of contraception by some women?

Table 31–7 illustrates these different problems by giving fairly large ranges of failure rates (theoretical and clinical), use-effectiveness, and the 1- and 2-year continuation rates, for the various contraceptive methods.

Life table methods (a classic tool of demography) allow a maximum use of all the available information, notably when discontinuations and interruptions are frequent (see, for example, Potter, 1960).

5. One Abortion Does Not Mean One Averted Birth

When a woman decides to have an abortion, she averts a live birth. Yet it is inaccurate to think that if, for example, 100,000 abortions are carried out each year in a population, 100,000 births will have been averted in this population. This is because the interval between two births is equal to the sum of the waiting time to conception ($1/p$), a gestation time (g_m), and a *postpartum* nonsusceptible period (t_m). Under natural fertility conditions, plausible values for these three component parts would be 5, 9, and 10 months, or 24 months in total. In the case of abortion, the last two components are reduced to approximately 3 and 1 months, respectively, making a total interval of 9 months instead of the 24 months for a live birth: Therefore 24/9 = 2.67 abortions are needed to avert one live birth. The ratio is, however, close to 1 where there is no breast-feeding (t_m is now only 2 months) and where a contraceptive method is used (which increases the ratio $1/p$). In general, the number of births averted by an abortion is equal to:

$$\frac{[1/p(1-E)] + g_m + t_m}{[1/p(1-E)] + g_a + t_a}$$

where g_a and t_a are, respectively, the durations of gestation and of the *postpartum* nonsusceptible period in the case of abortion.

Fetal Mortality

CATHERINE GOURBIN

Institut de démographie, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Fetal mortality has until now usually been studied as an attribute of other demographic phenomena, whether for its effect on fecundability in the analysis of fertility (Henry, 1964; Wood, 1989) or as a risk factor in the context of infant mortality. It acquired some importance through the concept of perinatal mortality (stillbirths plus infant deaths at 0–6 days) that Peller (1948) introduced to avoid the errors caused by unreliable data on infants' vital status at birth. However, studies on this subject have generally been based on civil registration data and the fetal deaths taken into account are those subject to compulsory declaration.

On that last point, note that registration of fetal deaths was slow to be introduced compared with that of live births. The explanation for this lack of interest is to be sought in the historic origins of civil registration. It is generally accepted that this developed from the parish registers in which baptisms, marriages and burials were recorded (see Chapter 121). The act of baptism allowed the infant to be given the status of a person (or more exactly, a Christian) by freeing it of original sin. Similar thinking informed legislation regulating the declaration of events for civil registration, whereby the newborn child, through birth certification, acquired a legal identity. The latter establishes rights with regard to filiation, inheritance, and settlement but is conditioned by the fact of the child being born alive and viable. Not until the 19th century[1] did most countries adopt the criterion of *gestation duration* and the limit of *28 weeks* (counted from the date of the last menstrual period), which is considered the length of time after which a fetus becomes capable of autonomous existence (Empire français, 1805).

Contemporary developments such as new patterns of fertility behavior (birth control, smaller families), the increasingly technical character of childbearing in the areas of reproduction (*in vitro* fertilization) and medical care for the newborn, the ethical debates over embryo status are combining to give the levels and determinants of fetal mortality greater priority as research topics.

The importance of standardized statistics in this field was illustrated in 1950, when the World Health Organization (WHO) Committee of experts on health statistics recommended that late fetal mortality statistics include only fetal deaths occurring after week 28 of gestation (WHO, 1950a), thereby reaffirming the measures adopted in 1925 by the League of Nations Health Office. Concurrently with this decision, the WHO acknowledged that fetal mortality was a major problem whose full extent was not reflected in the existing official figures. The representatives of the American National Committee on Population Statistics who appeared before this committee quoted the frequency of fetal deaths for 1948 in New York city, where 67% of recorded fetal deaths occurred before week 20 of gestation, 12% between weeks 20 and 28, and 18% after week 28 (WHO, 1950b). The limit of 20 weeks' gestation was in fact the legal limit for declaration of stillbirths in New York. Influenced by this example, the WHO proposed classifying fetal deaths according to the gestation duration at

[1] Except in Sweden and Norway, where the first legal provisions for declaration of stillbirths date from 1686 and 1797, respectively.

which they occur, with the following divisions: *early fetal mortality* (less than 20 weeks), *intermediate fetal mortality* (20–27 weeks), and *late fetal mortality* (28 weeks or more).

I. FETAL MORTALITY LEVELS

Evaluation of fetal mortality levels is necessarily limited by data availability. Conventional demographic statistics derived from the stillbirths recorded by civil registration systems pertain to late fetal mortality only. Many countries use the criterion and limit of 28 weeks' gestation, but the substitution between criteria proposed by the WHO (1000 g in weight, 35 cm in length, or 28 weeks of gestation, for the production of international statistics) creates problems for comparability of the levels, because the limits are not equivalent (Gourbin, 1995). Further definitional disparities arise from the adoption of different limits for the same criterion. Mention was made above of the case (noteworthy) of many states in the United States registering fetal deaths after 20 weeks of gestation from the end of the 1940s, but more recently other countries such as Portugal and Finland have adopted the WHO recommendations (WHO, 1977) for the compilation of national statistics, which provide for reporting all births with a weight of at least 500 g (or 22 weeks of gestation or 25 cm in length).

1. Late Fetal Mortality

Because civil registration declaration of stillborn children is compulsory in developed countries, it can generally be assumed that the number of fetal deaths at 28 weeks or more of gestation is known, at least in those countries with a long tradition of keeping statistical records. Table 32–1 shows the levels of late fetal mortality (or stillbirths, often referred to in French as *mortinatalité*) calculated from these data for the various world regions.

To facilitate international comparisons, the WHO recommends standardization of perinatal mortality rates for weight or gestational duration, including in the calculation only infants with a birth weight of at least 1000 g or a minimum gestation of 28 weeks. In practice, it is usual for the denominator to include the fetal deaths recorded by civil registration

plus all live births regardless of weight or gestation duration.

In Western and Central Europe and the other industrialized countries,[2] late fetal mortality at the end of the 1980s was usually around 4 per 1,000 to 6 per 1,000, levels that are extremely low and, it may be noted, consistently lower than those for infant mortality (Masuy-Stroobant, 1994). This situation is the result largely of more accessible and effective care during pregnancy and at birth, although also of a favorable socioeconomic context. Coverage appears to be complete, and if any bias does occur it tends toward overestimation of late fetal mortality when the legislation specifies the signs of life by which to recognize a live birth[3] (presence of heart beat or respiration in Austria and Switzerland) or when infants are included who were live born but died before their birth was registered, or in the 24 hours after birth (Gourbin and Masuy-Stroobant, 1995).

Data on late fetal mortality are conspicuously lacking in Africa and some South American and Asian countries due to civil registration systems that are still defective or to the lack of statutory provision for the declaration of stillbirths. Local surveys have attempted to estimate levels of perinatal mortality; conducted in the 1970s, these studies situated late fetal mortality at between 18 per 1,000 (Kinshasa, Zaire) and 95 per 1,000 (Mulamfashi, Zambia). However, these surveys were carried out on women giving birth in hospitals thus it would be unsafe to generalize these levels. Furthermore, differences in collection procedures and high levels of drop out from the initial samples undermine the validity of the results and make comparison impossible (Nzita Kikhela, 1986).

Using the surveys conducted in the *World Fertility Survey* (WFS) program, Casterline (1989) has attempted to evaluate levels of fetal mortality, whether the event is classified as a miscarriage (before 28 weeks of gestation, the pregnancy having been recognized by the mother) or a stillbirth (28 weeks and over). For an observation period limited to the 5 years preceding the survey, comparison of 22 African, South American, and Asian countries shows the percentage of pregnancies ending with fetal death (miscarriage plus stillbirth) to vary between 5.6% (5.2 + 0.4) in Ghana and 20.4% (17.8 + 2.6) in Guyana. In countries where induced abortion is authorized, an induced abortion is less likely to be deliberately misreported as a spontaneous abortion and so the figures will be more reliable. Overall these estimations appear to give 50% to 80% coverage of fetal deaths compared with the results obtained from intrauterine mortality life tables (see below). Despite results that it might have been fruitful to develop in subsequent research, those in charge of the *Demographic and Health Survey* (DHS), which was partly a continuation of the WFS, decided to discontinue collection of this kind of data, judging that the costs outweighed the potential returns (Casterline, 1989).

[2] Excluding the newly industrialized countries of Asia.

[3] The live-born child who dies a few moments later without having presented these signs will be recorded as stillborn on condition of satisfying the criteria for stillbirth declaration.

2. The Risks of Fetal Death in Pregnancy

Although levels of late fetal mortality can be evaluated in countries with a long tradition of statistical record keeping, the situation is different when analysis encompasses the entire duration of pregnancy. Estimation of the risk will depend closely on the study protocols for early pregnancy detection. Before reviewing these, a short description of the hormonal responses initiated by conception is useful for understanding the difficulties associated with measurement of very early fetal loss.

Pregnancy Detection

Ovulation in the human female occurs on average about 15 days after the start of the last menses.[4] Between 36 and 40 hours before ovulation there is a surge in production of LH (luteinizing hormone) that unblocks the meiotic process of the ovum. A fertilized ovum moves through the fallopian tube to the uterine cavity, reaching it 3 to 4 days later. Finally, 1 week after ovulation, the embryo attaches to the lining of the uterine wall. This implantation is accompanied by an increase in production of the hormone hCG (human chorionic gonadotrophin).

Early detection of pregnancy (and its development[5]) is based on identification of the surges in hormone production. Research reviewed by Wilcox *et al*. (1993) involved establishing the serum presence of a protein known as *early pregnancy factor* that is detectable within 24 hours of fertilization. Measurement of this factor is problematic, however, and doubts exist over its specificity as a marker of pregnancy. What happens to ova in the first week after fertilization remains uncertain, and the study by Hertig (1959) to determine the risks of subclinical loss remains unique in this field, both for

[4] To be exact, between the 8th and 24th days.

[5] *In vitro* pregnancies are not considered here.

the information obtained and for the methods used. This study was conducted on women undergoing hysterectomy for reasons other than pathologic states that could prevent fertilization. The patients were asked to have sexual intercourse around the presumed date of ovulation and the operation was carried out in the days that followed. Any product of conception that existed was removed. Histologic examination was performed to determine the egg's developmental stage and the normal or abnormal character of its evolution. The results obtained, however, have been subject to differing interpretations (Leridon, 1973). In summary, of all the conceptions observed, 37% would result in a live birth, whereas half of all fertilizations, that is potential pregnancies, would end in fetal death before the end of week 4 of gestation. Over and above the ethical problem raised by the methods used to obtain these results, a number of criticisms can be made:

Measurement of the rates is based on too few observations;

The study conditions: Hysterectomy is rarely performed on women younger than 30 years, yet risks of fetal death are known to increase with age;

The hypotheses underlying the results: (1) All morphologically abnormal conceptions end with expulsion of the fertilized ovum and (2) these are the only conceptions to end in this way. Although the first hypothesis appears correct in most cases, it is unsafe to assume normal embryo development solely on the basis of an oocyte's normalcy at a very early stage of development (Kline *et al*., 1989).

Notwithstanding these criticisms, Hertig's study drew attention to the extremely high levels of intrauterine mortality during the first weeks of pregnancy. It also showed (or confirmed) that the series of risks associated with the different stages of the gestation period declines exponentially at the start of the pregnancy. Although other studies have confirmed this hypothesis, estimations of total risk levels and of variation in fetal mortality rates by gestation duration remain unclear, the results obtained being heavily influenced by the aims and protocols of individual studies (Modvig *et al*., 1990).

II. INFLUENCE OF DATA COLLECTION METHODS

The most frequently made criticism of retrospective studies concerns the bias caused by misreporting of events. In the field of fetal mortality, the three most common biases are the following:

A fetal death can be forgotten, this recall failure depending on socioeconomic factors, the gestational age at which loss occurs, and the length of time since the event[6];

Irregular menstrual cycles can be confused with spontaneous abortion;

An induced abortion can be presented as a spontaneous abortion.

In addition, retrospective studies that cover women's complete reproductive histories (Tietze, 1948; Risch *et al*., 1988) and calculate the risk of fetal death in relation to all recorded pregnancies are liable to overestimate fetal mortality by overrepresenting the least fertile women if these are trying to achieve a desired number of children (the problem is identical in panel surveys).

The recruitment of women for *prospective surveys* depends on whether the study aims to identify very early fetal losses or those occurring after a first missed menstrual period. In the former case, the participants are all volunteers, want to have a baby, and agree to submit to the strict biologic observation[7] necessary for very early detection of pregnancy (Edmonds *et al*., 1982; Wilcox *et al*., 1988, 1993). Pregnancy is detected by measuring urinary concentration of the hCG secreted by the placenta after implantation.[8] Detection of this hormone is the basis of early pregnancy diagnosis and the accuracy of the result depends on the specificity of the assay used.[9] In the second case, the study uses women who enter observation at the point when their pregnancy is clinically recognized (medical visit or ultrasound scan), or who agree to keep an accurate menstrual record and to report any pregnancy that is followed by a recognized fetal death

[6] On the latter points, the comparison by Wilcox and Horney (1984) of data from a study of spontaneous abortions recorded in hospital when they occurred with those obtained by retrospective questioning of the same women, show that 25% of subjects did not recall having suffered a spontaneous abortion. This difference was directly related to the gestation duration at which death took place and to the length of time since the event: the coverage achieved was 82% if the fetal death took place in the 10 years before the survey, 73% if it occurred more than 20 years earlier.

[7] Urine specimens had to be taken every morning and stored in the refrigerator for collection once a week by the laboratory doing the analyses.

[8] Then implantation occurs, a large and rapid rise is observed in hCG circulating rates. This hormone, with others, stimulates hormonal production and maintains the pregnancy.

[9] It is noteworthy that the results of the studies conducted before the mid 1980s are better than those obtained subsequently, these differences apparently being due to the non-specific nature of the assay (Wilcox *et al*., 1993).

TABLE 32–2 Estimation of Risks of Fetal Death by Recognized Pregnancy in Various Studies (per 100 Pregnancies)

Sources	Date and place of study	Study type	No. of pregnancies	Risk of fetal death, %
Tietze *et al.*, 1948	1937–1946 United States Baltimore	Prospective, prenatal visit	10,397	12.2
		Retrospective	30,133	17.0
Leridon, 1976	1971 France Créteil	Prospective, prenatal visit	1,304	11.5
		Retrospective	2,248	15.3[a]
Wilcox *et al.*, 1981	1961–1970 United States Minnesota	Prospective, menstrual cycle monitoring	1,493	13.1[b]
Edmonds *et al.*, 1982	1980–1981 England Southampton	hCG measurement	118	62.0
Wilson *et al.*, 1986	1981–1983 Canada Vancouver	Prospective, first ultrasound scan	747	2.9
Risch *et al.*, 1988	1974–1978 Canada and United States	Retrospective	6,282	12.8
Santow and Bracher, 1988	1986–1987 Australia	Retrospective	6,213	15.1
Wilcox *et al.*, 1993	1983–1985 United States Columbia	hCG measurement	197	32.0
Gourbin, 2000	1984–1988 Hungary	Statistical registration records	708,950	12.1

hCG, human chorionic gonadotropin.
[a] Induced abortions are excluded from the denominator.
[b] Until week 20 of gestation.

(even if the facts have not been clinically diagnosed) (Wilcox *et al.*, 1981).[10] Some of these prospective studies have been used for constructing intrauterine mortality life tables.

Table 32–2 shows the differences in estimation of risk according to the method used. The mortality rates were calculated by dividing the number of fetal deaths by the number of recognized pregnancies. Except for the study by Harvey Risch *et al.* (1988), retrospective surveys find levels of risk of fetal death higher than those estimated in prospective studies. Heterogeneity among individuals is partly responsible for these differences—women who have had the desired number of children avoid becoming pregnant again, whereas women who have suffered repetitive spontaneous abortions go on trying in the hope of a favorable outcome. In other words, the number of pregnancies will be influenced by the outcomes of previous pregnancies. Furthermore, some of the fetal deaths reported over the woman's reproductive life in retrospective studies have occurred before any medical visit or too early in gestation for hospitalization to be necessary. In most prospective studies, however, entrance to observation is at the initial prenatal visit. Since fetal death occurs mainly in the first weeks of pregnancy, the levels of intrauterine mortality will depend closely on how early this visit takes place. Lastly, it can be noted that a study based on a systematic recording of fetal deaths in Hungary shows a level of risk of fetal mortality similar to those observed in prospective studies (Gourbin, 2002).

[10] The level of fetal mortality in the former case will be closely related to the gestation duration recommended for the start of prenatal visits (thus conditioning an earlier or later recognition of the pregnancy) or for the first ultrasound scan. In the second case (self-observation), the results can be biased by the greater or lesser vigilance (or ability) of the women in spotting the signs of pregnancy, or by irregular menstrual cycles.

III. INTRAUTERINE MORTALITY RATES BY GESTATION DURATION

Although prospective surveys are more reliable for estimating fetal death frequencies, we also need to know the distribution of these deaths at the different stages of pregnancy in order to analyze the variation in the risk of fetal death by gestation duration and to evaluate the total level of intrauterine mortality. This approach has been used in some studies and has led to the construction of intrauterine mortality life tables, the first of which, published by French and Bierman in 1962, remains a reference in this field (Kline *et al.*, 1989; Leridon, 1977). In theory, the life tables should be constructed using probabilities that allow for the different pregnancy outcomes that can be competing with death—each of these outcomes is exclusive, so if one occurs the other cannot. This is the case between fetal mortality and induced abortion in early pregnancy, therapeutic abortion during pregnancy, and live birth at full term. In the six series of fetal death probabilities presented here (Table 32–3), French and Bierman exclude live births from the denominator, Ehrardt (1963) estimates the probabilities (see below), Shapiro *et al.* (1962) do not give a clear explanation of the method used, Taylor (1960) and Goldhaber and Fireman (1991) compute daily proba-

TABLE 32–3 Risk of Fetal Death by Gestation Duration in Different Studies (for 1000 Recognized Pregnancies)

Gestation duration, weeks	Survey					
	French and Bierman (1962) Kauai Island, Hawaii, 1953–1956	Schapiro *et al.* (1962) New York, United States, 1958–1959	Erhardt (1963) New York, United States, 1960	Taylor (1970) California, United States, 1959–1966	Goldhaber and Fireman (1991) California, United States, 1981–1982	Gourbin (2002) Hungary, 1984–1988
4–7	108.1	13.7	82.4	61.2	23.1	20.1
8–11	69.9	58.8	67.1	48.7	56.3	40.8
12–15	44.8	40.0	28.2	25.3	33.3	20.2
16–19	13.3	14.0	10.7	11.0	11.5	9.3
20–23	8.5	6.5	8.9	7.7	4.4	7.1
24–27	3.2	3.6	2.1	3.3	2.4	4.0
28–31	3.0	2.2	4.3	3.6	1.5	1.8
32–35	3.0	2.6	2.0	3.3	1.5	2.0
36–39	3.4	4.0	6.9	4.2	1.0	2.9
40+	6.8	9.3	10.8	14.3	2.5	3.0
Total risk	239.6	145.8	182.4	170.0	130.8	121.0

bilities,[11] and Gourbin (2002) estimates single-decrement probabilities of fetal loss to allow for induced abortions.

Whichever method is used, determining the risks encounters two major problems:

The number of fertilizations cannot be known because of the difficulty, if not impossibility, of detecting the very earliest stages of pregnancy, which is when large numbers of zygotes[12] are lost;

The risk of death by gestational age is usually calculated for the gestation duration at which the fetus (or embryo) is expelled. However, death can occur well before this expulsion and the resulting difference between fetal age (length of time between fertilization and fetal death) and gestational age can be very large (Boué and Leridon, 1971); fetal age is extremely hard to ascertain, and the risks of fetal death are usually calculated for the gestation duration at the time of expulsion.

[11] Estimation of the rates included extrauterine pregnancies for the tables of French and Bierman and Shapiro; conversely, women whose pregnancy ended with fetal death in the 2 days following the medical visit were excluded for the tables of French and Bierman, Taylor, and Goldhaber and Fireman.

[12] Development of the fertilized egg in the uterus is reflected in a changing terminology: From fertilization to day 19, we speak of an egg or a zygote, from day 20 to month 3 is the period of embryogenesis, and from month 4 to term is the period of fetal development. For the sake of simplicity the term *fetal death* is mainly used in this chapter.

From week 4 of gestation, the total risk of fetal mortality varies between 24% and 12%, a disparity that is due mainly to the level of mortality between 4 and 8 weeks. The lower fetal mortality rates between 4 and 7 weeks reported in studies by Goldhaber and Fireman and Gourbin, are evidence of an underrecording of fetal deaths at these low gestation durations. After 8 weeks of gestation, the six series of mortality probabilities follow the same pattern of intrauterine mortality, characterized by a probability of fetal death that is very high at the start of the pregnancy and declines rapidly up to week 20. It remains fairly constant between gestational weeks 24 and 36 before rising slightly at the higher gestation durations. The series of mortality probabilities published by French and Bierman, which is considered the most reliable, especially for the early stages of pregnancy, is a good example of this mortality pattern—the risks of fetal morality decline in a completely linear fashion up to week 20, then stabilize, before increasing after week 40. It should be noted, however, that the more recent studies by Goldhaber and Fireman and Gourbin find only a small increase in risk at the end of normal pregnancy duration, probably as a consequence of medical interventions for pregnancies that have gone beyond the forecast term. Ehrardt assessed intrauterine mortality during the early weeks by extrapolating the level of intrauterine mortality in weeks 8 to 11 (judged to be reliable) to calculate the rates for 0 to 4 weeks and 4 to 7 weeks. For the period 0 to 4 weeks the value of the rate was 11%, corresponding to a total risk for the pregnancy of 29%, a level that is still below the 32% estimated by Allen Wilcox *et al*. (1988) from hCG concentrations and for the period from 3 weeks' gestation (or 1 week after fertilization) to the end of the pregnancy. Although this estimation is considered one of the best currently available, the frequency with which zygotes are lost during the very first week of their development remains an unknown.

IV. THE DETERMINANTS OF FETAL MORTALITY

Research in this field was for long limited to work by the United Nations (1954) and Morris and Heady (1955) on the determinants of late fetal mortality and that by Shapiro *et al*. (1962) and Taylor (1970) who, when constructing their intrauterine life tables, highlighted the role of biologic variables (mother's age, parity) in the etiology of fetal mortality. The 1970s and 1980s saw a growth in studies on perinatal mortality, most of which failed to distinguish between late fetal mortality and early neonatal mortality, the two phenomena being thought to have identical determinants. Gradually, however, more research has been done into the biologic and social determinants of fetal mortality, stimulated by new models of family formation, improved obstetrical and neonatal techniques, and spectacular advances in fetal medicine. Due to the scarcity of data, however, this research usually concerns only late fetal mortality.

1. Biologic Factors

Genetic Abnormalities

The literature of demography (relatively poor in this respect) and epidemiology identify chromosomal and genetic anomalies, which are usually incompatible with fetal development, as the main causes of first-trimester intrauterine mortality (Simpson and Carson, 1992; Kline *et al*., 1989; Boué and Leridon, 1971). According to these authors, 50% to 60% of first-trimester fetal deaths are due to chromosomal anomalies, of which the most common are autosomal trisomies (responsible for approximately 25% of deaths) and monosomies X (about 20% of deaths). Although several studies have reported broadly similar frequencies, underreporting is potentially large given that successful karyotyping is influenced by the type of tissue used for culturing and by the length of time until expulsion, which may be long if the embryos with anomalies have died very early in gestation. In addition, these figures do not include deaths in the first week after fertilization, although elimination of the zygote in this period probably results from severe chromosomal abnormalities[13] (Kline *et al*., 1989). Once through the first trimester of pregnancy, the malformations that can affect embryos are usually compatible with their development (although these anomalies have a higher frequency among fetal deaths than among liveborn infants [EUROCAT, 1995]) and other factors, biologic and social, acquire a determinant role in explaining fetal mortality.

2. Other Biologic Factors

The other biologic factors relate to the mother or to the infant itself and are chiefly age, reproductive history, and health status of the mother; the sex of the fetus; multiple pregnancies; and retarded intrauterine growth. The studies used in the construction of intrauterine mortality life tables also analyzed the relationship between maternal characteristics and fetal mortality, thus making it possible to evaluate their impact on mortality before 28 weeks of gestation.

Maternal Characteristics

Fetal mortality varies considerably over the mother's reproductive career and this variation in risk can be examined using the conventional characteristics of *age* and *parity*. Their influence on late fetal mortality was evaluated in 1938 by Yerushalmy (quoted by Morris and Heady, 1955); Shapiro *et al*. (1962) emphasized their importance throughout fetal life by describing the increasing risk of death with age and parity. Other aspects of women's reproductive life are also implicated.

Maternal age[14]. The risk of fetal mortality is lowest (around 11 per 1,000) when the mother is aged 20 to 24 years. This risk doubles between ages 20 and 40. Harvey Risch *et al*. (1988) have even reported a risk of fetal death before 28 weeks multiplied by 3 for women aged 45 compared with women aged 20. Similarly, a study describing fetal mortality profiles by gestation duration, reports risks of fetal mortality after 28 weeks of gestation multiplied by 4 for women over 40 compared with women aged 20 to 24 years, and a risk multiplied by 6 at the start of pregnancy (8–11 weeks) (Gourbin, 2002).

This increase is due partly to the specific effect of aging on the woman's reproductive capital and the accumulation of pathologic risks or morbid conditions,

[13] Experimental studies carried out using mice have shown an incomplete chromosome set to be responsible for the loss of zygotes in this period.

[14] The impact of paternal age on fetal mortality has rarely been studied. It seems however that it plays a role too (Rychtarikova *et al*., 2004).

but also to the effect of heterogeneity described earlier. The risk is also higher among very young women (under age 18) though the relationship is hard to evaluate because the small numbers that can be observed mean that the probabilities of dying are subject to large random variations.

Parity. The risk of fetal mortality is slightly higher in primiparous women, falls back at birth orders two and three, and then rises steadily in the higher parities (Pinelli, 1984). Some studies have claimed a doubling of risk from the sixth birth (Heady *et al*., 1955; United Nations, 1954). The differences in risk between first births and second and third births are not always obvious (Leridon, 1976; Bross and Shapiro, 1982), and regardless of the birth order considered, the results have to be qualified to allow for the difficulty of distinguishing the effects of age from those of parity (Wilcox and Gladen, 1982; Risch *et al*., 1988). A study conducted in Finland on early and intermediate fetal deaths found a higher risk only when the mother was aged 25 or over with at least of parity three (Hemminki *et al*., 1983). Similarly, an increased risk is observed for primiparous women at age 40 and older. These types of combinations (low age and high parity, or vice versa) appear to be the most problematic for fetal survival, suggesting that the association between parity and fetal mortality reflects other risk factors.

Interval between live birth and fetal death. Family planning programs have often drawn attention to the U-shaped curve of risks associated with the length of interval since previous pregnancy. Risks are particularly high for intervals of less than 9 months (Casterline, 1989) and even 6 months (10.9 per 1,000 versus 5.5 per 1,000 for the 13- to 24-month interval) (Kallan, 1992) and at the other extreme for intervals of over 60 months. In the former case, excess fetal mortality is explained by the fact that repeated and closely spaced pregnancies prevent the mother from recovering a satisfactory physiologic state (Gribble, 1993; Dupin and Rimbault, 1978). In the latter case, excess risk arises from subfecundity or an impaired endocrine function that prevents the mother from carrying a pregnancy to live birth.

Previous fetal deaths. The above argument would explain the close association observed between the number of previous fetal deaths and the risk of recurrent fetal death. Leridon (1987) notes that in a third pregnancy the risk of fetal death is around 20% to 25% if one of the earlier pregnancies has ended with intrauterine death; a similar risk (20%) was observed by Risch *et al*. (1988). Gourbin (2002) found risk of fetal death between 16 and 28 weeks of gestation more than doubled for women who had suffered one previous fetal death and more than quadrupled for those who had suffered two or more previous fetal deaths, compared with women who had never had a fetal death in their previous pregnancies. This repetition of the fetal death outcome in successive pregnancies can be seen as evidence of the heterogeneity already described (i.e., of interindividual variability in the capacity to conceive and produce a live-born baby). In this model, fetal death is a risk marker for a higher frequency of fetal death in future pregnancies. However, the occurrence of a fetal death is also a potential risk factor, in that fetal death can be a source of infections responsible for spontaneous abortions in future pregnancies.

Previous induced abortions. Most studies show that in the countries where abortion is legal, carrying out an induced abortion does not increase the risk of fetal death in subsequent pregnancies (Frank *et al*., 1991; Chung *et al*., 1982), except however in the countries where traumatic techniques are in use (WHO, 1979; Kline *et al*., 1978). The risks described in the latter case were thus due to the methods used to perform this intervention, the problem being especially acute in the countries which had legalized induced abortion very early (at the end of the 1950s) (WHO, 1979; Kline *et al*., 1978). Results from the study using Hungarian data (Gourbin, 2002) show risks of fetal death before 28 weeks of gestation at least 60% higher for women who have already had an induced abortion compared with women who have not, and the risk is more than double for women who have had two or more previous induced abortions. Today, the move away from techniques involving excessive and violent dilations of the cervix has reduced the risks of cervical incompetence, which is a risk factor for spontaneous abortion and prematurity. In the countries where abortion is illegal, recourse to clandestine abortion carries a risk of infections which are potentially serious, with consequences for the woman's subsequent reproductive career.

Maternal health status. In addition to risk behaviors such as smoking and drinking (discussed later), a number of pathologic conditions can affect fetal survival. These may be anatomic (serious uterine malformation), metabolic (diabetes), autoimmune (maternal-fetal blood incompatibility,[15] lupus erythematosus), chronic (renal or cardiac insufficiency), plus infections. Not all contribute equally to the etiology of fetal mortality, but the importance of some of them has been quantified. Uterine malformation, which occurs in 0.1% of women, causes spontaneous abortions in as

[15] Fetal-maternal blood incompatibility usually involves Rhesus sensitization: if the mother is Rhesus negative (Rh–; recessive characteristic) and the father Rhesus positive (Rh+; dominant characteristic), the mother who has been immunized against Rh+ in a previous pregnancy possesses antibodies that will cross the placenta and cause hemolysis of the fetal red blood cells of group RH+.

many as 25% of cases (Simpson and Carson, 1992). Even when well-controlled, diabetes still accounts for nearly 7% of late fetal deaths (Thomas, 1989). Pregnancy toxemia (arterial hypertension and edemas caused by pregnancy) and eclampsia (convulsions due to raised blood pressure) remain major causes of fetal and perinatal mortality. Of infectious diseases present in developed countries, toxoplasmosis and cytomegalovirus infections are responsible for intrauterine deaths or embryopathies if the nonimmune mother becomes infected during pregnancy. The figures are not comparable, however, with those for infectious diseases in developing countries, where malaria and sexually transmitted diseases are the main pathologies implicated in fetal death.

Malaria. Malaria can lead to fetal death through several clinical mechanisms.

1. Bouts of fever in the pregnant woman can cause a fetal tachycardia that results in death.
2. The severe anemias malaria produces can lead to increased fetal morbidity due to iron deficiencies.
3. In the case of malaria, the parasite *Plasmodium falciparum* is able to cross the placenta and cause it to dysfunction, thus preventing adequate nutrition of the fetus. This species of plasmodia is especially serious in a pregnant woman because it is estimated that nearly half of malarial episodes with *P. falciparum* that occur during pregnancy result in fetal death (Gentilini, 1993).

Sexually transmitted diseases. Gonorrhea and syphilis have direct consequences for women's reproductive careers, the former causing sterility by tubal obstruction, the latter increasing significantly the risk of fetal death. The lack of standardized data makes estimations difficult. Nevertheless, according to the WHO, more than a third of pregnancies in women suffering from untreated syphilis end with a late fetal death (Rowe, 1994).

Fetal Characteristics

Sex. According to a survey conducted by the WHO in several countries on the determinants of perinatal mortality (WHO, 1978), the infant's sex has an uncertain role in late fetal mortality, because the results vary from country to country. However, an analysis of the data for England and Wales by Waldron (1983) shows that the excess male mortality existing before 1960 subsequently declined and the differential is now almost nonexistent. The hypothesis put forward to explain this decline is of a change in the causes of excess male mortality. Because boys usually have a higher birth weight than girls (for the same gestational age), their delivery can take longer, thus increasing the risks of fetal distress and death during birth. This would imply that boys have gained most from the improved obstetric techniques that are responsible for a reduction in mortality from hypoxia and trauma. Early and intermediate fetal mortality by sex is harder to study because of the technical difficulty of determining fetal sex in the case of spontaneous abortions, difficulties caused by the excessive interval between fetal death and expulsion, or by an X monosomy[16] that leads to identifying a fetus as male. On this last point, improved identification techniques now make it possible to detect real X monosomies or those due to prior loss of another X or Y chromosome.

Multiple-fetus pregnancies. Multiple-fetus pregnancies are associated with increased risks of prematurity and growth retardation and late fetal mortality. Kiely (1990) used data for New York City between 1978 and 1984 to analyze perinatal mortality in multiple births and found late fetal mortality rates three times higher than those in single births. Similarly, a study of late fetal mortality in multiple births using data for 1994 for England and Wales showed a risk four times higher than for simple births (Office for National Statistics, 1994). Placental structure may be a contributory factor in this excess fetal mortality, with a monochormial placenta for a multiple-fetus pregnancy increasing the risk of *in utero* death or malformations.

Fetal development. Intrauterine growth retardation is the most common complication of elevated maternal arterial blood pressure during pregnancy, with a frequency roughly double that of normotensive women (Boutroy, 1995). The prognosis is more unfavorable the earlier in gestation the retardation begins and usually leads to the birth being induced.

3. Social Factors

Fetal mortality is no exception to the social inequalities in mortality patterns observed at all ages. Here we consider only those variables that are generally considered to be the most relevant (and the easiest to observe) for identifying the factors associated with the greatest risks to fetal survival. It is now accepted that the characteristics should be primarily those of the mother, since she alone has access to prenatal care facilities. Lack of data means that the available results usually apply to late fetal mortality only.

Legitimacy. That children born out of wedlock and without paternal recognition (illegitimate) suffer high excess mortality has long been known. The increased

[16] It can be recalled that the pair of sex chromosomes is XX for females and XY for males.

risk is due partly to the mother's social isolation, combined with less favorable economic conditions. This risk persists despite changes in patterns of behavior that have led to a growing number of extra-marital births and greater social acceptance of the phenomenon. Statistics derived from civil registration data (1985–1990) show that with the exception of Denmark, Iceland, and Sweden, all the European countries have excess late fetal mortality for extra-marital births, the relative risks ranging between 1.3 and 1.9 (except for Spain where it is 2.7). At present the inequality is even greater for late fetal mortality than for infant mortality (Burban, 1996). At shorter gestation durations (8–20 weeks), unmarried women have risks of fetal mortality double those for married women (Carlson *et al*., 1999, Gourbin, 2002).

Immigrant or nonimmigrant status, culture and social group. Studies have reported higher than average late fetal mortality for women of North African origin in France, for women of Pakistani origin in England, and for black women in the United States (Saurel-Cubizolles *et al*., 1986; Macfarlane and Mugford, 1984; Buck *et al*., 1995). With the role of biologic factors rejected, the first explanation put forward is that of membership of socially disadvantaged strata. However, the fact that these differences are found to hold after socioeconomic level is controlled for has opened the way for other explanatory hypotheses. These are based on the individual's cultural environment and more specifically on the different health-related values and norms that are transmitted to children in the home. The family equips its members with a model of reactions that reflects their group of origin. Geographic origin and *race* (as used in the United States to distinguish individuals by their skin color or geographic origin) are thus indicators of varying precision and relevance for the existence of behavioral differences.

Maternal education. The mother's educational level is an indicator of her ability to adopt health-promoting behaviors during pregnancy and make effective use of prenatal care services (Rutter and Quine, 1990; Masuy-Stroobant, 1988). Most studies report an excess late fetal mortality of between 30% and 80% for infants of the least educated women (Cnattingius and Haglund, 1992; Notkola and Valkonen, 1989). On the other hand, the study by Taylor that analyzed fetal mortality from month 4 of pregnancy detected no significant association with the mother's educational level at any gestation duration. This result could be explained by the small number of fetal deaths in each of the groups examined. Moreover, the two studies conducted using Czech and Hungarian data, each including several thousand fetal deaths, found higher risks of second-trimester fetal mortality for women of low educational attainment (Carlson *et al*., 1999; Gourbin, 2002).

Social class. Social inequality in mortality has often been equated with membership of a particular social class (or social group or socio-occupational group). Commonly defined in terms of occupational groups (England, Finland), the social classes influence mortality through other characteristics they are assumed to reflect; the educational levels and incomes associated with different occupations thus serve as indirect indicators of the material environment and health behaviors of women and households (on this subject see the Chapter 54). In England, the first country to define social class categories along these lines,[17] analysis of differential mortality is based on the father's characteristics, thus excluding from analysis all children born out of wedlock. A difference in late fetal mortality between extreme social classes is observed regardless of period, country and gestation duration. For England the relative risks when comparing late fetal mortality in social class V (highest mortality) with social class I (lowest mortality) are approximately 1.7 for 1934 and 1.5 for 1989. In Finland, a study by Hemminki *et al*. (1980) between 1973 and 1975 reports a risk of fetal mortality before 28 weeks of gestation of 5.9 per 1,000 for the highest class, compared with 8.5 per 1,000 for the class composed of unskilled workers (representing a relative risk of 1.5). However, although membership of a disadvantaged social group appears to be a risk for the fetus, the concept's vagueness and multidimensional nature make it hard to elucidate the causal mechanisms responsible for this increase in risks: Does it reflect barriers (financial and educational) to getting access to care, inappropriate health practices, the mother's employment situation, or a combination of several of these different factors?

Mother's employment situation and occupation. The influence of mother's employment on fetal mortality cannot be judged without reference to social constructs of female employment and without knowing the characteristics of the work environment. Until the middle of the 20th century, surveys conducted on the mother's *employment situation* and her *status in the profession* usually reported adverse effects. Since then, as a consequence of far-reaching changes in the structure of women's occupations and in the characteristics of economically active women, the influence of female employment on pregnancy has changed. Thanks to

[17] Elaborated in 1911 by Stevenson and based on the father's occupation and the social position it conferred, the classes were formed by grouping the occupations according to their common characteristics and the differences in mortality rates of each occupation (Quoted by Macfarlane and Mugford, 1984).

legislative measures to protect mothers during pregnancy, women employees benefit from certain rights and are better informed about prenatal care facilities (Saurel-Cubizolles and Kaminski, 1986). Regarding the actual *occupation* of the mother, findings vary depending on the indicators used to collect the information: occupation narrowly defined, socio-occupational category, or industry sector. The imprecision of information about *occupation* (inaccurate reporting, work characteristics often unspecified) impedes reliable evaluation of differences in risks. Results from several studies, however, indicate risks of spontaneous abortion (defined in these studies as fetal death before week 28 of gestation) that are significantly higher when the difficulty of the work (posture, heavy lifting, stress) is taken into account (Bryant and Love, 1991; McDonald *et al*., 1988). The *socio-occupational categories* were constructed to examine the relationship between different occupations and social behavior, but in most studies occupations are combined at very broad levels of aggregation. The resulting categories are too large and too heterogeneous to give an accurate representation of the associated risks. The *industry sector* refers more specifically to the risks related to the occupational environment, but inadequate information about the products with which individuals come in contact means that it is seldom possible to infer the toxicity of particular products.

Toxic substances and occupational environment. Research into substances with adverse effects on reproductive health has progressed since the discovery (in 1961) of thalidomide's role in causing congenital malformations. It has been extended to cover substances present in the occupational environment, and studies conducted mainly in developed countries have increased understanding of the risks associated with an array of toxins. These risks include impaired fertility in the mother (or father), and teratogenic or mutagenic effects leading to congenital malformations and spontaneous abortions. Unfortunately it is extremely difficult to isolate the contribution of the toxic products and distinguish it from other risk factors (behavioral), and the difficulty of evaluating the dose-response relationship is a further obstacle to identifying a link between polluting agent and health status. Are the effects cumulative (when exposure precedes pregnancy, but causes an accumulation in body tissues or damage to the reproductive system with potentially detrimental consequences for a future pregnancy), or are they adverse only if exposure occurs actually during pregnancy? In the latter case, are the effects constant or do they depend on the stage of pregnancy at which exposure occurs (Selevan, 1991)? In studies of the relationship between occurrence of spontaneous abortion and exposure to toxic products in the occupational environment, the most commonly observed group are women working in hospitals, where two substances have been identified as potentially harmful to fetal survival—antineoplastic agents, responsible for spontaneous first-trimester abortions, and ethylene oxide (better known as ether), with a risk of fetal death increased by 130% for the first toxin and by 60% for the second[18] (Hatch and Marcus, 1991). Several studies have also found harmful effects for organic solvents, such as toluene, which become more marked with daily exposure. They are also thought to have a renal toxicity associated with a maternal hypertension that is detrimental to the fetus. High exposures, like those experienced by house painters, can have a toxic effect on the male reproductive system and mutagenetic effects during spermatogenesis (Baker, 1994). Results from a recent study have shown that women exposed to solvents during pregnancy have a higher risk of giving birth to a child with multiple congenital malformations or malformations of the digestive system. Other research has tried to determine the toxicity of specific products (cadmium, lead, pesticides) on fetal development, but the results are often contradictory, due to imprecise information on exposure, the difficulty of forming control groups, or variables that are too numerous to control. Finally, a toxic substance may go unidentified if its effects cause the death of the zygote before the pregnancy has been recognized.

Other risk situations, both common and rare, are also possible. The risks of genetic mutations in the case of fetal exposure to ionizing radiation are known: they are greatest at the start of pregnancy, during the period of embryogenesis when the organs are being formed. If a therapeutic radiograph has been performed before the pregnancy was recognized, it is advisable to evaluate the dose of radiation that has been administered. It should be noted, however, that these risks are very low in the case of routine radiography. In exceptional situations, involving massive irradiation of the fetus (Hiroshima atomic bomb, Chernobyl nuclear accident), increases in perinatal mortality (Kato, 1971; Korblein and Kuchenhoff, 1997) and of morbidity in the early years of life (cancers of thyroid, acute leukemias) have been documented (Leenhardt and Aurengo, 2000; Noshchenko *et al*., 2001). Although these effects appear undeniable in the case of exposure to high doses of radiation, determining a threshold dose beyond which radiation can be teratogenic or cause intrauterine death proves difficult.

[18] These products are thought not to act, however, on the germinal cells or to have cumulative effects.

4. Behavioral Factors

Discussion will be limited here to alcohol consumption and smoking, both of which are hard to evaluate. The factors that determine these behaviors are social and cultural (education, income, social class, religion), and psychological (acceptance of the pregnancy, in particular). Drinking and smoking during pregnancy are usually reported to have a probable effect on fetal development, manifested for the former by retarded psychomotor development termed the *fetal alcohol syndrome* and for the latter by low birth weight. The effects appear less clear regarding a relationship between smoking or drinking and fetal death, and the results are the subject of much debate, the main problem being over the choice of variables to be controlled (since these behaviors are often associated with other risk factors) (Simpson and Carson, 1992; Kline *et al*., 1989).

Smoking. Cigarette smoking is a known risk factor for retroplacental hematomas and *placenta praevia*[19] (English and Eskenazi, 1992) that can lead to fetal death. But the direct relationship that has sometimes been observed between smoking and fetal mortality either disappears when alcohol consumption is controlled for (Harlap and Shioni, 1980) or is found to be completely nonexistent (Axelsson *et al*., 1984).

Alcohol. A number of studies have reported a correlation between increased fetal loss and alcohol consumption during pregnancy (Harlap and Shiono, 1980), possibly due to formation of a retroplacental hematoma (Kaminski *et al*., 1976; Little *et al*., 1986). However, a threshold of consumption beyond which a harmful effect can be observed proves hard to define (Kline *et al*., 1989).

This short literature review has made it clear that most first-trimester fetal deaths result from chromosomal and genetic abnormalities that are incompatible with fetal development. The *age of the mother* at fertilization, associated with an aging of her reproductive capital, is partly responsible for these anomalies in women aged 35 and over, although malformations can also result from exposure to certain toxins. Except for these effects on embryo structure, the weight to be assigned to the various factors of fetal mortality after the first trimester of pregnancy is hard to evaluate. Positive or nonexistent associations are reported for the same factor by different studies, reflecting inadequate sample size or the number of variables examined. Furthermore, the distinction between broad categories of variables is purely theoretical, and some variables relate to dimensions that are as much social as biologic. Thus maternal age and parity are not merely indicators of a woman's physiologic maturity and reproductive capacity; they also reflect the fertility behavior of her social milieu. Further, behaviors relating to health and illness may have been formed during childhood in the family home. At what level does each of these variables operate? To what extent are drinking and smoking among the mechanisms whereby variables of social identification contribute to the risk of fetal death? Generally, women who have experienced a fetal death have multiple handicaps that are both socioeconomic (low educational and income levels, unfavorable material conditions) and demographic (teenage pregnancies, fertility patterns characterized by high parity and short birth intervals). Viewed thus, fetal death can be seen as the culmination of a complex process involving the interaction and combination of different factors whose individual effects are hard to isolate.

[19] Nicotine and carbon monoxide can cause a risk of hypoxia through a reduced placental blood flow. This risk may be compensated for by placental hypertrophy resulting in a larger insertion.

V. HEALTH-CARE PROVISION AND FETAL MORTALITY

The decline in late fetal mortality (the only one for which long series of statistics are available) has been steady in the industrialized world since the end of World War II. It results from a combination of demographic factors (completed fertility at second child, hence fewer high-parity births and at high ages) and above all from major advances in the fields of prevention, fetal surveillance, and obstetric and neonatal techniques, which have led to an extreme medicalization of childbirth and to increasingly common intervention practices, not always with due attention to the medium- and long-term consequences for parents and children.

1. Legislative Measures and Recommendations for Pregnancy Protection[20]

The introduction of social protection systems and preventive health care policies has been responsible for an improvement in working conditions during pregnancy and for more effective prenatal monitoring. Working conditions for pregnant women are regulated in most industrialized countries.[21] The most common

[20] This paragraph focuses specifically on the industrialized countries, due to the lack of information about conditions elsewhere.

[21] It can be noted however that at the end of the 1980s Denmark, Sweden, and Norway, countries where levels of late fetal mortality have been low for many years, had no mandatory protection of pregnant women at work. There were instead merely recommendations (Demont *et al*., 1990).

measures are exemption from night working, change of work place if it represents a physical (i.e., toxic or mechanical) hazard for the mother or unborn child, permission to make prenatal medical visits in work time. In the case of sickness (with a medical certificate), the woman is put on sick leave and is entitled to receive all or part of her salary for however long its duration (WHO, 1988).[22]

Medical supervision of pregnancy can be compulsory or based on government recommendations (Denmark) or be the responsibility of occupational organizations (The Netherlands) (Demont *et al*., 1990). The minimum statutory number of compulsory *prenatal visits* is usually smaller than that recommended by the medical profession, three or four instead of nine, the latter figure being close to the average number of visits actually carried out (usually 12). It is generally recommended that the first visit take place in the first trimester of pregnancy, and some countries offer a financial incentive to this end. In France, where such a payment exists, a survey conducted in 1987 found that 4.3% of mothers in the most disadvantaged social strata nonetheless did not receive this allowance because they had failed to respect the conditions (Blondel and Saurel-Cubizolles, 1991). The proportion was 21% in the United States in 1993 (National Center for Health Statistics, 1995), reaching 34% in the black population. Medical check-ups can be carried out by midwives, general practitioners or specialists. The trend is to a greater role for doctors, in particular obstetricians. A system of home visits to pregnant women by midwives or specialist nurses is also operated in some countries (WHO, 1988). Prenatal visits are also an opportunity for women to be informed and educated about pregnancy and birth, and to receive advice about their personal life styles and the preventive behaviors they should adopt.

2. Medical Visits

Prenatal visits vary in content, and from the many studies carried out to validate the usefulness of one or other test it is hard to define a minimum standard of care that would give the best chances for fetal survival and development. Among the tests offered, however, one constant element is ABO and Rh blood group determination. Administration of anti-D gamma globulins to Rh– women has made it possible to prevent fetomaternal sensitization and to reduce the number of perinatal deaths from this incompatibility (0.06 per 1,000 of perinatal deaths in the United Kingdom in 1983). Screening for infections (syphilis, toxoplasmosis, rubella) that carry a high risk for the health of the fetus is almost systematic in Western Europe and helps to avoid harmful consequences such as congenital defects, either through prevention (vaccination against rubella for women without protective immunity) or by therapeutic abortion. Prenatal visits during pregnancy are the occasion to monitor for the appearance of hypertension and of toxoplasmosis in nonimmune mothers. Depending on the country, serologic tests can also be performed for hepatitis B, listeria, cytomegalovirus or HIV[23] (human immune deficiency virus) on women at risk. Because the 1970s, ultrasound scans have become a routine procedure for monitoring fetal survival and development, as well as for accurately estimating gestational age,[24] observing certain fetal malformations and as an aid to amniocentesis. The recommended number of scans during pregnancy is two, and the maximum three, although the actual number is often higher. The practice of measuring α-fetoprotein between gestational weeks 16 and 20,[25] lowered levels of which are associated with an increased risk of trisomy 21, is gradually being extended beyond its indications (family history of trisomy 21, high maternal age). The risk scoring sometimes used to identify problem pregnancies seems of questionable effectiveness given its arbitrary construction (confusion of determinants and intermediate variables, arbitrary weights assigned to these variables) and poor predictive power[26] (Alexander and Keirse, 1989).

Hospitalization for birth,[27] by ensuring the presence of medical personnel and facilitating any necessary intervention, has contributed to reducing the risks of fetal death during birth. Fetal cardiac monitoring during labour is now routinely used in the great majority of births (more than 75% in the United States [Ruzek, 1991]) to detect fetal distress. Although the practice of fetal monitoring is associated with a significant fall in fetal mortality during labor[28] (Vintzileos

[22] These measures seldom extend to self-employed groups and female farm workers.

[23] Vertical transmission of HIV can be greatly reduced by appropriate therapy during pregnancy (European Collaborative Study, 2001).

[24] An ultrasound scan performed before 12 weeks allows the term to be defined to within 1 week and should therefore avoid inductions being carried out too early.

[25] An error in gestational age modifies the results, and 10% of abnormal results could be normal if an error of 1 week is made (Alexander *et al*., 1989).

[26] This technique is based largely on the woman's reproductive history and is almost completely inoperative for nulliparous subjects.

[27] In the industrialized countries over 98% of births now occur in a maternity clinic or hospital, the exception being The Netherlands, where more than 30% of births take place at home.

[28] The saving appears to be in the order of 1 per 1,000: Studies conducted in Denmark and at Boston produced the following results: the number of *intrapartum* deaths went from 1.7 per 1,000 in the period when births with monitoring were only 9% of cases, to 0.3 per 1,000 in the later period when they were 93% (Thoulon *et al*., 1995).

et al., 1995), it is also associated with a significant increase in instrumental intervention in birth (forceps or caesarian delivery)[29] (Thoulon *et al*., 1995; Parer, 1990). Intrauterine growth retardation is often accompanied by fetal distress before the forecast term for birth: A study conducted in France in 1993 of obstetricians and neonatologists found that in such cases, 14% of obstetricians and 36% of neonatologists would decide to perform a caesarian delivery before the end of gestational week 27 (Bréart, 1996), this decision is justified by the improved care techniques for very premature babies. The progress in techniques is even more striking in treatments for subfecundity. Use of *in vitro* fertilization and, in particular, ovulation induction is becoming increasingly widespread, often resulting in multiple pregnancies (triplets or more) with a high risk of fetal and infant mortality. Embryo reduction and selective abortions performed in the first trimester of multiple pregnancies can improve the survival chances of the remaining embryos (Boulot *et al*., 1995); but the reduction in risk of fetal death thus achieved is merely fictitious, since the embryos that have been suppressed are never included in the calculation of these risks.

3. Prenatal Diagnosis and Therapeutic Abortion

Like embryo reduction though on a larger scale, prenatal diagnosis and the therapeutic abortion it sometimes leads to has generated extensive discussion, less for its statistical repercussions on measurement of fetal mortality than for its ethical and psychological implications.

Increased knowledge in the field of genetics, identification of the association between maternal age and trisomy 21, systematic use of ultrasound to detect morphologic abnormalities, and improvements in prenatal diagnostic techniques, have all contributed to make screening a common practice. In the case of trisomy 21 (or Down syndrome), screening should be offered to mothers aged 32 or over in the United States, 35 in most European countries and in Canada, and 38 in France and Italy. Although it is now accepted that the risk of trisomy 21 increases exponentially after age 35, no policy of systematic screening has been introduced (Aymé, 1996; Reid, 1990). As well as ultrasound, screening uses the biologic detection techniques of fetal karyotyping, fetal blood testing, and serum markers in the mother. Those involving fetal karyotyping are the most commonly used, because not all malformations can be identified by fetal blood testing, while serum markers[30] are at present used only for a more effective targeting of the populations at highest risk for trisomy 21 and who are thus possible candidates for amniocentesis (Haddow *et al*., 1994).

Fetal karyotype testing. Amniocentesis (sampling of amniotic fluid) is the oldest technique for detecting the presence of congenital malformations. It is performed in the second trimester of pregnancy, usually around week 15 or 16. The results are only obtained after 3 to 4 weeks, the time to culture the cells removed, which can mean a fairly late abortion if this course of action is decided upon. The risk of fetal death associated with amniocentesis varies between 0.5% and 1%. A more recent technique is *chorionic villus sampling* (sampling of placental tissue guided by ultrasound), which became more widely used in Europe in the early 1980s. It has the advantage that it can be performed earlier in gestation (between 10 and 14 weeks) and only a few days are needed to obtain the diagnosis. The risk of fetal death appears similar to that for amniocentesis (Aymé, 1996).

Once diagnosis has been made, the decision to terminate the pregnancy will depend on the severity of the disorder. In the case of anencephalia, for example, therapeutic abortion is performed unless the parents refuse. The problem is more delicate (both for medical teams and for parents) in the case of malformations where the severity of the handicap cannot be evaluated. This type of problem arises with trisomy 21, which is frequently associated with other severe malformations (primarily cardiac) that seriously compromise the vital prognosis. However, what should the decision be when there is only this chromosomal abnormality or when prenatal diagnosis shows a limb is missing? This is an area in which the answers are far from codified and clinical practice varies when parents request termination of the pregnancy (Papiernik, 1990).[31]

Data collected by the fourteen regional EUROCAT (European Registration of Congenital Anomalies) registers in the countries where abortion is legal show that when malformations are diagnosed, the percentages of terminated pregnancies vary from over 85% in cases of anencephalia and Down syndrome to around 58% in cases of omphalocele (Table 32–4). It should be stressed that practices of prenatal diagnosis and therapeutic

[29] This increase can be avoided if the monitoring is combined with a microanalysis of the fetal blood.

[30] Three serum markers are used: chorionic gonadotrophin hormone, α-fetoprotein, and estriol. Combining the results obtained for these facilitates identification of indications for amniocentesis.

[31] Parents and medical teams have a role in this decision-making, but levels of financial support for, and social attitudes to, the handicapped are also factors for consideration.

TABLE 32–4 Number of Cases of Anomalies Observed, Frequency of Prenatal Diagnosis (PND) and Postdiagnosis Therapeutic Pregnancy Interruptions (TPIs) Recorded in 14 EUROCAT Registers

Anomaly	No. of cases		% with PND		% TPI		% TPI/PND	
	1980–1984	*1990–1994*	*1980–1984*	*1990–1994*	*1980–1984*	*1990–1994*	*1980–1984*	*1990–1994*
Anencephaly	564	449	80	97	53	84	67	87

abortion do not differ between the regions in which the registers are operated and the rest of the country. The prevalence of malformations appears greater, however, because data collection is more complete.

Given that maternal age is a risk factor for trisomy 21 and probably also for other chromosomal malformations, can the trend to later entry into motherhood be expected to produce an increase in these malformations? A simulation performed by Cornel *et al*. (1993) based on the situation prevailing in 1992 in The Netherlands found that if coverage for trisomy 21 screening was unchanged (around 50% for women aged 36 and over), the prevalence of this pathology among live births would rise from 1.4 per 1,000 to 1.8 per 1,000 in 2001.

A very general definition of therapeutic abortion is the voluntary interruption of a pregnancy on serious medical grounds not later than the date at which civil registration declaration of fetal death becomes compulsory (usually 28 weeks of gestation). Two major exceptions to this rule are France and Finland. In France, the 1975 abortion law allows for therapeutic interruption of pregnancy at any gestation length, on condition that the pathology involved is sufficiently serious and untreatable. This decision (taken by at least two doctors) concerns abnormalities that are thought to be incompatible with the infant's survival, but nearly 20% of the therapeutic abortions recorded in the French EUROCAT[32] registers are performed after the legal limit for declaration of 28 weeks of gestation. This is a large proportion,[33] and it may affect the statistics for late fetal mortality, because these deaths are not systematically reported for civil registration. If none of these deaths were reported, adding them to those declared to civil registration for the three regions covered by the French registers in the period 1980 to 1992, causes late fetal mortality to rise by 0.7%. This increase is not negligible given the low levels of late fetal mortality in developed countries (and corresponds to a relative increase of 8%). In Finland, all fetal deaths must be reported after week 22 of gestation although therapeutic abortion is allowed up to week 24. Disregarding the limit for civil registration declaration, estimation was made in Finland of the effect on perinatal mortality of therapeutic abortions performed after week 16 of gestation. Working from the hypothesis that of the therapeutic abortions, only one third of diagnoses would actually have resulted in perinatal death, Gissler *et al*. (1994) estimate the increase in the level of perinatal mortality at 1%, had these therapeutic abortions not been performed.

Large disparities are observed between countries and between social groups in the same country, as reflected in mortality indices that are consistently higher for the most disadvantaged categories. Several elements can be advanced as partial explanations for these inequalities:

Advice on personal health practices during pregnancy, distributed in public health campaigns and in prenatal visits, is more easily followed by mothers whose educational level enables them to understand the benefit of these preventive behaviors. The policies of positive discrimination sometimes advocated (Ruzek, 1991) are of unproven effectiveness (Blondel and Bréart, 1992);

Although medical costs are reimbursed as long as the woman follows the prenatal care program of her country's social protection system, any additional examinations (to reassure the mother-to-be or

[32] All fetal deaths after 20 weeks of gestation and all therapeutic abortions, regardless of the gestational duration at which they are carried out, are recorded.

[33] In the United States, 0.01% of abortions are performed after week 24 of gestation (20 weeks' minimum gestation being the legal limit in most States for declaration of a fetal death). Nearly half involve teenage pregnancies; the rest are for fetuses suffering from serious congenital malformation.

anticipate possible morbid conditions for the fetus) are accessible only to women in favorable economic conditions. In France, for example, very sharp sociocultural inequalities are observed in use of prenatal diagnosis for trisomy 21 among women under the age at which it is recommended and with no other risk factors and who therefore have to pay for the test. Similarly, despite free provision and systematic promotion of health care facilities after age 38, social inequalities in access to prenatal diagnosis remain (Moatti *et al*., 1990). The problem is thus one of information (as when the woman accepts without questioning a doctor's decision that a pregnancy interruption is unjustified) and understanding (in her perception of the handicap, for example).

The increasing complexity of medical techniques accentuates inequalities in use of health care facilities. The recent trends observed in treatment for subfecundity, however, could distort perception of these inequalities if it was confirmed that better educated women make greatest use of these reproductive techniques which usually carry high risks of fetal mortality (Bréart, 1996).

VI. INDUCED ABORTION AND FETAL DEATH

Induced abortion (see Chapter 35) can be considered either as a potential risk factor for fetal death[34] or, on the contrary, as an event that tends to reduce intrauterine mortality by removing a certain number of high-risk pregnancies that otherwise would have ended with fetal death. In the mid 1990s, an estimated 46 million induced abortions were performed in the world annually, of which more than 40% are thought to have been clandestine (Alan Guttmacher Institute, 1999). Induced abortion is certainly one of the oldest forms of birth control, one practiced in all societies albeit to varying degrees before modern methods of contraception made possible an effective regulation of fertility.

1. Induced Abortion as a Risk Factor for Fetal Mortality

A prime consideration when assessing the risks is whether abortion is legal. In countries where abortion is legal, the risk is associated chiefly with the methods used. Abortion is currently legal in more than 30 countries (available on request or for a wide range of medical and social reasons). Most of the developed countries are in this category, as are China, India, South Africa, Tunisia, and Turkey. Induced abortion is usually carried out in the first trimester of pregnancy, but whereas in most of the developed countries it is viewed as a backup to failed contraception, in Central and Eastern Europe it has been used since legalization as an instrument of family planning (Blayo, 1993). In countries where abortion is still subject to numerous legal restrictions, women use unsafe practices that can be a source of infections leading to maternal death, repeated fetal loss in subsequent pregnancies, or secondary sterility. In 42 countries situated mainly in sub-Saharan Africa and the Middle East, abortion is prohibited unless there is a threat to the woman's life. In the remaining countries, abortion is allowed on a variety of grounds, both medical (physical or mental health of the mother) and legal (in rape or incest cases) (United Nations, 1992, 1995).

The countries where abortion is prohibited are also those where information on fetal deaths, even at advanced gestational ages, is nonexistent. Consequently it is not possible to estimate the effect of clandestine abortion practices on intrauterine mortality. The most commonly proposed evaluations are for maternal mortality: WHO estimates the proportion of maternal deaths that result from this kind of abortion at 13% (WHO, 1989). Proportions as high as 31% have been reported for Matlab in Bangladesh and over 50% in Ethiopia (United Nations, 1992), figures that may imply equally high levels of uterine damage with adverse implications for subsequent reproductive careers.

The laws on pregnancy termination allow for it to be carried out in the best medical conditions. The Central and Eastern European countries liberalized abortion at the end of the 1950s,[35] and were followed nearly 15 years later by most of the industrialized countries.[36] Usually performed in hospitals or clinics, abortion has become safer and physically less traumatic, thanks to the development of suction curettage in particular. For early terminations (before week 7 of amenorrhea) a choice is now available (e.g., Belgium, England and Wales, France, Sweden) between a med-

[34] This term, it can be recalled, includes all fetal deaths (i.e., spontaneous abortions [fetal deaths occurring before the limit for compulsory civil registration declaration] + stillbirths [fetal deaths declared for civil registration]).

[35] Abortion was legalized in the USSR in 1921. Prohibited in 1936, it was made legal again in 1955 (Blayo, 1993).

[36] The usual reasons for which it is authorized are as follows: When the mother's life or her mental or physical health are threatened, on eugenic grounds (genetic diseases transmitted by the parents, or malformation), legal (rape, incest), and because of economic and social circumstances.

ication-based method (RU 486 + prostaglandins) or surgery, which are equally effective. The possible consequences for subsequent reproductive careers of induced abortions by vacuum aspiration or curettage[37] have been studied and found to be the same as those after normal delivery. A slightly higher proportion of extrauterine pregnancies (not significant) was observed, however, among women with a history of pregnancy termination and is perhaps indicative of postoperative infection (Buekens and Kaminski, 1996). But higher risks of prematurity, low birth weight and, to a lesser extent, fetal death have been previously reported in the Central and Eastern European countries, as a result of the excessive cervical dilation caused by the abortion methods in use until recently in these countries.[38]

2. Induced Abortion and Reduced Fetal Mortality

Conversely, induced abortion can serve to avoid pregnancies with high risk for fetal death when it is performed on women whose biologic and social characteristics are unfavorable for fetal survival. These variables can only be identified in the countries where induced abortion is legalized and where its registration is accompanied by collection of various demographic and socioeconomic information (some European countries and the United States).

The characteristics of women who have abortions differ sharply between the countries of Central Europe and the others. In the former, abortion was used to limit family size once certain parity has been reached, whereas in the latter most women who have abortions are young, nulliparous and unmarried (Blayo, 1991).

Woman's age. In the nineties, women younger than 25 years accounted for the highest frequency of abortions in Sweden and Finland (44%) but especially in Norway, England and Wales, and the United States (respectively 52%, 54%, and 60%). This contrasts with the situation in the Czech Republic, Hungary, but also in France, where abortion is a more generalized phenomenon that concerns all age groups (around 20% by age group), with a proportion of around 20% in 2000 for women after 35 years (HCSO, 2002). As regards the frequency of induced abortions after age 35, in Hungary, and until 1988, it was more or less identical to that observed before age 25, and thus marks both beginning and end of the reproductive calendar.

Parity. Differences in parity are more sharply drawn, since 63% of the abortions carried out in Hungary in 2000 were on women with at least two previous pregnancies. In Norway, Finland, and Sweden, on the other hand, induced abortion is more frequent among nulliparous women (roughly 50%). This pattern is even more marked in the United States and in England and Wales, where nearly 60% of women having abortions are nulliparous.[39] France occupies an intermediate position, closer to that of Hungary, since the proportion of women who have had two previous pregnancies account for over 44% in 1995 (INED, 1999). It should be remembered, however, that the differences observed between countries may also reflect disparity in the classificatory criteria used for this characteristic.[40]

Marital status. In the 1990s, the same contrasts are observed when we consider the mother's marital status at the time of the abortion—England and Wales and the United States are at one extreme, the Czech Republic is at the other. In the former countries, induced abortion involves overwhelmingly unmarried women (74% for England and Wales and 67% for the United States), whereas three fourths of women who abort in the Czech Republic are married, regardless of the year considered. Hungary shared the same distribution pattern until the end of the 1980s, when the proportion of married women fell sharply, to stand at 45% in 2000. The same change is also observed for the two previous characteristics and is probably the result of improved access to chemical and mechanical means of contraception; its effect is to bring Hungary gradually into line with the countries of Western and Northern Europe. In Finland and Norway, the frequency of induced abortion among married women has remained stable at around 30%. In France, the trend to a greater frequency of induced abortion among married women has slowly been reversed in the years since abortion was legalized and unmarried women now account for the larger share.[41]

[37] For pregnancy interruption using RU486 plus prostaglandins, it is too early for any possible consequences to be assessed.

[38] The total induced abortion rate remains extremely high in these countries. It still stood at over one abortion per woman in the countries of Central Europe in 1990 and reached record levels of four per woman in Russia and six in Romania (Blayo, 1993).

[39] Of women who abort, 21% in the United States and 26% in England and Wales are of at least parity two. But among women who do not want any more children sterilization is much more common in England and Wales and the United States, than in the other countries considered.

[40] Number of previous pregnancies in France, number of previous births (or previous deliveries) in England and Wales, Finland, Norway, Czech Republic, and Sweden, number of previous live births in the United States, and number of infants still alive in Hungary.

[41] The quality of registration, particularly in the early days of legalized abortion, can be questioned, however, because abortions performed in private clinics may have gone unrecorded.

The legal status of abortion, ranging from total prohibition to full legalization, has a series of consequences for the woman's future reproductive health that extend from secondary sterility to no observable effect. In countries where abortion has been legalized, women using pregnancy termination usually present characteristics associated with an unfavorable pregnancy outcome—women aged over 35 in the countries of Central Europe, young unmarried women in the other countries. Consequently, when it is performed in hygienic settings, using up-to-date techniques that minimize the risk of infection and traumatic lesions, pregnancy termination may indeed reduce the number of spontaneous fetal deaths since it is more frequent in the groups where exposure to this risk is highest.

CONCLUSION AND FUTURE RESEARCH DIRECTIONS

The relatively recent growth of interest in fetal mortality, linked to new models of family formation (in which fertility regulation achieves a majority of wanted births) and development of increasingly effective medical techniques in the areas of reproduction, fetal care, and birth, has exposed the gaps in our knowledge as regards both levels and determinants of fetal mortality. Data on fetal mortality before 28 weeks are seriously deficient in the industrialized countries and is nonexistent elsewhere. Identification of pregnancies and fetal deaths in the subclinical phase (before any delay in menstrual period) requires surveillance protocols that are too restrictive to be implemented on large populations. What could be envisaged, however, is the creation of a system for collecting information as of the first prenatal visit (a pregnancy *log book* containing the basic biologic and social characteristics of the mother, fetal death record). In the countries where an initial obstetric visit is compulsory in the first trimester of pregnancy, a system on these lines would contribute to a more accurate evaluation of levels of intrauterine mortality after gestational week 12 and identification of the risk factors for fetal death during pregnancy, although remember that women in the most disadvantaged social strata are usually the last to make use of health care facilities. Improving information on fetal mortality is more problematic in developing countries. As the quality of civil registration systems gets better, levels of late fetal mortality will be known; for the moment, however, both for this and for early and intermediate fetal mortality, surveys are perhaps the only means to improve our knowledge of the phenomenon. However, another problem immediately arises—these are typically the countries where pregnancy interruption is prohibited and where, in the absence of means of contraception, women have recourse to clandestine abortions with a high risk for their subsequent reproductive health. The consequences of such practices for reproductive health, unfortunately unmeasured, should be made the object of in-depth studies. A modest first step in this direction would be to conduct surveys on women who are hospitalized for secondary complications from a clandestine abortion.

CHAPTER

33

Sterility

Causes and Treatment

HENRI LERIDON

Institut national d'études démographiques (INED), Paris, France

In most traditional societies, procreation is regarded as part of every individual's natural vocation, and sterility is experienced as a deep personal misfortune. A sterile couple is unable to fulfill one of its key social functions and the sterile partner (when he or she can be identified, or failing this the partner to whom the sterility is attributed) bears the responsibility for inflicting this reproductive failure on the other partner. In the low-fertility posttransition industrialized societies, social pressures to reproduce are of course weaker, yet sterility continues to be experienced as a tragedy by many of the couples it afflicts.

We begin by reviewing the problems associated with the observation and measurement of sterility, and then consider the biologic and social factors responsible for different types of sterility and examine the effectiveness of the treatments currently available.

I. FROM INFERTILITY TO STERILITY

Although there is little consensus over the definition of sterility, the most frequently quoted *estimations* of the scale of the problem converge to a remarkable degree. One often reads statements like "10% to 15% of couples are sterile." But their authors not only fail to specify exactly what is meant by *sterile*, they also often they use the impersonal form ("it is estimated that . . .") without giving details of the source or when a source is given it usually turns out to be completely unscientific or merely refers to another, equally unscientific source. The reason for this is quite simply the lack of reliable epidemiologic surveys on sterility, apart from some work carried out in a number of countries as part of demographic surveys. The results from these surveys in no way corroborate the estimations quoted above.

Even without specific surveys on the subject, the demographic sources supply one extremely simple indicator of sterility, namely *the proportion of marriages still infertile* (no live-born child) after 10, 15, or 20 years or when the woman reaches age 45 or 50. Two objections immediately come to mind. First, some couples will have remained *voluntarily* infertile; second, some types of sterility will have been overcome by specialist treatment. The first argument implies that there are fewer physiologically sterile couples than infertile couples (i.e., who remain childless); the second argument, conversely, implies that in the history of the cohort under examination, more couples have suffered from sterility than have remained permanently infertile. A simple way of overcoming these difficulties is to start by examining populations that dispose of only crude and inefficient fertility control techniques and nonexistent or extremely inadequate treatments for difficulties in conceiving.

An example is provided by the populations of preindustrial Europe. The evidence for the French provinces in the 18th century, for instance, is that *in general fewer than 5% of marriages* remained childless. Another example comes from developing countries that have not yet begun the fertility transition. Several

TABLE 33–1 Proportion of Couples Still Childless at 45 Years (Age of Woman) in Selected Countries

Population	Birth cohorts (C) or years of marriage (M)	Age at marriage, years	Proportion still childless at 45 years, %
France preindustrial	M: 1670–1769	20–24	4
France preindustrial	M: 1670–1769	25–29	6
France	C: 1935–1939	20–24	≤6
France	C: 1935–1939	25–29	<10
United States (white population)	C: 1930–1935	<45	7
Finland	C: 1931–1935	<45	6
Bangladesh	C: 1925–1930	<45	3
Mexico	C: 1925–1930	<45	5

Source: Henri Leridon, 1982. Stérilité, hypofertilité et infécondité en France, *Population*, vol. 37(4–5), p. 807–836.

dozen of these countries participated in the World Fertility Survey in the 1970s. In three fourths of them the proportion of married women who remained childless at 40 to 44 years *was less than 4%* and none exceeded 7% (Vaessen, 1983).[1] Table 33–1 shows a selection of the proportions obtained in a number of countries.

It is hard to see how the situation could be significantly different in the developed countries, and indeed all the evidence is that they do not have a higher frequency of unsurmounted sterility. Our first source for this is census data. In 1975, in the United States and France, the proportion of women remaining infertile among married women aged 35 to 39 years was 7% to 8%, and this proportion undoubtedly includes cases of *voluntary* infertility. Our other source is survey data. In France, the INED-INSEE surveys of 1978 and 1988 provided confirmation for the view that fewer than 6% of couples experienced permanent involuntary childlessness, although many more reported having had difficulty conceiving at one time or another (Leridon, 1982, 1991).

That last point is the key to much of the confusion. For if we count as sterile every couple who starts to express impatience because a conception (not necessarily the first) is proving slow to be achieved, the proportion of *sterile* couples will far exceed 5%. Indeed, it is not fanciful to think that their number will grow as the scope for obtaining medical advice expands. In France, as early as the 1970s, *roughly one in ten couples had been to a doctor for this reason*. We return to this point later.

The proportions of couples who are involuntarily childless at a particular age can thus be treated as estimations of *primary sterility* at this age. When age 50 (for women) has been reached, we can speak of *total sterility*, because the couple has never produced a child during its reproductive life span. In the case of a couple who has already had one or several children but is unable to have any more, the sterility is said to be *secondary*; it thus includes the possible consequences of delivery. Such cases seem to be fairly widespread in Africa, where, as mentioned above, levels of primary sterility are generally low.

[1] The sample analyzed included a few African countries. A more recent study, based on surveys carried out in Africa in the 1980s, has confirmed these results. See Larsen, 1994.

II. STERILITY AND AGE

Although some couples have the misfortune to discover that they are sterile very early on, all couples become sterile eventually. As we saw in Chapter 30, menopause forms a natural limit to the reproductive span. However, it is a *lagged* indicator because although mean age at menopause is around 50 years, mean age at last birth is closer to 40 years in populations subject to a *natural fertility* regime (see for example the table compiled by James Wood, 1994, p. 442). This time lag can have two sources, however. First, it may result from the onset of *permanent sterility* several years before the completion of menopause (menopause is not considered to be complete until after a minimum length of time without menstruation, usually set at 1 year), which could be attributable to an anovulatory phase preceding the final cessation of menses. Second, it can be assumed that the time needed to conceive increases with age, as too does the risk of fetal mortality. This means that a woman who was still *fecund* at a particular age might not have enough time to conceive a child who would be live-born in the years remaining until menopause (or permanent sterility). In terms of live births, which are usually the only observations available to the demographer, the two explanations are confounded and any estimation of the proportion of women already sterile at a particular age incorporates these two dimensions.

Several authors have proposed estimations for this *permanent sterility* based on the proportion of women still infertile beyond a certain age (Vincent, 1950; Henry, 1961; Leridon, 1977; Trussell and Wilson, 1985; Larsen and Menken, 1989). Figure 33–1 presents two types of estimation, the first for the proportion of sterile couples among newly married couples, by age at marriage (we are thus dealing with primary sterility), the second for the whole population of married couples, by the age of the woman (the sterility can therefore be secondary). On Figure 33–1A I have plotted an estimation by Trussell and Wilson (1985) and my own (Leridon, 1977), plus an exponential function fitted to the latter, for *newly married couples* at age x (age of the woman); the proportion of couples already sterile is given by:

$$y = 0.370 \exp (0.109x)$$

Figure 33–1B concerns *all the women* in couples at an age x; the proportion of couples already sterile is given by:

$$y = 0.427 \exp (0.113x)$$

From these results, it appears that approximately 10% of newly married couples are already sterile when

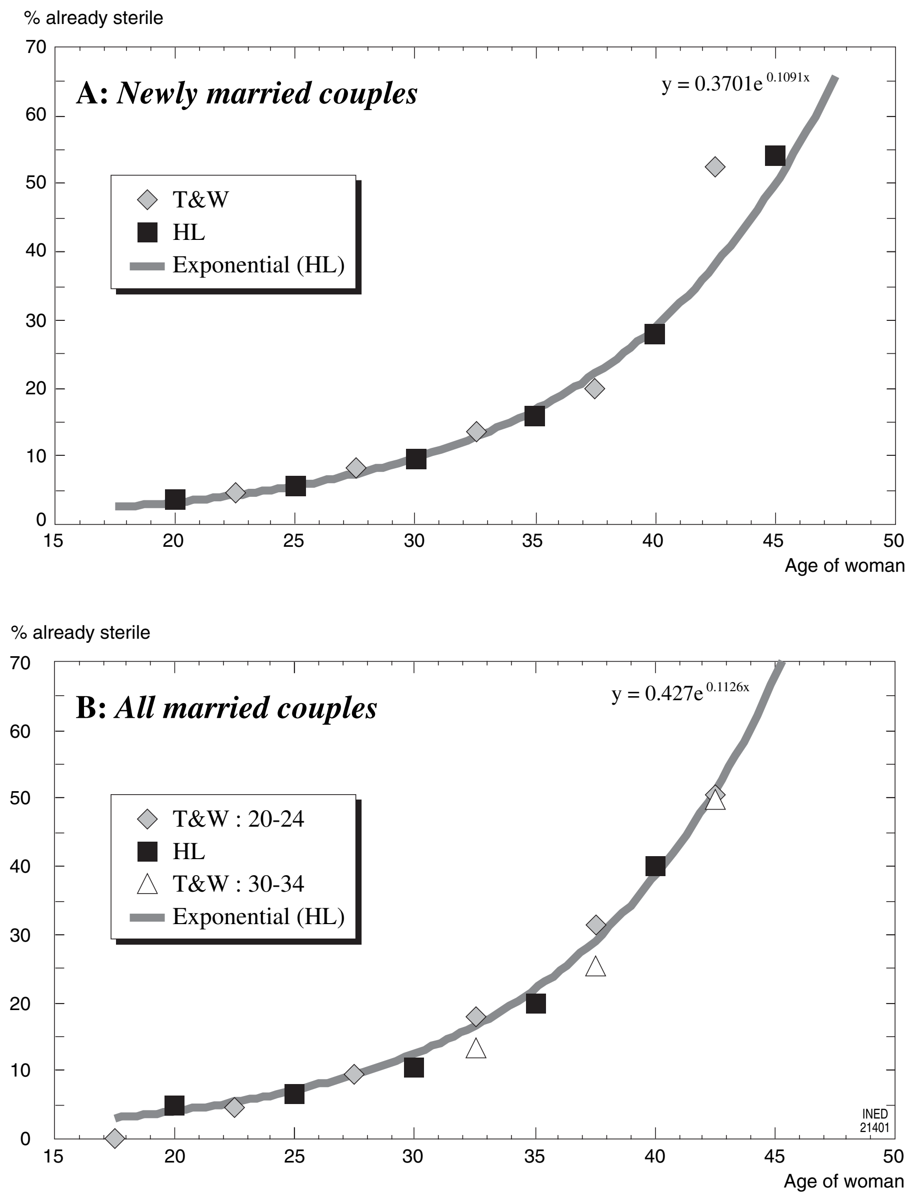

FIGURE 33–1 Proportion of couples already sterile. Source TRUSSELL James, WILSON Christopher, 1985. Sterility in a population with natural fertility, *Population Studies*, vol. 39(2), p. 269–286; LERIDON Henri, 1977. Sur l'estimation de la stérilité, *Population*, vol. 32, Special issue, p. 231–248.

the woman is 30 years old, 17% at 35 years, and 29% at 40 years. If cases of secondary sterility are included, the respective proportions rise to 12%, 22%, and 39%. In contexts where no treatments are available, this sterility would be permanent; in contemporary populations, the existence of effective treatments will have the effect of reducing these values.

III. THE CAUSES OF STERILITY

After having been assumed to be negligible, male sterility is currently thought to be the problem in three to four 10 cases of sterility. Some authors favor use of a third category to accommodate cases where responsibility is shared: "In roughly 30% of barren marriages, the husband has been found to be the significant factor. In another 20%, he plays an important contributing role" (Kempers, 1979, p. 273; see also Sherris and Fox, 1983). The idea is an *addition of two subfecundities* (of the man and of the woman) leading to an apparent sterility. Indeed, pursuing this line of reasoning a little further, it could be argued that in most cases the doctor is treating not a *single case of sterility* but *one* or *two* cases of subfecundity, thereby making illusory the distinction between *female sterility* and *male sterility*. Ideally, we would be able to say for a particular couple, that the difficulties are 30% due to the woman and 70% due to the man, but this is virtually impossible to establish in practice and contributes little to resolving the problem.

For want of a better solution let us accept this distribution of roles. We must now turn our attention to identifying the possible causes of sterility in one or other of the partners.

In men, cases of secretory azoospermia seem to be relatively rare, and involve mainly congenital abnormalities (chiefly cryptorchism). More frequently diagnosed conditions include excretory azoospermias, resulting from tubercular or gonococcal infections, while still more common are complex oligoasthenoteratospermic conditions, which also result from viral or other infections, hormonal imbalances, histories of cryptorchism, or which are attributed (rightly or wrongly) to presence of a varicocele.

In women, researchers are agreed that the main cause is *tubal disease*. This usually results from infections of various origins: puerperal infections (postpartum or postabortal), which thus cause secondary sterility, and pelvic inflammatory disease resulting from sexually transmitted diseases (gonococcal and, increasingly, chlamydial infections). If we include in this category most *endometriosis*, we can *explain* 20% to 30% of all sterility (including male). A further 20% to 30% is accounted for by *ovulatory problems* and *hormonal imbalances* (Sherris and Fox, 1983). This covers anovulation with genetic or autoimmune (congenital) origins, failure of follicle to rupture, and, especially, polycystic ovarian disease. Hormonal disorders are also responsible for failures in fertilization. In most studies there is a residual proportion, in the order of 20% to 40%, of unexplained sterility (termed *idiopathic*).

TABLE 33–2 Distribution of Causes of Involuntary Infertility

Cause	Couples, %
Ovulatory disorder	20–29
Tubal abnormality	15
Endometriosis	6
Cervical factors	3
Spermatic abnormalities	21–24
Other male causes	2
Problems of coitus	6
No cause identified	18–28

Table 33–2 summarizes the distribution of the causes of *infertility*, which also includes the cases of total sterility. This breakdown is necessarily approximate because it is obtained by combining nonexhaustive studies. More recent results proposed by Snick *et al*. (1997) broadly confirm the proportions given in the table.

Note that most factors mentioned above can also explain a rise in fetal mortality, which in addition has a large genetic component (involving mainly chromosomal injuries occurring at random during fertilization and early cellular division, more than hereditary anomalies).

At another level, these dysfunctions can originate in exposure to polluting agents in the environment or in the workplace. The adverse effect of smoking has also been proved as has that of female sexual mutilation (see Sherris and Fox, 1983).

Finally, childbirth can also be responsible for secondary sterility (as was noted earlier), in particular through the risk of puerperal infection. The conditions of childbirth are thus determinant. The risk is very low when childbirth takes place under full medical supervision. At the other extreme, for Europe between the 17th and 19th centuries, we have estimated at 2% to 5% the risk of becoming sterile as a direct result of childbirth (Leridon, 1977). For similar reasons, abortion performed in unsatisfactory conditions can have the same type of consequences.

IV. MEASURING TREATMENT EFFECTIVENESS

The first point to note is that the *chances of success for the treatments* that are available vary greatly depending on the origin of the sterility. For the main cause (ovulatory disorders) probabilities of success in the order of 30% to 40% are usually advanced. However, not every pregnancy achieved after a hormone treatment should be automatically attributed to the treatment. To interpret the reported success rates correctly we need to know (as well as the length of treatment) the selection conditions for the couples receiving treatment. Selection operates in three ways—through the initiatives made by couples (changing doctors, abandoned attempts, delays, etc.), through the choices made by the clinician (diagnostic techniques, type of treatment, etc.), and through the time elapsed since first trying to become pregnant. The third criterion is especially important, because as this period lengthens so the group of couples who have still not conceived includes a growing proportion of authentically sterile (nil fecundability) couples and of subfecund couples with very low fecundability.

Let us assume that we observe a population of nonsterile couples, with a mean fecundability of 0.25, from the point in time when they first try to conceive (Table 33–3A, based on Schwartz, 1981).

After 2 years, 3% of couples will still not have conceived, and the mean fecundability of these couples will be 0.08 (a third of the level in the initial population): This group would thus appear to be eligible to be treated for sterility; yet, *57% of them will go on to conceive successfully in the following 12 months* without any treatment. Consequently it is with 57%, rather than with 0%, that we should compare the success rate obtained in the group of couples who received treatment (Leridon and Spira, 1984).

The reasoning set out above is only valid for couples who are not totally sterile. When a cause of total sterility (complete azoospermia, complete tubal blockage) can be diagnosed with certainty, any pregnancy has to be credited to the treatment. This may be the case in tubal surgery, artificial insemination with donor, or *in vitro* fertilization (IVF), on condition that only couples who are totally sterile have been selected. Yet, with IVF, for example, this is often far from the case; the technique is also used on women with an *unexplained*

TABLE 33–3 Evolution of a Population Including Fecund Couples and Sterile Couples (Fecundability Initially Distributed According to a Beta Function with Parameters $a = 2.75$ and $b = 8.25$)

Time elapsed (in months)	Number of couples who have not yet conceived	Mean fecundability of these couples	Proportion of sterile couples, %	Proportion conceiving before 1 year, %
A: No sterile couples				
0	1000	0.250	0	90.1
1	750	0.229	0	88.4
2	578	0.212	0	86.7
3	456	0.196	0	85.0
6	248	0.162	0	80.0
12	99	0.120	0	71.0
24	29	0.079	0	57.3
36	12	0.059	0	47.7
48	6	0.047	0	40.8
60	4	0.039	0	35.6
B: Plus 5% sterile couples				
0	1053	0.237	5.0	85.6
1	803	0.214	6.6	82.6
2	631	0.194	8.4	79.4
3	509	0.176	10.4	76.1
6	301	0.133	17.6	65.9
12	152	0.078	34.9	46.2
24	82	0.028	64.6	20.3
36	65	0.011	81.5	8.8
48	59	0.005	89.8	4.2
60	57	0.003	93.0	2.5

sterility, and there is no certainty that the pregnancies obtained can all be attributed to IVF.

Table 33–3B is constructed on the same base as Table 33–3A but to the initial population have been added 5% of totally sterile couples. After 2 years, 8% of the couples still infertile and within this group, 65% of couples are totally sterile. Consequently there is even more reason for these couples to be offered treatment promptly, although it can be noted that a further 20% will conceive unaided in the following 12 months.

V. HOW EFFECTIVE, IN PRACTICE, ARE THE VARIOUS INFERTILITY TREATMENTS?

In the 1960s and 1970s, treatment was mainly *hormonal* or, in the case of tubal obstruction, *surgical*. The success rates reported in the literature were often between 30% and 40% in both cases, without precise indications being given about the duration under consideration or the selection conditions for the women treated. Working on a large sample of couples consulting after at least 1 year of infertility, Collins *et al*. showed in 1983 that the pregnancy rates for the treated women were in fact little higher than those for the women not treated, being, respectively, 41% and 35%. It is true that the first group selected women known to have indications for treatment, hence signs of impaired fecundity, while the second group could include more women presenting no obvious sign of low fecundity. That said, the study provided a clear illustration of the process described above and showed the need for caution when interpreting success rates for these treatments; these results were moreover confirmed by later studies (see for example Collins *et al*., 1995; Snick *et al*., 1997).

The 1980s and 1990s saw a rapid development of the techniques of *artificial insemination by donor* (AID) (in the case of male sterility) and *in vitro fertilization with embryo transfer* (IVF). The maximum success rate per AID cycle is 15%, corresponding to 7% in live births (CECOS, 1998). However, repeated attempts are possible, and the cumulative rate can then reach 40% or 50% for conceptions and 20% to 25% for births. In IVF, the conception rate achieved with egg harvest (oocyte retrieval after hormonal stimulation of the cycle) is around 20% (FIVNAT, 1998a) and approximately 15% as live births. This technique can also be repeated, although because it is much more complicated and invasive it is unusual for more than three attempts to be made. The success rate (in births) then reaches 34% (FIVNAT, 1998b).

AID and a proportion of IVFs are being replaced by the new technique of ICSI (intracytoplasmic sperm injection), which involves injecting a single sperm directly into the inner structure of the egg. The success rate seems to be slightly higher than with IVF.

Two further points must also be made. First, all these rates decline as the woman's age increases, especially after 40 years—medically assisted procreation is only a partial remedy for the effects of aging on fecundity. Second, both hormonal treatments and IVF frequently result in multiple births, the increased number of which shows up even in national-level figures.

Lastly, mention can be made of the nonmedical alternative to infertility treatment, adoption, which, though its legal framework varies between countries, is present everywhere.

VI. ESTIMATING THE DEMAND FOR TREATMENT

According to the most recent French survey, 15% of couples aged 25 to 45 years (who had already tried to conceive) had sought medical advice at least once for a *sterility problem* (Leridon, 1991). Can this proportion be taken to represent the *demand for treatment*? Definitely not, insofar as the initiative of some of these couples could be judged premature (less than 1 or 2 years of trying for a pregnancy, for example) or at any rate not a justification for immediately starting on a major treatment—a third of couples who reported having sought medical advice had done so before 1 year of infertility and were thus being overimpatient. Data from an earlier (1978) survey allow us to approach the problem from a different angle (Leridon, 1982). At that time only 10% of married women reported a fertility problem, but for the reasons given above this estimate may be more realistic; it also seems more consistent with results from American surveys, according to which approximately 5% of married women (15–44 years) had sought medical help during the previous 5 years (Mosher and Pratt, 1990).

In the 1978 French survey, "Did you ever take longer than you would have liked to get pregnant, or not manage to at all?" Of these, 3.7% were still infertile at the time of the survey; 14.7% had eventually conceived (one fifth of these after treatment or surgery). The second group was thus made up mainly of subfecund subjects and, related to this, those with correctable sterility.

Usually (approximately six in 10 cases), the difficulties were apparent from the first attempt to become pregnant. This enables us to estimate the mean fecundability of the subfecund couples. We do this by com-

TABLE 33–4 Distribution of Time to Conception in a Group of Subfecund Couples

	Time to conception (months)						Mean time	Median
	0–11	12–23	24–35	36–47	48+	Total		
Observed[a]	36	23	16	10	15	100	26.5	17
Model[b]	37	21	13	8	21	100	33.6	8

[a] Distribution of the interval between marriage and first birth, reduced by 16 months (mean duration of pregnancy, 9 months; mean voluntary waiting period at start of marriage, 7 months) for couples who have had difficulties conceiving (INED-INSEE survey, 1978; Author's computation).

[b] Distribution of the time to conception in a population whose fecundability is distributed according to a beta function of mean 0.04 and standard deviation 0.02.

paring the mean interval between marriage and first birth for the women reporting difficulty in conceiving their first child, with the mean for those did not report any difficulty: the figures are 42.5 months for the former and 21.8 for the latter, giving a difference of *20 months*. This interval can be broken up into three components:

- A *voluntary waiting time*, from use of birth-spacing contraception
- The *necessary time to conception*, after contraception has been discontinued
- The *duration of pregnancy*, corresponding on average to 9 months

We can reasonably assume that the voluntary waiting time is the same among the subfecund as among the others, since the difficulties in conceiving do not actually become apparent until after this period. Mean fecundability—the monthly risk of conception when no contraception is used—is well known for *normal* populations, that is, those not subject to selection: It is usually around 0.25, giving a mean time to conception of 5 to 6 months (see Chapter 30); the mean interval between marriage and first birth is 21.8 months for couples not reporting a problem, so we can estimate at: 22 − 6 − 9 = *7 months, approximately, the voluntary waiting time* at the start of marriage.

For the subfecund group, mean time to conception would thus be: 42.5 − 7 − 9 = 26.5 months. The earlier studies showed that the fecundability of the couples could be fitted to a beta function (Pearson I) with two parameters a and b. An advantage of this function is that the fecundability of couples who have not yet conceived at duration n is also distributed according to a beta function, with parameters a and $b + n$. Thus it is not unreasonable to assume that the fecundability of the group of subfecund couples is also distributed according to a beta function and to try to estimate the mean fecundability. What is needed, therefore, is a beta function that gives a distribution of the times to conception as close as possible to that observed for the subfecund group. Strictly speaking, the latter distribution is not known, since the voluntary waiting period at the start of marriage is not known for each couple *individually*: The mean has merely been estimated (indirectly) at 7 months. Accordingly we simply make a uniform reduction in the interval between marriage and first birth of 7 months for the voluntary wait and of 9 months for the duration of pregnancy.

The result appears in Table 33–4. A beta distribution of mean 0.04 (parameters, 3.80 and 91.20) is found to give the best fit.

The main inconsistency is over the long periods (in excess of 4 years), which makes a large difference to the mean value, but it must be noted that the observed distributions are necessarily truncated here, because the time elapsed since marriage is not always adequate. With that qualification made, the fit is good, and we can reasonably conclude that *the mean fecundability of couples self-reporting as subfecund is in the order of 0.04*.[2]

This result is directly applicable in our attempt to estimate the demand for treatment to combat sterility. It would scarcely be reasonable for this estimation to include couples who identify themselves as subfecund and who may have sought medical help, but who have been trying to conceive for a few months only. What should the minimum wait be before proceeding with a medical intervention? There is probably no single answer to this question, and the speed and precision of the diagnosis will vary with each individual situation. *A minimum wait of 2 years is often specified*. Yet as Table 33–4 shows, 58% of subfecund couples conceive before 2 years (59% in our population had in fact conceived within 2 years). So *only the others* (42%) *should* be considered as clinically *sterile* and thus be accepted as possible candidates for treatment. If the waiting time for treatment is increased to 4 years (to allow for the investigations necessary before deciding on a

[2] Comparable to the result after 4 years in Table 33–3.

surgical intervention, for example), the proportion of subfecund couples who have still failed to conceive unaided and who therefore ought to be offered treatment stands at only 21%.

The difference between these two figures (42 and 21%) is worth considering. It results from those couples who satisfy the usual definition of sterile (2 years without conception) but who then manage to become pregnant—usually without medical assistance—in the following 2 years. Would complicated treatment or potentially costly operations have been justified in such cases? How is the choice to be made between an additional waiting period (which in any case cannot be predicted at the individual level) and an *immediate cost*? The question obviously only arises for subfecund couples, whose chances of conception are not completely nil but who as we have seen make up the great majority of potential candidates for treatment.

VII. THE DEMAND FOR TREATMENT: STOCKS AND FLOWS

Let us recapitulate the example analyzed above:

- 3.7% of couples suffer from sterilities that are not overcome, with 2.6% of couples remaining childless;
- 14.7% of couples report difficulty in conceiving, 8.2% of them from the first pregnancy.

In the latter group, those who have experienced difficulty from the first pregnancy form the subfecund group that we have just analyzed. Between 21% and 42% of them may be candidates for treatment, depending on whether the requirement is set at 2 or 4 years of previous infertility, representing 1.7% to 3.4% of all couples. Couples who have experienced difficulties achieving a pregnancy other than the first probably have a higher mean fertility, because their mean interval between marriage and first birth is much closer to that of *no-problem* couples, than to the previous couples. Let us accept that 10% to 20% of them would be eligible for a treatment[3]: 0.7% to 1.3% of all couples would thus be involved on the grounds of a secondary sterility.

In all, *6% to 8% of couples are potential candidates for a treatment* against sterility, and this breaks down as follows:

- 2% to 3% of couples who will remain totally infertile unless treated successfully,
- 1% of couples who have a secondary sterility,
- 2% to 3% of subfecund couples, who experience serious difficulty achieving a first pregnancy,
- Approximately 1% who are secondary subfecund, whose difficulties become apparent only after one or more births.

If it is accepted that all cases of tubal sterility (20%–30% of infecund couples) are indications for IVF, and if we add to this approximately 10% of other indications, we have 2% to 3% of all couples who are potential candidates for this kind of intervention.

In France as a whole, 300,000 to 400,000 couples are formed each year: *7000 to 12,000 could therefore be expected to request IVF each year*. In fact, in 1997 more than 20,000 first egg harvests (on women who had never previously had one) were carried out, and 3200 first AID: the indications have thus been significantly extended, well beyond the hypotheses adopted here. Increasingly, sterile couples are systematically offered IVF, especially using the ICSI procedure, regardless of the origin of the sterility.

[3] If the mean Fecundability of this group was 0.10—which is already a fairly low level—15% of them would still have not conceived after 2 years, and fewer than 5% after 4 years.

Natural Fertility and Controlled Fertility

Levels and Models

HENRI LERIDON

Institut national d'études démographiques (INED), Paris, France

I. THE "INTERMEDIATE VARIABLES"

With their article "Social structure and fertility: an analytical framework," published in 1956, Kingsley Davis and Judith Blake opened a new field of research. After analyzing and classifying a large corpus of anthropological studies, the authors identified several levels of variables that influence fertility. These were the intermediate variables, through which social and cultural factors operate to influence fertility; the social norms, closely linked to the social organization an individual belongs to, which govern fertility and marriage behavior and the other intermediate variables; and the structural characteristics that define the position of the individual within society. This classification proved analytically fruitful, and the long list of intermediate variables proposed by Kingsley Davis and Judith Blake drew attention to a number of factors that had previously been unjustly neglected, such as age at the beginning and end of the reproductive period, pregnancy wastage, periods of sexual abstinence, plus of course the variables that describe the regime of conjugal unions (age at marriage, divorce, remarriage, etc.).

A serious omission from their list, however, and that for almost 20 years continued to receive little or even no attention, was the key role of breast-feeding, despite research that had established its importance in influencing the duration of postpartum amenorrhea. This variable had to be reintroduced into Blake and Davis' analytical framework, and more importantly into the questionnaires employed in demographic surveys from the mid 1970s.

Table 34–1 presents a classification of all the variables that are currently thought to be potential determinants of fertility.

1. Recombining the Intermediate Variables

The list in Table 34–1 is of course intended primarily as an analytic framework. It is not possible to assemble at any one time all the information pertaining to a given population, and the impact of the different variables depends greatly on the general fertility level, according to whether or not couples are already controlling fertility. In many countries, the process of reproduction is largely dominated by behavioral variables (desire to have children, number of children wanted, use of contraception, etc.), which makes it reasonable to draw on theories from sociology and economics for the keys to explain the observed behavior. But it was not always so, and is still not so in some regions of the world.

The response of demographers has been to concentrate first on describing the situations of natural fertility, in which couples individually do not adopt behavior deliberately intended to space or limit the

TABLE 34–1 Determinants of Fertility: a Classification

A. THE INTERMEDIATE VARIABLES
These are the variables, to use the terminology of Davis and Blake (1956), through which the cultural factors operate to influence fertility. It will be noted that the authors' framework did not include the duration of breastfeeding.
1. Biologic capability
a. Ages at puberty, menopause, and permanent sterility
b. Monthly probability of conception (fecundability)
c. Intrauterine mortality (spontaneous)
d. Duration of postpartum nonsusceptible period
2. Conjugal regime
a. Age at marriage (or entry into sexual union)
b. Frequency of permanent celibacy
c. Frequency of, and ages at, death, widowhood, or divorce
d. Frequency and ages of remarriage
e. Periods of separation of partners (seasonal work, illness, etc.)
3. Other sociocultural variables
a. Frequency of intercourse (affecting 1b)
b. Duration of breastfeeding (affecting 1d)
c. Sexual taboos and restrictions (affecting 1d)
4. Fertility regulation variables
a. Individual action on length of union (affecting 2)
b. Action on exposure to conception: abstinence, use of contraception (affecting 3 and 1b)
c. Action on pregnancy outcome: induced abortion (affecting 1c)
d. Voluntary sterilization (of one partner) (affecting 1a)

B. SOCIOECONOMIC STATUS VARIABLES
These variables describe an individual's socioeconomic context (his or her *milieu*) and may explain (through the variables in groups A-2, -3, -4) differences in fertility levels. In this sense, therefore, they are external to the previous framework.
a. Ethnic origin, cultural group
b. Religion
c. Educational level
d. Socio-occupational status
e. Economic status, income
f. Family structure
g. Place of residence (urban, rural)
NB: Ronald Freedman's *Community-level Variables* (1974) could be included here. These variables seek to describe the individual's immediate environment: proximity of school, clinic, shops, administrative services, access to electricity, public transport, etc. The necessary information can be collected directly by the survey taker for all the inhabitants of the same neighborhood or same village.

C. THE *ENVIRONMENT* VARIABLES
These variables describe some of the constraints faced by individuals. They act mainly on the variables of group A-1, or describe general structural changes.
a. Health
b. Nutrition
c. Age structure
d. Political system

D. THE PSYCHOSOCIOLOGIC VARIABLES
These variables describe in a direct way individual attitudes towards fertility problems or towards the intermediate variables, relative to the norms prevailing in their social group (see B).
a. Desires with respect to fertility (number of children, sex, spacing, and so forth)
b. Attitudes toward marriage and the family
c. Attitudes toward sexuality
d. Attitudes toward birth control

(Économie et statistiques avancées); adapted from Davis, Kingsley, and Blake, Judith, 1956. Social structure and fertility: an analytic framework, *Economic Development and Cultural Change*, vol. 4(4), p. 211–235.

number of births. In such a context, the biologic variables of reproduction assume their full importance, though they are never the only ones involved—fertility is always part of a specific social context, and customs in respect of marriage, sexuality, and breast-feeding also play a crucial role. The concept of natural fertility (*fécondité naturelle*) was introduced by Louis Henry in 1953, who referred to "the fertility that a human population would have if it made no conscious attempt to limit the number of births," and in 1961 he added that such fertility "is the one most influenced by physiological factors." In practice, it must also be pointed out that Louis Henry was referring basically to legitimate fertility, thus nuptiality was left out of his definition. With a view to removing some of the ambiguity I have given the following definition (Leridon, 1989):

> A natural fertility regime characterizes a situation in which the level of fertility results, above all, from a combination between these physiological factors of reproduction and behavior that is simply consistent with the norms of the social group. In particular, it is excluded that any preferences that individuals and couples may have as regards the size of their family can influence their age at marriage, the spacing of their births, and their completed family size (p. 33).

It was seen in Chapter 30 that by breaking up the interval between two successive conceptions it is possible to identify some intermediate variables. We can also attempt to reconstruct the process, on the basis of these elements, to obtain the observed (or observable) fertility. This procedure has given rise to various attempts to model the reproductive process.

2. The Early Approaches

Using the previously identified variables, efforts focused on constructing models that would describe real processes. The early models did not include the risk of sterility and merely made the assumption that fecundability tended to zero beyond a certain age. In addition, they only applied to women who were already married (i.e., assumed to be exposed to the risk of conception).

Henry (1957) was the first to develop a purely algebraic approach. This involved setting the following integral equation, if continuous notation is being used (or the equivalent recurrent equation, if using discrete notation):

$$C(x) = p(x)\left[1 - \int_0^G C(x-g)k(x-g,g)dg\right]$$

where:

—x age (or the duration since marriage, which is taken to have occurred at an exact age);
—C(x) number of conceptions at age x (per woman);
—p(x) fecundability at age x (identical for all the couples of age x);
—k(x − g, g) probability of still being in the nonsusceptible period (see chapter 31) at duration g, for a conception at age x − g;
—G maximum duration of the nonsusceptible period.

The nonsusceptible period is the sum of the length of the gestation period and the longer of the two postpartum periods of amenorrhea and abstinence. The formula given above makes no distinction between pregnancies that result in live births and the others; this can be done in a subsequent stage by splitting the function k (into k_v and k_a) and the function C (into C_v and C_a).

We denote as Q(x) the number of conceptions before x. If marriage occurs at age x_0, the mean rate of conception from age x_0 to age x will be:

$$\frac{Q(x)}{x - x_0} = \int_{x_0}^{x} C(t)dt$$

Since all women are assumed to be at risk of conceiving at the start of marriage, the rate is at its maximum during the first month. This value is never again attained, since at any given time a certain proportion of the women will have a nonsusceptible status, i.e. will have nil probability of conceiving.

The mean interval between marriage and the first conception is simply equal to 1/p(x) for women married at age x (p varying little during the early years). If $\bar{p}$ denotes mean fecundability for the group of ages under consideration, v the proportion of conceptions that lead to live births, and $\bar{g}$ the mean length of the nonsusceptible period for all conceptions, the mean interval between live births is:

$$\bar{i} = \frac{1}{v}\left(\frac{1}{\bar{p}} + \bar{g}\right)$$

These formulas are valid only in the simplified case where all women are assumed to have the same functions p and k. For a heterogeneous population, the results are more complex. The interval between marriage and first conception, for example, will be equal to the harmonic mean of $f(p)$, if $f(p)$ is the distribution function of fecundability between all the women of a particular age:

$$m = \int \frac{1}{p} f(p)dp \neq \frac{1}{\bar{p}}$$

Several authors have preferred to use the theory of Markov chains (see especially Potter and Sakoda, 1966; Sheps and Menken, 1973). This involves defining a set of possible states (e.g., fecund, pregnant, postpartum nonsusceptible) and the probabilities of transition between states, and then calculating the length of time spent in each state and the number of entries and exits for each state. The time spent in state *I* can depend on state *I* and on $I+1$, but does not usually depend on the external time (the total time elapsed since the start of the process, which in this case is age). The main advantage of the method is that it lets us analyse the convergence of the process towards the stationary state and to describe the latter, over the period when fecundity varies little (20–35 years). Inclusion of fetal mortality and sterility is not problematic.

3. Simulations Using the Monte Carlo Method

Simulations using the Monte Carlo procedure are useful in several cases where the models mentioned above are inadequate. Greater complexity can be added to make the model more realistic, for example, by introducing the probabilities of marriage, and of divorce or widowhood. The various functions can be made to depend on age or duration of marriage or both. The heterogeneity of real cohorts in relation to these variables can be introduced. Particularly valuable is the applicability of the analysis to populations practicing birth control. This method enjoyed great popularity in the 1960s and 1970s (see Ridley and Sheps, 1966; Jacquard, 1967; Barrett, 1969; Horvitz *et al.*, 1971; Dyke and MacCluer, 1973; Jacquard and Leridon, 1973), but was somewhat discredited by the construction of excessively complex models. It remains useful, however, for carefully targeted uses, such as evaluating the effect of a particular variable.

The life of an individual is simulated by applying to him or her, during each unit of time (month or trimester), the probabilities appropriate to his or her situation during the period in question. Figure 34–1 gives the schematic representation of such a model, which also incorporates variables for fertility control. A circle corresponds to a calculation (increment change in a duration variable, for example), a triangle to a "yes/no" test, and a rectangle to a random drawing. Consider a woman aged 15, still single. Step one is to

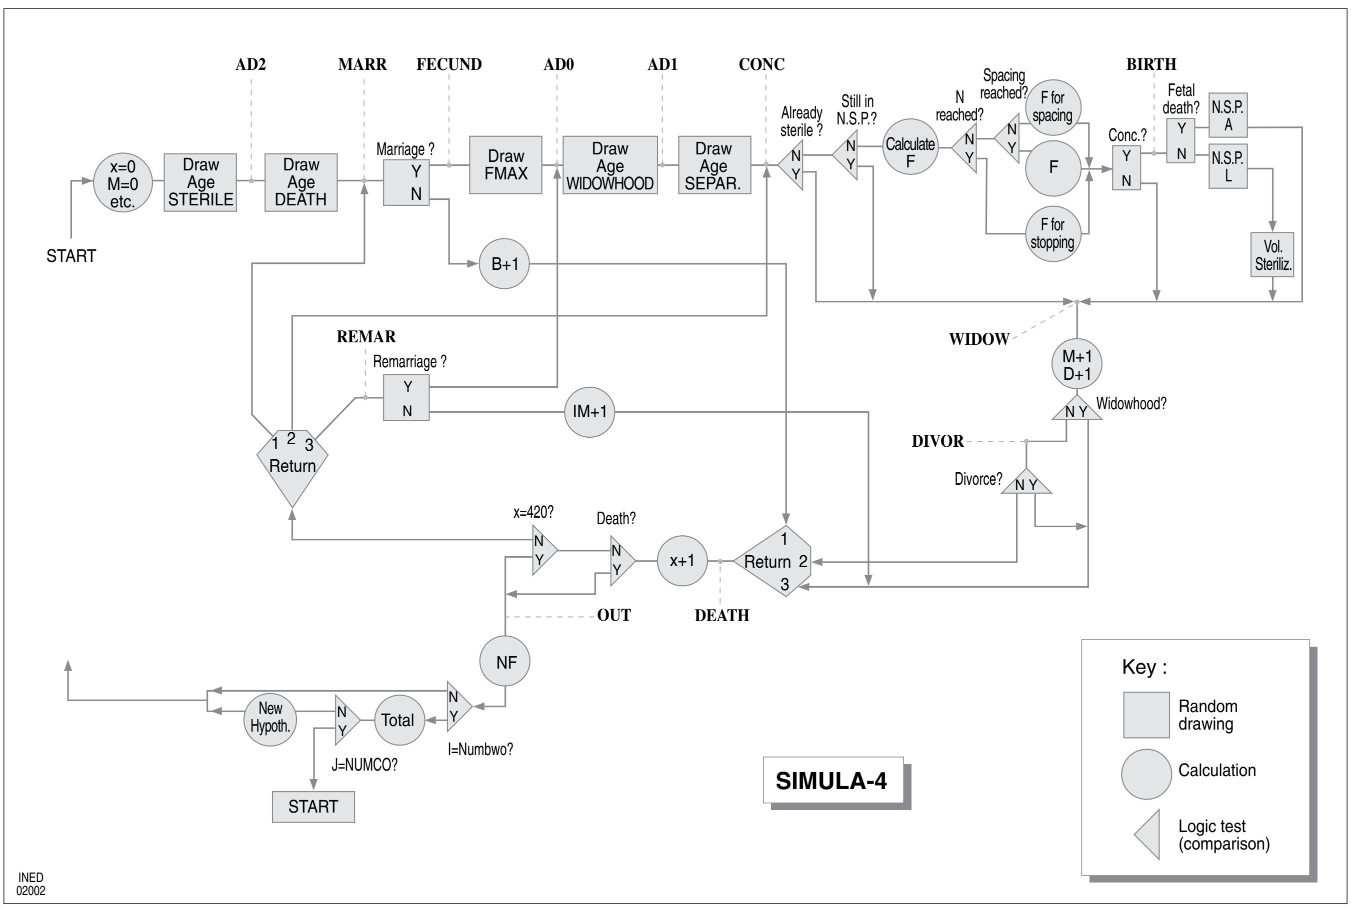

FIGURE 34–1 Schematic flow chart of the Simula program. Source: Leridon (1977).

determine by random drawing in distribution functions adapted to the population under examination, an age at death and an age of onset of permanent sterility, the assumption being made that these two events are unrelated to the reproductive history. The same procedure is followed for age at widowhood or at divorce (after marriage). The woman is then exposed to the risk of marriage during the first period (first month of her 15th year), then in each successive period. As long as the woman is unmarried, we stay on a short program loop in which we simply check that age at death and birthday 50 are not reached. Once marriage occurs, the woman is presumed to be exposed to the risk of conception. We check that she is not in a nonsusceptible period (which cannot be the case before the first pregnancy) and is not already sterile (permanently), and calculate her fecundability (which varies from one woman to another and with age); we draw to determine whether or not there is a conception, and draw again to determine the outcome of the pregnancy. If the couple is planning its fertility, a special module allows contraception to be included by reducing the value of fecundability, by a greater amount if the desired number of children has already been reached (stopping contraception) than if it has not yet been reached (spacing contraception). The length of the nonsusceptible period is then determined from an appropriate distribution (depending on the outcome of the pregnancy and the duration assumed for breast-feeding). The main loop is ended by a decision on voluntary sterilization, and the checking of ages at widowhood, divorce, and death. In the case of widowhood or divorce, the process starts again at the stage of marriage.

This process is repeated several thousand times, building up a sample of birth histories comparable to what would be obtained with a retrospective survey in a real population and which can be analyzed in the same way. As in any sample, the results have a margin of uncertainty (variance), which represents a disadvantage but also an advantage: a disadvantage because to reduce this margin of error it is necessary to work with large numbers; an advantage because it is also possible to calculate the variance estimates by repeating the process with the same parameter values.

The following sections contain examples of results obtained with a model of this kind.

4. The Princeton Indexes

As part of a vast project of comparative research on the demographic transition in Europe, Coale and his colleagues at Princeton proposed using a set of three indexes to separate the respective roles of marriage and marital fertility in the evolution of general fertility (Coale and Watkins, 1986). These were in fact the only parameters that could be analyzed given the available data. The approach is based on a double standardization, with calculation of a proportion of married women standardized for age, using reference fertility rates as weighting coefficients, and an index of marital fertility standardized for age, using the age-specific marriage rates as weighting coefficients. The general fertility index is then equal to the product of these two indexes and can be used to compare the observed fertility with that of a reference population. For each age a, let:

$w(a)$ number of women in the population;
$w_m(a)$ number of married women in the population;
$h(a)$ fertility rate in a reference population (fertility of Hutterite women);
$f(a)$ fertility rate in the population;
$f_m(a)$ marital fertility rate in the population

All births are assumed to occur within marriage. The indexes calculated are:

Index of marriage:

$$I_m = \frac{\sum w_m(a)h(a)}{\sum w(a)h(a)}$$

Index of marital fertility

$$I_g = \frac{\sum w_m(a)f_m(a)}{\sum w_m(a)h(a)}$$

Index of general fertility

$$I_f = \frac{\sum w(a)f(a)}{\sum w(a)h(a)} = I_m I_g$$

(we can verify that I_f is equal to the product of $I_m I_g$ by developing the two formulas and, bearing in mind the assumption of no extramarital fertility, $w_m f_m = wf$).

The fertility of the Hutterites (an anabaptist sect living in the northern United States) was chosen as the standard since this population has one of the highest fertility levels on record, along with that of female French Canadians in the 17th and 18th centuries (see Table 34–4).

5. The Coale and Trussell Schedules

As the first stage of research into age-specific model schedules of fertility, Ansley Coale began by examining age patterns of marriage. It is obvious that when the overwhelming majority of births occur within marriage, the first part of the age-specific (general) fertility curve depends essentially on that of marriage. A comparison of the age distributions of first marriage frequencies in various populations led Coale (1971) to conclude that they could all be deduced from each other by means of the following transformation:

$$G(a) = CG_S\left(\frac{a - a_0}{k}\right)$$

$G(a)$ proportion ever-married at age a;
G_s proportion observed in a standard population;
C proportion ultimately (at age 50) ever-married;
a_0 age at earliest marriage;
k defines the *pace* of nuptiality (the number of years of nuptiality equivalent to 1 year in the standard population S).

The function G_s selected represents the situation in the Swedish population in the mid 19th century, after dividing by a factor C_s (proportion ultimately married), so that its value reaches 1.0 40 years after the earliest marriages.

If we are only interested in the tempo of nuptiality, $G(a)$ depends on just two parameters: a_0, which is easily located, and k.

Likewise, the frequency function $g(a)$ can be deduced from the function $g_s(a)$. Ansley Coale also defined an algebraic expression of $g(a)$, which is a double exponential:

$$g(a) = \frac{k_1}{k}\exp\left[-\frac{k_2}{k}(a - a_0 - k_3 k) - \exp\left\{-\frac{k_4}{k}(a - a_0 - k_5 k)\right\}\right]$$

(with: $k_1 = 0.19465$, $k_2 = 0.174$, $k_3 = 6.06$, $k_4 = 0.2881$, $k_5 = 6.06$),

hence:

$$g(a) = \alpha \exp[\beta - \gamma a - \exp(\beta' - \gamma' a)]$$

Subsequently, Coale (1977) linked this formulation for g(a) to the notion of *marriage circles* (*cercles de nuptialité*) that Henry had developed in 1968.

Turning next to age-specific fertility, he merely defined the *model schedules* without taking into account the actual level of fertility. Given the function $G(a)$ defined earlier (proportion ever-married at age a), we can write:

$$f(a) = G(a)\, r(a)$$

$f(a)$ fertility rate at age a;
$r(a)$ marital fertility rate at age a.

This formula assumes there are no:

—extramarital births
—union dissolutions, through widowhood or divorce.

These two restrictions can be removed by slightly modifying functions $G(a)$ and $r(a)$.

As was done for the proportion ever-married, the marital fertility rates $r(a)$ are defined on the basis of a model schedule, representing a situation of natural fertility (no contraception). The relation is as follows (Coale and Trussell, 1974):

$$\frac{r(a)}{n(a)} = M\exp[m\nu(a)]$$

$n(a)$ natural fertility rate at age a;
M coefficient of total reduction in fertility;
m parameter representing the size of the fertility reduction resulting from use of contraception;
$v(a)$ modulating factor of m, by age a.

Since we are concerned only with the age pattern of fertility, not with its level, M can be disregarded. Its inclusion in Equation 2 expresses the fact that even when no attempt is being made to control births (m = 0), levels of fertility can vary widely. For this case, however, Coale admits a unique profile by age and hence a single-year schedule $n(a)$. The schedule $v(a)$ is also unique. This profile is intended to allow for the fact that when fertility is voluntarily controlled, the fertility rates that experience the largest reduction are those for older women who are attempting to limit the size of their family.

Two standard schedules are thus selected, for $n(a)$ and $v(a)$. Their M_T and V_T values are given in Table 34–2.

Ultimately, therefore, $r(a)$ depends only on parameter m (and the scale factor M).

Finally, by setting:

$$\sum_a f(a) = 1$$

we obtain:

$$f(a) = G_S\left(\frac{a - a_0}{k}\right) n_T(a)\exp[m\nu_T(a)]$$

TABLE 34–2 Values of by Age

	20–24 years	25–29 years	30–34 years	35–39 years	40–44 years	45–49 years
$n_T(a)$	0.460	0.431	0.396	0.321	0.167	0.024
$v_T(a)$	0	–0.316	–0.814	–1.048	–1.424	–1.667

The final set of schedules thus has three specified parameters: a_0, k, and m. The published tables (Coale and Trussell, 1974) are ordered by the values of these parameters, but other entries can also be used (various parameters that are easily calculated from observed distributions):

—Mean age of mother at birth (MEAN);
—Standard deviation of age at birth (STDEV);
—Ratio of fertility at ages 15–19 to fertility at ages 20–24 years (R1);
—Median age (MED);
—Coefficient of asymmetry (SKEW);
—Ratio of the average parity of women at 15–19 to that of women at 20–24 (PAR1);
—Same ratio for women at 20–24 and 25–29 (PAR2).

Using these entry parameters, we can look for the pattern that is closest to an actual distribution and thus determine, for example, the value of parameter m. That this parameter is a reasonably good indicator of fertility control in the population can be verified by comparing it with the value of the fertility rate at ages 40 to 44 or ages 35 to 39: the value of m rises steadily when these rates fall. Figure 34–2 compares the values of m with those of the average age at last birth calculated for a set of German villages studied by Knodel (1986), for marriages between 1740 and 1900. The experience of each village over time can thus be followed. We see that at the onset of the transition the mean age at last birth often rises slightly while m falls; next, the mean age falls steadily while m increases. Thus we go from a mean age close to 40 years with $m = 0$, to an age of around 38 years when m is 0.5.

6. The Bongaarts Model

Bongaarts (1976, 1983) has suggested a simplified model, based on a multiplicative decomposition of the fertility rate at a given age (or of the sum of these rates):

$$\text{TFR} = C_m C_c C_a C_i \text{ TBF}$$

where:

C_m index of nuptiality (1 if all women of reproductive age are married, 0 if there is no marriage);
C_c index of contraception (1 if there is no contraception, and 0 if all fertile women use a method that is 100% effective);
C_a index of abortion (1 if there is no abortion, 0 if all pregnancies are interrupted);

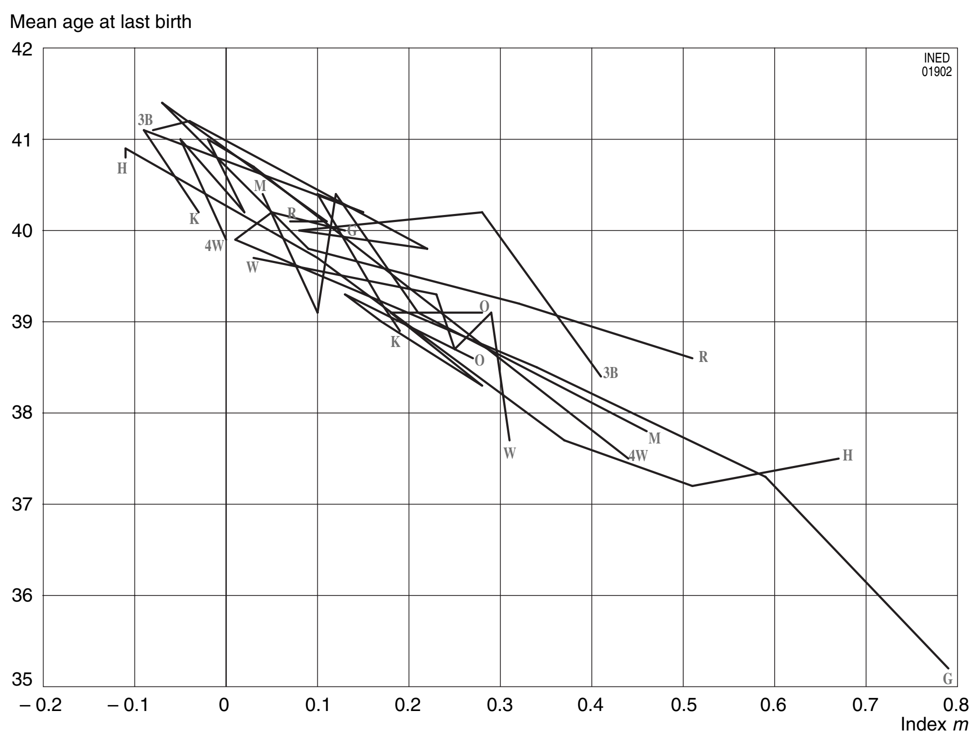

FIGURE 34–2 Correlation between mean age at last birth and the m index (German villages, marriages between 1740–1749 and 1875–1899). Source: Leridon (1989), based on Knodel (1986).

C_i index of postpartum nonsusceptibility (1 if there is no breast-feeding and no abstinence, 0 if the duration of sterility is infinite);
TBF total fecundity at biologic maximum (in this case, the sum of the age-specific rates is equal to 15.3 children).

Each of these indexes can also be expressed as the ratio of two fertility rates, with and without the effect of the factor under consideration:

C_m = TFR/TM = Total fertility rate/Marital fertility rate
C_c C_a = TM/TNM = Marital fertility rate/Natural fertility rate
C_i = TNM/TBF = Natural fertility rate/Total fecundity at biologic maximum

For example, for the sum of the rates (equal to the total fertility rate or the completed fertility) we obtain the following values:

	TFR	=	C_m	x	C_c	x	C_a	x	C_i	x	*TBF*
Crulai (Normandy) (marriages 1674–1742)	5.83		0.566		1.000		1.000		0.673		15.3
Hutterites (USA) (marriages 1921–1930)	9.15		0.733		1.000		1.000		0.816		15.3
Bangladesh (1976)	6.73		0.853		0.928		1.000		0.556		15.3
South Korea (1970)	3.90		0.586		0.780		0.848		0.658		15.3
France (1972)	2.40		0.519		0.334		0.973		0.930		15.3

Table 34–3 presents the results of calculating the three indexes C_m, C_c, and C_i, in various countries (World Fertility Surveys [WFSs] of the 1970s). Since total fertility rate (TFR) is also available in these surveys, the value of the *total fecundity at biologic maximum* (TBF) can now be calculated, so that the equation is no longer overdetermined. The values are seen to range from 10.0 to approximately 16.5, instead of the expected 15.3. The equation is thus imperfect, due to marked variation between populations in the factors omitted from the three C coefficients, errors in estimating each coefficient, disruptions caused by interactions between factors, or a combination of these explanations. Bongaarts' formula should thus only be used to obtain rough estimates of the different variables.

II. RESULTS: LEVELS OF FERTILITY

1. Observed Levels of Natural Fertility

Many studies in historical demography, notably those using the family reconstitution method, have made it possible to measure with precision the level of fertility in populations where fertility regulation was either absent or ineffective. Table 34–4 presents some results from this research.

These data show that even within a geographically limited area (France) and during the same period, natural fertility levels can vary widely between human population groups. The results of the simulations presented in the next section confirm that this variability can be explained by variables other than those of fertility regulation. No direct conclusion can therefore be reached (from the differences in the levels of overall fertility) concerning the wishes of couples in these populations regarding the desire to limit or not the number of their children.

2. Study of Possible Levels for Natural Fertility

The simulation models presented earlier can be used to explore the possible levels for natural fertility, by combining the values of the various parameters as observed or estimated for historical populations. Table 34–5, constructed using the SIMNAT model, which is a simplified version of SIMULA (developed by the present author from Jacquard's model) (see Figure 34–1), displays the number of children per woman under the stated assumptions and with no mortality or other causes of premature union dissolution.

According to this model, a woman who remained fecund and married between ages 15 and 45, would have, on average, 17.5 children, if she did not breast-feed. If the effect of sterility is introduced, the maximum is reduced to 15.2, a value that is close to Bongaarts' *biologic maximum fecundity*. In practice, there is no known population in which all women marry at age 15 and do not breast-feed their children. Thus the number of 15 children, although possible at an individual level, is not possible at the level of an entire population or subgroup. The values observed for real populations are between five and 10 children per woman and are thus obtained by combining the

TABLE 34–3 Parameter Values of the Bongaarts Model in Various Populations

hypotheses of early or late marriage and short or long breast-feeding. These two variables alone can thus account for a doubling of fertility levels, all of which, however, are considered to represent *natural* fertility regimes.

3. From Natural Fertility to Controlled Fertility

By introducing into these models some fertility control parameters (desired number of children, effectiveness of stopping or spacing contraception), it is also possible to evaluate the fertility-reducing impact of the contraceptive methods used. The advantages include that of being able to measure the impact both at couple level (how many couples would have more children than they want?) and at the aggregate level (by how much is fertility reduced?). Thus use of a contraceptive that is 95% effective, following the birth of the second child, will greatly reduce the overall fertility of the population (from eight to three children, for example) yet will leave a large majority of couples dissatisfied, because they will have had at least one more child than expected!

TABLE 34–4 Data on Natural Fertility

Place	Period	Mean number of children	
		Completed families of women married age 20[a]	All women surviving to age 50[b]
French Villages			
Ile-de-France	M 1740–1779	10.1	6.1

Villages near Bombay (India)	N 1954–1955	5.4	5.3

M, year of marriage; G, years of birth of women; N, years of birth of children
[a] Sum of marital fertility rates ages 20–49 years.
[b] Sum of general fertility rates ages 15–49 years.
Source: Adapted from Leridon, 1977.

TABLE 34–5 Completed Family Size with Different Levels of Natural Fertility (No Mortality and No Marriage Dissolutions)

Permanent sterility[a]	Postpartum nonsusceptible period[b]	Marriage at age 15	Distribution of marriage: early[c]	Distribution of marriage: late[d]
Normal	No breast-feeding	15.2	12.8	8.1
	Short breast-feeding	12.3	10.3	6.5
	Long breast-feeding	10.0	8.4	5.3

Shared assumptions:
Mean fecundability = 0.25 at ages 20–24 years (with a fecundability of half this value, the results have to be multiplied by a coefficient of around 0.8). Fecundability varies with age and between women; mean intrauterine mortality: 15% (varying with age).
Additional assumptions:
[a] Normal sterility: proportion of permanently sterile couples by age, as estimated by Louis Henry (mean age at onset of sterility: 41 years).
[b] Length of postpartum nonsusceptible period: with no breast-feeding: mean = 2 months; with short breast-feeding (15 months average): mean = 7 months; with long breast-feeding (24 months average): mean = 13 months
[c] Early marriage: Asiatic and African type: mean age: 19 years, no permanent celibacy.
[d] Late marriage: European type: 25 years, proportion never married: 8%

Table 34–6 shows the stages of the passage from a situation of noncontrolled fertility (in this example the situation in France in the middle of the eighteenth century) to a contemporary regime, with fertility in the region of two children per woman. This relies on the assumption that after the birth of their second child, couples use contraception that is 99% effective, this measure of effectiveness including the possible recourse to induced abortion. A 90% effectiveness, though it might appear already high, would lead to an average close to four children, well in excess of the two children desired.

TABLE 34–6 Comparison of Various Fertility Regimes (France, Historical and Contemporary): Results of the SIMULA Model

	Historic regime (no voluntary fertility limitation)	Contemporary regime (desired number of children: 2). Effectiveness of contraception:		
		0	90%	99%
Life expectancy (female)	25 years	70.5 years	75 years	75 years
Probability of survival at 15 years	0.46	0.95	0.98	0.98
Mean age at marriage	25 years	21.5 years	21.5 years	21.5 years
Probability of conception/month	0.25	0.25	0.025	0.0025
Duration of breast-feeding	2 years	1 year	0	0
Mean number of live births, per woman at 15 years	4.1	8.6	3.8	2.0
Mean number of children surviving to 15 years, per woman at 15 years	1.9	8.4	3.8	2.0
Net reproduction rate	0.93	4.1	1.8	0.95
Annual rate of natural increase	–0.2%	+4.5%	+2.0%	–0.2%
Proportion of married women having more than desired number of children	—	98%	86%	18%

CHAPTER

35

Induced Abortion

GIANPIERO DALLA ZUANNA

Dipartimento di Scienze Statistiche, Università degli Studi di Padova, Padova, Italy

ABORTION DURING THE DEMOGRAPHIC TRANSITION

Voluntary abortion (referred to here for reasons of convenience as abortion) is the end point of a complex succession of acts and decisions which can be mapped as indicated in the schema below:

From Conception to Abortion: Stages in Decision Making

Conception	Abortion	
	Yes	No
Wanted	A	B
Unwanted	C	D

Studying abortion, involves studying the four situations (A, B, C, and D) represented in the table within the population, in an attempt to clarify the underlying mechanisms of the different choices (or of nonchoice) by individuals and couples. Situation A, which is undoubtedly uncommon, occurs when, after a child has been willingly conceived, the couple decides to prevent the birth. For example, the couple may decide that the result of conception does not correspond to their expectations. This may be a reason for selective abortion (depending on sex) or a so-called *therapeutic* abortion (following an antenatal examination showing congenital malformations).

The incidence and relative weight of the three other situations are determined by the population's position on the path of demographic transition. During the *pretransition stage*, most couples consider conception within marriage as a normal thing, and the arrival of a child is rarely perceived as a threat to the well-being of the parents or to children already born. Moreover, health and hygiene are generally deplorable, and for a woman an induced abortion is more of a risk than childbirth. During this pretransition stage, undesired conception (which at certain periods or in certain circumstances may be quite frequent, especially outside wedlock) leads to unwanted births, which, in certain social circumstances may result in the abandonment (exposure) of the child or even to infanticide.

During the *demographic transition*, a growing number of couples wish to limit the number of children they have. In countries that experienced an *early demographic transition* (EDT) and in which the drop in fertility took place essentially before or at the time of World War I, lack of access to effective contraceptives led to an increase in the number of undesired births and at the same time to an increase in the number of abortions which, even if illegal, had become less dangerous for mothers, thanks to progress in medicine and hygiene. The combination of these factors led to an increase in the frequency of abortions. In these same countries, during the subsequent phase (*posttransition*), recourse to abortion declined as more effective methods of contraception were made available.

Table 35–1 shows a number of empirical examples. These data represent those countries in which abortion is available on demand or for socioeconomic reasons

TABLE 35–1 Fertility and Abortion when Abortion becomes Legal on Economic and Social Grounds or on Demand, and Abortion Rates in 1987

Country	Year abortion liberalized	Year TAR[a] calculated	Year TFR[a] calculated	TFR[b]	TAR[a]	TAR[a] towards 1987

[a] TAR, total abortion rate (average no. of abortions per woman), see note 1.
[b] TFR, total fertility rate (average no. of children per woman).
Source: For abortion: United Nations, 1992, 1993, 1995. Abortion policies: a global review. New York, United Nations, vol. I: Afghanistan to France, 158 p; vol. II: Gabon to Norway, 243 p.; vol. III: Oman to Zimbabwe, 236 p.; for fertility: United Nations, Demographic Yearbook, different years.

and data on fertility and abortion are available for the years immediately following the liberalisation of abortion laws. Excluding Hungary from the calculation, the correlation coefficient between fertility and total abortion is 0.753, and the two indicators are linked by the following linear relation:

$$\text{TAR} = 0.125 + 0.285 \times \text{TFR}^{1}$$

Thus presented, the trend appears excessively simple. In reality, the pattern has varied considerably from one country to another. Although there has been insufficient research in this area, it has been determined that during the demographic transition, the balance between abortion and traditional contraception has varied considerably (Frejka, 1985; Mundigo, 1993). Generally speaking in countries where abortion was legalized at a time when fertility was still high, abortion seems to have played a predominant role to the extent of having been the principle method of birth control. In the other countries, abortion was for most couples a resort used only when contraception had failed; limitation of births essentially involved periodic abstinence or coitus interruptus or (in only few countries) use of condoms.

It may appear as though the correlation between the two measures is high simply because levels of abortion and fertility are themselves high where the rates of pregnancy are high. In reality, abortion rates were high where legislation was introduced while fertility was also high and it is in these same countries that several decades after legislation, abortion levels remain the highest (the final column in Table 35–1) although fertility has dropped substantially. It appears that in countries where abortion was legalised while fertility

[1] The usual measurements of *abortion* are very simple: the two most common indicators are the *abortion rate* (induced abortions/women aged 15–49 or 15–44) and the *abortion ratio* (induced abortions/pregnancies), in which the denominator is the total number of induced abortions and of births in the same period. Obviously, both these measurements give different and complementary values for the incidence of induced *abortion* and are used in conjunction to describe the phenomenon. The *abortion rate* fails to take into account the age structure of the female population of childbearing age. To offset this drawback, it is possible to use the *total abortion rate* (TAR), or average number of abortions per woman, which is analogous to the total fertility rate (TFR), calculated as the sum of the *abortion* rates per age (or age groups). If the age structure of women of childbearing age is roughly rectangular, it is possible to estimate TAR by multiplying the *abortion rate* by the number of years involved (for example, by multiplying, as in Table 35–1, the abortion rate of women aged 15–49 by 35). If there is little variance in the age groups structure of the countries being compared, they may be thus transformed into TAR to render the measurement more significant.

remained high, the spread of contraception was less rapid than in countries where contraception was introduced while abortion remained illegal.

However, this chart is rather superficial and cannot fully represent the significance of the differences observed in levels of abortion from one population to another. For example, in the Soviet Union, and more generally in the Slav countries, or in Japan, the success of abortion as a means of birth control may be linked to factors other than the mere legislative calendar: possibly, among these populations, the pretransition *cultural environment* was more favorably disposed toward abortion than in the other EDTs (Frejka, 1985; Blayo, 1993; Avdeev *et al*., 1994; Otha and Sawayama, 1994; Dalla Zuanna, 1996; Stloukal, 1996).

Another challenge to the linear representation of the trend comes from *the still high levels of abortion in some western EDTs, despite the widespread availability of modern contraceptive techniques* (Dalla Zuanna, 1996). In the early 1990s, in France, Denmark, Sweden, the United Kingdom, and Norway, to cite but a few, although 70% of couples used modern contraceptive techniques (sterilization, the pill, intrauterine devices [IUDs]), the average number of abortions per woman was still 0.3 to 0.4. As young nulliparous women largely sought these, the explanation may be found in the young age at which they begin having sexual relations, when contraceptive protection is often inadequate. Among couples who have already had all the children they want, abortion is much less common in these countries than in those EDTs in which modern contraceptive techniques are less widespread. However, the existence of a direct relationship between the availability of modern contraceptives and low levels of abortion is debatable.

To conclude, the positioning of abortion during the demographic transition in EDTs is controversial. Causal structures of the simple type,

increase in undesired conceptions $\rightarrow$ *more abortions*

or

wider availability of modern contraceptive techniques $\rightarrow$ *less abortions*

must be viewed with caution and evaluated within diverse cultural and social contexts. As we will discuss in subsequent sections, in accounting for differences in abortion, it is not sufficient to consider merely those variables directly linked to reproductive behavior.

In countries that experienced a late demographic transition (*LDT*), the role played by abortion is different because the widespread desire to limit the number of births in marriage appeared at a time when modern contraceptive techniques were already (at least from the technical angle) available. The diversity of conditions is due to four factors: *traditional views of abortion; current legislation; the availability of means of contraception; and the capacity/willingness of couples to practice effective contraception*.

The observation made of the Slav countries remains valid: When traditional moral values do not disapprove of abortion and when legislation is (either formally or de facto) liberal before fertility begins to decline, the number of abortions may be high, although modern contraception is fairly widespread, as for example in Cuba, China, or Viet Nam (Feng, 1994; Farina, 1996). However, in most LDTs, abortion legislation is very restrictive (Table 35–2), even if the predominant religions are morally tolerant toward it (whether during the entire pregnancy, as in the case of Buddhism and Hinduism, or during only the first 4 months of pregnancy, as in the case of certain Islamic schools of thought). In these countries, abortion is rarely as frequent as in Japan or in the Slav countries. However, in many LDTs with restrictive legislation and in the throes of demographic transition, clandestine abortions are far from negligible, despite the wide availability of modern family planning techniques. This is attributable to the fourth of the factors: the capacity/willingness of couples to practice effective contraception. Indeed, some couples who want to limit births may find it difficult to adopt the rational choice (even when there are facilities to assist with family planning): the use of effective contraception. In numerous LDTs (especially in Latin America), the early age of marriage and low use of contraception to space births mean that couples achieve the desired number of children while the mother is still young and will remain fertile for another 20 years; in addition, gender relations are such that the couple's equilibrium is not very compatible with women taking responsibility for contraception (Pinnelli and Milan, 1996; Paiewonsky, 1999). Lastly, the manner in which birth control is

TABLE 35–2 Proportion of Developing Countries with Authorized Abortion (Early 1990s)

Recognized grounds for abortion	Proportion, %
To save the mother's life	91
To preserve the mother's physical health	52
To preserve the mother's mental health	35
Sexual violence or incest	26
Fetal malformation	23
Request	6

Source: WHO, 1994. *Abortion: a tabulation of available data on the frequency and mortality of unsafe abortion*, 2nd ed. Geneva, World Health Organization.

introduced to a community rarely respects the culture of the target population and may give rise to suspicion or even refusal among potential users.

As we have already observed, in many LDTs, the combination of the factors described seems to lead to situations in which abortion is widely practiced and the proportion of illegal abortions, often carried out in deplorable sanitary conditions, is high. Nevertheless, caution is required because it is often difficult to estimate the scale of illegal abortion. Estimates by different sources and using different methods yield very different results, whether for abortion itself or for its consequences, particularly maternal mortality. Consequently, the data available must be taken with caution, even when they come from the most reputable organizations or from solemn declarations made at major international conferences (Mauldin, 1994); this is all the more so since they are not necessarily exempt from the constraints of diplomacy and political compromise. This same caution is necessary when examining the data gathered by Singh and Henshaw (Table 35–3), most of which concern LDTs and adopt the average hypothesis proposed for the early 1990s by the World Health Organization (WHO, 1994).

Thus, there is no doubt that in many LDTs, abortion has become a dramatic problem since the decline in fertility. As a result, research on abortion has begun to seek data, focusing on LDTs at the expense of EDTs (Table 35–4). Studies have multiplied in a number of directions, although it is possible to identify three major ones: (1) estimation of the number of abortions in the absence of satisfactory registration; (2) analysis of the pathways to abortion, using a statistical–quantitative approach; and (3) favoring qualitative techniques and adopting an anthropologic approach to examine an individual's decision as the expression of a choice that has been historically determined by particular sociodemographic contexts. We will describe the *how things stand* from these three angles, emphasizing methodologic aspects rather than results. To do so, we will sort the possible themes, setting aside aspects that have been much debated recently, such as

TABLE 35–3 Estimate (Circa 1990) of No. of Abortions by Degree of Safety for Mothers, Abortion Rates, and Ratios

Regions	No. of abortions by sanitary conditions			Rates[a]	Ratios[b]
	Total	Good conditions	Poor conditions		
World total	***49,666,000***	***29,666,000***	***20,000,000***	**1.20**	**26**

induced early abortion by the suction method carried out at the first sign of a delayed period regardless of whether the cause is the fertilization of an ovule or sex-selective abortion depending on the sex of the children already born or that of the fetus.

1. Estimation of the Number of Abortions in the Absence of Regular Registration

The techniques used to estimate the number of abortions vary, particularly depending on the data available. We will adopt the classification of Singh and Henshaw (1996) to present those techniques of greatest interest from a methodologic angle.

a. Retrospective Surveys (Random or Selected Populations)

Estimating the number of abortions by retrospective survey, which might appear to be the simplest approach, is actually flawed by women's systematic tendency to report a lower number of induced abortions than those they have actually had: Whenever the results of such surveys are compared with those from other sources, a systematic underevaluation, which may exceed 50%, appears even in countries in which abortion has long been legal (Casterline, 1989; Henshaw, 1989; Jones and Forrest, 1992; Huntington *et al*., 1996). This is clearly linked to the psychological and ethical implications of abortion, which may cause interviewed women to conceal something they consider to be a failure, a fault, or at the very least a private matter, especially if they rejected their pregnancy for nontherapeutic reasons (Atkin, 1989). In contrast, the data provided by retrospective surveys are more reliable in countries such as Romania, Turkey, or China, where abortion is more often used as a method of birth control.

However, significant improvements may be achieved by complying with a number of recommendations on how to handle sensitive, strictly personal questions or matters that verge on illegality (or that are illegal). The question of the number (and date) of induced abortions may, for example, be included in a questionnaire on sexual behavior that interviewees fill in themselves and return to the interviewer in a sealed envelope. Similarly, honesty during the interview is improved if questions on induced abortion are included as part of a questionnaire on health, rather than on reproduction. Finally, better results are obtained when questions regarding abortion are administered during a gynecologic interview of women consulting gynecologic and obstetric services; statements are obviously more truthful and complete when they are made in connection with concrete health problems (Bonarini, 1984).

The problem of underrecording would not be so important if the tendency to conceal were independent of the women's characteristics. Unfortunately, this is not the case. Some surveys, based on hospital abortion registers, make it possible to check the truthfulness of retrospective health histories. For example, in Estonia, it has been found that failure to report an abortion is relatively more frequent among Estonian women than among Russian women, women older than 40 years, those who have had an abortion after the third month of pregnancy, unmarried women, and women who have more than three children (Anderson *et al*., 1994). In the United States, omission is more frequent among nonwhite women, the less educated, and those whose previous abortion was a long time ago (Udry *et al*. 1996).

b. Estimates Based on Hospital Registers of Abortion Complications

In countries where abortion is illegal and it is possible to carry out surveys (even nonexhaustive ones) on reasons for admission to hospital, it is possible to estimate the average number of abortions per woman (n_{av}) by the following formula:

$$n_{av} = \frac{n_e \times H_{av}}{H_{ac}} \times K \qquad \text{(Eq. 1)}$$

in which n_e is the average number of children per woman; H_{av} the number of hospital admissions for abortion, whether induced or not; H_{ac} the number of childbirths in the same hospitals and K a coefficient that takes into account spontaneous abortions, the proportion of abortions not involving admission to hospital, the proportion of deliveries in hospital, and prevalence of contraception (WHO, 1994; Singh and Wulf, 1991, 1994). Estimation of coefficients H_{av} and K in this formula is quite complicated because, for each country, adjustments must be made to take account of their specific situation (for further details, see the articles cited). The estimate is a very crude one, although its advantage is that it uses data generally available in countries where, for example, surveys similar to Demographic and Health Surveys (DHSs) of women's fertility have recently been carried out. A considerable proportion of the estimates in Table 35–3 have been produced using this formula, which, when compared with other estimation techniques, yields results that are generally deemed acceptable.

c. Estimates Based on Bongaarts' Model for Analyzing Intermediate Variables of Fertility

We know that in Bongaarts' model (see Chapter 34), the average number of children per woman n is derived from the maximum number of children n_{max} a woman may have (generally estimated to be 15) using the following expression (Bongaarts and Potter, 1983):

$$n = n_{\max} \times C_m \times C_c \times C_a \times C_i \qquad \text{(Eq. 2)}$$

in which the four coefficients C measure the reducer effects of marital fertility C_m, contraception C_c, induced abortion C_a, and postpartum amenorrhea C_i, the last of which in practice combines the effects of breast-feeding and postpartum abstinence. This method may be used only if there are few births outside wedlock and thus makes it possible to estimate abortion only among married women. Without going into the technical details of the estimation of the coefficients, note that it is fairly easy to measure the average number of children per woman, C_m, C_c, and C_i on the basis of different types of surveys of reproductive behaviour (*World Fertility Survey* [*WFS*], *DHS, or Fertility and Family Survey* [*FFS*][2] to cite but the most well-known and accessible). This leaves C_a as the only unknown value in the Equation 2. This method of measuring abortion (with a number of variations) has been and still is widely used (Frejka, 1985; Foreit and Norman, 1992; Johnston and Hill, 1996) because it has the advantage of requiring no data on abortion. In addition C_a (between 0 and 1) is of important demographic significance because it measures the proportion of potential fertility lost through induced abortion; comparison of C_a and C_c (the coefficient of contraception) also makes it possible to speculate as to the relative importance of these two factors in birth control.

For example, for 1972 in Poland, using data from the World Fertility Survey and other official data on n, the Equation 2 may be quantified as follows (Frejka, 1985):

$$n = n_{\max} \times C_m \times C_c \times C_a \times C_i$$

$$2.3 = 15.3 \times 0.52 \times 0.41 \times C_a \times 0.95 \rightarrow C_a = 0.74$$

This means that in this particular case, induced abortion reduces theoretical fertility by 25%. The estimate for C_a using official sources (administrative statistics) would be 0.88. Thus, at the beginning of the 1970s in Poland there was an unrecorded level of abortion, as the article referred to also points out.

The method's main technical shortcoming is that any inaccuracy in the estimation of coefficients other than C_a directly affects the value of C_a and hence the number of abortions. The problem is perhaps C_c (the contraception coefficient), especially in countries where methods such as periodic abstinence and coitus interruptus, whose efficacy (which largely depends on the level of motivation of those who practice them) is difficult to determine, are widespread. Moreover, C_a may also be affected by the weight of factors the model fails to take into consideration because they are assumed to be invariable whatever the population, (such as the level of sterility and the frequency of sexual relations). The model may be applied only in countries where having children outside marriage is proscribed; consequently, the coefficient C_a represents only abortions among married women, unless very precise data are available for unmarried women.

If we do not have values for all the coefficients in Bongaarts' model, it is possible to adopt the same *residual* logic to estimate abortion, by reducing or grouping the intermediate variables required for the estimate. For example, one can estimate the average number of abortions per woman in the years immediately after liberalization using data solely on fertility, by the regression line for the data in Table 35–1 (paragraph 1). However, this has the drawback of not taking contraception into account. Whatever the case, such methods produce results that are heavily dependent on simplistic and often unacceptable hypotheses (Bonarini, 1992).

d. Estimates Based on the Trend in the Proportion of Repeated Abortions

If *abortion* remains roughly constant over a ten year period, the proportion of *repeat abortions* is heavily dependent on the level of *abortion* (Tietze and Jain, 1978).

[2] Fertility and Family Surveys, collected in Europe during the 1990s.

Using data for 12 countries with poor statistics, Stanley Henshaw (1989) made an empirical estimate for the following quadratic equation that, for the 12 countries, fits the data quite well ($R^2 = 90\%$).

$$a_{15-44} = 1000 \times \frac{A}{F_{15-44}} = 135.9 \times P^2 + 4.8 \quad \text{(Eq. 3)}$$

in which a_{15-44} is the abortion rate between the ages of 15 and 44, A the number of abortions, F_{15-44} the number of women aged from 15 to 44, and p the proportion of repeated abortions.

If we have reliable data on the proportion of abortions ranking above 1 (from hospital surveys, for example), the equation allows us to estimate the abortion rate without requiring any other data.

However, as the author himself emphasizes, the model has been highly criticized from a theoretical angle (Henshaw, 1989; Singh and Henshaw, 1986). First, it is applicable only to countries in which there is no decisive variation in abortions over time, otherwise the estimates obtained reflect the average level of abortion during the last 10 years. Second, the database used (a few EDTs in the 1970s and 1980s) is very limited in time and space; if we apply the model to other countries, we implicitly assume that the ratio of overall abortions to repeated abortions is the same as in the countries (and the periods) used to estimate the Equation 3. The problem with this hypothesis is that because the ratio of overall abortions to repeated abortions may vary from one population to another due to differences in the internal heterogeneity of populations (Dalla Zuanna and Garofolin, 1991; Bonarini, 1992; Singh and Henshaw, 1996). It is possible to clarify this with an extreme example of maximum heterogeneity: Let us assume that within a given population 1% of women use abortion only as a means of birth control and the remaining 99% have never aborted; the abortion rate will be relatively low (10/1000), but virtually all these abortions will be repeated abortions. Moreover, in countries where there is no regular registration of abortion (i.e., precisely those for which an estimative method has to be used), to determine the proportion of repeated abortions in many cases the only source is hospital data on women hospitalized for abortion-related complications, who do not constitute a representative population. Finally, as we have already pointed out, reconstituting abortion histories is a sensitive matter because women may not mention their previous experiences of abortion. Consequently, estimation of the proportion of repeat abortions on the basis of declarations made by women themselves may underestimate the number.

In spite of its somewhat fragile foundations, this method may be used to provide an idea of the level of abortion and, in countries with regular statistics, to speculate as to the possible level of underrecording. For example, in 1987, in two regions of Italy, official data produced very similar abortion rates for women aged 15 to 44: 8/1000 in the Veneto and 10/1000 in Calabria, at the lower end of the ladder of Italy's 20 regions. However, the proportion of repeated abortions was 27% in Calabria and only 15% in Venezia. If we apply the Equation 3, it gives an abortion rate of 8/1000 for Venezia (equal to that of the official statistics), but for Calabria the figure is 15/1000 (i.e., 50% higher than the official figure). This estimate concurs with other indices, suggesting that not legal induced abortions are common in southern Italy.

To close this section, let us revert to the problem posed in the first paragraph. It is difficult to estimate the number of clandestine abortions and the results depend heavily on the method adopted. If we partly follow the recommendations on estimation of maternal mortality made by Parker Mauldin (1994), to obtain scientifically valid indicators of clandestine abortion we must (1) not adopt a single method but rather compare the results of different approaches; (2) for each method used, not accept a one-off estimate but provide an idea of the scale of possible variations by altering the basic hypotheses; (3) strictly control the data sources and examine the possible effects of errors of observation.

2. Study of the Causes of Abortion: A Statistical and Quantitative Approach

The complexity of the causal chain leading to induced abortion has already been emphasized: To fully to understand the phenomenon, it would be necessary to take into account the entire process leading to the decision. Reverting to the initial scheme (Table 35–1), we would need to distinguish between the causes of a conception (whether wanted or not) and the causes of a decision to terminate a pregnancy by induced abortion rather than trying (or accepting) to allow the pregnancy to run its course to birth (whether wanted or not). Unfortunately, in practice it is far from simple to do so, if only because, as we have already seen, abortion does not easily lend itself to observation through a conventional quantitative survey. In addition, as we will explain more fully in the next paragraph, causal analysis is marred by the lack of a theoretical explanation for abortive behavior. In most cases, studies are merely descriptive and are intended at the very most to highlight categories among whom the risk of abortion is high or low. Even the most sophisticated analyses, capable of correctly isolating the effect of some factors on abortion, ultimately serve only to clarify the description rather than to improve our ability to explain, simply because we have no behavioural hypothesis to verify. Rather than *causal analyses of abortion*, it would be more accurate to talk of *differential analyses of abortion*.

Thus, we may distinguish two groups of analytic techniques. The purpose of the first group is to measure abortion by isolating different groups of women and analysing the differences observed.

As we explained in note 2 above, the two most commonly used measurements are the *abortion rate* (the number of abortions per woman) and the *abortion ratio* (the number of abortions per pregnancy or per birth). The great majority of demographic studies on abortion are based on these measurements in terms of age, marital status, the number of previous births, race, religion etc.; the sole constraint is the availability of data to permit classification, using these same criteria, both of women who abort (the numerator) and of all women or women who give birth (the denominator). These measurements are also the basis of the compilations regularly published by the Alan Guttmacher Institute until the late 1990s (*Abortion, a world review*) and by the United Nations (in particular, *Abortion Policy, a global review*, published in three volumes in 1992, 1993 and 1995) and of the series generally available in those countries with regular registration systems. As we have already seen, we may go beyond the mere calculation of abortion rates or ratios and assess the net impact on abortion of a number of potential explanatory variables. Studies based on *logistic regression*, in which the *abortion/pregnancy* ratio is modelled so as to calculate the relative risk of abortion for each category (or cross-classification) of explanatory variables are increasingly common (see, for example, Feng, 1996). In order to apply this technique a set of data on pregnancies classified by outcome (abortion or birth) and by explanatory variable is required; this is generally based on survey data, although it may also be based on comparison between registers of abortions and births, provided the explanatory variables may be classified in the same way for both events.

The second group of techniques used to study differential abortion (of which demographers, unfortunately, make less use) adopts the case-control analysis. Women who have had abortions are the *cases* and those who have not had abortions (properly selected at random) the control group; a variable is linked to abortion if it is not similarly distributed among the cases and the control group. In contrast to the methods described previously, it is possible to use this technique even if the overall population distribution (or the distribution of women having had a child) in terms of the variables concerned by the differential study is unknown: it is sufficient to know the distribution among a sufficiently representative control group. In addition, where case-control analyses are concerned, we may call on proven techniques to highlight the effect on abortion of each variable, regardless of composition in terms of the other possible explanatory variables. Examples of this type of differential analysis of abortion (in most cases carried out by epidemiologists) show the importance of careful choice of method for selecting the control groups (La Vecchia, 1986; Skjeldestad, 1994; Houghton, 1994). In the same scheme as case-control studies, although simpler to handle, we have research based on comparison of the distribution (by the available variables) of women who have had an abortion and the total population (see, for example, Henshaw and Kost, 1996).

3. The Causes of Abortion: An Anthropologic Approach

Anthropologists have long been interested in abortion (and in everything connected with human reproduction). Nonetheless, two factors have recently oriented these topics in a new direction: realization of the growing importance of abortions in the LDTs and the specific and longstanding interest of anthropologists in matters concerning women, and more recently, gender relations. In her introduction to the collection of articles *Abortion from a Cross-cultural Perspective* (1996, p. 481) Barbara Rylko-Bauer makes the following conclusion:

The value of an anthropologic and cross-cultural perspective on abortion may not lie so much in measuring precise, quantifiable features (*although this should be an integral part of such work when possible*)*, but rather in:* (1) *documenting the socio-cultural, economic, ideological and political complexity of abortion across cultures, as these case studies have done; and* (2) *in identifying the processes and contexts that define abortion at the various levels* (*individual, community, national*) *of analysis and how they articulate with each other. The end result will provide a more realistic picture of abortion world-wide and will focus attention on the women who have remained invisible for far too long, and whose lives, after all, are ultimately affected by the debates, policies, and studies of abortion.*

From a methodologic perspective, anthropologic studies are quite distinct from those described so far. As is also apparent from the above quotation, anthropologists emphasize complexity, interaction between the different levels of analysis and more generally the impossibility of understanding abortion outside the framework of relations between body–spirit, man–woman, family–community and community–state. They set out to interpret each experience of abortion as the response by an individual will to a set of social, historic and cultural determinants. In contrast, the quantitative studies described above take another (and thus perfectly complementary) tack: once the variables that may be linked to abortion have been identified, we adopt the implicit hypothesis that there is no other source of heterogeneity, in other words that the individuals characterized by a given vector of explanatory variables are equal in terms of the risk of abortion. Another fundamental difference of this method is that anthropologists choose a deductive approach: the sole purpose of field study is to validate hypotheses, adopted *a priori*, for the behavior of individuals and communities. In contrast, for the most inductive of the statistical-descriptive studies presented above, the objective, which is often implicit, is to *let the data speak for themselves*.

The methods of field research too are different. As emphasized in the passage cited above, the prime concern of anthropologic research is not to measure abortion as a phenomenon. First and foremost it is concerned by the collection of detailed data on the lives of women (and of men) who decide to abort (or not to abort), information on their family, professional or social environment, on the moral values of their friends and relatives and of the community to which they belong. Consequently, an anthropologic study requires lengthy and detailed observation of the community in question, involving the reconstitution of lengthy life histories, bringing together key witnesses, the dynamics of focus group discussions, in other words groups of women with common characteristics (such as those who have recently had abortions or given birth) with whom the investigator leads a discussion in order to bring out the chain of events and factors responsible for their having aborted or having given birth.

Examples of the application of this information gathering technique to the study of abortion may be found in the compilation of articles referred to above (Rylko-Bauer, 1996) and in the proceedings of an IUSSP seminar (1996). Moreover, more and more studies of abortion during the pretransition stage adopt historico-anthropologic approaches, as may be seen from a review of the papers presented to the seminar organized in October 1994 by IUSSP on *Abortion, infanticide and neglect in the Asian past: Japan in Asian comparative perspective*, and in the results of research into abortion in the Soviet Union during the communist era (Avdeev *et al*., 1994). Clearly, these are very recent studies whose results have not yet been confirmed, and *the behavioral dimension of induced abortion remains largely a question mark* (Mundigo, 1996, p.15). The two most noteworthy arguments in favour of a behavioral theory of induced abortion are perhaps the emphasis placed on the dialectic between religious, individual and collective norms and on negotiation between men and women over decisions in respect of contraception (and the methods) and the outcome of a pregnancy; in this regard, the study made by Georges (1996) on Greece is highly instructive.

In comparison with these studies, conventional differential analyses seem to have very little to offer, particularly in terms of a genuine explanation. Nevertheless, anthropologic studies themselves have limits. By necessity, anthropologists deal with very small groups of individuals who, moreover, are not chosen at random. For example, in an article entitled, *Abortion Policy and Practice in Greece*, the author restricts himself to two samples of married women on the island of Rhodes (i.e., 26 and 62 women in each group) chosen on a voluntary basis after most of the women selected by random sampling had refused to participate in the study (Georges, 1996). In actual fact, the well-known complexity and specificity of the various situations that may account for abortion prevent us from easily accepting any abusive extrapolations from observations that can only be highly specific.

As we have already observed, the deductive nature of anthropologic studies means that hypotheses are predetermined before being tested against observations in the field; consequently, the results of empirical verification may to some extent themselves be predetermined. Thus the sentence of Barbara Rylko-Bauer, referred to above, places a strong emphasis on the key role of women in the abortion process. This insistence may lead us to forget that

> High levels of abortion may signal a crisis of cultural representation of the unborn children, which assumes a "relational" nature, since for anyone who has an abortion the subjective right to be born is subordinated to other rights of the parents (or of the mother), or alternatively springs from society's willingness to accept it, specifically expressed by the parents (or woman)[3] (De Sandre, 1995, p. 19).

In this particular instance, the rich tradition of anthropologic studies of the cultural representation of reproduction might provide the tools for interpreting and more deeply understanding the problems referred to by De Sandre. Possibly, the different *cultural representations* of birth and nonbirth may hold one of the keys to interpreting the different combinations

[3] *Elevati livelli di abortività possono essere un segnale della crisi della rappresentazione culturale del figlio-nascituro, che assume una natura "relazionale"* [*virgolette dell'autore*], *nel senso che, per chi abortisce, il diritto soggettivo alla nascita è subordinato ad altri diritti dei genitori* (*o della madre*) *o, alternativamente, sorge sulla base dell'accoglienza sociale specificatamente manifestata dai genitori* (*o dalla donna*).

between abortion/contraception noted from one country to another during the different stages of the demographic transition.

To conclude, the anthropologic approach and the differential statistical–quantitative approach may mutually reinforce each other; as has already been observed, a number of recent scientific initiatives, especially under the aegis of IUSSP, seem to have taken this direction. Interaction between these, and other disciplines may perhaps allow us to build, stone by stone, more satisfactory explanations for the phenomenon of abortion.

Demography and Sexuality

MICHEL BOZON
Institut national d'études démographiques (INED), Paris, France

In common with the sociology of the family and the anthropology of kinship, demography only very belatedly turned its attention to sexuality, which is ironic given the discipline's comprehensive treatment of couple formation and nuptiality, divorce and partnership breakdown, fertility, and contraception. Not examining sexuality explicitly amounts tacitly to taking it as a natural and relatively fixed element of human behavior. Only with the advent of modern contraception and, more important, the emergence of the acquired immunodeficiency syndrome (AIDS) epidemic, did demographers develop instruments for detailed observation of sexual behavior, thereby acknowledging that it was a phenomenon subject to meaningful variation. The historic context for demographers to direct their attention to sexual behavior was the transformation and decline of nuptiality in developed countries; it was not directly linked to earlier efforts to explain and follow fertility reduction in developing countries.

The reasons for this difficulty in considering sexuality are discussed and illustrated in the first part of this chapter. The next section argues that demography is in fact technically well equipped for a rigorous and critical approach to observation of sexuality. Three fields are then identified where analytical observation of sexual behavior from a demographic standpoint (sometimes in conjunction with other social sciences) can increase understanding of major societal processes. Analysis of sexual histories elucidates contemporary shifts in sexual standards and changes in family and partnership behaviors. Analysis of differences between men and women in sexual attitudes, behavior, and experiences is of fundamental importance to the study of gender relations. The fertility decline and contraceptive revolution have had a profound impact on women's sexual lifestyles; freed from the constraints of reproduction, women have acquired an unprecedented room for maneuver in their inevitable confrontation with men. Finally, cross-cultural analysis of sexual behavior reveals unexpected differences between cultures, in the sphere of representations but also in the practices and context of sexual activity.

I. DEMOGRAPHY'S DIFFICULT INCLUSION OF SEXUALITY

In its early days, demography followed the course traced by institutional statistics—at the end of the 19th century the discipline dealt only with the phenomena that were objectified and recorded by the official statistical system. In addition, because actual sexual behavior was unrecorded, it was ignored by demography. Initially, therefore, sexuality was approached only through its consequences and institutional expressions—civil registration data were used to study fertility and nuptiality and to measure extrainstitutional behavior such as illegitimate fertility. Before long, however, demographers developed an analytic approach for separating the various demographic factors and variables, most of which were in interaction with each other. But this new approach did not immediately cause demographers to direct their attention to sexual behavior. Typical in this respect was the

Italian statistician and demographer Corrado Gini. In the 1920s Gini introduced the concept of fecundability, defining it as

> The probability for a married woman to conceive during a month, in the absence of any Malthusian or neo-Malthusian practice intended to limit procreation (Gini, 1928).

This probability obviously depends on the frequency of intercourse, yet Gini does not make this point, thereby implicitly assuming that all married couples have sexual intercourse, that the frequency of their relations is unconnected to such variables as age and duration of union, and that the probability of conceiving is independent of the frequency and forms of sexual activity. None of these assumptions is correct—a couple may have no sexual relations, sexual activity does vary with age and duration of union (as we shall see later), and it can take a variety of forms, regardless of whether contraception is being used. Corrado Gini, like the early sociologists and anthropologists, implicitly adopts a naturalistic model of sexuality, which holds sexual activity to be a natural given for human kind, fixed in its forms of expression and solely biological in its determinants. This essentialist ideology of the early demographers was certainly a more serious impediment than inadequate sources. Demography began to examine sexuality and make it an object of study only when demographers had adopted the social constructionist stance characteristic of modern social science, which emphasizes instead the social and cultural construction of human behavior, and hence the social frameworks for sexual interaction, the varied repertoires of human sexual practices and their relative independence from biology.

The sexual life of married couples, brought to light by historic demography, might also have drawn the attention of demographers. Historic demographers established early on that fertility had begun to decline in many countries well before the advent of modern means of contraception (the pill, the intrauterine device [IUD], surgical sterilization, the condom etc.). In France for instance, couples were actually *malthusian* or *neo-Malthusian* before Malthus, in that from the end of the 18th century they were deliberately limiting their progeny, using methods other than the *moral restraint* advocated by the English clergyman. In Latin countries like France, this conscious control of fertility has been attributed to the practice of withdrawal or *coitus interruptus*. But how was such a radical change and constraint introduced into the exercise of the most *legitimate* sexuality, that of married couples? With Philippe Ariès and a few others, Jean-Louis Flandrin is one of the small number of French historians to have examined the question. From his analysis of confessors' manuals, theological writings, juridical records and popular culture, he concludes that the range of sexual expression was much more diverse in the 17th and 18th centuries than is generally recognized. A particularity of Northern and Western Europe was the invention, at the end of the Middles Ages, of a pattern of late marriage, in which women seldom married before 25 (and men even later). The question to be addressed therefore concerns the response of young people to this constraint, given that illegitimate births—subject to severe social censure—remained rare. Two hypotheses can be advanced. One is prolonged sexual abstinence, with young people waiting until marriage or thereabouts to commence sexual relations; the other involves recourse to sexual practices that carried no risk of pregnancy. Some historians favor the first hypothesis, invoking the possibility of a strict policing of *courtship* in premodern societies. Others, including Jean-Louis Flandrin, and with whom we tend to agree, argue for the second hypothesis:

> Unmarried men of all ages must have had to seek sexual satisfaction with prostitutes, or in adultery, or in "unnatural" practices such as homosexuality, bestiality, masturbation, heavy petting, etc. [. . .]. There was also, increasingly frequently, between the sixteenth and mid-twentieth centuries, withdrawal. [. . .] Before the large-scale introduction of contraception to marriage, initiation to these practices was done "in sin" [i.e. in the context of illegitimate relations] (Flandrin, 1981, p. 348 and p. 125).

In addition, in several regions of France communities appear to have tolerated a degree of premarital promiscuity, including fondling and nongenital practices. Because individuals were already familiar with these practices, so in the privacy of their marriage bed, couples were able to start reducing their fertility, despite the hostility of the Church:

> Jean-Louis Flandrin and John T. Noonan have clearly established the great importance attached by the Church from the 1850s onwards to the new scourge referred to as "conjugal onanism." By this euphemism were designated all the techniques whereby the married couple could obtain pleasure without a risk of pregnancy. […] The authors have provided an exhaustive catalogue of this "cheating": withdrawal, mutual masturbation (termed "ignoble service"), orogenital caresses, anal intercourse (A. Corbin, 1984, p. 238).

The term *coitus interruptus* used by historic demographers would thus appear to be a blanket term for a wide range of practices that allowed sexual activity to occur without risk of pregnancy well before the introduction of modern contraceptive methods. These practices, however, long remained invisible to demographers.

A third occasion for demography to direct its attention to sexuality was the pioneering article by Kingsley Davis and Judith Blake *Social Structure and Fertility: an Analytic Framework* (1956), which heralded the arrival of *intermediate variables* in fertility studies. Inspired primarily by anthropologic research, the authors proposed analysis using a set of variables that not only had a direct effect on fertility patterns but were themselves determined by the classic socioeconomic characteristics. In this perspective, the effect of educational level, for example, would be considered not for its direct impact on fertility but for its influence on determinants such as age at marriage or the incidence of breast-feeding. Blake and Davis group the variables thus defined into three broad categories: factors affecting exposure to intercourse; factors affecting exposure to conception; factors affecting gestation and successful parturition.

The first category contains, to begin with, the variables characterizing types of union (age at marriage, etc.), then those governing exposure to the risk of pregnancy for couples: voluntary and involuntary abstinence (the latter due to illness or temporary separation, for example), and frequency of intercourse. The second category includes sterility and subfecundity, and the forms of contraception, including those that are neither mechanical nor chemical, which the authors describe thus:

> Means of contraception other than mechanical and chemical include the "rhythm method" (which can also be classed as voluntary abstinence), withdrawal, simulated intercourse without penetration, various perversions, etc. (Davis and Blake, 1956, p. 212, note 3).

Unfortunately the authors barely expand on these points in their article, and instead concentrate mainly on postpartum abstinence. This analytic framework later strongly influenced the design of questionnaires used in national fertility surveys in the 1970s, but nearly always with the same lack of attention to sexual relations. Other reproductive models developed in the 1960s and 1970s did include an exploration of the link between coital frequency and fecundability, although lack of empirical data prevented any firm results being reached (see, for example, Bongaarts and Potter, 1983). This stream of demographic research was linked to the expansion of family planning in the developing countries and it focused mainly on the variables that were susceptible to interventions, which was believed not to be the case for sexuality.

Lack of empirical data and the implicit essentialist ideology of the demographers were durable obstacles to any demographic investigation of sexuality. Two things helped to change this situation. The first was the gradual emergence of the sample survey, and notably the longitudinal survey, able to capture more intimate and informal behavior, as one of demographers' main sources, while at the same time use of civil registration data declined. The second was a series of societal changes, including the transformation of partnership and family behavior, the widespread adoption of modern contraception, and the emergence of the AIDS epidemic, which motivated demographers to include questions on sexuality in their surveys and then to collaborate with scholars from other disciplines in conducting specific investigations into sexual behavior (Caraël, 1995; Hubert *et al*., 1998). Demographic interest in sexual behavior, which became apparent around the time of the *second demographic transition* (van de Kaa, 1987), focuses less on reproductive sexuality than on sexual behavior as a component of relationships, whether conjugal or not, and as an element of individual well-being and health in the broadest sense.

II. DEMOGRAPHIC OBSERVATION OF SEXUALITY: CONCEPTS, INDICATORS, LIMITATIONS

Demography's principal contribution to social scientific study of sexuality is to introduce a rigorous analytical viewpoint for the description of sexual phenomena. It does this without closing its eyes to the difficulties, limitations and biases that affect observation in this field; indeed, these are integral to the analysis. Observation in this context means the *construction of observation protocols* (i.e., of questionnaires) because the self-reports of the actors themselves are the only basis for apprehending sexual behavior (Bozon, 1995 and 1998a).

Any observation protocol rests on a handful of key concepts, which, reflecting demography's strong quantitative orientation, are operationalized as indicators. The key concepts in demographic analysis of sexual behavior are sexual history, sexual relations, and type of sexual activity. Standard procedures of demographic analysis, such as precise dating of events, recording of durations, and assigning of observed behavior to reference periods, are also important in the demography of sexual behavior.

The start of an individual's sexual history corresponds to sexual initiation, which in a sociodemographic perspective is understood as the onset of sexual activity with a partner. For the analysis of the social construction of sexuality, this threshold is considered more significant than the period of infantile sexuality, to which psychoanalysts, in contrast, attach great importance (Bozon and Leridon, 1996). Sexual initiation coincides with neither the biological transition of menarche (first menstrual period), nor the socially recognized threshold of couple formation. Particular attention is given to age at first intercourse and the characteristics of the first sexual partner, and also to the length of time between first intercourse and first union formation, known as the duration of sexual exposure before first regular partnership—in the case of virginity at couple formation, this duration is nil. In practice, it is always shorter for women (Macro International, 1994; Caraël, 1995; Bozon and Kontula, 1998; Bozon, 2003).

In addition to the characteristics of sexual initiation, a retrospective sexual history is characterized using two general indicators—number of sexual partners and length of time in sexual relationship. These two indicators are quite distinct. Most of a life spent in sexual relationship is usually though not necessarily associated with a small number of partners or indeed with a single partner. Conversely, a large number of partners can correspond to a relatively short total length of time in sexual relationship. It should be noted that number of sexual partners and time spent in sexual relationship differ clearly from classic demographic indicators such as number of conjugal partners or time spent in union. Classic demographic observation of the course of individuals' unions may involve description of periods of life in a couple, with successive partners. In demographic analysis of sexual behavior, by contrast, an individual's relations with partners can be thought as simultaneous (simultaneous *multipartnership*, i.e., having simultaneous multiple partners). More generally, a sexual partner is not necessarily a spouse, whereas in some cases a spouse may not become a sexual partner from the start of the union or may cease to be one after a certain time even though the couple still exists.

The sexual history of each individual thus comprises sexual relationships alternating through time with periods of sexual inactivity. Sexual relationships have a beginning, a development and an end; they can be categorized according to the type of bond between the partners—stable couple, one-night-stand, noncohabiting steady partner, holiday relationship, casual partner, and so on. Each relationship must be assessed in terms of its degree of exclusivity (or inversely its simultaneity with other relationships) and can be characterized by the types of contraception or protection used. The periods of sexual inactivity, meanwhile, correspond to two quite different situations—periods with no sexual partner or periods when the individual is in a union but has no sexual relations with his or her partner (spacing or cessation of sexual relations). For any given individual it is in fact hard, except in the case of major physiological problems, to conclude for a definitive cessation of sexual activity—indirect statistical evaluations are derived from the proportion of individuals who have not had any sexual activity in the previous year or in the previous 5 years.

Not all types of sexual activity are equivalent. An indicator can be constructed to express variability in the intensity of sexual activity, usually evaluated from frequency of intercourse (during the previous month or during an average month). Another issue of interest is the range of sexual activity, which can be explored from many different angles. When considering sexuality in its procreative dimension, it is important to show the diversity of the forms of contraception employed and how this varies over the life course. Surveys on young people, for example, must draw attention to forms of nonpenetrative sexual activity. Sexuality can also be analyzed in a more hedonistic perspective, from the angle of diversity of sexual repertoire. An increase in the range of sexual practices (used at least once in the lifetime), such as oral sex, anal penetration and masturbation has been observed between different generations of adults in developed countries. Questions about sexual practices can also take a recent sexual relation as reference (last intercourse): Questioning can examine the attainment of orgasm by one and the other partner. Achieving orgasm can become the object of an expectation or even a norm only in a historicocultural context where sexuality is losing its procreative function and where power is shared more equally between the partners. Last, sexual practices can be approached from the health angle. In the historic context of the AIDS epidemic, various protective or nonpenetrative sexual practices are promoted via prevention campaigns—hence men who have sexual relations with other men are encouraged to use safer sex practices. What needs to be measured here is the gap between the messages of the public health campaigns, the reported intentions of the actors and their actual practices.

Sexual behavior research in demography explores the meanings, representations and norms relating to sexuality, insofar as they contribute to understanding of sexual behavior. For instance, knowing the feelings for a partner (in love/not in love) when sexual relations begin is valuable for situating this relationship in an individual's sexual history. Respondents are often questioned about their attitudes to fidelity and extramarital relationships. In this domain there is a fairly high consistency between norms and practices, though it is not systematic—young adults and in particular young couples are, for example, the most severe in their judgment of extra-marital relations and the least likely to have them. However, this does not mean that norms govern behavior: rather they provide an interpretation of behavior. In every setting and in every period, the domain of sexuality has been subject to norms, but they are losing their power as absolute and immutable laws, based on religious or social rules. Increasingly, normative orientations are flexible, transitory and adaptable; rather than setting the boundaries of behavior, they express the meaning of behavior and reflect the growing individualization of life histories. This is a general historic evolution, although change is proceeding more slowly in those cultures where sexual norms remain based on sacred and immutable foundations. In many cultures, moreover, the normative systems are still sharply differentiated along sex lines.

Data quality is of crucial importance for a demographic description of sexual behavior. In quantitative surveys on this topic, interviewer effects (particularly the interaction between the sex of interviewer and of respondent) need careful analysis. The questions dealing with sexual activity proper are not usually asked face-to-face. In the sphere of private life and sexuality, the honesty of answers cannot be verified or checked against external sources. The only way to assess the reliability of the data is by an analysis of the internal consistency of the questionnaires. Data on coital frequency have been shown to be acceptably reliable (Leridon, 1996), as also have those for partner numbers (Leridon, 1998). The discrepancy observed in all surveys between the number of partners reported by men and women is evidence less of bias than of a gender difference in the way that sexuality is lived—men report more partners because they attach importance to the number of sexual encounters, whereas women ignore the experiences which have lacked emotional involvement and which as far as they are concerned did not count.

If demography can be used to produce a rigorous description of sexual behavior, it is nonetheless important not to abstract sexuality from its broader nonsexual environment. Demographic study of sexual behavior is not to be confused with sexology or sex therapy. Detailed analysis of sexual behavior does not create a new discipline—it contributes to demographic and sociological investigation of conjugal relationships, family behavior and gender relations, notably for the purpose of international comparison.

III. SEXUALITY AND THE TRANSFORMATION OF CONJUGAL TRAJECTORIES

Conjugal trajectories have undergone multiple transformations in recent decades. The contemporary decline of formal marriage in developed countries, the rise of informal cohabitation, and the growing proportion of women living in lone-parent families following union breakdown, bring into focus the elementary forms of relationships between two individuals prior to union formation, and the crystallizing but also disruptive potentials of sexual partnership. The conditions in which a sexual bond is established, its course over time, its degree of exclusivity, and the living arrangements that accompany it must be examined to understand the growing importance of *infraconjugal* or nonconjugal relationships before, during and after more conventional conjugal relationships.

Young adults in developed countries can have durable sexual relationships with stable partners, without even considering cohabitation. Today, the relationship is created by the start of the sexual bond, thus marking the first step in the couple's formation. The initial sexuality no longer depends for its legitimation on the power of a social institution (marriage), which in the process also legitimated any children that were produced. This reversal in the order of operations, such that sexuality precedes its social acknowledgment, confers a different meaning on sexual activity. The intensity and continuity of sexual activity gradually establishes the couple, signaling the desire for it to continue and perhaps for children to be produced. Another fast-increasing situation is that of women with children, who after a union breakdown, experience an essentially permanent phase of lone-parent family living. A large proportion of these single mothers are also in a stable but noncohabiting relationship with a new sexual partner. Sexual life and family life are here sharply compartmentalized. The increase in conjugal dissolution thus favors the emergence of new attitudes, in which sexuality and couple no longer coincide.

For a given individual, being in a sexual partnership does not necessarily preclude other relationships—a situation that is expressed by the notion of simultaneous *multipartnership*. This distinguishes sexual partnership from marriage-type relationships, which in nonpolygamous societies are exclusive of other such relationships and therefore can only be experienced sequentially. Description of a society's conjugal and family behaviors cannot be limited to the official and visible bonds. Treating sexual partnerships, even of the most transient kind, as a form of relationship implies acknowledging the existence of a hidden polygamy in nonpolygamous societies. The AIDS epidemic has been a powerful impetus to systematic examination of individuals' secondary and parallel relationships. A society also reveals much about itself in the forms of simultaneous multiple partnerships that it tolerates, even when these concern only a minority. Stable sexual multipartnership, common in the Caribbean and found also in some European countries, involves the coexistence of several sexual relationships over a long period—and is always characterized by a hierarchical ordering of the partners. Also observed is having multiple partners at separation, which is tolerated when it corresponds to the transition from one partner to the other. Finally, a form frequently encountered in developed societies is casual sexual multipartnership, which is accepted as a rare and covert exception in an otherwise stable conjugal context.

A sociodemographic approach offers a new perspective on homosexuality, which avoids explaining homosexual behavior either as the expression of a nature that defines and delimits a discrete population category, or as the simple consequence of socialization within a minority culture. Sociodemographic descriptive analysis has established that the life histories of homo–bisexuals are not significantly different from those of heterosexuals. In particular, they experience periods of life in couples, with same- or other-sex partners, as well as periods of separation and isolation (Messiah and Mouret-Fourme, 1996; Schiltz, 1997).

Studying the complexity of partnership and sexual histories and how they are linked to family and conjugal behaviors is in fact to assess the place sexuality occupies in the lives of individuals (Bozon, 1998b). Individuals' profiles are formed very early, at the time of sexual initiation. The priority that some individuals give to conjugal relationships, leads them not to put sexual activity at the forefront of their lives; sexual pleasure is not sought for its own sake and sexuality is important chiefly for its symbolic role in the life of a couple that is itself reasonably orderly. Individuals with this conjugal orientation tend to be those who have had a late sexual initiation. For them, sexuality is merely one component of the couple's life and has a secondary place among their preoccupations. For other individuals, by contrast, whose sexual careers have usually started young, sexual activity is in some sense independent and a source of essentially personal gratification—in this perspective, stimulating desire within the couple and acquiring new sexual partners are valued for their own sakes, and partnership histories are likely to be more *eventful*, containing more separations and parallel adventures. This coexistence in the population of contradictory attitudes (conjugal orientation/individual orientation) is long-standing, but in the past it remained below the surface. The conjugal and family changes of the 1970s and 1980s occurred in part because these contrasting attitudes toward sexuality began to find open expression in much more diverse conjugal behaviors and itineraries.

The sociohistoric contexts specific to groups of birth cohorts thus help to construct and shape the sexual experiences of those cohorts. A sexual life that began in a post-AIDS world cannot be analyzed in the same terms as a sexuality that began in the 1950s at the time of the baby boom. The availability of treatments for AIDS (from 1996 on) has changed the lives of persons living with AIDS and the general conditions of sexual experience, but more so in the developed countries than in the developing world. Whatever the period, however, a major component in the study of sexuality is the state of gender relations in the period under consideration.

IV. GENDER RELATIONS AND SEXUALITY

Surveys of sexual behavior invariably record systematic differences in the responses of men and women. This cannot be attributed simply to reporting effects. These divergences are the expression of differences both in norms and attitudes, and in behavior. Some even take the form of inconsistencies, when the same event is the subject of contradictory accounts. Such inconsistencies are nonetheless highly revealing of what has changed and what has persisted in gender relations.

Women's sexuality continues to be expressed in commitments and frameworks very different from those of men. The transformations of female sexuality observed in different countries since the 1960s and 1970s have not been reflected in greater tolerance of women in regard to men, but rather in a more demanding attitude toward their spouses or partners and an increased willingness to break off unsatisfactory relationships and to embark on new ones. In France, for example, the proportion of women who consider extraconjugal relationships unacceptable was higher in the 1990s than it was around 1970. If the sexual and conjugal itineraries of women have become more varied, this is not because of any change in their aspirations—their fundamental ambition remains that of living their sexuality within a stable couple. Women attach far more importance than men to the commitment or bond, be it conjugal or simply affectional, as the basis for the sexual relationship. Accordingly, sharp contrasts are observed in how sexual histories are experienced and interpreted.

When women are questioned about their first sexual intercourse, they often report that this was with a stable partner, with whom they were in love and who was older than them. Men usually begin their sexual lives younger, especially in the southern

European countries, and have more occasional partners with whom they are not emotionally involved. As a general rule, men have many more sexual partners than women before forming their first stable relationship.

Men living in a couple or in a stable relationship are consistently more likely than women to report having had a recent sexual partner outside their relationship. In line with this behavior, they are more ready to approve the statement that "having sex affairs during one's marriage is not wrong ('acceptable')" Unlike men, women are very reluctant to report autoerotic activity, and they are less likely to report having practiced oral sex or experimented with anal penetration. Other systematic differences are observed—men more often report use of condoms, including in last intercourse, while more women report having had a sexually transmitted infection (STI).

The sexual experiences of men and women tend to diverge sharply after age 50. The menopause is the end of a woman's fertile life and in many societies this was traditionally held to be the end of her sexual life, whereas a man faces no such symbolic limit. The transformations in the social position of women over the last 30 years, more than treatments for the menopause, have reduced the importance of this threshold and the existence of a female sexuality after age 50 has become more acceptable. At this age, women in couples in the 1990s have a much more active sexual life than their mothers had at the same age. But the inequalities between men and women persist—because of men's preference for younger women and women's longer life expectancy, women without spouses (due to divorce and, above all, widowhood) still have difficulty finding a new partner (Delbès and Gaymu, 1997).

These differences between men and women can be interpreted from two opposing perspectives. In a psychobiologic perspective, it could be argued that gender differentiation in sexual behavior derives primarily from the different roles of males and females in the reproductive process. But this explanation is inadequate, particularly for historic contexts where the development of medical contraception has freed the exercise of sexuality from the constraints of procreation. In a gender-relations perspective, the norms, representations, and behavior of men and women in the sexual domain are the results of an explicit socialization; they express one of the fundamental forms of male power.

Not all countries have completed the historic and demographic process that allows women's sexuality to be viewed as other than a strictly controlled social obligation to procreate (Tabet, 1985). The process is least advanced in Africa, even though fertility decline is now apparent in all countries of the continent (Locoh and Makdessi, 1995; Locoh and Vallin, 1997; Tabutin and Schoumaker, 2004). This is where girls' age at marriage is lowest, close to puberty in some rural zones (Niger, Mali), and where the proportion of a woman's lifetime spent in reproduction (pregnancy and breastfeeding) remains largest; it is here too that sterility carries the greatest stigma and women's sexuality after menopause is least accepted. Moreover, given the widespread practice of female genital cutting in Africa, questions must be asked about the place of pleasure in women's sexuality.

Most non-African countries have completed their demographic transition and achieved a twin stabilization of fertility and mortality at relatively low levels. The historic decline in fertility occurred earlier in the developed countries, where it was due primarily to nonmedical forms of contraception. These methods relied heavily on self-mastery by the man (Fisher, 2000), although fear of unwanted pregnancy and its consequences were still borne primarily by the woman. In France, for example, fertility decline began just before the Revolution of 1789 and extended over almost 150 years. In Britain, it was not until the second half of the 19th century (Szreter, 1996). Not until the 1960s did much more reliable modern forms of contraception become widely available, in a sociohistoric context characterized by greater independence and agency for women (Leridon, 1987). These changes prepared for the major transformations that revolutionized the way women actually lived their sexuality. In the developing countries, the shift from high fertility to fertility close to replacement level, is occurring much faster, in the space of three or four decades, causing serious adjustment problems, notably in the area of gender relations (see for instance, Martine *et al.*, 1998).

A new life course is emerging in which the reproductive thresholds play a less important role. The time spent either pregnant or breast-feeding has come to represent only a small proportion of a woman's total reproductive lifespan. Periods of active sexuality with no procreative objective are appearing—a conjugal sexual life that continues longer though produces few offspring; a juvenile sexual life that precedes partnership formation; a sexuality following partnership dissolution; an active postmenopausal sexuality. In this way sexuality is associated with more hedonist values of pleasure, well-being, and mutual support between partners. For women, sexuality can become, in ideal conditions, an intimate ritual of the egalitarian couple: it stops being considered a duty. Whether this view of the couple is fully endorsed by men is questionable. Even today the experience of men and women is largely contradictory.

The modernization of sexual attitudes, the development of contraception and the contemporary changes in the status of women, have produced no thoroughgoing upheaval in the representations and unequal roles of men and women in this field. Men tend to be viewed, and to view themselves, as free desire-driven subjects, whereas women are often still seen (and see themselves) as objects to be possessed. The persistence of an archaic sexual violence against women in all countries confirms that male power can take extreme forms when circumstances permit. Women's attitude remains that of trying to stabilize and regulate male desire by containing it within the framework of a relationship. Furthermore, due to their more sustained assumption of parental roles and the representations associated with them, women still tend to see sexual activity and even the relationship with their partner as being less important than longer-term bonds, like those of parent to child.

V. CROSS-CULTURAL COMPARISON OF SEXUAL BEHAVIOR: THE CONTRIBUTION OF DEMOGRAPHY

If demography is valuable for interpreting the historicocultural changes that have occurred in the field of sexuality, notably in the second half of the 20th century, it can also be used to characterize the differences of sexual climate or sexual culture observed between countries, both near and far, in the contemporary era. These comparisons are often done in an unscientific and unverifiable way, and using questionable national stereotypes—a group of people are broadly categorized as conservative and puritan, another as sexually open and sophisticated, yet another as having an unrestrained sexuality, and so on. One of the tasks for demographic analysis of sexual behavior is to introduce verifiable cultural characterizations, based on sets of comparable indicators. This approach is distinct from, although complementary to, that of anthropology, which is more concerned with capturing a culture in its entirety. The demographic approach, however, shifts emphasis away from a cultural explanation of differences, in that it attempts instead to decompose phenomena, by distinguishing how sexual behaviour in different cultures is influenced by variables or explanatory factors such as gender, rural–urban contrasts, marriage systems, and the social organization of age groups.

We have conducted a comparative analysis of the characteristics of sexual initiation of men and women in about 50 mainly European, African, and South American countries from the 1970s to the 1990s (for detailed figures, see Bozon, 2003). Comparison of the respective male and female ages at sexual initiation in older cohorts (born in the early 1950s) reveals three major traditional models of entry into sexual activity.

First is the large group of societies where parental and family strategies are designed to avoid any delay in female entry into conjugal, reproductive and sexual life through pressure to form a union as near puberty as possible with significantly older men, compounding gender domination by age domination. Although in such societies male may be later than female sexual initiation, males generally experience a significant period of premarital sexual activity. This model is traditionally found in sub-Saharan Africa (e.g., Mali, Senegal, and Ethiopia), and very likely also in the Indian subcontinent (represented in our sample only by Nepal).

This contrasts with a second group, which includes the Latin and Latin American cultures, where social control is exerted to delay women's union formation and entry into sexual activity by strenuous efforts to preserve their virginity, premarital loss of which breaks a cardinal rule and dishonors the family group and the spouse. By contrast, young males are urged to prove their manhood early on, either with prostitutes or older women, and their sexual initiation takes place well before that of females. This group of countries includes southern Europe (from Portugal to Greece and Romania), Latin America (Brazil, Chile, Dominican Republic), Thailand, and other Asian societies for which quantitative data are not available. In Brazil, for example, in the 45- to 49-year-old age group, the median age gap between first intercourse and first union is 7 years for males, but just 1 year for females. In the two models described, women are under great pressure to conform to social norms, but there are equally strong injunctions for males in due course to behave as *real men*.

There is a third group of societies, less homogeneous than the other two, characterized among the older cohorts by closely matched male and female timings of entry into sexual life. This may reflect later marriage and strict supervision of the conduct of young people, including males, as in Singapore or Sri Lanka (and doubtless also China and Vietnam). Late male and female sexual initiation is found in non-Latin Catholic societies like Poland and Lithuania. Finally, many European societies, like those of Northern Europe, but also Switzerland, Germany, and the Czech Republic, have for several generations been *gender-equal* in rather early sexual initiation timings.

There have been universal, but limited, changes in recent decades, as reveals an examination of the behaviors of the younger cohorts (born in the second half of the 1970s). In cultures where female is significantly earlier than male sexual initiation, the trend has reversed in two ways over the past 20 years, with a slight increase in female age at first coitus and a sharp drop in the male age. The female–male timing gap has narrowed in sub-Saharan Africa, as in Senegal, Togo, Cameroon, Mozambique, and Zimbabwe; likewise for Nepal. A new trend emerging in some countries (Kenya, Gabon, and Zambia) shows that male ages are now slightly earlier than females. In some societies, finally (Niger, Burkina Faso, Ethiopia), there is barely any discernible change. One common trait in all these trends is that young people are breaking free of a series of traditional controls: Males to become sexually active earlier, females to lighten the constraint of early marriage without necessarily relinquishing entry into sexual life. So, in eastern African countries, 40% to 50% of young women have at least 2 years of sexual activity before their first union. In some AIDS-ravaged countries, campaigns to delay first sexual intercourse may have had an inhibiting effect, particularly among females.

In the group of societies that prize early male and late female sexual activity, any changes have mainly concerned women—their comparatively late age at first intercourse has tended to fall, whereas the male age has remained unchanged. So, female–male timing gaps have narrowed in Brazil, Chile, and Spain, while in other countries—like Bolivia, Nicaragua, and the Dominican Republic—they are unchanged. In Portugal and Romania, sexual initiation timings are highly gender-specific, as in Italy, where female age at first intercourse has actually risen in the last decade. Even as virginity at marriage becomes a receding ideal and reality, a clear gender-based double standard still operates. Where male remains much earlier than female first intercourse, initiation by prostitution remains a significant factor, as in Central America and Thailand. But prostitution as a vehicle for first coitus declines where timing gaps narrow, as in Japan, where they have dropped from 26% in older cohorts to 11% in younger cohorts.

Where male and female ages at first intercourse were already close, they have fallen simultaneously: In many European countries and the United States, they have dropped by approximately a year in the last two decades, although age at first union—now very distinct from age at marriage—has trended upward over the same period. That this fall is not sharper may be due to a stabilizing and synchronizing effect of spreading secondary education on sexual initiation timings, which now occur within an increasingly shorter interval toward the end of secondary education. They mark the end of adolescence and entry into an age of personal free agency—youth—rather than transition to an increasingly later adulthood. The Nordic countries, especially Iceland, have become the *earliest* of developed countries, to the point where in some (Norway, Denmark), females enter their sexual life before males. These societies have long tolerated premarital relationships, and a long-standing and strongly egalitarian trend marks the behavior of men and women in the social, occupational and sexual spheres.

Another comparison, based on 15 surveys conducted in Africa and Asia and one in Rio de Janeiro, using a common protocol developed by the World Health Organization (WHO) also reveals variations of a sometimes-unexpected kind (Caraël, 1995). Clear cross-national differences are observed for the frequency of intercourse within married and stable cohabiting couples. Although fertility levels are high, African countries are characterized by infrequent and irregular sexual activity within stable couples, even when polygamous situations are excluded. This is a consequence of male migration and postpartum abstinence, which can last almost 2 years, in a context where fertility remains high; the irregularity also reflects the existence of noncohabiting couples. To a lesser degree, this low frequency is observed in Manila and Sri Lanka. Conversely, high levels of conjugal sexual activity characterize Rio de Janeiro and continental Asia (Thailand, Singapore). A comparative study was also performed on the proportions of men and women having sexual relations with casual partners or prostitutes, outside their stable partnership or conjugal relationship. Very high proportions are recorded for men in West and East Africa. The proportions are intermediate in Rio de Janeiro and in Thailand and very low in the rest of Asia. The role of commercial sex in casual relationships varies greatly between countries. A culture of using prostitutes exists among men in Tanzania (East Africa) and in Thailand, where prostitution accounts for almost all extraconjugal relations. In West Africa and Rio de Janeiro, on the other hand, commercial sex has much less relative importance in the casual relations of men in stable partnerships. Interpretation is problematic because of large cross-national variations in the social status of prostitution—it does not carry a stigma everywhere and does not always involve a monetary transaction.

Having simultaneous multiple partners is also observed in Europe though at much lower levels (Leridon, 1998; Hubert *et al*., 1998). France and Finland, one of the Nordic countries, report the highest frequencies, but with an interesting difference—in Finland this behavior is reported in almost equal proportions by men and women, whereas in France, as in most southern European countries, it is reported mainly by men. The same specificity of the two countries, and the same contrast between them, appears in the repertoire of sexual practices—in Finland this is quite varied for both men and women, whereas in France it is much less varied for women than for men. These variations should be interpreted not as sharp behavioral differences between French and Finnish women but as expressions of differing openness to women's sexuality.

Countries are also contrasted by their open and tolerant sexual climate. This climate is reflected in legislation on sexual orientation, the forms chosen for sex education, and the structures for the provision, and the distribution of contraception. It is noteworthy that a country like The Netherlands with a tradition of liberal legislation on sexual orientation and where discrimination against homosexuals is illegal, reports a higher proportion of homosexuals in the surveys than other European countries. Several countries have made provisions for the legal recognition of same-sex couples (Festy, 2001): Northern European countries being the first (Denmark in 1989), gradually followed by southern Europe (France in 1999). This translates and indeed strengthens a climate of tolerance.

Use of a sociodemographic perspective for the comparison of sexual behavior allows us to identify the points of cross-national difference more precisely and to suggest the main factors responsible. Of these, gender relations, in their specific national configurations, have a great impact, but primarily through their influence in each country on the social organization of unions and couples—the formal or informal character of unions, the proportion of noncohabitating couples, the independence of individual partners in couples, the degree of social control over women, the material possibility or impossibility for women to leave their partner and live alone, and acceptance of same-sex relationships. Norms and national sexual cultures operate more at a second stage to provide the form and justification for this social organization of relationships.

CONCLUSION

Demography does not hold a dominant position in social science research on sexuality; however, neither do any of the other disciplines (sociology, anthropology, history, social psychology, psychoanalysis, etc.) active in this field. It would be undesirable for a single discipline or even a subdiscipline to unify the investigation of sexuality by taking it for unique object and becoming the science of sexuality, in the way that oceanography is the science of the oceans, for example. Sexuality has a reality but it cannot be approached from a single perspective. The specific contributions of individual disciplines are as valuable as the interpretative incompatibilities sometimes observed between them. One of the strengths of demography is its attachment to the construction, application and generalization of rigorous indicators of sexual behavior, with which to achieve an objectification of sexuality, and substantiate the notion of behavioral diversity. A sharing of disciplinary perspectives is possible. The importance that demographers attach to the sexual and partnership history in the construction of behavior, creates affinities with more individual-oriented disciplines, such as psychoanalysis and psychology. Analysis of the links between gender relations and sexuality favors collaboration between demography and sociology. With anthropology, meanwhile, demography shares a deep interest in the social and cultural organization of marriage and unions. Sexuality is preeminently a relational activity and interdisciplinary object, whose full contours emerge only in the endless chain of interpretations produced by the different disciplines.

PART

III

SOCIOECONOMIC AND CULTURAL FACTORS OF FERTILITY

GRAZIELLA CASELLI, JACQUES VALLIN, AND GUILLAUME WUNSCH

Although fertility-control decisions are ultimately a matter of private sexual life, that does not make fertility strictly the affair of individuals and couples. Like all human behavior, reproductive behavior is influenced by the economic, social, political, and cultural context in which individuals and couples live. This vast topic has been addressed in a copious body of literature, which must be reflected here as exhaustively as possible.

In Chapter 37, Heather Joshi and Patricia David review the thinking of recent decades on the fertility impact of economic and social circumstances, and how the literature addresses seven key issues affecting developed and developing countries alike:

Why should fertility decline as development levels rise?
Can fertility decrease in poor countries?
Is the influence of women's education dependent on materialistic or cultural determinants?
Is reproduction a form of old-age security?
Why does fertility fluctuate in prosperous countries?
Do public policies promote faster fertility decline?
Can public policies prevent fertility declining below replacement level?

Connecting up with this initial survey, in Chapter 38 Ron Lesthaeghe and Karel Neels take two examples—France and Belgium—as the basis for a geographic interpretation of the fertility behavior changes observed over a 150-year transition, illustrating how new behaviors—demographic innovation—always arise at exactly the same places to spread nationwide following the same geographic dynamic. The same sociocultural patterns have driven the adoption of new behaviors in turn at the different stages of change.

In Chapter 39, which in a way sums up Section II, Bart de Bruijn reviews and comments on the many theories and explanatory models which have come out of post-18th century thinking on fertility trends and differentials, from Malthusian propositions to contemporary psychological approaches via the sociobiologic, economic, institutional, diffusionist, culturalist, and other theories, not, of course, forgetting demographic transition theory itself.

CHAPTER

37

The Social and Economic Context of Fertility

HEATHER JOSHI AND PATRICIA DAVID

Centre for Longitudinal Studies, Institute of Education, University of London, London, United Kingdom

Harvard School of Public Health, Boston, United States

Features of the world beyond the individual and the couple determine whether, why and how fertility is controlled. The economic and social systems provide the opportunities and constraints within which choices can be made. They also help determine whether people are aware that choice is possible, whether, as Coale (1973) put it, fertility is within the sphere of conscious control. The economic and social context may also help to set the standards of behavior between family members and the values to which they aspire. How far each sort of consideration applies to the explanation of fertility changes already observed, and how far social and economic variables can be used to predict, or manipulate, the future course of human reproduction remain controversial. This chapter is mainly concerned with the social and economic explanations of deliberate actions whose cumulated outcome is the rate of human reproduction. Leaving biologic factors aside, already discussed in Chapters 30 to 34, we treat fertility as a form of behavior rather than as a response to innate drive that has been *bred in* to survivors. We also leave aside, for the most part, the question of partnership formation and dissolution that are dealt with in Chapters 25 to 29.

Four topics will be considered. The first three sections elaborate some of the theoretical explanations of fertility offered in recent literature. First we describe a behavioral framework for the understanding of social reproduction (and make a passing reference to social biology). Next we review some approaches from just two of the social sciences, economics and sociology. Finally, we consider some contemporary issues, in both developing and industrial countries, on which empirical applications of these approaches have shed both heat and light. The questions selected are as follows:

Why does fertility decline with development?
Can fertility decline in poor countries?
Women's education: a materialist or ideational influence?
Is childbearing for old age security?
What makes fertility fluctuate in rich countries?
Are state policies effective in accelerating fertility decline?
Are state policies effective in preventing subreplacement fertility?

This is more an account of territory through which we have traveled than a complete *Michelin Guide*. We have not attempted a comprehensive coverage of topics or literature. We hope to spark enough interest to encourage the reader to discover the numerous authors we have neglected (particularly outside the Anglo-Saxon literature) and that what we do cover will show the way for further interdisciplinary endeavor.

I. SUPPLY AND DEMAND: A FRAMEWORK OF FACTORS INFLUENCING FERTILITY

The level of fertility in a society or a group is the cumulated outcome of deliberate actions (behavior) and biologic functioning, social pressures and chance operating for each pair of parents, actual or potential. The constraints that condition behavior are largely determined by the social environment they inhabit. Coleman and Schofield (1986) observed that demography still has no central paradigm linking processes at the microlevel with those operating at the societal level. Microlevel behavior must be involved if there is any change in fertility in the aggregate, at the macrolevel; but microlevel variation can also be observed, and linked to variations within an economic and social system that is in aggregate unchanging. The primary focus of most (nonbiologic) fertility theories is therefore on the individual.

Contextual factors external to the individual or couple that affect behavior and/or decision-making regarding family formation must work through mechanisms that operate at the individual level. One general framework that has proven useful is set out by Easterlin, Pollack, and Wachter (1980). They classify these mechanisms into those affecting the biologic production of births, *supply* or *natural fertility*, and *demand* factors, which may reduce wanted fertility below the biologically feasible maximum. Their approach, sometimes identified as that of the *Pennsylvania School*, is a general formulation not only because it allows for fertility sometimes being constrained by biologic limits, but also because it allows for the preferences, which define demand, themselves to be determined within the system.

The Pennsylvania approach is contrasted with the *Chicago-Columbia School* whose exponents include Becker (1981), Schultz (1981), and Cigno (1991). This group of writers adopt a *demand* approach to fertility, seeing decisions about the number, timing (and quality) of children as the outcome of rational decision making, maximizing the utility to be gained from fertility decisions subject to the resources available and the rates (*prices*) at which they may be transformed into competing sources of utility. It is assumed that tastes or preferences remain fixed, and are unified within couples. The reactions of the rational decision-maker to changes in *income* and *prices* are predicted.

One variant of the supply–demand framework is to investigate the constraints around which decisions are made. For Hobcraft and Kiernan (1995) the constraints on parenthood are biology, money, security, ideas, and especially time. For Folbre (1994), constraints are socially structured—by membership of social groups, such as social class, religious, or ethnic groups and gender. Membership of such groups overlaps, and thus individuals are subject to diverse, possibly conflicting pressures. In different circumstances different types of group membership may be dominant. Her book contains a very extensive review of the evolving structures over several continents and centuries. This recognition that the demographic actor's tastes and behavior are affected by group identity within broad societal influences helps to account for differential fertility within societies. It also suggests that group norms and interests may mediate the impact of social and economic considerations upon any given individual. The overlapping nature of group membership adds complexity to the notion of self-interest.

Another variant of the supply–demand framework, as adopted by Bulatao and Lee (1983) adds specific consideration of the reconciliation of supply and demand. The deliberate regulation of the *supply* of children is conditioned on both *demand* factors and the costs of, or obstacles to, fertility regulation. These include social influences on attitudes to, knowledge of, and access to contraception, abortion, or the practice of infanticide; the gender balance of power to make decisions regarding control of reproduction; and husband–wife communication regarding fertility regulation. Where births are *unwanted*, there is said to be *unmet need* for control of fertility.

The next two sections elaborate factors than can be thought of as influencing the supply–demand model of fertility decisions.

1. Supply

Supply factors affect the number of surviving children by regulating the length of the reproductive life span and the spacing of births within it. Beyond purely biologic factors, they include social constraints on the timing of entry into marriage or sexual union, and practices affecting the timing of parenthood. Constraints on behaviors directly affect the biology of childbearing, such as norms regarding breastfeeding and postpartum abstinence (Chapters 30 and 31), and use of contraception or abortion (Chapters 34 and 35). These regulate the pace of childbearing during the reproductive years. Supply factors also include features of the material environment (such as nutrition and hygiene) that may affect the chances of conception and spontaneous abortion.

Factors that affect survival of liveborn children, particularly where there are high rates of infant and child mortality, can be thought of as affecting the supply of surviving progeny. Infant mortality may indirectly affect subsequent fertility through shortened breastfeeding even if there is not any deliberate intention to replace a child who dies (Bongaarts, 1983). The end of childbearing is affected by social factors—also often group-specific—such as those affecting maternal survival and widowhood; norms governing separation, divorce, and remarriage; and those influencing deliberate means of terminating childbearing such as sterilization, terminal abstinence, or effective contraception.

Some *supply* determinants are more clearly the result of the behaviors of the individual, such as breastfeeding practices and the timing of marriage, variable across and often within societies around the world. Others, like child or maternal mortality levels, are not behavioral in nature, but are affected by the material conditions of life and available health technology. The social environment (a *macro* consideration) determines the resources available for the care of mother and child, and the knowledge (*technology*) of how this should be done, and sets norms for acceptable practices. The social environment also provides any knowledge about methods of birth control and affects their cost, social as well as monetary.

The technology of *producing* children of a given standard goes beyond biologic factors to the investment of resources made in children once born, building up their *human capital* of health and skills. Changes in any of this technology modify what reproductive outcomes are feasible and permit different outcomes to be chosen. The state of knowledge about producing everything else can also change, which will also affect the setting in which fertility decisions are made. Note, too, that in the production of successful surviving children, if nothing else, the venture is beset with risk and uncertainty. Outcomes could be quite different if it became possible to determine the sex of a child in advance or guarantee that a woman would still be able to conceive if she postponed motherhood until her 40s.

These factors, *proximate* determinants of childbearing, will be affected by the social and economic environment. Society, for example, can influence who enters sexual unions, at what age, and on what terms. In historic times in Europe, norms surrounding marriage acted as an important *safety valve* to control fertility (as well as containing sexuality), preventing the formation of new households when economic conditions were poor. Marriage is now less important with respect to childbearing in the United States and Europe, and other social norms regulate age at first birth. The first birth may precede formal marriage in many African societies, where proof of fecundity may be an important precondition to finalizing the marriage bond. Far more important to reducing the overall level of fertility is the deliberate regulation of fertility within marriage.

2. Demand

To economists at least, it seems natural to turn to the analogy of the buyer's side of a market once fertility enters the realm of control, not merely limited by biosocial *supply* constraints. When families can do little but accept however many (or few) children *God sends*, the question of whether they have adapted their behavior to achieve desired fertility does not arise. Once it becomes technically feasible, and thinkable, to reduce childbearing below the *natural* maximum, it becomes relevant to ask what fertility is desired, and to seek explanations for reproductive behavior in its motivation as well as its means.

People may be able to specify the fertility they would like to achieve by stating a family size, perhaps depending on sex composition. They may be able to distinguish between an *ideal* family and the number that they would prefer given existing circumstances. Even parents who embark on family formation with no clear goal, may come to weigh up the advantages and disadvantages of adding another birth: the *marginal child* (Leibenstein, 1974). The death of an existing child may motivate another birth as a *replacement* (Vallin and Lery, 1978), but the question still remains of why a particular target family size was desired, and whether it is worth the costs of achieving it. Those who decide to remain voluntarily childless (or *child-free* to put it more positively) can be thought of as taking the decision that even the first child is not worth having, but as being generally influenced by the same considerations as those who choose to limit a positive number of children (Keilman 1996).

The *demand* approach to fertility applies microeconomic theory of *rational decision making* to the whether and when to control fertility. The decision-maker is aiming to attain maximum feasible *utility* from the sources of satisfaction available, which include children. How much these are valued (i.e., how much satisfaction they provide) will be affected by the parents' *preferences*, or tastes. The parents' commitment to bringing a child into the world and bringing it up to adulthood is likened to investment in a consumer durable. The benefits expected must be weighed against the cost of achieving them, which is the forgone return from an alternative investment of their resources.

This reduction of complex, private, and moral decisions to the self-interested calculus of the counting house is not universally palatable. The theories do recognize that children are not exactly like physical assets, as they cannot be sold. They can also allow for parents acting in their children's, as well as their own, interests. Through the assumption of altruism, one decision-maker draws satisfaction from the well-being of another. Indeed Folbre (1994) caricatures the actors in neoclassical fertility theory as a family of *Rational Economic Men*, perfectly altruistic and harmonious at home, and single-mindedly self-seeking in the market place. Such agents need not be constantly adjusting their private lives to economic signals; it suffices that some economic changes induce some people to adjust their family formation behavior, for it to be worth thinking about what such adjustments might consist of. The assumption of a united household is being challenged by the application of game theory to bargaining models. This highly technical literature is not covered by the present review.

3. Social Biology: a Digression

Why is there a demand for children? Does biology help explain the demand as well as the supply side? The fundamental reasons people bear children are often assumed to lie in a biologic imperative to reproduce. Evolutionary biologists, working with animal models of reproductive behavior, have tried to extend these to the human organism. These theorists now propose that when it is in the individual's interest to overexploit existing resources, populations will grow too large for the available pool of resources and the population will experience excess deaths as a result (a *Malthusian check* on the growth of the population).

Lately, some of these theorists have examined reproductive strategies as adaptive mechanisms that individuals used to maximize the *fitness* of their genetic inheritance. These *life-history* theorists are concerned with understanding how alternative reproductive strategies evolve to affect reproductive success. Use of the term *strategy* suggests conscious choice, but its use by biologists does not make such an assumption.

One school of thought suggests that such *reproductive success* may be achieved by having fewer offspring, and investing more parental effort in their *quality*. This may be the best strategy for ensuring the long-term reproduction of their genetic traits (Chisholm, 1993). Attention is focused on how physiologic factors that directly affect reproduction have evolved, and why norms that affect birth spacing patterns, such as prohibitions on intercourse or prescribed breast-feeding durations, are found to vary across different cultural contexts (Wood, 1994). Why have these evolved in this particular way?

According to some life-history theorists, mortality risk is what determines these differences in the reproductive strategy that is adopted (Promislow and Harvey, 1990, 1991; cited in Chisholm, 1993). When mortality rates are high, the most efficient strategy is to maximize the number of offspring: a short-term strategy to ensure the survival of their genetic traits, because at least some of their offspring will survive to reproduce. When mortality is low, so the theory goes, the best strategy is to invest more parenting effort in fewer offspring: a long-term strategy to maximize the number of descendants in the distant future by maximizing the reproductive potential of their offspring.

Because theorists who focus on human fertility must contend with biologic mechanisms and psychological forces that drive human sexuality and control of conception or the number of surviving children, attempts are now being made to synthesize work from the fields of evolutionary biology and developmental psychology (Chisholm, 1993).

Do parents, in response to an innate drive to reproduce their own traits, adjust their family-building patterns in response to an assessment of risk or a calculation of the marginal returns on their investment, (Kaplan, 1994)? Is this how cultural differences in the *proximate determinants* of fertility evolve? Hobcraft and Kiernan (1995) wonder whether it is biologic drives that keeps reproduction going at all. Evolutionary biology can portray *regression to two-child norm* as a trade-off between carrying on the lineage or gene pool and the costs of childbearing. We turn to the social sciences for other perspectives.

II. ECONOMIC EXPLANATIONS OF FERTILITY BEHAVIOR

One feature of the environment is the economy, the availability of resources through production and exchange. The demand approach is to consider fertility decisions as being made by rational agents, setting advantages against disadvantages, benefits against cost. An objective, reflecting personal tastes and norms or values of the peer group or society at large, is maximized subject to the resources available, their relative prices and the technology. A rational choice would imply that taking any other decision would have left the parents worse off. Changes in the economic environment, if big enough, could lead to adjustment of family formation.

The *utility function* sets out the valuation the decision-maker puts on various sources of satisfaction. The objectives are essentially the fruits of reproduction, the fruits of production and the enjoyment of leisure. In *new home economics* models (as those originating in the Chicago-Columbia School are also known), the satisfaction parents derive from children depends on both their number and their quality. This key construct denotes health and skills, which will depend on how much parental time and other resources are invested in them. Parents have other sources of satisfaction in their own consumption of other goods. If they are altruistic toward their children they will also draw utility indirectly from their children's (and future descendants') standard of living. Parents therefore gain from an increase in either their own consumption, or *child services*, if there is an increase in their resources (*budget*) meaning they do not have to sacrifice any of the other. Whether they will choose to trade one for the other when the budget is fixed, depends on whether their relative valuation of the outcome exceeds the cost of achieving it. The valuation reflects individual (or socially conditioned) preferences. The question of relative costs is central to the analysis, as being the most likely front on which the economy may send signals to formers of families, who may react by engaging in *substitution*, a reaction to changes in relative prices.

The level of resources, the *budget*, is given by the couple's endowment of physical and human capital. The latter represents their earning potential that can be accumulated through past investments in their health and skills. The greater the resources at the couple's disposal, the larger the range of possible combinations of consumption and children they may choose. Increases in the budget lead to *income* effects in contrast to *substitution* or *price* effects. The range of opportunities may also be widened by improvements in technology, the rate at which resources may be transformed into either of the desired outputs, or indeed in the safety, reliability, and cheapness of fertility control. The range of outcomes chosen may be constrained by peer pressure or social prescriptions. Hence the contrast between neoclassical economists' interests in what choices people make with what Duesenbery (1960) described as sociologists' interests in why people have little choice to make. Because we are interested in apparently deliberate behavior in fertility control, we elaborate the economic framework a little further.

1. Benefits

Before examining what costs of childrearing might consist of, let us first list ways in which parents may benefit from having children:

Consumption-like benefits: the intrinsic value of the child to the parents, for its own sake;
Income earning: the value of the child's labor to the parents;
Security: especially in old age and in times of stress;
Perpetuation of the lineage;
Net cash benefits for children from the state

Blake (1972) adds to the customary economist's catalogue of utilities an item recognizing the social roles of parenthood. It confers status within the kinship system and provides channels for mutual emotional support between generations. Every sort of benefit varies according to the number of children already in the family, and across social settings. It may vary between males and females and be subject to numerous sources of uncertainty. Benefits may or may not take into account the welfare of the next generation. They need to be evaluated as a present value, giving a smaller weight to benefits in the distant future than to those nearer the present. This weight (*discount factor*) represents the couples' rate of time preference and any allowance they make to write down risky outcomes. A low discount rate and altruism toward future generations (which tend to go together) would increase the *present value* of any given stream of benefits expected, and tend to increase fertility. Conversely, a reduction in altruism (*intergenerational solidarity*), all else equal, would lead to lower fertility. This could be a special case of the sociological notion of *individualization* (Lesthaeghe and Surkyn 1988).

2. Costs

Among the costs of an additional child are as follows:

Physiologic wear and tear of pregnancy, childbirth, and lactation (maternal depletion), risks to the mother, and costs of obstetric care;
Value of goods and services spent on the child, and invested in *quality*;
Value of market time devoted to child-rearing: earnings forgone, usually by the mother;
Value of time diverted from nonmarket activities, such a leisure, sleep, care of existing children;
Any planned bequest (transfers of nonhuman capital; e.g., dowries)

Once again the importance of each item depends on the context. Uncertainties affect how much any one birth *project* might cost. A lower risk of infant and child mortality can raise the rate of return on investments in children considerably. Improved child survival is often thought to reduce fertility, by cutting the number of births needed to produce a given surviving family size. But the *demand approach* to fertility points out that the rising rate of return could induce increased *investment*. This could involve a higher number of births but the investment might also be in the quality of existing children (Schultz 1981). It is sometimes also assumed that *rational* parents will assess the child's own risk or future potential (a child's endowment) as they make decisions to invest in or curtail the care they give—their investment in child quality.

Even given the context, the cost of any particular child is not fixed, different levels and timing of investment will produce different levels of *quality*, and different children will need different *investments* to produce the same result. There is enormous variation in the world as to how much is invested in children, and also enormous variation in the amount of investment that is paid for by the family and the state, depending for example on how medical and educational services are financed. For the moment, we assume that the private costs of children (i.e., those not born by the state) are borne by the family. Distribution of costs between mothers and fathers is considered in subsequent sections. Note that other family members, particularly siblings, may bear some of the cost of an additional child.

The item within costs referring to the diversion of the mother's productive labor into reproduction has received massive attention. Childrearing is assumed to displace time from other work, and it is the woman whose time is assumed to be interchangeable between production and childrearing, rather than the man's, because that is how parents generally divide up the work. Almost universally, the woman is the primary care giver, taking responsibility for childrearing and domestic work as well as her biologic role of carrying and nurturing the newborn. The father, assuming he is around, takes the primary breadwinning role in the economy beyond the family. The traditional division of labor leads to gains from specialization, realized by both parties if resources are pooled. It is normal, natural, and, according to Becker (1991) and Cigno (1991), an efficient way of maximizing gains from specialization without running into coordination and enforcement problems that might beset a larger commune. However, the domestic division of labor between men and women is often reinforced by wage discrimination against women in the labor market, which will tend to discourage women's participation in the paid economy, and might not be economically efficient.

Whatever the merits or shortcomings of this interpretation of the sexual division of labor, wherever it exists, it implies a trade-off between women's paid work and reproduction, which had come to play a central role in economists' attempts to model fertility trends in developed countries. Because the family is assumed to be choosing both childbearing and the woman's labor force participation at the same time, some further factor determining them both must be identified if the *chicken and egg* problem of reciprocal causation is to be disentangled. Easterlin (1980) suggests that in the (then) contemporary United States the primary factor would be the generation's relative income and dismisses the *liberation* of the *new woman*, as a major explanatory force. This contrasts with the view of Davis (1984), but Easterlin's dismissal of the *importance of women's social and economic status as an engine of demographic change in the U.S.* is echoed by Joshi (1985,1990) also pointing to the very modest nature of women's advance into the labor market. For new home economics, the independent factor is the woman's wage if she's a potential labor force participant. It is the relevant price of her time, reflecting income foregone for every hour devoted to unpaid maternal duties. The higher the woman's wage, for example because of her education, the lower would fertility be predicted.

3. Preferences and Values

The set of *preferences*, which evaluates the objectives in the demand model can almost interchangeably be described as *tastes, desires, wants, needs, aspirations, goals, values, interests*, and *ideologies* (Pollak and Watkins, 1993, p. 481). One might add *norms*. The orthodox approach prefers to treat preferences as given outside the system (Stigler and Becker, 1977), as not being the source of change into which economists should inquire or hope to make predictions and that can either be safely ignored or left to other social sciences. Economists have therefore generally seen little point in subtle differentiation between influences on motivation.

The Pennsylvania School of economic demography is an exception. They declare a need for interdisciplinary dialogue to understand how preferences are formed and may themselves adapt to changes in the economic environment (endogenous preferences). They point out that the Chicago School's definition of the maximand as a set of unmeasurable commodities generated by household production would enable them to describe the results of a change in tastes as if it had been a change in unobservable household technology. Although the two interpretations are observationally equivalent, the conclusions to be drawn about whether a change is for the better are different. If preferences do not change and a technical change increases household production possibilities, the family must be at least no worse off. If household production changes because preferences change, the utility of the two situations is not comparable (Pollak and Watkins, 1993).

What can be studied about changing preferences are social mechanisms of diffusing new values or norms, and the role that economic change may play in setting the goals to which people aspire. The most well known hypothesis of an economic influence on agents' aspirations (endogenous preferences) is Easterlin's *relative income hypothesis*, which states that young people planning to start family life will attempt to achieve or improve upon the standard of living their own parents managed to set for them. This is also an example of a theory formulated at a macro rather than a micro level.

4. Gender Relations

So far the exposition has gone along with the assumption of *home sweet home*, the couple and the family acting in concert. This assumption deserves scrutiny. It would be reasonable if we knew that some mechanism was at work regulating the standards of private behavior, ensuring that family members treated one another fairly, if not lovingly, so that each party shared the *gains of marriage* for example. Religions have generally taken the lead at promulgating *family values*, and so, to a lesser extent have secular value systems. It was the early Catholic Church, for example, that insisted that each spouse should consent to a marriage. The state, in the form of social workers and family law, sets sanctions for those who break the rules, although it does not normally venture into private territory and it has changed the rule to allow more individual freedom. State regulation of the responsibilities of marriage partners and of parenthood is seen by Cigno (1991) as essential to ensure that contracts are enforced. If the sexual division of labor keeps a woman away from the labor market, she loses, forever, the opportunity to accumulate marketable skills, and is vulnerable should the marriage end without proper compensation.

As Folbre (1994) points out, parents do not necessarily share costs and benefits equally, particularly when the father parts company with the mother. If the father deserts without contributing to the child's maintenance, the mother is left with double demands on her time and fewer resources to invest in the child's *quality*. The absent father probably loses out on the joys of parenthood, but if he stays around he may get more than his fair share of the benefits. If he has patriarchal control over the family, he is likely to contribute less, at least of time and effort to domestic activities and be able to get the children, as well as their mother, to do his bidding.

Situations of marked difference between the economic and social status of men and women are likely to affect parents' perceptions of the value of a child's contribution—sons and daughters will be valued differently. Sons are also more valuable, provided parents have access to their earnings, wherever the earning opportunities for females are inferior to those for males. Daughters have an alternative value in principle as auxiliary household labor, but where marriage takes young women away to live with the bridegroom's family, it is sons' wives who make this contribution, and any dowry to be paid for daughters would be an example of a *bequest* adding to her cost.
