Introduction

The health care of immigrants and the health effects of migration on sending and receiving communities have been issues of concern worldwide. Given increasing globalization it is likely that migration and the health of immigrants will become even more important. These multifaceted and complex issues demand a multidisciplinary, multilevel perspective and immigrant health can no longer be considered a niche in health care that can be outside of the interest or expertise of health care systems and health care providers. The *Encyclopedia of Immigrant Health* represents our effort to provide a foundational reference work for health care providers, public health professionals, advocates, agency personnel, and policymakers as they increasingly are called upon to provide optimal support for immigrants and their families.

Contributors to these volumes approach their topics from diverse disciplinary, political, and cultural viewpoints and, wherever possible, approach their subject from a biopsychosocial perspective. Many, if not most, of the contributors have direct experience in one or more domains of immigrant health, including medicine, nursing, health-related research, law, human rights, public health, health education, economics, demography, psychology, sociology, social work, religion and theology, medical anthropology, and history.

The *Encyclopedia of Immigrant Health* comprises two major sections. Part I consists of overview chapters that provide the reader with an in-depth examination of various dimensions of immigrant health. Rausa and Lloyd focus on global patterns of migration as well as the various factors that motivate individuals to leave their countries of origin for another locale. Loue's chapter follows, with an examination of the interplay between immigration processes and health concerns, using U.S. immigration policy as an example.

The four chapters that follow focus on dimensions of health and health care that, while relevant to all populations, are particularly salient in the context of immigrant health. Regardless of where they are coming from and where they are going to, all immigrants bring with them their understandings of health, illness, disease, healing, and cure. Health care providers and researchers may find the chapters on alternative and complementary medicine, authored by Lovell, Daneshnia and Fries, and culture-specific diagnoses, authored by Smith, Mayes and Smith, particularly useful, with their examinations of conceptualizations of illness and approaches to healing that have been endorsed by various cultures, are often relied upon by immigrants in their new environments, and have in varying degrees been adopted by residents of their new host communities. Low and Low review the multitude of factors that can affect the health of immigrants and immigrant communities. Brugge and Siqueira examine health issues associated with occupational and environmental exposures, which represent a growing concern in view of the global increase in labor migration.

Significant methodological issues may arise in the context of immigrant health research. Murphy, Allen and Sin provide a review of the various study designs that can be utilized in conducting research related to immigrant health and the advantages and challenges associated with each such approach. Both immigrant health research and the provision of health care to immigrants often present significant ethical issues. Loue reviews the many aspects that must be considered in designing a study involving immigrants and their communities. Ioan reviews the ethical issues confronting health care providers in their efforts to provide quality care to their immigrant patients.

Part II consists of encyclopedic entries arranged in alphabetical order. These entries cover a broad range of topics, including specific diseases or disorders particularly relevant to immigrant groups, culture specific health concerns, international conventions and nongovernmental organizations. Each entry provides an overview of the current understandings of the subject and its relation to immigrant health. Other entries focus on specific countries that are particularly notable as sending or receiving countries for migration or individuals who are especially noteworthy for their effort to address issues related to immigrant health. All entries are followed by a listing of suggested readings that includes references and cross-references to other topics. In many cases, suggested web-based resources are also provided.

Immigrant health is an exciting and dynamic field that challenges the researcher, the clinician, and the policymaker with its complexity, breadth, and richness. As such, participation in this field in any capacity offers the professional immense opportunities to be of service to others beyond one's own community and, on a personal level, for the development of knowledge and understanding of diverse cultures and the enhancement of one's self-knowledge and sensitivity towards others.

Immigrant Health Overview Chapters

Immigration in the Global Context

Bettina Rausa[1] · *Linda S. Lloyd*[2]
[1]Salk Institute for Biological Studies, La Jolla, CA, USA
[2]Center for Research, The Institute for Palliative Medicine at San Diego Hospice, San Diego, CA, USA

Introduction

Studies of human DNA indicate that migration has been a part of human existence for at least 100,000 years, when it is estimated that the first migrations of humans from Africa to Asia occurred (Stanyon et al., 2009). Migration has been part of the human story from the days of strictly hunting and gathering-based societies to the establishment of prolific urban areas that accommodate millions of human beings in small concentrated areas. Most human migration is in search of better opportunities reflecting the desire for an improved quality of life. In some cases, migration is the only means of survival, and yet in others, migration is forced, either by violence, political unrest, or natural disaster.

Some of the most significant historical movements of people include over 1.2 million Spaniards, Portuguese, and British subjects migrating to the Americas beginning in the 1490s, closely followed by up to 12 million African migrants forced to move as slaves across the Atlantic Ocean through the nineteenth century. From the 1840s to 1900, 3.6 million Chinese and Indians migrated as laborers to South-East Asia, Africa, and North America. Although differing cultural encounters have and still lead to conflicts, there are records of rather peaceful coexistence as far back as the eighteenth century BCE in ancient Babylon. Writings in the Old Testament and the Qur'an encourage people to treat others as themselves and provide safe havens to those from different lands and different faiths. Large movements of people have also played a critical role in transforming economies of scale, including spreading farming practices and providing large labor forces which fueled the British Industrial Revolution via rural to urban movements. In the nineteenth century, hunger and poverty were large drivers for the movement of people out of Europe. During this time, 14% of the Irish population left their homeland, in part due to the potato famine facilitated by the simultaneous and significant drop in the cost of passenger travel from Britain to New York (UNDP, 2009).

According to the International Organization for Migration's (IOM) *World Migration Report 2010*, the estimated total number of international migrants today is 214 million persons, or 3.1% of the global human population (the figures in this chapter are from the period 2008 to 2010 via census information gathered by the United Nations Department of Economic and Social Affairs (UN DESA), unless otherwise indicated). Migration used to be dominated by men, but it is estimated that now half of all migrants are women. Most of those migrants, 57%, live in developed countries, also referred to as high-income countries. The United States has the highest number of foreign-born individuals with current estimates as high as 42 million, followed by The Russian Federation with approximately 12 million immigrants. Germany has approximately 10.5 million foreign-born residents, followed by Saudi Arabia, Canada, France, the United Kingdom, Spain, India, and Ukraine, with numbers ranging from 7.5 million to 5 million, respectively. In terms of percentage of total population, however, Qatar has the highest percentage of non-native-born people residing within its borders, with 86.5% of its population foreign-born. Qatar is followed by the United Arab Emirates (70%), Kuwait (68.8%), Jordan (45.9%), the Occupied Palestinian Territories (43.6%), Singapore (40.7 %), Israel (40.4%), Hong Kong SAR (Special Administrative Region of China) (38.8%), Oman (28.4%), and Saudi Arabia (27.8%).

Although 57% of all migrants live in developed regions, they constitute only 10% of those populations (IOM, 2010). Given these figures, it would seem that most migrants move beyond the borders of their country of origin, but in fact, most migration occurs

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

internally, that is, movement within a country's borders such as rural to urban movement or individuals forced to move from one area to another due to war, violence, or natural disaster. The comparison is striking: there are 740 million internal migrants in the world today, compared to 214 million migrants internationally. A closer look at general migration patterns reveals that almost half of all international migrants move within their region of origin, and close to 40% move to a neighboring country. The reasons for this are complex, but, in general, they can be attributed to the cost of moving. Moving costs are not only related to transportation but also to policy-based restrictions such as the cost of a passport, visa, or work permit, which for many migrants are prohibitive. Economics, however, are not the only determinant of where people migrate; statistics show that six out of ten migrants move to a country with the same major religion as their country of birth, and four out of ten move to a country that shares the dominant language (UNDP, 2009).

Several of the countries that are main destination areas for migrants are also in the top 10 countries of origin for those who emigrate: Germany, India, The Russian Federation, Ukraine, and the United Kingdom (IOM, 2010). However, internal migration in these countries is much greater than migration to other countries, as previously noted (UNDP, 2009). The term "migrant" is used in this chapter for all individuals who have left their place of origin; where relevant, specific migrant groups will be highlighted. General migration patterns within and between geographic regions will be reviewed first, followed by migration trends due to factors such as demand for specific types of labor, the impact of war and environmental changes on migration, and the migration during the ongoing global economic crisis.

Regional View of Migration

Africa

In 2010, Africa accounted for almost 9% of the total number of global migrants (19 million) – although this figure is considered an underestimate due to insufficient immigration data from the region. Almost 40% of internally displaced people, or refugees, in the world live in Africa. War and other conflicts, extreme poverty, and climate change are the most common reasons for internal displacement. In 2008, environmental disasters alone were responsible for the displacement of 700,000 people. Urban areas in Africa are growing rapidly and some estimates predict that by 2050, 1.2 billion Africans will be living in urban areas, with much of the growth due to internal migration, specifically rural to urban movement. This growth, however, is predicted to be temporary because urban areas in Africa have high costs of living, which could eventually push people to return to rural areas (IOM, 2010).

Emigration of Africans is high: in 2000, almost 23 million people left their country of origin, with most moving to a sub-Saharan country. In fact, migration within the region accounts for three quarters of all movement. The top destination for migrants in Africa is Kenya, which in 2010 hosted 818,000 migrants. After Kenya, the United Republic of Tanzania, Uganda, Ethiopia, Rwanda, and Mozambique were the top receiving countries in the region. East African migrants include many who have been forced to move due to conflicts and regional instability, an estimated ten million in 2008. The Democratic Republic of the Congo and Somalia together account for more than one million internally displaced individuals. North Africa hosts an estimated total of 1.8 million migrants, 753,000 of whom live in Sudan, 682,000 in Libya, 242,000 in Algeria, 53,000 in Morocco, and 34,000 in Tunisia. Traditionally, North African countries have been the source of immigrants, but they are now becoming either transit or destination countries for not only internal migrants, but external ones as well. Additionally, a growing number of migrants are moving to the southern African region as a result of better economic growth and because of economic and political crisis in bordering countries, such as Zimbabwe. The country of South Africa alone currently hosts 2.2 million migrants. The total estimated number of migrants to West Africa is 8.4 million people, two thirds of whom live in Cote d'Ivoire, Ghana, and Nigeria (IOM, 2010).

Americas

The Americas (North, Central, and South America, and the Caribbean) host the greatest number of international migrants, increasing from 47 million in 2000 to more than 57.5 million today. Twenty-seven percent of all migrants in the world live in the Americas. However, the majority of migration in the Americas is between countries in the region – with the main destination country being the United States. Seventy percent of Canadian and more than two thirds of Latin American and Caribbean emigrants live in the United States. Migrants make up 14.2% of the total US population, numbering about 50 million. The Mexico-US migration corridor is the largest in the world, with 30% of the United States' 50 million immigrants coming from Mexico. Following Mexico, the other primary countries of origin for migrants living in the United States are the Philippines, Germany, India, China, Vietnam, Canada, Cuba, El Salvador, and the United Kingdom. Asians currently make up 27% of the US migrant population with two million Chinese, 1.7 million Filipinos, and 1.6 million Indians. Of the 50 million international migrants currently living in the United States, as much as 30% are estimated to be "irregular migrants." Irregular migrants are individuals who have entered a country without proper immigration documents, commonly referred to as "undocumented immigrants." An estimated 40% of irregular migrants in the United States are women. Emigration from North America to other regions is relatively low; about 3.6 million individuals are currently living outside of the region, 60% of whom are from the United States.

Twenty-one percent of Canada's population is made up of immigrants, numbering about 7.2 million. In contrast to the United States, Canada's main source countries for immigrants are China, India, Italy, and the United Kingdom. Canada is also a source country of migrants living elsewhere: in 2005, about 1.3 million Canadians were living abroad, primarily in the United States, the United Kingdom, and Australia.

Latin America and the Caribbean are hosts to 7.5 million international migrants. Of note is the steady increase in the number of female migrants in the subregions since 1960, from 44.2% to 50.1% in 2010 (see section on ➋ "Women"). Argentina, the Bolivarian Republic of Venezuela, and Mexico (recently taking the third spot from Brazil) are the top three destination countries. Argentina and the Bolivarian Republic of Venezuela, together with Paraguay and Puerto Rico, have experienced a decrease in the number of immigrants in recent years. Ecuador on the other hand has seen an increase and is now ranked as seventh in destination countries in Latin America.

For both Latin America and the Caribbean, however, emigration from the region is greater than immigration to the subregions. Eleven million people left Latin America and the Caribbean between 2000 and 2010: 6.8 million Central Americans, three million South Americans, and 1.2 million Caribbeans. Emigrants from these areas make up 15% of international migrants globally. The country with the largest number of people emigrating is Mexico, with 10.1 billion, or 10% of its population currently living abroad, followed by Colombia, Puerto Rico, Cuba, El Salvador, Brazil, Jamaica, the Dominican Republic, Haiti, and Peru. As is the case for Mexican migrants, the United States is the main destination for Latin American migrants, followed by Argentina, Spain, the Bolivarian Republic of Venezuela, and Canada.

Migration to Latin America and Caribbean countries comes from neighboring countries. Argentina is a destination country for migrants from the Plurinational State of Bolivia, Chile, Paraguay, and Uruguay. The Bolivarian Republic of Venezuela is a destination for Colombian migrants, while Costa Rica is the primary destination for Nicaraguans. For those Latin American and Caribbean migrants who move to Europe, Spain is the main country of destination, accounting for 38% of Spain's immigrant population. Twenty percent of Brazilians however, migrate to Japan, ranking as the third largest migrant group in that country. It is interesting to note that most of the Brazilian migrants in Japan are of Japanese origin, and as such are able to benefit from special visa programs as well as better wages. Colombia, due to civil conflicts, ranks third in the world for internally displaced persons with an estimated 2.5 million or 6% of the current population (IOM, 2010).

Asia

As of 2010, Asia is host to 13%, or 25.7 million, of the international migrant population. With the exception of South-Central Asia, close to half of all migrants in Asia are women. The countries with the highest migration rates are Singapore, Macau, and China, while Sri Lanka, Lao People's Democratic Republic, Myanmar, the Philippines, and Pakistan all have negative rates of migration; that is, more people leave than enter the country. The majority (43%) of Asian migration occurs within the region: 37% is to countries that form the

Organization for Economic Co-operation and Development (OECD, currently made up of 34 countries, primarily those referred to as “developed” countries), and the remaining 20% migrate to other non-OECD countries outside the region. Although the United States is the main destination of Asian migrants (7.9 million in 2000), countries within the region are also primary destinations. For example, migrants from Bangladesh and Pakistan account for 6.1 million of India’s immigrants, even though Pakistan itself is host to 2.8 million intra-regional migrants. Hong Kong SAR hosts almost 2.5 million regional migrants, Iran 1.9 million, and Malaysia 1.7 million.

Irregular migration has become an increasing concern in Asia, with some estimates as high as 17 million people without proper immigration documentation. Refugee numbers are also on the rise, currently accounting for 3.9 million, or 14%, of all international migrants in the region. The region is host to 25% of the global refugee population. Natural disasters have increased internal migration within the Asian region. For example, the 2008 Sichuan earthquake displaced 15 million people in China. In fact, Asia accounts for 31 million, or 86% of all people displaced by natural disasters with 17 of the biggest disasters occurring in Asia in 2010 (IOM, 2010).

The number of immigrants in East Asia has also been growing, with the subregion now hosting approximately 6.5 million migrants, including the highest percentage of female international migrants in all of Asia (approximately 55%). The current top destination countries in the subregion are Hong Kong SAR with 2.7 million migrants (2.3 million from China), Japan with 2.2 million, and China, which topped the Republic of Korea (South Korea) in 2010, with 686,000. Prior to 2010, the Republic of Korea held the third spot with 568,000 migrants in 2000 compared to China’s 508,000. Emigration from East Asia is also significant, with around ten million people leaving the subregion, six million from China alone. The main countries of destination for East Asian immigrants are the United States, with about three million; Japan with 783,000; Canada, 775,000; and Australia, 300,000. Chinese students represent 25% of East Asian immigrants to Australia (IOM, 2010).

The countries of South-East Asia that currently have the largest number of migrants include Malaysia with almost 2.4 million (1.7 million of whom are from within the Asian region), Singapore with just over two million, and Thailand with 1.1 million. In Singapore, migrants make up almost 41% of the total population. While the Philippines is a destination country for migrants, ranking fourth with 435,000 migrants, it is a major exporter of human capital with 3.4 million of its citizens, half of whom are women, now living abroad. Of the total 10.2 million migrants in the subregion overall, 1.2 million are labor migrants working in Malaysia. The main country of destination for South-East Asian migrants is the United States (3.2 million); however, Saudi Arabia, with 700,000 immigrants, has become increasingly important as a labor migration destination for people from this subregion (IOM, 2010). Emigrants from Vietnam currently number two million, and Indonesia has been the source for 1.8 million emigrants. Recently, extreme weather conditions have played an important role in the number of migrants from South-East Asia. In 2007, massive floods displaced almost 421,000 people from Jakarta, Indonesia, and one million people were displaced in 2009 by tropical storms, primarily in the Philippines (IOM, 2010).

In South-Central Asia, there are about 14.3 million international migrants. After declining for several years, migration started to increase in 2005. The increase, however, is attributed mainly to Pakistan becoming, after India, the most important country of destination in the subregion, with 4.2 million migrants living within its borders in 2010. India’s share of international migrants has decreased over the past 10 years, from 6.4 million in 2000 to 5.4 million in 2010. The Islamic Republic of Iran hosts almost 2.2 million migrants, representing a slight increase since 2005 (two million), but an overall decrease since 2000 (2.8 million). India, along with having the highest number of migrants in the subregion, is also the largest source country of migrants, with an estimated 25 million people living abroad, 10% of whom live in the United States. Estimates for 2010 show that Bangladesh is also a major source country of immigrants in this Asian subregion, with 6.9 million emigrants; Pakistani emigrants number 3.4 million, followed by Afghanistan with 2.6 million, and Nepal with one million. It is estimated that close to half of these individuals remain in the region, and approximately 5.1 million move to countries of the Gulf Cooperation Council (GCC, made up of six countries: United Arab Emirates, The Kingdom of Bahrain, The Kingdom of Saudi Arabia, The Sultanate of Oman, Qatar, and Kuwait) in search of work. The United States and Canada together host 2.4 million South-Central Asians, and the United Kingdom is home to about 1.1 million. The demand for migrant labor from the region is significant in the Middle East, primarily in Saudi Arabia, Kuwait, the United Arab Emirates, Jordan, and Qatar. Notably, what is termed as the feminization of the migrant labor force has been a prominent feature of emigration from Sri Lanka, with women making up 54% of the estimated 200,000 Sri Lankans who leave the country each year (IOM, 2010).

Europe

Migrants currently make up 8.7% of the total European population, which hosts one of every three migrants in the world (72.6 million in 2010). Migration to Europe has increased consistently since 2005, with Western and Central Europe experiencing the highest net increase in migration in the countries of Cyprus, Luxemburg, Spain, Iceland, and Ireland. On the other hand, Eastern European and new European Union member states have seen a reduction in net migration. Albania, Georgia, the Republic of Moldova, Lithuania, and Tajikistan are still source countries of migrants, although the numbers have decreased since the 1990s. Since 2005, Southern Europe has had an annual immigration growth rate of 5.2%, with 3.4 million migrants currently living in the subregion.

The flow of migrants moving within the region is very high, with the majority of Western and Central European migrants moving within European Union (E.U.) member States. Eastern European migrants, on the other hand, migrate to former Soviet republics, including The Russian Federation and Western Europe. The Russian Federation currently has 12 million migrants residing within its borders and is a source country for an equal number of migrants living abroad. Second to The Russian Federation is Ukraine with an international migrant population of 5.9 million, the United Kingdom with 4.2 million, Germany with 4.1 million, and Kazakhstan with 3.6 million migrants. Female migrants in Eastern Europe comprise an estimated 57.3% of all migrants, compared to Western Europe where women make up 49% of the migrant population. A significant number of migrants live in urban centers in Europe: London, Paris, and Moscow each have one million foreign-born residents. In Amsterdam, Brussels, Frankfurt, and London, over 25% of the population are foreign-born (IOM, 2010).

When looking at all international migrants living in Europe (51 million), over 65% live in Western and Central Europe. The most important countries of destination are Germany with 10.5 million migrants, France with 6.7 million, the United Kingdom with 6.5 million, Spain with 6.4 million, and Italy with 4.5 million. In Western Europe alone, an increase of 5.6 million migrants has occurred since 2005, with Spain and Italy experiencing the highest increase. The increases are primarily due to declining populations, most prominently in Southern Europe, family reunification processes, and high rates of economic growth in countries like Ireland. An interesting note is that although Europe has had significant and sustained increases in the number of migrants, it also has large outflows of foreign-born populations. Some of this is due to movement between the European Union's older and newer member States. For example, European Union States with more open economies tend to be older E.U. members, and those countries attract large numbers of younger, educated migrants from the newer member States. The largest numbers of emigrants from Europe originate from Britain. In 2006, European emigration numbered 1.7 million, with most Europeans moving within the continent or to other OECD countries (IOM, 2010).

The International Organization for Migration also examines migration patterns in Eastern Europe and Central Asia combined. The individual countries in this subregion include Albania, Armenia, Azerbaijan, Belarus, Bosnia and Herzegovina, Georgia, Kazakhstan, Kosovo, Kyrgyzstan, Macedonia, Moldova, Montenegro, The Russian Federation, Serbia, Tajikistan, Turkmenistan, Ukraine, and Uzbekistan. In this subregion, the decline in both the number of migrants and refugees has lead to a decline in the total number of international migrants since 2005, even though, along with the Western Balkans and Central Europe, this subregion hosted 25.6 million migrants in 2010. The Russian Federation, Ukraine, and Kazakhstan are the top countries of destination, with 80% of international migrants living in these three countries. Notably, immigration to The Russian

Federation is led by ethnic Russian citizens from countries of the former Union of Soviet Socialist Republics (USSR). In fact, the vast majority, between 70% and 75%, already have Russian citizenship (IOM, 2010).

Middle East

About 13.5% of the total global migrant population lives in the Middle East, an estimated 26.6 million, and this region is growing as a destination by 3.8% annually. Migrants make up 11.9% of the total population, and although countries like Kuwait and the United Arab Emirates have seen some decrease in the number of immigrants, Qatar grew from 59 to 94 migrants per 1,000 population between 2005 and 2010. Israel and the GCC countries (United Arab Emirates, The Kingdom of Bahrain, The Kingdom of Saudi Arabia, The Sultanate of Oman, Qatar, and Kuwait) are the primary destination countries, with labor the main driver of movement to this region. The number of female migrants to the area has also grown; current numbers are 10.2 million women, about 38% of the total number of migrants in 2010. However, a closer look at the number of female migrants in individual countries shows that there are certain areas where women tend to migrate, for example, to Israel, where they make up close to 56% of the total number of migrants. In contrast, women account for just under 21% of the migrant population in Oman. Migrants to this region are attracted to urban centers, with the most popular migrant destination cities being Jeddah, Riyadh, Dubai, Tel Aviv, Muscat, Medina, and Jerusalem (IOM, 2010).

The Arab Mashreq, or Eastern Mediterranean region of the Middle East, has also experienced an increase in the number of migrants, with an estimated 8.7 million in the region in 2010. Countries that make up this region include Jordan, the Syrian Arab Republic, the Occupied Palestinian Territories, Lebanon, Yemen, Egypt, and Iraq. Egypt and Iraq have both experienced a decrease in the number of migrants during the last 7 and 10 years, respectively, with Iraq's number decreasing dramatically, from 147,000 to 83,000 during the height of the US invasion in 2003, while Egypt's declined modestly from 247,000 migrants in 2005 to 245,000 in 2010. However, the remaining countries in this region have experienced significant growth in the number of migrants. During the period of 2000–2010, the number of immigrants in Jordan grew from just over 1.9 million to more than 2.9 million and foreign-born residents make up almost 46% of the total population. The Syrian Arab Republic saw a growth of 924,000 to 2.2 million during the same period, with migrants representing 43.6% of the total population.

Forced migration was the primary reason for migration to this region; in fact, the vast majority of migrants to this region were refugees from Iraq and the Occupied Palestinian Territories. An estimated 1.6 million Iraqis, or 5.5% of the population, were displaced as a result of war with the United States. There was also growth in the number of African migrants and refugees from Somalia and Ethiopia crossing through the Gulf of Aden into Yemen, with some estimates showing a 50% increase, approximately 74,000 people, between 2008 and 2009. Climate change, specifically droughts in the region have also caused forced migration, with estimates between 40,000 and 60,000 families forced to move from drought-affected areas in the Syrian Arab Republic in recent years. Another important factor regarding the movement of people in this region is demographics. In 2010, 57% of the population was younger than 24 years of age, with unemployment rates ranging between 14% and 50%; it is likely this region will remain a significant source of young, mostly skilled migrants in the future (IOM, 2010).

The Gulf Cooperation Council (GCC) countries of the Middle East are major destinations for migrants of all labor skill levels. Estimations are that the six countries that make up the GCC had over 15.2 million migrants in 2010 – an increase of 19% since 2005. The GCC countries are primarily oil-rich countries where labor is in high demand, even more so since some are concentrating on developing and expanding more service and knowledge-based economies in an effort to diversify their revenue streams. Contractual foreign workers, mostly temporary, will remain a significant portion of the labor force, currently representing around 66% of the migrant population in Qatar, 70% in the United Arab Emirates, and almost 69% in Kuwait (IOM, 2010).

Immigrants account for 40% of the total current population of Israel, numbering approximately three million. Israel is unique in that it has passed specific legislation to bring people of Jewish ancestry to the country (the Law of Return enacted in 1950). Russian and Ethiopian Jews represent the largest flows of migrants in recent years. Other source countries are member States of the European Union, Thailand, the Philippines, India, China, and Nepal. As of 2008, the majority (55%) of work permits issued to migrants in Israel went to women (IOM, 2010).

Oceania

Six million international migrants live in the countries of Oceania (Australia, New Zealand, and the island states that make up Melanesia, Polynesia, and Micronesia), representing 16.8% of the regional population. This region has the highest proportion of migrants in its population – even though it only has about 3% of the total global number of migrants. More people enter than exit the region, and the close to 22% population growth in the last several years has been the result of new immigrants, especially to Australia and New Zealand. Both countries have promoted immigration over the last decade and, interestingly, British migrants make up the largest group of immigrants in both countries. The two countries also share immigrants, with Australia being home to 68% of New Zealand's emigrants and New Zealand hosting 13% of Australia's emigrants. The top two destination countries for Australian emigrants, however, are the United Kingdom and the United States, followed by New Zealand.

All indications are that both Australia and New Zealand will remain high-net immigrant receiving countries for some time to come. In recent years, the steady increase has been attributed to large numbers of overseas students, over 409,000 in 2008 (Chinese and Indian students account for the greatest portion), a strong Australian economy, and specific programs aimed at increasing migration to the area. After New Zealanders, the largest numbers of Australia's migrants come from India, China, and South Africa. Foreign-born workers currently make up about 25% of Australia's workforce. Australia also reports a growing number of irregular migrants, about 50,000 in 2008. Most enter the country as tourists, 10% of whom are travelers from the United States and China, which, together, account for the highest number of "overstayers." Emigration from Oceania accounts for about 1.5 million people globally, 37% of which comes from the Pacific Islands and 35% from New Zealand. About half of the regional migration is internal, and those leaving the region emigrate primarily to the United States and the United Kingdom. Of note, female migration to the region has been growing, reaching 51.2% in 2010 (IOM, 2010).

The subregion of Melanesia, Polynesia, and Micronesia also saw migrant numbers increase between 2000 and 2010, with a current count of 340,000. Of those, 151,000 are in Micronesia. Emigration from these countries is regional about 50% of the time, primarily to New Zealand, followed by Australia. The United States and Canada currently host 36% of Pacific Islander migrants. Much of the movement out of the Pacific Islands can be attributed to various factors, including: political and economic disparities in the region; freedom of movement among countries within the region; citizenship granted to Pacific Islanders by New Zealand and the United States; and active recruitment of migrants by the government of New Zealand. As a result, Micronesia and Polynesia have negative migration rates. For example, Polynesia has −8.5 migrants for every 1,000 people, and diaspora from some of the islands are larger than the resident populations. Skilled labor leaving the islands is a major concern; in fact, 52% of emigrants now living outside of these small countries have a post-secondary education. Eight nations in this tiny subregion have made the list of the top 30 countries with the highest skilled labor migration to OECD states: Palau, 80.9%; Tonga, 75.6%; Samoa, 73.4%; Nauru, 72%; Tuvalu, 65%; Fiji, 62.8%; Kiribati, 55.7%; and Marshall Islands, 42.8%. Women make up a large portion of emigrants from the islands, 63% of whom are skilled migrants (IOM, 2010).

Trends in Migration

According to the United Nations Development Programme (UNDP), migration is primarily shaped by government policies. Prior to the end of the nineteenth century, migration policies around the globe were fairly unrestrictive, with some countries openly encouraging migration. Despite periods of anti-immigrant sentiment, most governments acknowledged that migration was advantageous to both source and destination countries. By the end of the 1800s, however, entry restrictions began to emerge for various reasons, but primarily due to labor market pressures and popular sentiment. Countries like Australia and the United States created entry barriers which included race and nationality quotas. As countries curtailed migration, they actually expedited the liberalization of trade in goods and the movement of capital. To respond to labor shortages, some countries developed bilateral agreements like the US's Mexican Farm Labor Program, also known as the *Bracero* program in 1942. Over 4.6 million labor contracts were issued through the program during a 22-year period. At the same time, the United Kingdom and Australia developed a labor exchange program, but by 1964 and the 1970s, respectively, both the US-Mexico program and the United Kingdom-Australia labor exchange agreements had closed (UNDP, 2009).

Contemporary migration occurs primarily for the same reasons migration has traditionally occurred: the search for labor on the part of migrants and the need for labor on the part of individual countries and regions, family reunification, escape from war and other conflicts, and forced migration due to environmental changes and natural disasters. Regardless of how governments view migration, individuals will continue to seek opportunities in other countries through established or, when necessary, irregular immigration processes.

Labor Migration

Labor migration is often divided into two categories: skilled and low-skilled labor. Skilled labor consists of people who typically have higher education levels, often completing university and graduate school (tertiary education) and are considered professionals. Their careers are usually in medicine, law, higher education such as university professors, research and development professionals, information and communication technology experts, and business leaders. Low-skilled labor typically consists of agricultural workers, factory and processing plants workers, domestic and nursing home aides and hospital workers, janitorial and landscape services, food service and hotel workers, construction workers, child-care providers, and numerous other service-oriented jobs (Martin, 2001).

Skilled Labor

One of the advantages that skilled labor migrants have over low-skilled migrants is that destination countries usually make the migration and settlement path much easier because migrants with specialized skills, training, and experience are highly sought out by destination countries. Based on labor market tests and the demands of business and industry, countries develop and enact policies that facilitate skilled labor migrants to move to and settle in the host country. They may have an easier path to permanent residency as well because it is often offered to the skilled migrant by the host country as an incentive to move.

For example, in the United States, high-skilled workers are granted admission for up to 6 years, while low-skilled, usually seasonal, workers are granted admission for only 3 years (UNDP, 2009). First introduced in Canada, some countries looking for skilled labor have implemented a points-based system in which a minimum number of points via an admissions exam are needed to gain entry and residency. The criteria are based on age, language, education, and work experience. If an applicant for permanent residency scores a minimum number of points, they may be granted permanent residency – higher scores usually are achieved based on age (younger individuals are given a higher number of points), education level, language skills (especially the ability to speak English and/or French), and work experience, including managerial. The United Kingdom uses the same system, but has options for migrants to attain permanent or temporary residency. Here too, skilled migrants have a better chance to achieve higher scores in the areas of education and work experience that lead to permanent residency, whereas low-skilled laborers do not. In fact, permanent residency admissions in the United Kingdom are dominated by migrants with experience and education in finance and business, information and communication technology, and medicine (Luckanachai 2010).

"Brain Drain"

For destination countries, attracting and retaining skilled labor means a stronger competitive edge in both the local and global markets (commonly known as "brain drain"). For the migrant, it means better wages and often times, better workplace stability. Although there are benefits for the country of origin in terms of increased remittances, which in some cases can be higher than GDP or foreign aid, and increased transfer of knowledge and information, the loss of skilled and well-educated workers can have a devastating effect on the local economy and population (UNDP, 2009).

Most skilled labor migrants are currently from Asia, about 35% of the world's total. Europeans are very close behind with 34%, followed by North America, Latin America, and the Caribbean which together make up 23%. African migrants are about 7% of the world's total skilled mobile population. The Asian skilled labor movement is primarily the result of people from developing countries searching for improved opportunities, whereas Europeans tend to move mostly within their region due to a common history and culture, along with the expansion of the European Union (IOM, 2008).

Even though Asians account for a large portion of the skilled migrants received by the United States and Canada, a significant portion of the skilled labor movement occurs within regions. Thirty-three percent of the United States' skilled migrants are from Canada and Mexico. The same is true for Europe, and other Asian countries account for the largest share of skilled migrants in both the Republic of Korea (South Korea) and Japan.

One of the industry areas in which local brain drain is most prominent is health care. For some small countries, the numbers are staggering. In Africa, estimates are that as many as 19% of doctors and 8% of nurses currently work in other countries. In sub-Saharan African countries, it is reported that 28% of doctors and 11% of nurses trained domestically work in other countries. In some African countries, the figures are even more alarming. Mozambique has lost 75% of its doctors to migration; Liberia has lost 81% of its nurses. An important note is that while Africa accounts for 24% of the global disease burden, it only has 3% of global health workers (UN, 2010).

In terms of absolute numbers, India is the top country of origin for the number of doctors practicing medicine in OECD countries, about 56,000. OECD countries also account for 17,000 German doctors and 32,000 nurses; 17,000 doctors and 46,000 nurses from the United Kingdom; 16,000 doctors and 110,000 nurses from the Philippines; 16,000 Chinese doctors; 31,000 Jamaican nurses; and 25,000 nurses from Canada. Emigration rates for nurses alone are highest in the Caribbean: Haiti has a current nurse emigration rate of 94%; Jamaica, 87.7%; Grenada, 87.6%; St. Vincent and the Grenadines, 81.6%; and Guyana 81% (IOM, 2010). Almost half of all foreign-born doctors living in OECD countries live in the United States, 40% live in Europe, and the remaining 10% in Australia and Canada. The World Health Organization (WHO) reported in 2006 that 14 countries had more than 50% of their native-born doctors living abroad: Antigua and Barbuda, Grenada, Guyana, Mozambique, Angola, Dominica, Fiji, Sierra Leone, the United Republic of Tanzania, Trinidad and Tobago, Liberia, Cook Islands, Saint Vincent and the Grenadines, and Haiti. Of those, six countries, Angola, Haiti, Liberia, Mozambique, Sierra Leone, and the United Republic of Tanzania, were considered to be experiencing severe and critical shortages of health professionals. Research indicates that people in these countries are motivated to migrate by the success of others as a result of their education and migration to pursue careers as health professionals (UN, 2010).

This movement or concentration of medical professionals is also observed in rural to urban migration. In March 2010, the United Nations reported that while almost half of the world's population lives in rural areas, only 25% of the world's doctors and 38% of nurses live in a rural area. Health professionals who stay in their countries of origin often pursue work in the private sector and live in urban areas, causing additional shortages of health services for the poor in rural areas (UN, 2010).

In an effort to improve the experiences of migrant medical professionals in destination countries, and to strengthen health systems where losses in medical professionals are high, in March 2011, WHO developed a survey instrument and introduced voluntary guidelines for member states to use the survey to monitor the international recruitment of health personnel. WHO proposes that governments complete the survey every 3 years beginning in 2012 with the goal of advancing global cooperation on the ethical international recruitment of health professionals and strengthen health systems worldwide (WHO, 2011).

Another sector that has seen much growth in the area of skilled labor migration is information, communications, and technology (ICT). Beginning in the 1990s and up through the end of 2001, skilled migration in this industry grew from 15% of all migrants to more than 25%. During the initial period of the ICT economic boom, the United States had about 25% of all recently arrived ICT skilled migrants, reaching 30% by the mid-1990s. At about the same time, however, the share of intake of ICT-skilled migrants by European countries grew significantly, from 15% to 25%, peaking around 2000. Many European countries implemented specific policies designed to attract this skilled labor set during that period and beyond (IOM, 2008).

Low-Skilled Labor

Low-skilled migrants are also highly sought after, but they are almost always temporary and/or seasonal. The number of temporary foreign workers admitted for employment in OECD countries in Europe and North America, Australia, and New Zealand has increased steadily since 2000. However, this category of migrants also moves significantly between developing countries, most prominently from South Asia and Southeast Asia to GCC countries, and within developing regions such as Latin America and South Africa. A notable area of growth of movement of low-skilled migration is women. Although women make up approximately 50% of all migrants in the world, the majority of female migrants are in temporary labor categories which are dominated by traditional gender roles like domestic caretaking and the entertainment industry, which often means they are vulnerable to exploitation, including forced labor and/or slavery (IOM, 2008).

Irregular migrants ("undocumented") are those without formal permission for entry into the host country. Irregular workers also tend to be those with low skills and little or no formal education, especially those migrating to OECD countries. Not all irregular migrants have entered a country in an unauthorized fashion, however. Many overstay the expiration date of their temporary work or tourism permits; it is estimated that two thirds of Europe's irregular migrants have overstayed.

It is difficult to obtain accurate figures on the number of irregular migrants, thus estimates are based primarily on census counts because census counts attempt to capture the number of all residents, regardless of citizenship or residency status. But, irregular migrants and those who provide harbor for them tend to omit information about irregular migrants in fear of government authorities, therefore creating an undercount of irregular migrants. These migrants are also more mobile than others by the nature of their seasonal work and fear of deportation, and this adds to the difficulty of assessing their true numbers. According to the United Nations, one third of all migration in developing countries is irregular, which translates into an underestimation of official migrant counts of about 30 million migrants worldwide. It is estimated that irregular migrants currently living in the United States make up 4% of the total population, which accounts for 30% of all migrants in the United States. European estimates in 2005 suggest that from 6% to 15% of migrants were irregular migrants, equaling about 1% of the total population of the European Union (UNDP 2010).

Women

Although women account for half of all migrants, there is a general lack of data regarding the movement and experiences of women across the globe. A 2008 World Bank publication, however, provides some insight into female migration. In 2005, there were about 95 million female migrants worldwide. Oceania had the largest proportion of women immigrants at 51%; Latin America and the Caribbean with 50%; Africa, 47%; and in the former Soviet Union, 58% of its migrants were women. Asia, on the other hand, reported a decrease in the number of female migrants, from 46% to 43%. In the Middle East, female migrants made up 38.4% of all migrants.

Most women, like men, migrate voluntarily. Family reunification is a major driver for female migration. Since men have traditionally dominated migration, women are much more likely than men to be migrating spouses. The United States registers twice as many women than men as migrating spouses of citizens and permanent residents; European reports are similar (Martin, 2003). However, more and more women are migrating for work. Low-skilled labor is predominant among women, including such jobs as picking farm crops, garment manufacturing, meat and poultry processing plants workers, nursing home and hospital aides, and maidservants in hotels. These jobs can be attained via official contracted labor with the host country, or through information networks prior to or after irregular migration. However, more women are also migrating as part of the skilled labor pool. One of the most prominent industries is health care, where women make up the vast majority of migrating nurses, but an increasing number are in academia, research and development, and ICT, to name a few (Martin, 2003).

Currently, women and their dependent children make up 70–75% of the world's refugees and displaced persons. This is not true, however, for asylum-seekers, who are predominantly men. Women who are forced to migrate as refugees often face serious challenges. In many parts of the world, rape and sexual violence are used as weapons of war and are, in fact, considered by most countries to be war crimes. Women residing in refugee camps around the globe may also be under the threat of rape, precluding them from performing daily tasks such as gathering firewood or water. Sometimes, in order to procure food for themselves and their families, they are forced to provide sexual favors (Martin, 2003).

Another way women migrate is through smuggling and trafficking. Smuggling and especially trafficking are highly exploitative and third only to drugs and guns in the realm of international crime smuggling rings. The act of smuggling people across borders has existed since the establishment of the regulation of movement across international boundaries; however, the scale of smuggling has increased exponentially in recent years (UNDP, 2009). Smuggling can be informal where individuals help each other cross borders illegally, or it can be organized where smugglers help migrants obtain travel documents, provide transportation and access to houses in which they can hide from immigration and other authorities, and provide links to employment. Along the US-Mexico border, for example, male migrants tend to use experienced smugglers, also referred to as "coyotes," to help them cross deserted and desolate border areas, whereas women migrants are more likely to purchase fraudulent documents to gain access through legal points of entry.

Trafficking involves not just being smuggled across borders, but also exploitation and abuse. Although men are trafficked as forced labor, women and children are especially vulnerable and predominantly trafficked for the purposes of prostitution. Because human trafficking is usually conducted by international organized crime rings and other highly clandestine operations, there is no precise information regarding the actual numbers of women who are trafficked. In 2000, the United Nations estimated that four million women and children had been trafficked worldwide. Since then, despite the attempt of many countries to curtail trafficking, that number is very likely to have risen.

Traffickers obtain female victims a variety of ways: kidnapping, enticement with false promises of well-paying jobs in foreign countries, advertising bogus jobs and fake marriage opportunities. Most women who are trafficked are under the age of 25; many are still teenagers, with some victims as young as 7 years old. Trafficking victims are often physically, sexually, and mentally abused by their traffickers, forced to live in squalid conditions that are confined and secluded, often starved or malnourished, forced to take drugs, and forced to have unprotected sex with large numbers of partners over many long hours. Victims suffer emotional and mental breakdowns, become ill with sexually transmitted and other diseases, may be denied medical care and, once they become a "burden" to the trafficker or pimp, are sometimes killed. There may be few to no opportunities to escape their situation, either by running away or paying off the "debt" imposed upon them by the traffickers. For example, if the women are moved to a new location, which happens frequently in an effort to avoid law enforcement, the costs of the move are imposed upon the women as a debt, thus creating a never-ending situation of financial obligation to the traffickers (Martin, 2003).

Conflicts and War

In 2008, there were 14 million refugees as a result of conflicts around the globe. This number represents about 7% of all international migrants. People who are displaced by conflict and violence within a country number even higher, with some estimates at 26 million displaced persons. Of those, 4.9 million were in Sudan, 2.8 million in Iraq, and 1.4 million in the Democratic Republic of the Congo (UNDP, 2009).

Despite the 1951 Refugee Convention (UNHCR 1951), which has assisted millions of people to move to safer environments, most people who escape from war and insecurity do not typically fare well. To an increasing and growing extent, war is associated with large population movements as the displacement of civilians is used as a deliberate weapon of war, as is the case in Darfur, Sudan. Since most displaced individuals – 80% of whom are women and children – relocate within their country's borders, refugee camps host only about one third of all displaced persons, with the remainder left to survive on their own. Unfortunately, this is representative of the dilemma of the poor in many war-torn areas, most especially on the African continent (UNDP, 2009). Even so, refugees have certain internationally recognized legal rights, whereas the majority of displaced persons do not (UNDP, 2009).

Although conflict drives a very small share of global movement, only 1/10th of international and 1/20th of internal movement, the sudden need to flee their homes and livelihoods often destroys all forms of existing sources of income, access to services and social networks, leaving these migrants extremely vulnerable in general. They face overwhelming challenges including local hostility, harassment, and animosity not just from other people, but also from government officials, especially in the case of civil war (UNDP, 2009).

Africa is affected more by war and instability than any other area of the globe, and war accounts for 13% of international movement on the continent. Some of the largest migrations of people fleeing conflict include Sudan with 4.9 million displaced individuals, the Democratic Republic of Congo with 1.4 million, Somalia with 1.3 million, and Zimbabwe with figures as high as one million. In some countries, like Liberia and Rwanda, the number of people who have fled war and conflict remains undetermined (UNDP, 2009).

Environment

According to the United Nations and the Internal Displacement Monitoring Centre, more than 36 million people were displaced because of environmental events in 2008. Those events included earthquakes and severe weather occurrences – 15 million due to the Sichuan, China earthquake alone. The most affected region was Asia, which had almost 31.4 million persons displaced as a result of natural disasters. The Americas were the second most environmentally affected region (IOM, 2010).

The environment has always been an important driver of human movement as people have moved in search of water sources and fertile land for crops and favorable animal grazing conditions. Most experts agree that environmental factors, more specifically climate change, will be an increasingly important driver of human migration in the future. Over the last 30 years, drought has affected twice as many people as storms, demonstrating that slow-onset changes in the environment are likely to have a greater impact than sudden-onset disasters which usually receive much of the policy-focused attention (IOM, 2010).

Future predictions, although subject to considerable uncertainty, include the reduction by half of the agricultural output in Southern Africa by 2020 due to drought with the potential of causing severe famine. The area of the Himalayas will also suffer a severe reduction in water from river flows due to diminishing glacial water banks. Rising sea levels will affect people in coastal areas, especially in East and South Asia. Some predictions are that as many as 145 million people are currently at risk of rising sea levels, and some countries, like the Maldives, are contemplating buying land in other countries in expectation of having to move entire communities due to severe flooding and water submersion. The most extreme prediction is that climate change will force anywhere from 200 million to 1 billion people to move. Of course, many people who will be affected by environmental change, whether it's sudden or over time, cannot afford to move. In fact, some studies have found that the effects of rainfall, for example, on migration patterns is determined by socio-economic conditions and the ability to finance the cost of moving. Examples of this can be found in Mexico and Nicaragua where people who moved due to lack of rainfall in Mexico and as a result of Hurricane Mitch in Nicaragua were more often than not people who had the ability to finance the cost of moving (UNDP, 2009).

Economic Crisis

The countries that have been hit hardest by the current economic crisis are the more developed countries, and they also happen to be the same countries where most migrants live. By April 2009, Spain, for example, had reached a national unemployment rate of 15%, with rates as high as 28% among migrants. Since economic growth has drastically slowed down, countries where migrants have been experiencing good employment opportunities besides the OECD countries are also likely to be significantly affected, such as the GCC countries, East Asia, and South Africa. A jobs crisis can be especially difficult for migrants – just as economies tend to seek migrants from abroad to fill labor shortages, they tend to lay off migrants first during a recession. In fact, studies have shown that the unemployment rate of migrants tends to increase more rapidly than that of any other group during a recession (UNDP, 2009).

There is some evidence that declines in migration flows toward developed countries started as early as 2008. One of the measurements used as an indicator of this comes from the United Kingdom, where there was a 25% drop in the number of applications for national insurance cards from foreign-born individuals. Another indicator comes from the United States, where a census in August 2008 revealed that there was a 25% decline in the flow of migrants from Mexico. Historically, an economic crisis does not indicate that there will be major return flows of migrants to their country of origin as they are generally encouraged to ride out these periods of economic uncertainty for a variety of reasons. Primarily, the prospects of reentry to the host country are diminished, and the needs of family members and conditions in the country of origin have a profound effect on a migrant's decision to remain. In addition, the generosity of the host country's welfare system also plays a critical role (UNDP, 2009).

Some countries have already introduced policies to reduce the number of permanent and temporary migrants they admit for the first time in many years. Beginning as early as 2009, Australia reduced its permanent skilled labor admissions from 155,000 to 108,000 a year and has removed several job categories from its list of "critical skills" such as bricklaying, plumbing, and carpentry. English language skill demands were also introduced for lower-skilled occupations. New Zealand implemented policy changes that curtail the inflow of labor migrants such as mandating certain processes to ensure that no local workers are available for any work permits issued to migrants, and those work permits have been reduced from 3 years to 1 year. In a 13-month period beginning December 2008, the issuance of work permits to foreign laborers declined by 20% (UNDP, 2009)

In addition to job losses, another consequence of the current economic crisis for migrants and countries of origin is the effect on remittances. Collectively, migrants send home a substantial amount of money; women tend to send a larger portion of their incomes on a more regular basis – even though their lower wages mean that the absolute amounts are less (UNDP, 2009). Although it is difficult to obtain precise numbers because of the many channels used to send money abroad, some of which are informal, some estimates of the total dollar amount of remittances in 2009 were US $414 billion, US $316 billion of which went to developing countries. For some for the smaller island nations of the Caribbean and Pacific Islands where GDP is very low, remittances are often higher than GDP and/or the total amount of foreign aid (*World Migration Report*, 2010). In some areas of India and Bangladesh, poverty rates in households with a migrant fell by roughly half between 2001 and 2006. It should not be assumed, however, that remittances always go to the neediest households. Studies of remittances to Peru and Nicaragua showed that money tended to flow to residents who had higher education and income levels. This could be a result of limited opportunities for low skilled labor to move across borders (UNDP, 2009).

The effect of remittances on the receiving households and communities can be substantial. Remittances can be spent in ways that generate local employment such as starting or expanding a business, and even home building. In fact, some studies indicate that remittances encourage entrepreneurship and investments. Remittances can help create a store of capital which can be used to finance future migration of additional household members. Because remittances are spent on consumption, they can also lead to improvements in nutrition. Studies indicate that families receiving remittances often prioritize the use of this money to pay for education, and the rates of children attending and remaining in school have improved for remittance-receiving families in Mexico, Bangladesh, Fiji, and the Philippines, among others (UNDP, 2009).

The economic crisis has shrunk the flow of remittances to developing countries with evidence of significant declines in Bangladesh, Egypt, El Salvador, and the Philippines – all countries that are heavily dependent on remittances (UNDP, 2009). El Salvador's remittances have accounted for more than 18% of its GDP. Remittance shares are highest in Moldova and Tajikistan, 45% and 38%, respectively, and were projected to shrink by at least 10% in 2009. Three fourths of the remittances to sub-Saharan Africa come from the United States and Europe – two of the hardest hit countries by the economic downturn. The full effect of the current crisis on migrants in general remains to be seen (UNDP, 2009).

Conclusion

At the microlevel, migration can sometimes seem random: an individual or family decides to pick up and move to another country or from their rural home to an urban area in search of a job to improve their standard of living. From a global perspective, however, migration is quite systematic, with treaties and policies either by individual countries or in coordination with other countries prescribing how many people can move, where they can move to, what their conditions will be upon arrival to new destinations, and when they may have to depart. Depending on how the current global recession plays out, countries and regions that have not traditionally been the ultimate migrant destinations, such as the United States or Canada, may become much more important and desired as destinations should they fare better through the economic turmoil. Developed countries that experience labor shortages may soon have labor surpluses as evidenced by increases in unemployment rates, especially in the United States and major migrant destination countries of the European Union.

Furthermore, demographic trends are expected to play a large part in the future picture of global immigration as many developed countries have significantly large aging populations. Younger labor pools will be needed to not only fill jobs, but to offset the costs of supporting an older aged population. Natural disasters and especially climate change are also expected to play significant roles in predicating future human movement. War and other conflicts, political and civil unrest have always been, and will likely remain a permanent feature of human societies and major drivers of people to leave their places or countries of origin. At the time of this writing, political upheaval, civil unrest, and violence are forcing thousands of people in Libya to flee the country, moving primarily toward the Tunisian border and arriving on the shores of Italy in significantly large numbers. Tunisia itself has very recently experienced mass civil unrest leading to the ouster of its president of 23 years. Following Tunisia, this same scenario is currently being playing out in Egypt, Bahrain, Yemen, and Lebanon, along with Libya. Refugees will no doubt continue to be an international responsibility.

Immigration Processes and Health in the U.S.: A Brief History

Sana Loue
Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Introduction

Concern with contagion from travelers from afar existed in the colonies that were to become the United States, as evidenced by colonial laws mandating quarantine of foreign passengers and the exclusion of those who were ill or disabled (Proper, 1967). And, ever since its formation as an independent nation, the United States has promulgated laws that exclude prospective immigrants from entry into the United States on the basis of specified health conditions. Even individuals who have legally immigrated to the United States but not yet obtained United States citizenship have been and continue to be potentially inadmissible because of certain health conditions. Although the specified health conditions have changed over time, three themes are evident throughout this history: (1) fear that citizens of the United States would be contaminated by germs and disease carried by foreigners to the United States; (2) concern that the admission into the United States of individuals deemed to be of an inferior “race” would diminish the quality of the national “stock,” a viewpoint borne from eugenics; and (3) alarm at the prospect that the US economy could be faced with the costs of caring for individuals from other countries who were too ill or disabled to support themselves, who would, in other words, become a “public charge.” These three themes were often intertwined in the immigration policies and procedures that were developed to protect the US populace. In order to allay such fears, elaborate procedures for the medical examination of prospective immigrants were established. The specific components of this “inspection,” as it is known, have changed over time, but the goals and basic framework have remained constant. (These same concerns have been shared and continue to be shared by many countries, which have also implemented their own procedures in order to address them. Readers are referred to other sources for discussions about the health-related exclusion provisions and procedures in Canada (Comeau & Allahar, 2001; Gushulak & Williams, 2004), Australia (Bashford, 2002; Bashford & Howard, 2004; Leask, Sheikh-Mohammed, MacIntyre, Leask, & Wood, 2006), and the United Kingdom (Hansen & King, 2001).)

This chapter first provides an overview of each of these three major themes in relation to the immigration statutes, regulations, and medical examination procedures as they have existed over time. It is beyond the scope of this chapter to address these issues in great depth, and the reader is referred to additional sources for a more detailed examination (Kraut, 1994; Markel, 1997). The discussion then focuses on current medical examination procedures for individuals wishing to enter the United States as permanent residents, also known as holders of a “green card” or “mica.”

Health and Exclusion: Major Themes

Foreignness and Fear of Contagion

In the mind of the larger public, illness and epidemics have been associated with or attributed to newly arriving foreigners to the United States since the earliest days of the nationhood. In part, the association drawn between foreignness or differentness and illness represents scapegoating, most easily recognizable in recent years in the context of the response to HIV/AIDS, but also evident in the response in the United States (and other nations, for that matter) to leprosy, typhus, and various other diseases (Cartwright & Biddiss, 1972). As examples, consider the following:

- Yellow fever epidemics in Philadelphia during the early 1790s were attributed to arrivals from the Caribbean; the disease was then called “Barbados

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

distemper." In 1793, the disease was renamed "Palatine fever" when it was observed that many of its victims hailed from that particular area in the German states (Powell, 1949).

- The cholera epidemic of 1832 was attributed to the arrival in the United States of increasing numbers of immigrants from Ireland, many of whom were Roman Catholic. Although cholera was then believed to be caused by bacteria, media representatives, Protestant clergy, and even public health officials accused the Irish Catholic newcomers of harboring and transmitting the disease through their perceived intemperance, uncleanliness, and excessive eating. Protestant clergy, in particular, viewed the disease as a scourge from God, sent in retribution for the victims' violations of natural law (Rosenberg, 1987).
- Dr. John Meares, the city health officer for San Francisco, blamed the city's 1876 smallpox epidemic on the "willful and diabolical disregard of [the city's] sanitary laws" by the 30,000 "unscrupulous, lying and treacherous Chinamen" who resided in the city (Shah, 2001, p. 53).
- In arguing against Chinese immigration in 1882, Oregon senator James H. Slater advised the US Senate that immigrating Chinese would "bring with them their filth and frightful and nameless diseases and contagions" (Slater, 1882, p. 1636).
- Officers of the United States Public Health Services attributed the appearance of bubonic plague in Honolulu's Chinatown in 1899 to the perceived Chinese proclivity to live in filthy and overcrowded conditions, despite existing knowledge that the disease was transmitted by rats. In an effort to end the epidemic, the president of the city's Board of Health ordered in January 1900 the burning of all buildings in the city's Chinatown; the fire destroyed 4,000 homes and left 4,500 people homeless (Shah, 2001).
- Native-born Americans variously attributed the arrival of the influenza pandemic of 1918 to the United States on immigrants from Italy and Germany. Germans were especially targeted as the causative agent of the disease, with many believing that they had intentionally spread the disease as part of their war effort (Kraut, 2010).
- A temporary nurse working in Irwindale, California, in 1916 reported having difficulty obtaining accurate records due to "the secretive nature of the Mexican" and the one case of syphilis that had been diagnosed evidenced the lack of privacy and the low "moral tone" that prevailed among the village's Mexican inhabitants (Anon, n.d.).
- Efforts were made in the 1920s to expel Filipinos from the country, based on claims that they were importers of "loathsome diseases" and, as such, required expensive medical care (Abel, 2004, p. 936).
- As recently as 1982, within a year of identifying the first cases of what would come to be called AIDS, the Centers for Disease Control and Prevention (CDC) labeled Haitians a "risk group." This emphasis on group membership as a risk factor, rather than relevant activities or behaviors, ultimately resulted in the medical and social construction of "risk groups," whose members were presumed to be at higher risk of contracting and transmitting the infection by virtue of their membership in the specified group, regardless of their individual behaviors (Schiller, Crystal, & Lewellen, 1994). Haitians, together with homosexuals, heroin addicts, and hemophiliacs, came to be known as "the 4-H club." Indeed, the United States was so fearful that the admission of HIV-infected Haitians would result in contagion of those already in the United States that HIV-infected Haitian refugees were initially prevented from entering into the country and were quarantined by the US government at Guantanamo Bay. The quarantine ended and the individuals were admitted into the United States only as the result of a lawsuit and worldwide condemnation for the establishment of what was the only prison camp for HIV-infected refugees in the world (*Haitian Centers Council, Inc. v. Sale*, 1993; White, 2007). (Many countries in addition to the United States perceived HIV/AIDS as a foreign problem, including India, Japan, South Korea, Malaysia, Indonesia, and Singapore (Garrett, 1994, pp. 457–527).)

Indeed, our immigration laws have consistently excluded those individuals believed to carry disease that could potentially infect those already present in the United States (see ➋ *Table 1*). These exclusion provisions have been established by the US Congress through the promulgation of statutes. The meaning of

Table 1

Health conditions serving as basis for denial of admission to prospective immigrants into the United States

Legal and other sources	Key grounds of exclusion or revisions	Definition
Act of 1882	Lunatics	
	Idiots	
Act of March 3, 1891	Lunatics	
	Idiots	
	Loathsome and dangerous contagious disease	
Act of February 5, 1917	Loathsome and dangerous contagious disease	Included trachoma (granular conjunctivitis), favus (fungal infection of the scalp and nails), venereal diseases, parasitic infections, tuberculosis
Casimano v. Commissioner of Immigration (1926)	Insanity	
Patton v. Tod (1924)	Feeble-minded persons	
Saclarides v. Shaughnessy (1950)	Imbeciles	
United States Public Health Service (1917)	Idiots	
	Epilepsy	
	Insane persons	
	Persons who have had one or more attacks of insanity at any time previously	
	Persons of constitutional psychopathic inferiority	
	Persons with chronic alcoholism	
	Tuberculosis	
	Mental or physical defect	Physical defect being of a nature which may affect the ability of such an alien to earn a living
Act of June 27, 1952	Retained provisions relating to chronic alcoholics, tuberculosis, and dangerous contagious diseases	No longer referred to diseases as "loathsome" Included chancroid, gonorrhea, granuloma inguinale, infectious leprosy (Hansen's disease), lymphogranuloma venereum, infectious-stage syphilis, active tuberculosis (TB). Leprosy added.
Senate Report No. 1137 (1952)	Feeble minded	Considered to be "an inclusive generic term represented by subclasses of idiots, imbeciles, morons, and persons of borderline intelligence"
United States Public Health Service (1985a, b, 1987)	Insanity	Aliens "who exhibit signs and symptoms of a psychotic disorder" Psychosis defined as an "impairment in a person's ability to think, respond emotionally, remember, communicate, interpret reality, and behave appropriately, so as to interfere grossly with the capacity to meet the ordinary demands of life"
	One or more attacks of insanity	Recovery said to be demonstrated if the individual was free of symptoms for 1 year or more

Table 1 (continued)

Legal and other sources	Key grounds of exclusion or revisions	Definition
	Psychopathic personality	"History of continuous and chronic antisocial behavior in which the rights of others are violated, persistence into adult life of a pattern of antisocial behavior that began before age 15, and a failure to sustain good vocational performance over a period of several years." Diagnosis required onset before age 15, age of 18 or older at time of examination, persistence of behavior for 5 years or more, and at least four of the following: an inability to work continuously, an inability to be a responsible parent, a "failure to accept social norms," an inability to maintain attachment of a sexual partner, a failure to plan, recklessness, a disregard for truth, and irritability and aggressiveness Encompassed "sexual deviation" including paraphilias, including fetishism, transvestism, zoophilia, pedophilia, exhibitionism, voyeurism, sexual masochism, sexual sadism, homosexuality
	Mental defect	
	Narcotic drug addition	Evidence of either tolerance or withdrawal Tolerance referred to the need for increasing amounts of the substance to achieve a desired effect or a diminished effect with maintenance of the usual dose Withdrawal referred to a constellation of symptoms resulting from cessation of the substance's use or from a reduction in intake of the substance Factors to be considered included the amount of drug used, the frequency of use, and the duration of use
	Chronic alcoholism	Synonymous with alcohol dependence Said to be characterized by a pattern of "pathological use" or "impairment in social or occupational functioning and evidence of tolerance or withdrawal" Evidence from laboratory procedures and physical examination were required to justify this diagnosis
	Dangerous contagious disease	Included chancroid, gonorrhea, granuloma inguinale, lymphogranuloma venereum, infectious-stage syphilis
	Tuberculosis	
	Leprosy	
	Physical defect, disease, or disability	Any other significant finding from the immigration medical examination that could affect the individual's ability to earn a living
Act of September 26, 1961	Deleted leprosy and tuberculosis as specific grounds of exclusion; replaced with a broader provision excluding "aliens who are afflicted with any dangerous contagious disease"	

Table 1 (continued)

Legal and other sources	Key grounds of exclusion or revisions	Definition
Immigration and Nationality Act Amendments of 1965	Deleted provisions relating to feeble minded and replaced it with mental retardation	
	Added sexual deviation, following court decision that homosexuality was not encompassed in provision relating to psychopathic personality	
Act of July 11, 1987	Added human immunodeficiency virus (HIV) to list of dangerous contagious diseases contained in regulations	
Immigration Act of 1990 United States Public Health Service (1991) 73 Federal Register 58056 (October 13, 2008) President Executive Order 13295 (2003)	Communicable disease of public health significance	Initially included chancroid, gonorrhea, granuloma inguinale, infectious leprosy (Hansen's disease), lymphogranuloma venereum, infectious-stage syphilis, active tuberculosis (TB), and human immunodeficiency virus (HIV) Expanded in 2008 to include (1) diseases listed in a presidential order pursuant to Section 361(b) of the Public Health Act: cholera, diphtheria, infectious tuberculosis, plague, smallpox, yellow fever, viral hemorrhagic fevers (Lassa, Marburg, Ebola, Crimean-Congo, South American, and others not isolated or named), and severe acute respiratory syndrome (SARS); and (2) any communicable disease that "may pose a public health emergency of international concern" HIV was removed from the list in January 2010. (Congress voted in July 2008 to repeal the HIV ban. The United States Department of Health and Human Services did not publish a proposed rule to remove HIV from the listing of communicable diseases of public health significance until July 2009. In October 2009, President Barack Obama announced the lifting of the HIV immigration ban at a ceremony at the White House and characterized the ban as having been "a decision rooted in fear rather than fact" (Eleveld & Garcia, 2009). HIV was officially removed from the list in January 2010.)
	A physical or mental disorder and behavior associated with the disorder that may pose, or has posed, a threat to the property, safety, or welfare of the alien or others	"Harmful behavior" is defined as a "dangerous action or series of actions by the alien that has resulted in injury (psychological or physical) to the alien or another person, or that has threatened the safety of the alien or another person, or that has resulted in property damage"
	An alien who has had a physical or mental disorder and a history of behavior associated with the disorder, which behavior has posed a threat to the property, safety, or welfare of the alien or others and which is likely to recur or to lead to other harmful behavior	See above

Table 1 (continued)

Legal and other sources	Key grounds of exclusion or revisions	Definition
	Drug abuser or addict	Refers to any nonmedical use during the previous 5 years of any substance listed in Section 202 of the Controlled Substances Act and any nonmedical use during the previous 2 years of any psychoactive substance not listed in Section 202 of the Controlled Substances Act
Illegal Immigration Reform and Immigration Responsibility Act of 1996	Failure to obtain or present documentation of specified vaccinations	Encompasses mumps, measles, rubella, polio, tetanus, diphtheria, pertussis, influenza type B, hepatitis B, and any others recommended by the Advisory Committee for Immunization Practices. These have included varicella, haemophilus influenza type B, and pneumococcus

Sources: Baynton, 2006; Fairchild, 2004; Loue, 2009; Shah, 2001

the statutes has been amplified by regulations established by the federal agency or agencies designated to do so in the statute. The agencies currently responsible for the interpretation or enforcement of the statutory provisions relating to these health grounds are the United States Departments of State, of Homeland Security, and of Health and Human Services. The United States Public Health Service is responsible for the development of instructions for the physicians involved in conducting immigration-related medical examinations, which are discussed further below. (Changes in these technical instructions for physicians have been issued at irregular intervals during the effective periods of controlling legislation. Consequently, the interpretation of a specific ground of inadmissibility may vary even though the controlling statutory and regulatory provisions do not. ➲ *Table 1* provides a general overview of the statutory and regulatory provisions, but does not for the most part reflect interim changes in interpretations occasioned by the United States Public Health Service.)

Eugenics, Immigration, and Immigrants

Eugenics, first defined by Sir Francis Galton as the science of improving heredity, became the basis for eugenicists' efforts in the United States and elsewhere to improve human heredity (Pernick, 1997). Eugenicists concerned with the integrity of humans in the United States premised their agenda on concepts derived from animal breeding, such as those of the zoologist Michael Guyer, who opined in 1916 that the breeding of unrelated species would bring about the "mongrelization" of species. Although eugenicists understood the relationships between germs and disease, many believed that hereditary resistance would both prevent and cure the disease (Guyer, 1916). The segregation of "defectives" through institutionalization or other isolation strategies would prevent their reproduction and limit the spread of hereditary disease (Pernick, 1997).

The eugenicists' equation of race with disease and degeneracy was clear. Some advocated for the exclusion of all non-Germanic people from the United States, arguing that they were of inferior intelligence in comparison with immigrants from Germanic nations (Brown, 1922). Immigrants arriving from Southern Europe to the United States during the 1920s were perceived to be of an inferior "race" and, it was claimed, were often feeble minded, while those arriving from Eastern Europe were characterized as genetically defective (Nelkin & Michaels, 1998). One physician with the United States Public Health Service charged with the responsibility of examining arriving immigrants to Ellis Island characterized Jews as "a highly inbred and psychopathically inclined race" with defects "almost entirely due to heredity" (Wilson, 1913, p. 271). This equation of race and culture with deficiency continues to persist; it has been suggested, for example, that the admission of Latino and Black immigrants will result in the "downward pressure on the distribution of intelligence" (Herrnstein & Murray, 1995, p. 342) and that some immigrant groups will cause an increase in crime because of their "impulsiveness and present orientation" (Brimelow, 1995, p. 184).

The eugenicists of the 1920s–1940s advocated a variety of strategies in furtherance of their goal, including the imposition of restrictions on immigration and the forced sterilization or euthanasia of those deemed to be degenerate or deficient in some way (Enoch, 2005; Kluchin, 2007; Nelkin & Michaels, 1998; Stern, 2005). Health officials inspecting intending immigrants to the United States could make use of the laws' disease categories to safeguard the population from the threat of "inferior races." Accordingly, public health officials were able to easily effectuate the repatriation of Mexican immigrants and Mexican-American citizens in the West on the basis of tuberculosis (TB) (Abel, 2003).

Even after gaining admission to the United States, immigrants deemed to be of an inferior race remained vulnerable to efforts designed to stem their reproduction. Twenty-seven states had promulgated laws by 1932 that permitted compulsory sterilization of those deemed to be defective, which included immigrants perceived as being of an inferior race (Reilly, 1991). These legislative provisions were nevertheless viewed as inadequate protection of the nation's populace from potential degeneracy. Newspaper columnist Fred Hogue nevertheless wrote in dismay in 1941 that "in this country we have wiped out the mosquito carriers of yellow fever and are in a fair way to extinguish the malaria carriers: but the human breeders of the hereditary physical and mental unfit are only in exceptional cases placed under restraint" (Hogue, 1941, p. 27). Many of the state laws facilitating the sterilization of those deemed to be deficient remained in force through the 1970s, at the very time that family planning efforts were being championed and abortion was being legalized (Stern, 2005).

California justified its legislation through the 1950s as an attempt to rid the population of undesirable qualities and strengthen the state. Efforts "to restrain" those deemed to be unfit disproportionately impacted persons who had been born outside of the United States. For example, Gosney and Popenoe (1938) found from a survey conducted of California state hospitals and homes in the late 1920s that 39% of the men and 31% of the women who were sterilized had been born outside of the United States. Those who were most frequently affected had arrived here from Britain, Germany, Italy, Poland, Russia, and Scandinavia (Stern, 2005).

Illness, Disability, and Public Charge

From the earliest days of this nation, our immigration laws have excluded those who have been viewed as potentially unable to earn a living or, in the language currently used by US immigration law, "are likely to become a public charge." It has been argued that the underlying intent of such provisions at the time of their initial promulgation was not to restrict immigration to this country, but rather to control immigration in order to ensure that those who were allowed entry were healthy enough to support themselves, to contribute to the burgeoning industrial economy, and could find employment even during periods of economic downturn (Fairchild, 2004).

Nevertheless, individuals with apparent ability to earn a living or who had sufficient family assets to ensure their support could be and were denied admission to the United States on the basis of perceived inability to support themselves. These perceptions often reflected existing beliefs based on intertwined conceptualizations of race, disease, and disability. As an example, during the period from 1882 through 1924, deaf individuals were almost invariably denied admission to the United States based on a belief that deaf people were social dependents rather than social contributors and, like those of inferior race, they were "bearers of a potentially defective heredity" (Baynton, 2006, p. 395). Their exclusion both safeguarded public dollars from unwanted burden and protected the integrity of the nation's populace from degeneracy, thereby addressing the varied concerns of the public, Congress, and the eugenicists.

Concerns relating to immigrants' reliance on public support and taxpayer burden continue to this day, reflected in the promulgation of the Personal Responsibility and Work Opportunity Reconciliation Act of 1996. With relatively few exceptions, the law bars most lawfully admitted permanent residents from receiving Supplemental Security Income, food stamps, cash assistance, and Medicaid and Medicare. Although permanent residents may become eligible to receive some forms of assistance 5 years after becoming permanent residents, the amount of assistance will be reduced by the amount of their sponsor's – typically a family member who is either a United States citizen or permanent resident – income and financial resources that are "deemed" to be available to the individual. Individuals who are in the country illegally are entitled to few services, with the exception of vaccinations and noncash forms of assistance (Loue, 2009).

The Medical Examination for Immigration

Discussion of the immigration medical examination or inspection still conjures up for many an image of the "line" at Ellis Island, the major processing center for immigrants to the United States (Fairchild, 2004). Similar procedures existed at Angels Island in San Francisco, Port Huron and Detroit in Michigan, and in El Paso and Laredo along the US–Mexico border. An individual's future could be determined in a split second based on the assessment of the public health inspector. However, as Baynton (2006) has cogently argued, the selection procedure likely began long before individuals arrived at Ellis Island.

Many individuals wishing to come to the United States may have ultimately decided against undertaking the voyage. The requirements for entry were widely advertised in Europe and individuals with limited means who were uncertain about the likelihood of being granted admission may have decided to save themselves the time and expense. Additionally, ships may have refused passage to individuals with a physical disability in order to avoid the possibility of a fine for the rejected passenger and the costs of returning the individual to his or her country of origin. Agents for steamship lines may have refused to sell tickets to individuals with physical disabilities for much the same reason; they could be fined if they sold a ticket to a passenger who was later denied boarding (Baynton, 2006). Indeed, it was estimated in 1911 that 10 times as many people were denied transportation because of medical reasons as were refused admission to the United States upon arrival (Immigration Commission, 1911).

Only six physicians from the Public Health Service were on hand at Ellis Island in 1892 to screen the passengers arriving there. During peak immigration years, prior to World War I, that number had increased to 25 (Markel & Stern, 1999). It was unlikely that these few physicians could give each arriving passenger more than a cursory inspection. Only 2% of those who were excluded at Ellis Island in 1898 were rejected for medical reasons (Markel & Stern, 1999). That percentage rose sharply, however, so that in 1913, 57% of the denials were premised on medical grounds and in 1915, 69% of the denials were for medical reasons (Kraut, 1994; Yew, 1980). As Baynton (2006) observed,

> ► The process of judging which immigrants to admit and which to reject was inevitably, to some extent, arbitrary and capricious. The criteria were never clear-cut and could not possibly be precisely constructed to cover every individual case. Instead, officials had to make rough-and-ready judgments of employability, eugenic worth, and general social desirability. Their decisions necessarily relied in good part on unexamined assumptions and prejudices . . . Multiple factors came into play, such as immigrants' ethnicity, class status, and general appearance . . ..

Angel Island in San Francisco processed approximately 100,000 individuals during its operation, in comparison with more than 10 million individuals processed through Ellis Island (Markel & Stern, 1999). The majority of the individuals processed through Angel Island were Asian. Arriving passengers were screened for hookworm, threadworm, liver fluke, pneumonic plague, bubonic plague, trachoma, sexually transmitted diseases, tuberculosis, and a variety of chronic physical conditions, including hernias, varicose veins, and cardiac abnormalities.

Similar screenings were conducted at checkpoints along the US–Mexico border. Immigrants arriving through the El Paso station, however, were required to be disinfected. Following the outbreak of a typhus epidemic in Mexico in 1915, Mexicans arriving at the El Paso checkpoint were subjected to showers with kerosene, an examination for lice, and vaccination for smallpox. Although in 1910 less than 1% of individuals arriving through the border stations were denied admission on the basis of medical grounds, that proportion increased following the Mexican typhus epidemic (Markel & Stern, 1999).

By the end of World War II, the inspection process had been revised to require the medical examination prior to departure from one's country of origin, a procedure which continues to the present day. All individuals seeking permanent resident status are required to undergo a mental and physical examination as a part of the application process, whether they are overseas applying through what is known as consular processing or in the United States applying through the process known as adjustment of status. Additionally, some individuals seeking entry for only limited periods of time are also required to undergo the medical examination. In general, the medical examination now consists of a medical history, serologic testing for specified diseases (see ➋ *Table 1*), and, depending on several factors, either a tuberculin skin test or chest x-ray (United States Public Health Service, 1991, 2008). The medical examination can only be conducted by a physician authorized to perform immigration-associated medical examinations: a panel physician in the case of an individual applying for a visa through a consulate or a civil surgeon, in the case of a person applying for adjustment of status in the United States (8 Code of Federal Regulations, 2010; 42 Code of Federal Regulations, 2010).

Only individuals who can demonstrate that they are the spouse or unmarried son or daughter or the minor unmarried and lawfully adopted child of a United States citizen, an alien lawfully admitted for permanent residence, or an alien who has been issued an immigrant visa can potentially qualify for a waiver of excludability due to "a communicable disease of public health significance." This relationship is not required for those seeking a waiver of excludability for mental illness or failure to fulfill the vaccination requirement. An exemption from the vaccination requirement is potentially available to those who are able to demonstrate that they are opposed to vaccinations in any form, that the objection is based on religious belief or moral conviction, and that the belief or conviction is sincere. In almost all circumstances, waivers are not available for drug abusers or addicts.

Conclusion

The United States has attempted to protect its population from disease and its economy from undue burden through the promulgation of health-related immigration restrictions and procedures, and to simultaneously accommodate the need to preserve families and to respect diverse belief systems through the implementation of waiver provisions. Specific exclusion provisions have changed over time in response to perceived threats of disease and contagion. In retrospect, it is evident that many of these provisions were premised on fear rather than the knowledge that was available even at the time that these provisions were conceived. Increased globalization and international travel have underscored the oft-stated observation that disease knows no political boundaries. Accordingly, immigration restrictions designed to halt disease transmission and susceptibility at a national border can only be doomed to fail.

History and Background

Biomedicine is at the height of its success, delivering more health care products and services to more people, at greater expense than ever before (Jonas, 2002). Prior to this, historical events such as The Meiji Restoration in Japan, the Scientific Revolution, and advancement of colonialism emphasized scientific enquiry and empirical thought over traditional healing methods (Mkize, 2009; Nishimura et al., 2009; Twohig, 2008). The introduction of antibiotics, rapid expansion of pharmaceuticals, and improved public health programs further contributed to the decline of traditional medicine (TM), and later complementary and alternative medicine (CAM) especially after World War II (Twohig, 2008). To maintain continuity throughout this entry, we will define traditional medicine (TM) as indigenous health traditions of the world in their original settings, and complementary and alternative medicine (CAM) as health care therapies outside the biomedical mainstream in industrialized countries. Where we discuss forms of healing from all settings, we will use traditional, complementary, and alternative medicine (TCAM) (Bodeker et al., 2007).

Biomedicine has achieved great strides in treating acute illness, and combating infectious disease; however, it has been unsuccessful in combating the endemic increases in many chronic diseases among Western countries such as the USA, Canada, UK, and Australia (Leonard, 2001). In the USA, 80% of all illnesses are considered chronic that are long lasting with regular occurring episodes (Keegan, 2001). This increase can be attributed to inadequate health promotion and prevention in health care systems, as well as societal/individual behaviors that have contributed to ill health and disharmony (Hales, 2009; Larson, 2007).

People are recognizing a need to take greater control of their health, and are increasingly embarking on their own personal path by seeking out holistic approaches to restore or maintain health (Keegan, 2001; Larson, 2007). The concept of holism was first developed in South Africa in the mid-1920s, although whole person theories came to prominence in North America after research discovered a correlation between lifestyle and the onset of illness (Keegan, 2001). Holistic health care practitioners recognized that wellness included looking after one's mind, spirit, thoughts, feelings, emotions as well as the physical body (Keegan, 2001). The bio-psychosocial perspective stems from this belief that our bodies, emotions, and thoughts are connected (Keegan, 2001) and that social, psychological, biological, and environmental factors impact health and wellness (Sarifino, 2008). This perspective supports the principle that optimum health is best achieved with a holistic approach taking into account diet, lifestyle, exercise, spirituality, social and work environments as key determinants of health (Keegan, 2001). This has led to growing public demand for diverse health care services, based on the perception that no one type of health care modality can provide the full range of benefits desired (North, 2008). The Internet and advanced communications have facilitated the flow of and access to health information, coupled with global migration that has resulted in increasing exposure to diverse health beliefs and medical systems (Twohig, 2008).

Although the earliest societies have been dependent on TM for many centuries, countries such as Canada, the UK, Germany, and Australia have been experiencing surging interest in CAM (Bodeker et al., 2007). For

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

example, the UK is experiencing a significant increase in the use of CAM with one in ten individuals having consulted a practitioner, and 90% of these health seeking behaviors occurred outside of the National Health Service (Thachil & Bhugra, 2009).

Some of this increase may be attributed to the perceived effectiveness of traditional, complementary, and alternative medicine (TCAM), a lower incidence of adverse effects, greater emphasis on partnership building, and a holistic approach to individual problems (Thachil & Bhugra, 2009). Indications are that consultations with TCAM practitioners provide simple language and lay explanations, recognition of the existence of illness without pathology, and investigation of emotional and social factors as potential underlying causes for illness (Thachil & Bhugra, 2009). Other authors and scholars have pointed out that emotions are important for healing, and that having positive emotions may trigger endorphin release and aid in health restoration (Larson, 2007). Similarly, research has found that expressing positive emotions in biomedical consultations was also strongly associated with shared understanding between physicians and their patients (Lee et al., 2010).

The National Centre for Complementary and Alternative Medicine classifies TCAM into the following groups (Hales, 2009; National Centre for Complementary and Alternative Medicine, 2010):

1. Traditional, whole medical systems – these are complete systems of theory and practice that have evolved independently from or parallel to biomedicine (Satow et al., 2009). These include Traditional Chinese medicine, Ayurveda (from India), and Indigenous healing.
2. Mind–body integration – this involves behavioral, psychological, social, and spiritual approaches (Keegan, 2001) designed to enhance the mind's ability to heal and stimulate optimal body functioning (Hales, 2009).These approaches follow closely the historical view that mind and body are seen as one, and that positive attitudes are core for optimal psychological functioning, quality of life, and overall health and wellness (Hales, 2009). These approaches benefit all patients irrespective of culture, gender, or age with minimal physical and emotional risk, and are especially beneficial for those with chronic physical and mental illness (Hales, 2009). Mind–body approaches include hypnosis, meditation, yoga, prayer, visual imagery, aromatherapy, animal-assisted therapy, and other forms of creative expression such as art, music, and dance therapy.
3. Biologically based therapy – these therapies involve the use of natural, biologically based products divided into the following categories: phytotherapy or more commonly called herbalism, orthomolecular medicine, and special diets (Keegan, 2001). Herbalism involves the use of plant derivatives for therapeutic and illness prevention. Orthomolecular medicine refers to nutritional and food supplements used for preventive or therapeutic purposes. Special diets such as macrobiotics and the Atkins diet are used to promote health and aid in the treatment of chronic diseases (Keegan, 2001)
4. Manipulation and body-based methods – these involve manipulation or movement of the body and are classified as follows: chiropractic, elements of bodywork, Pilates, reflexology, craniosacral therapy, and various types of massage therapies. All of these focus on the musculoskeletal system and spinal column which are thought to be the framework for healthy functioning (Keegan, 2001).
5. Energy therapies – these came to prominence in the 1800s drawing upon Oriental medicine meridians and Indian chakras (Keegan, 2001). These therapies are based upon the belief that energy fields surround the physical body, and that the transference of energy within the body will open blocked channels and realign unbalanced energy. Domains within energy therapies are therapeutic touch, aura healing, chakra opening and closing, and electromagnetic healing (Keegan, 2001).

Traditional Whole Medical Systems

Traditional Chinese Medicine

Traditional Chinese Medicine (TCM) is a total system of health care that has been documented to exist for 3,000 years (Keegan, 2001; Larson, 2007). The practice of TCM is based on the philosophy of Taoism and belief that a "life force" or "chi" energy flows through the human body via 12 meridians (Benfield & Korngold, 1991; Keegan, 2001). Four methods of diagnosis are observing, listening, questioning, and pulse taking, which are used to understand the psychological factors related to diseases (Zhao, 2009). Illness is thought to be the result of blockages in the feminine and masculine energy flows called yin and yang, with a variety of methods such as acupuncture, acupressure, moxibustion (heat therapy), herbal remedies, massage, diet, tai chi, breathing, and meditation used to restore the flow or chi energy. Acupuncture is a widely used form of TCM and consists of inserting needles along points of the meridian to restore the flow of chi energy, used mainly for pain control, skin disorders, fertility problems, asthma, and arthritis (Keegan, 2001; Larson, 2007).

Indigenous Healing

Ancient societies are intimately connected with nature, animal, and plant kingdoms, believing that they possess a spirit or soul (Keegan, 2001). Illness is attributed to spiritual deficits that can be mediated with interventions intended to restore harmony and health. Shamanism is one type of intervention originating among indigenous populations and is one of the world's oldest forms of human healing (Wurges, 2001). The shaman is called upon to mediate between the people in the community and the spirit world to cure disease, and bring balance between the physical and spiritual worlds. Shamans believe that disease is caused by straying souls which come into contact with evil spirits and demons. The shaman's role is to provide relief from emotional and physical suffering by communicating with spirits in order to gain insight needed for healing. To accomplish this, shamans enter into an altered state of consciousness where they travel to other plains of existence. For example, shamans in the Americas, South Asia, and Tibet use hallucinogenic plants, herbs, chemicals, crystals, amulets, chants, and drums, to aid in spirit flight, soul retrieval, and healing (Gadit, 2007; Wurges, 2001). Teaching involves training by master shamans on altered states, techniques, spirit names and functions, mythology of clans, and forces that threaten the soul (Wurges, 2001). Shamanism is still practiced widely among indigenous people from Africa, the America and in the South Pacific, South Asia, Far and Near East, and Arctic regions, especially in rural locations where access to Western medicine is limited (Gadit, 2007).

Ayurveda

Ayurveda, meaning science of life, has its origins in Hinduism, and has been practiced in India for more than 5,000 years (Larson, 2007). Although a longstanding traditional therapy in India, the introduction of Western medicine during the colonial period resulted in a de-emphasizing of traditional medicine (Selby, 2001). Ayurveda does not purport to treat serious conditions, but is a preventive medicine and philosophy that aims to reduce stress, enhance the immune system, improve chronic illness, and increase energy levels (Selby, 2001). The underlying tenets behind this system of health care are that to be healthy one must achieve harmony within oneself and the outside world. Second, one must achieve a balance within the body and soul, which will act as a defense mechanism against illness (Selby, 2001). Diagnosis and treatment involves analyzing one's emotional and physical state, one's natural constitution/body type or prakriti, and the unhealthy behaviors that are contributing to imbalance (Larson, 2007). In Ayurveda, the human physiology is divided into three doshas which are vata (circulation and nervous system), kapha (immune system), and pitta (digestive system) (Larson, 2007). When dosha becomes aggravated it will lead to system imbalance and feeling unwell. The aim of Ayurveda is to overcome these imbalances, and restore natural harmony (Selby, 2001). The methods utilized are vast and can include breathing techniques, time management, massage, diet, exercise, herbal remedies, and yoga (Satow et al., 2009; Selby, 2001). Some health conditions that are treated with Ayurveda include colds, arthritis, gastrointestinal problems, heartburn, as well as general overall well-being (Satow et al., 2009).To become a licensed Ayurvedic practitioner in India requires completion of training at a state approved school; however, in the USA there are no standards or state licensing requirements (Satow et al., 2009).

Mind–Body Integration

Spirituality and Prayer

Spirituality is a belief in a higher power, specifically "someone or something that rises above the boundaries of self" (Hales, 2009). Prayer is defined as an active process of appealing to a higher spiritual power specifically for health reasons, and is the most commonly used form of TCAM worldwide (Hales, 2009; Qidwai et al., 2009). Prayer is thought to decrease the side effects from disease, hasten recovery, boost immune functioning, and improve the efficacy of treatment (Hales, 2009). Other benefits include better physical health, and less use of health services (Hales, 2009; Qidwai et al., 2009). Brain imaging techniques have shown that prayer may assist in reducing blood pressure, decreasing anxiety, and slowing down the heart rate (Hales, 2009). Although prayer for health is an ancient form of healing, the majority of patients from Pakistan indicated that they consider prayer an important complement to conventional medicine, rather than an alternative one (Qidwai et al., 2009).

Meditation

Meditation is the art of bringing harmony to the body, mind, and conscience, by soothing the body and decreasing stress (Kayne, 2009a). It is a systematic focus on aspects of inner and outer experiences in association with religious and spiritual contexts. One type of meditative practice is mindfulness where attention is paid to emotions, perceptions, and sensations, cultivating open-mindedness in life (Kayne, 2009b). Meditation is an effective intervention for emotional and psychological dysfunction, and has been used for chronic pain, drug addictions, and posttraumatic stress syndrome (Freeman & Lawlis, 2001). Other health problems such as anxiety and panic disorders, chronic fatigue syndrome, insomnia, separation anxiety, and hypertension are also amenable to meditation (Freeman & Lawlis, 2001; Kayne, 2009b).

Positive Thinking

A significant breakthrough for medicine in the last century was renewed interest in the role that attitudes, emotions, and beliefs have for health outcomes aptly described as "mind-body medicine" (Dossey, 2006). Central for many types of TCAM is the concept that the mind is powerful, and that thoughts and feelings impact the body at all levels. Positive thinking and feeling enables the body to work smoothly and efficiently (Jouret, 2010), restoring an individual's sense of personal empowerment, control, and efficacy (Adamson, 2003; Jouret, 2010). Some of the most important benefits from positive thinking are better immunological strength, absence of negative mood, increase in health promoting behaviors, better medical compliance, and less depression (Levin, 2009; Seligman, 2000). Frequent users of positive thinking are cancer and palliative care patients, as evidence suggests that a hopeless coping style is associated with unfavorable outcomes for patients (Adamson, 2003).

Animal-Assisted Therapy

The bond between animals and people has existed for centuries, with animals taking part in therapeutic treatments during the ninth century (Morrison, 2007). Since then, research has demonstrated health benefits in the form of lower depression and blood pressure, as well as other lasting beneficial physiological effects (Johnson & Meadows, 2002; Morrison, 2007). Studies conducted in the USA have found that many institutions include animals as part of psychotherapy. Other studies have indicated that introducing animals to postoperative pediatric patients improved their emotional and physical pain (Morrison, 2007). Owning a pet was also found to have health benefits for older Latino adults who have more chronic conditions than other ethnic groups (Johnson & Meadows, 2002) and who may be experiencing loss of family support, adjustment difficulties, and depression, especially if immigration occurred later in life (Gelfand, 1994). The Delta Society was formed with its mission as follows: "To promote animals helping people improve their health, independence, and quality of life" (The Delta Society, 2009). The society has developed "Standards of Practice for Animal-Assisted Activities and Therapy," and offers training toward certification in animal-assisted therapy (Morrison, 2007).

Aromatherapy

The term "Aromatherapy" was introduced by French chemist René-Maurice Gattefosse during the 1920s, although the practice dates to ancient Egypt (Harden & Harden, 1997). It is a therapeutic modality in which highly concentrated essences from plant extracts are placed in baths/showers, absorbed through the skin, and/or inhaled inducing emotional responses from the limbic system in the brain (Keegan, 2001). They may also be used in conjunction with other types of TCAM such as acupuncture, reflexology, and chiropractic, and are used to treat wide ranging ailments including emotional problems such as stress and anxiety (Keegan, 2001; Shealy, 1999).

Relaxation Techniques

Chronic stress produces physiological changes in the body, impairs sleep, and can trigger other unhealthy behaviors such as excessive smoking, drinking, and food consumption (Sarifino, 2008). These stressors can wear on the body and eventually lead to the onset of illnesses such as cardiovascular disease and reduced immune function. Effective relaxation techniques can help to prevent flare-ups from chronic conditions such as asthma and diabetes caused by stress and anxiety (Sarifino, 2008). Specific relaxation techniques include deep breathing, naps, stretch breaks, and eye breaks (Keegan, 2001).

Art Therapy

Art therapy uses art mediums, images, the creative process, and patient/client responses to express one's unique development, abilities, personality, interests, concerns, and conflicts (National Coalition of Creative Arts Therapies Associations, 2010). Art therapy began in England and the USA, with European scholars describing art created by patients hospitalized with mental illness. Art therapy draws upon theories of psychoanalysis and art education, and allows for an expressive outlet to reconcile emotional conflicts, manage behavior, and reduce anxiety. In particular, Asian immigrants described the art therapy group as a way to express their feelings of isolation and distress coping with a new culture (Liebmann, 2002). It is suitable for all population groups, and immigrants of different ethnic backgrounds, with training programs and graduate degrees regulated by the American Art Therapy Association. Upon completing graduate level education, supervised work experience, and a written exam, art therapists are board certified to use the designation ATR (National Coalition of Creative Arts Therapies Associations, 2010).

Music Therapy

Music therapy involves the use of music to bring about positive changes in the psychological, physical, cognitive, and social functioning of individuals with health problems, and is an ancient healing modality that dates to 500 B.C. (Kayne, 2009b). Children with developmental and learning disabilities, elderly people with age-related conditions such as Alzheimer's disease, drug addicted individuals, the physically disabled, and those suffering with pain are the groups most benefiting from music therapy (Kayne, 2009b). In the USA, hospitals routinely utilize music therapy as a CAM modality, and in particular it was found to reduce patient stress and anxiety in the surgical waiting area (Winter et al., 1994).

Biologically Based Therapies

Herbal and Botanical Medicine

The use of plants for medicinal purposes has been practiced in many cultures and regions for thousands of years (Saper, 2010). Herbal medicine, also referred to phytotherapy, is the use of plant-based products for prevention or treatment of disease (Keegan, 2001). Botanical products are those that also include woody plants where the main structure is comprised of wood. Herbs, in contrast, grow from seed, dry up and fade after the season's growth (Keegan, 2001). Herb usage in Europe is extensive with up to 40% of physicians in France and Germany using them in their daily practices (Keegan, 2001). Formal training on phytotherapy is provided in medical schools in these countries and is also a component of the training program for licensed naturopaths. About 65% of herbs have positive health benefits, promoting optimal health and reducing the effects of chronic conditions (Keegan, 2001). Several studies have indicated that ethnic groups in the USA use more herbal medicine than Caucasians, and that immigrants obtained them from pharmacists in their own cultural community, home gardens, botanicas, trips abroad, picking in the woods, ethnic stores, and mail order (Gomez-Beloz & Chavez, 2001; Graham et al., 2005; Mackenzie et al., 2003; Satow et al., 2009; Tagintseva, 2005).

Manipulation and Body-Based Therapies

Chiropractic

The chiropractic system was founded in the USA in 1895 by David Daniel Palmer (Coulter, 1992). This system is based on the premise that the spinal cord is central to well-being and fundamental for a healthy nervous system (Hales, 2009). A misalignment of vertebrae will result in pressure to be applied to the spinal nerves, causing impaired functioning. By adjusting the spinal vertebrae through manipulation, the flow from the nerves to spinal column can be restored. Other modalities such as massage, applied kinesiology, X-rays, and magnetic resonance imaging are also utilized. Research has indicated that chiropractic care helps relieve acute lower back pain, with other ongoing research investigating its benefits for menstrual cramps, headaches, and arthritic pain (Hales, 2009). This is the most widely accepted type of CAM among managed care health systems, with licenses to practice issued by all 50 states in the USA (Hales, 2009).

Massage Therapy

There are over 75 different types of massage, all with common approaches such as manual manipulation of muscles, ligaments, tendons, and other soft tissues (Tarver, 2003). Massage has been an important therapeutic treatment for thousands of years with extensive use in TCM and Indian Ayurveda, and later during the Hellenistic and Roman Empire periods (Keegan, 2001). After a period of relative anonymity during the Middle Ages, Per Henrik Ling (1776–1839) formulated Swedish Massage to relieve pain, improve blood circulation, and eliminate lactic acid buildup (Harden & Harden, 1997; Keegan, 2001). It can benefit infants and adults by reducing anxiety, depression, hypertension, and pain (Sarifino, 2008). Massage therapy continues to be an important component of TCAM in Eastern and Western culture.

Yoga

Yoga is an ancient modality derived from the religious beliefs of the Indian religions and Buddhism (Kayne, 2009b). It is a Sanskrit word meaning union of the mind, body, and spirit and is an intervention that uses a combination of muscular activity, self-awareness, and breathing to promote mental and physical vitality (Collins, 1998; Kayne, 2009a). In Indian traditional medicine, yoga helps to prevent disease by enhancing the flow of energy through the body, keeping energy meridians open, calming the nerves, as well as balancing the body, mind, and spirit (Kayne, 2009a). In the USA, 20–30 million people practice yoga (Jeng et al., 2011), however, in contemporary societies the emphasis for some becomes muscle stretching, mental relaxation, and improving vitality (Kayne, 2009b). Yoga is beneficial for a variety of health issues such as geriatric depression, palliative care, renal disease, and mental and sexual health (Kayne, 2009b). Yoga alone, or in combination with other therapies, decreases stress and tension (Kayne, 2009b), and is effective in reducing back and neck pain (Jeng et al., 2011).

Energy Therapies

Biofeedback

Biofeedback is a form of electromagnetic healing and is used to empower the mind to take control of conscious and autonomic processes (Keegan, 2001). This therapeutic modality provides light, sound, or metered feedback on metabolic changes such as temperature, blood pressure, heart rate, muscle tension, and brain waves provided through the use of biomedical sensors and instrumentation (Burton Goldberg Group, 1997; Keegan, 2001). The theory underlying this therapy is that as one becomes aware of autonomic body functions (e.g., breathing, heartbeat, bladder control), meditative concentration and repeated practice can be used to control physical changes and psychological states. Biofeedback is also used to teach individuals to become aware of physiological responses associated with elevated emotional states caused by stress or anxiety, in an effort to achieve a more balanced inner state (Keegan, 2001; Shealy, 1999). Disorders that are amendable to interventions by biofeedback and neurofeedback include alcoholism, epilepsy, asthma, arthritis, attention deficit disorder, incontinence, irritable bowel syndrome, and chronic pain (Sarifino, 2008). The Association of Applied Psychophysiology and Biofeedback has operated the Biofeedback Certification Institute of America in order to establish and maintain professional standards for biofeedback services, to certify qualified professionals, and provide citations for research studies in support of these health claims (Association of Applied Psychophysiology and Biofeedback, 2008).

Other Therapies

Homeopathy

Homeopathy was developed by Samuel Hahnemann (1755–1843), a late eighteenth–early nineteenth century German physician. In experimenting with quinine, which was, at that time, a preferred treatment for malaria, Hahnemann noted that it produced symptoms similar to those associated with the disease (Coulter, 1984). From this arose "*The Law of Similars*" or the notion that "like could be used to cure like." The idea of 'like curing like' has been around from the time of the ancient Greeks, and Hahnemann's contribution was a refinement of this basic idea (Coulter, 1984). Through further refinement came the process of "proving." In the process of "proving" a chemical compound is ingested with careful note of its physiological and psychological effects. These effects are then matched with a disease whose symptoms are reproduced by ingestion of the compound in a healthy person. The compound, thus "proved" is used as the basis for treatment of the matched disease. As Hahnemann continued to develop homeopathy, he asserted that the smaller the dose of the compound the more powerful its curative effects. Current homeopathic treatment consists of the homeopathic practitioner taking an elaborate case history from the patient, noting all physical and psychological symptoms no matter how seemingly insignificant. The homeopathy then prescribes a "proven" compound that matches the patient's unique symptoms. Today, there are over 5,000 compounds that have undergone the process of "proving" and are used to treat many types of illness (Coulter, 1984).

Naturopathy

Naturopathy was formulated in Western culture using only natural substances and techniques to treat illness; it draws upon ancient healing remedies from China, India, Greece, and Native American cultures (Lovellm, 2009; Shealy, 1999). Naturopathy is an eclectic combination of various "natural" treatments, for example, herbalism, homeopathy, acupuncture, hydrotherapy, massage, osteopathy, and chiropractic (Burton Goldberg Group, 1997). What contributes to the naturopathic modality is its commitment to a drug and surgery-free, natural approach to holistic wellness, encompassing positive thinking, a balanced diet, detoxification, exercise, and healthy lifestyle habits. It can encompass a wide range of treatments including nutritional advice, herbs, homeopathic medicines, iridology, reflexology, kinesiology, vitamins, and mineral supplements (Twohig, 2008).

The Canadian Association of Naturopathic Doctors (formerly Canadian Naturopathic Association) highlights six "principles of naturopathic medicine" (Canadian Association of Naturopathic Doctors, 2010):

1. *Primum Non Nocere* – "do no harm."
2. *Vis Medicatrix Naturae* – "recognize, respect, and promote the self-healing power of nature inherent in each individual human being."
3. *Tolle Causum* – "strive to identify and remove the causes of illness, rather than to eliminate or suppress symptoms."
4. Doctor as Teacher – "the Naturopathic Physician shall educate his/her patients, inspire rational hope, and encourage self-responsibility for health."
5. Treat the Whole Person – "treat each person by considering all individual health factors and influences."
6. Health Promotion, the Best Prevention – "emphasize the condition of health to promote well-being and to prevent diseases for the individual, each community, and our world."

Health Care Systems

Despite the popularity of CAM, most health care insurers in Western countries do not provide insurance coverage for the full range of CAM products and services (Tillman, 2002). Explanations put forth include: (1) lack of scientific evidence to support medical efficacy of the products, in contrast to conventional medicines that have undergone stringent clinical trials; (2) practitioner training outside of accredited educational institutions; and (3) administrative difficulties with existing health care billing and accounting systems oriented toward diagnosis and treatment of underlying pathology/disease (Tillman, 2002). In Australia, CAM is regarded as health care practices that operate parallel with but not part of the biomedical system, limiting reimbursement to services such as acupuncture and chiropractic (Bodeker et al., 2007; Twohig, 2008). This differs from neighboring New Zealand which reimburses for services provided by Maori traditional healers (Burford et al., 2007). In the USA, medical insurers provide reimbursement for chiropractic, massage, and acupuncture through employee programs, with limited support for other CAM services (Bodeker et al., 2007). Canada's health care system provides reimbursement for a portion of chiropractic services, (North, 2008) and regulates naturopathy and TCM in only a small number of provinces (Andrews & Boon, 2005). In Europe, 22 countries provide full or part coverage for a number of services comprising mainly chiropractic, acupuncture, homeopathy, and massage (Bodeker et al., 2007). In most cases, providers must be registered allopathic physicians, or belong to professional organizations (Burford et al., 2007). In China, Latin America, India, and Africa biomedicine exists along with traditional healing with efforts made to facilitate access to both systems (Bodeker et al., 2005; Burford et al., 2007; Mkize, 2009; Zhao, 2009). The provision of basic health services and mental health services in these regions is underdeveloped in rural locations, with traditional healing mainly practiced (Mkize, 2009; Zhao, 2009).

Japan's traditional Kampo medicine is similar to TCM in that the government provides coverage under public health insurance (Nishimura et al., 2009). The Chinese system issues licenses for TCM practitioners separate from allopathic physicians, in contrast to the Japanese system which licenses only biomedical Western style trained physicians who prescribe Kampo medicines. The Japanese health care system has combined the modern and traditional to form an integrated health care system. Kampo education is provided in all medical schools, more than 70% of physicians prescribe in practice and hospital settings, and all traditional medicines are manufactured by pharmaceutical companies (Nishimura et al., 2009).

Immigrants and TCAM

Mass immigration from the European colonies to Europe began after World War II in light of the economic boom associated with post-war reconstruction (Ben-David, 2009). This is in contrast to the eighteenth, nineteenth, and early twentieth centuries which saw widespread exodus of Europeans and enslaved Africans to continents such as Australia and North America (Gelfand, 1994; Roberts, 2009; Twohig, 2008). Today, the majority of immigrants to the USA are from Latin America and Asia, followed by India and Canada. Immigrants from India, Australia, UK, and South Africa have the highest median household income, while immigrants from Somalia and Latin American the lowest (Roberts, 2009). Similarly, Muslims comprise a large number of immigrants to Europe with forecasts for increasing immigration from other ethnic groups as well (Ben-David, 2009; Thachil & Bhugra, 2009). Many of these newcomers will be refugees, who left their home country due to fear of persecution because of political, economic, or social affiliation (MacDuff et al., 2010). Many obtain initial health care from benevolent organizations and traditional healers' during the early immigration period if access to state provided health care is not available or affordable (Bollini, 1992; Neumann & Bodeker, 2007).

Safety of TCAM

While most TCAM therapies pose little or no safety risk, consumption of some types of herbs poses a safety risk from toxic effects, allergic reactions, contaminants, and herb–herb or herb–prescription drug interactions (Keegan, 2001; Tagintseva, 2005). Some argue that the safety and efficacy of herbal medicine has been proven over the centuries; however, others argue that this does not take into account the advent of modern illnesses such as AIDS, and the manner in which the public uses herbal medicines today (Barnes, 2007). Areas of concern that are put forth include the following: (1) Climate conditions, harvesting, and storage of some herbs can change from crop to crop, resulting in varying strengths of the plants' pharmacologic properties (Barnes, 2007; Bent & Ko, 2004; Saper, 2010). (2) Inadequate regulation and monitoring of herbal products. For example, the USA classifies herbal medicines as dietary products which are not subject to FDA regulation (Hales, 2009; Tagintseva, 2005), and in other cases herbs from China are marketed without having to demonstrate quality and safety (Barnes, 2007). In India, only a small percentage of Ayurvedic product manufacturers belong to the manufacturing association, resulting in medicines not controlled, supervised, or inspected (Satow et al., 2009). In comparison, some of the former Soviet bloc countries, the Japanese, and some European countries regulate, test, and approve herbal products for distribution in the same manner as pharmaceutical drugs (Keegan, 2001). (3) Herbal medicine and prescription drugs are frequently taken simultaneously without guidance and counseling from a health care professional or pharmacist (Barnes, 2007; North, 2008; Tagintseva, 2005).

Healthy adults are better able to metabolize herbal medicines; however, there is increased risk associated with these medicines for children, the elderly, and those with chronic diseases (Crone & Wise, 1998). In particular, children and the elderly have reduced ability to metabolize active agents, and those with chronic disease have reduced physiologic reserve (Barnes, 2007; Crone & Wise, 1998). In the USA, ginseng, kava, valerian, echinacea, garlic, St. Johns Wort, and ginkgo biloba account for one-half of all sales of herbal medicines (Bent & Ko, 2004; Hales, 2009). Many of these herbs have documented reports of interactions, such as echinacea in combination with anabolic steroids, and perioperative bleeding associated with ginkgo biloba and saw palmetto (Hales, 2009; Saper, 2010). Another example is valerian, used for medicinal purposes by the ancient Greeks, and in recent times to treat anxiety (Yager et al., 1999). Under certain conditions it has the potential to interact with conventional psychopharmacologic drugs (Yager et al., 1999).

Adults have the ability to choose from a wide range of TCAM for themselves, and this right is exercised by many immigrants who frequently utilize alternative care that reflects their cultural heritage (Dudley, 2004). However, parental rights to insist on TCAM together with or instead of biomedicine to treat their acutely ill minor children may not be deemed to be in the best interest of the child, and may be overruled by the courts. This originates from child abuse reporting laws passed in the USA which included medical neglect in the definition of child abuse. Inevitably tension is bound to exist when parents feel that TCAM is the appropriate care for their child, but the state determines that such care would be inadequate or detrimental (Dudley, 2004). Further challenges exist because of a lack of statistical success rates with many forms of TCAM, inhibiting the courts from assessing the risks and benefits for the different treatment options. Some health professionals now advocate for a shared understanding approach with regards to the use of biomedicine and TCAM, which will enable a more positive outcome for children (Dudley, 2004).

Health Services

A National Health Survey conducted in Canada during the 1990s indicated that new immigrants were healthier with many fewer chronic conditions as compared to Canadian-born citizens (Barimah & van Teijlingen, 2008). However, with increasing years of residency, the prevalence of chronic conditions among immigrants reached levels similar to the Canadian-born (Barimah & van Teijlingen, 2008; Chen et al., 1996). The Canadian study classified immigrants into “Europeans” and “non-Europeans,” with the former including those from Europe, USA, Australia, and New Zealand, and the latter from all other countries (Chen et al., 1996). The non-European group recorded much higher levels of chronic conditions than the European group. Difficulties speaking a new language and problems acculturating to Western culture all contributed to poor adjustment in the host country. This is in contrast to immigrants of European origin, who more often speak the host languages and are acclimated to Western culture (Barimah & van Teijlingen, 2008). For example, Chinese immigrants attributed their onset of illness to underemployment, while factors such as inadequate housing, social status, and discrimination have been highlighted in other studies (Barimah & van Teijlingen, 2008; Thachil & Bhugra, 2009). Many immigrants will be accustomed to traditional healing practices, and will look for outlets in their host countries to continue with these traditions, especially for mental health concerns (Tagintseva, 2005; Thachil & Bhugra, 2009; Zhao, 2009). Patients felt that the encounter provided them with a comfort zone, where they feel relaxed, without having to reveal explicitly their mental health problems (Zhao, 2009). In addition, more severe difficulties adjusting to host countries arise from refugees who have fled their home country to escape persecution (MacDuff et al., 2010). In many cases they will be traumatized and used to predominantly traditional healing practices with internalized majico-religious beliefs, world views, and illness constructs different from Western-trained doctors (Neumann & Bodeker, 2007). The provision of traditional healers who have compatible world views, language, interaction styles, and belief systems may be the most appropriate, safe, and sensitive non-acute medical care for refugees at the point of first contact with their host country (Neumann & Bodeker, 2007).This will help avoid situations in which application of biomedical care resulted in false diagnosis and inappropriate care for refugees from Asia and Africa (Neumann & Bodeker, 2007).

Depression and anxiety are two of the leading indications for using TCAM worldwide (Thachil & Bhugra, 2009). Research from the UK has indicated that immigrants with mental health problems use both biomedical and traditional medicine, with increasing usage of biomedicine as they acculturate in the host country over time (Thachil & Bhugra, 2009). This pattern is similar with Chinese immigrants; however, if they had minor mental health problems, TCAM was the preferred choice (Choi & Kim, 2010; Zhao, 2009). Herbal medicines in the UK are taken to treat acute and chronic conditions such as cancer, AIDS, multiple sclerosis as well as gastrointestinal problems, arthritis, heartburn, constipation, and menopause (Gomez-Beloz & Chavez, 2001; Satow et al., 2009). Better physical and mental health reduced the use of herbal treatments (Lai & Chappell, 2007), whereas poor health status increased the use of herbal medicine for both prevention and treatment of illness (Tagintseva, 2005).

There were also differences in use of TCAM within cultural groups, reflecting divergent health beliefs. Health professionals need to consider that individual health beliefs are more likely to be the determining factor for the use of TCAM, rather than cultural affiliation (Lai & Chappell, 2007). Factors that had an impact on this were cost, accessibility, type of illness, quality of the TCAM practitioner, and the success rate of TCAM in treating the problem or illness (Barimah & van Teijlingen, 2008). Some people also choose not to use TCAM because they are unwilling to follow the lifestyle and diet changes that comprise most treatment plans (Barimah & van Teijlingen, 2008; North, 2008; Tagintseva, 2005).

Combining both TCAM and biomedicine simultaneously is widespread and applicable to many immigrant groups such as Ghanaians and Chinese in Canada, Jewish and Arabs in Israel, Russians, Latinos and Indians in the USA (Barimah & van Teijlingen, 2008; Ben-Ayre et al., 2009; Gomez-Beloz & Chavez, 2001; Lai & Chappell, 2007; Satow et al., 2009; Tagintseva, 2005). One precipitating factor behind this is that when whole medical systems such as TCM and Indian Ayurveda are practiced outside of their origins, not all components of TM may be retained, and they tend to become CAM once incorporated in Western countries (Bodeker et al., 2007; North, 2008). For example, traditional elements of Indian Ayurveda such as diet, social and cultural elements are modified to be more compatible with Western palate and context (Bodeker et al., 2007; Burford et al., 2007; Selby, 2001; Satow et al., 2009; North, 2008). One other significant finding is that patients may not tell their health care providers about their use of TCAM, and patient records are not always updated when disclosure has been made (Barnes, 2007; Golomb et al., 2003; Gomez-Beloz & Chavez, 2001; Lovell, 2009; Satow et al., 2009). The rates of non-disclosure have been found to be particularly high among Asians, Hispanics, and African Americans, necessitating the need to be proactive in investigating TCAM use among immigrant and minority patients (Graham et al., 2005). In a study of immigrant children being treated at a stroke clinic, more than 50% were reported to be using herbs and medications which had potential to affect coagulation and inhibit platelet activity (Golomb et al., 2003).

Maternal Health

Some of the more commonly experienced health problems particular to many immigrant women include cardiovascular disease, breast cancer, arthritis, menopausal symptom, osteoporosis, major depression, migraine headaches, and reproductive system issues (Murphy et al., 1999). Many health problems could be amenable to TCAM, however, there is a lack of well-organized evidenced-based studies among immigrant women (Adams et al., 2009; Checa et al., 2005). It is impractical to consider all immigrant women as a homogenous group, as each individual has unique social, cultural, and religious influences as well as beliefs, attitudes, and health practices that determine how they view and cope with, for example, pregnancy and child bearing (Checa et al., 2005).The pain and discomfort associated with menstruation, pregnancy-related complaints, labor preparation, and menopause are often the triggers that lead women to utilize alternative forms of health care to manage symptoms, especially when these negatively impact their quality of life (Adams et al., 2009; Murphy et al., 1999). Some of the more common TCAM practices in pregnancy include acupuncture/acupressure, aromatherapy, massage, yoga, homeopathy, and chiropractic care (Adams et al., 2009). Other commonly used methods of TCAM were vitamins, nutritional supplements, and herbal medicine (Chaves et al., 2010).

Postpartum depression (PPD) is another pressing immigrant women's health issue with approximately 12–14% of women at risk to develop PPD (Fonte & Horton-Deutsch, 2005; Fung & Dennis, 2010). Exposures to stressful life events, immigration, inadequate social support, and poor housing are significant predictors for PPD in immigrant women (Fonte & Horton-Deutsch, 2005; Page, 2004). Among Pakistani immigrant women living in Norway, the prevalence of PPD was 7.6%, reported to be lower than elsewhere in the world (Bjerke et al., 2008). In contrast, Asian Indian immigrants in the USA presented with symptoms of PPD similar to Caucasian women (Goyal et al., 2005).

Mexican immigrants have better birth outcomes as compared to US-born women, especially regarding low-birth-weight in infants (Page, 2004). Page has suggested that many Mexican women who emigrated with family and friends share housing, and have access to significant social support, including neighboring family and friends. Religion and prayer for health were significant predictors of a positive attitude toward pregnancy, providing ways to lessen emotional stressors, and ensure healthier outcomes for their babies (Page, 2004). Prayer and meditation were also important forms of TM that immigrant Muslim women desired for their PPD therapy sessions as they provide a connection with Allah, increase self-awareness, lessen anxiety, and promote better mental health (Fonte & Horton-Deutsch, 2005).

Herbal medicines are commonly used for women's reproductive health issues, including menstrual problems and infertility, morning sickness, labor preparation, and menopause (Beal, 1998). Ginger is one common effective herbal treatment used for nausea and vomiting during pregnancy (Adams et al., 2009; Zoorob et al., 2010). Other herbs commonly used were ginger, raspberry leaf, and enchinacea (Adams et al., 2009). Although herbs and nutritional supplements are commonly used among women, minimal data exist with regards to the safety and efficacy for the fetus or the mother (Chaves et al., 2010). There is a pressing need to assess how consumption of herbs affects women's health and consequences for fetal growth and development (Murphy et al., 1999).

Acupuncture and acupressure are two common forms of TCM used for pain relief. Reduction in pain is linked to the release of serotonin and endorphins during stimulation from the acupoints (Zoorob et al., 2010). Acupuncture has been used for centuries as TCM for fertility improvement in China (Zoorob et al., 2010) and pain relief during delivery (Kvorning et al., 1998). Research conducted in Sweden using acupuncture during labor and delivery indicated that it is a less invasive analgesic method for pain relief, is cost-efficient, easy to apply, with a low incidence of side effects. This was a popular form of therapy, with 94% of the participants indicating that they would consider acupuncture for their future deliveries (Kvorning et al., 1998).

Men's Health

A qualitative study of Korean male immigrants in Australia found that if they were seeking asylum, Chinese or Indian doctors were preferred for traditional medicine (Han, 2000). Use of herbal medicine, ginseng, nutritional tablets, royal jelly, aloe, deer antler, and acupuncture were commonly used for illness prevention, with one participant indicating he used it to enhance his libido. Some men indicated that they felt fatigued and had no time, and so consequently were neglecting their health, only visiting a doctor when they were seriously ill. However, once they obtained immigrant status, they would evaluate their state of health before deciding whether to use a biomedical doctor or TCAM (Han, 2000).

Studies of men who are HIV-positive in the USA found that the majority of participants were using some form of TCAM, alongside Western medicine (Jernewall et al., 2005). Among gay and bisexual Latino men, those using traditional Latino medicine and plant-based remedies had the highest rates of non-adherence to their medical treatment. This is particularly alarming as lower adherence correlates with increased disease progression. Providing access to some form of CAM such as acupuncture in the same location as their medical treatment facilitated better adherence to the medical regime. This same study indicated that acupuncture, massage, meditation, and herbs were the most commonly used TCAM therapies among this population group (Jernewall et al., 2005).

Prostate cancer is the second leading cause of death from cancers among men. Mortality rates are twice as high among African men as Caucasian men (Jones et al., 2007). A qualitative study of older African American men in the USA indicated that prayer for health, herbs, and meditation were the most commonly used forms of TCAM. Almost all of the men interviewed believed that prayer for health was an effective coping mechanism, and helped to reduce the stress associated with cancer. In particular it was a form of relaxation and was beneficial in gaining peace of mind. Most participants thought that prayer should be a compliment to their biomedical treatment, not a replacement (Jones et al., 2007).

Gender and Health

Some studies have indicated that there are no differences between males and females in their use of TCAM, with both parties wanting more control over their health (Satow et al., 2009). Other studies indicate that men use more acupuncture and chiropractic in contrast to females who use more herbal medicine, mind–body techniques, body movement, and prayer (Hales, 2009). A study of Chinese immigrants indicated that women used more TCAM than men, however, there were no sex differences in the use of biomedicine (Choi & Kim, 2010). Similarly, a study in Israel indicated that women used more CAM than men, especially body movement therapies (Ben-Ayre et al., 2009).This same study also found that among Jewish and Arab women there were significant differences. The Arab women used more traditional and herbal medicine in contrast to the Jewish women who used more CAM therapies such as meditation, chiropractor, body movement, and homeopathy (Ben-Ayre et al., 2009). Prayer for health purposes is one of the most utilized forms of TCAM, with use by African American women significantly higher than all other ethnic women, reflecting the degree of importance that they attach to spirituality as part of their approach to health (Graham et al., 2005).

In a global context, indications are that women are significant users of TCAM, which may also mirror their greater usage of health services in general (Bodeker & Burford, 2007). Our findings suggest that further inquiry and research are needed to understand, first, how TCAM can be used for immigrant men, women, boys, and girls to promote and/or restore their health (Bodeker & Burford, 2007), and second, how this knowledge can be used by health care systems in a constructive way to improve population health, and garner effective and efficient usage of health care services.

Conclusion

The vast majority of immigrants adopt a "mix-and-match" approach to their health care needs, with indications that this trend will continue for the foreseeable future (Barimah & van Teijlingen, 2008). Various authors have indicated that TCAM is sought for chronic conditions, when biomedicine is perceived to be inappropriate or ineffective (Lai & Chappell, 2007; North, 2008). Other authors have indicated that for health care systems to be patient-centered, consideration of TCAM should be part and parcel of culturally competent care (Leonard, 2001; Mackenzie et al., 2003).

Practitioners and patients have overwhelmingly indicted that there should be regulation to protect consumers from under-qualified TCAM practitioners (Gadit, 2007; North, 2008). For example, in Karachi, Pakistan, there are approximately 400 shamans who treat mental health problems among a significant percentage of the population, partly due to limited numbers of available psychiatrists (Gadit, 2007). There is, however, little collaboration between shamans and psychiatrists, with the lack of licensing and regulation of shamans a strong deterrent to an integrative mental health system in Pakistan (Gadit, 2007).

It is interesting to note that from all of the various articles and studies we examined throughout this entry, it is apparent that at least among developed and transitional continents and countries, TCAM is used to "complement" biomedicine, rather than become an "alternative" to biomedicine. Finally, we endeavored to cover many forms of TCAM. However, there are others, and some of these are described in the references, and in the suggested readings and websites.

Culture-Specific Diagnoses

Delaney Smith[1] · *Tara Mayes*[2] · *Riley Smith*[3]
[1]Timothy B Moritz Forensic Unit, Twin Valley Behavioral Healthcare, Columbus, OH, USA
[2]Twin Valley Behavioral Healthcare, Columbus, OH, USA
[3]Hahnemann University Hospital, Philadelphia, PA, USA

Introduction and History

Culture-specific diagnoses, also referred to as culture-bound syndromes, ethnic psychoses, and atypical culture-bound reactive syndromes, have been studied since the early eighteenth century. Culture-specific diagnoses encompass a diverse group of illnesses whose syndrome constellations are unique to certain cultural groups. While general medical conditions which localize to certain geographic regions or genetic groups have been historically included with the culture-specific diagnoses, the term is now primarily used to refer to mental health conditions. Culture-specific diagnoses are distinct from idioms of distress. Idioms of distress are a culturally unique presentation of coping with and expressing negative experiences and emotions (Kirmayer & Young, 1998). Idioms of distress are most commonly manifested as somatization with the body system and form of physical manifestation of the emotional distress varying by culture. Knowledge of both culture-specific diagnoses and idioms of distress is important in order to recognize treatment needs in immigrant populations whose culture-based illness presentations may vary from the native population.

A review of the terms race, ethnicity, and culture is helpful in the study of culture-specific diagnoses. The United States Department of Health and Human Services defines culture broadly as a common heritage or set of shared beliefs, norms, and values. Culture can be defined anthropologically as a system of shared understanding or meaning. Cultural beliefs are not static over time, but shift with changing moods and attitudes (Mental Health: Culture, Race, and Ethnicity A Supplement to Mental Health: A Report to the Surgeon General. Department of Health and Human Services, 1999). Additionally, one's own cultural identification can also change over time. Immigrants to a new country can slowly alter their own cultural identity to reflect their new home. The term race is defined in a report to the United States Surgeon General not as a biological or genetic category, but rather a social categorization that is defined by the culture itself. Ethnicity, on the other hand, is a common set of historical experiences, rites, and shared language. While individuals of the same racial or ethnic group may consider themselves a part of the same culture, this is not always the case and should not be assumed.

As early as the eighteenth century scientists were identifying differences in illnesses based on the geographic origin of the sufferer. In 1733, George Cheyne, a Scottish physician practicing in England, wrote of disorders which he felt were more common amongst the English in *The English Malady* (Cheyne, 1733). He attributed these disorders of low spirit, nervous distempers, melancholy, and hypochondria to the cultural factors of poor diet, "manner of living," and geographic factors including weather. By the late nineteenth century, the now famous Malaysian-specific disorders of amok and latah were identified by W. Gilmore Ellis (Prince & Tcheng-Laroche, 1987). In the 1950s and 1960s, P.M. Yap, a psychiatrist based at the Hong Kong University, wrote several papers examining these phenomenon commonly referred to at the time as "peculiar" (Tseng, 2006). He went through several descriptive terms for these illnesses and finally settled on the now commonly used term culture-bound syndrome in 1967. New disorders continued to be reported as mental health practitioners traveled to other lands, finding what they perceived to be unusual symptom constellations and "folk remedies." In the 1970s and 1980s, there was an emphasis on the subgrouping of disorders and ways to conduct empirical studies comparing and contrasting disorders across cultures. By the 1990s, culture-specific diagnoses began to decrease somewhat in relevance as more emphasis was placed on cultural sensitivity and consideration in all facets of psychiatric diagnosis and treatment.

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

Classifications of Disorders

Because of the clinical similarities between certain culture-specific disorders, there has been a push to classify these diseases by their constituent behaviors (Simons & Hughes, 1993). A grouping of symptomatically similar culture-specific diagnoses was first referred to as a taxon by Ronald C. Simons, and the concept quickly spread (Simons, 1985). Sorting the culture-specific diagnoses into sets was meant to facilitate an appreciation of the similarities of distinct disorders. These groupings also served to facilitate easier study of the disorders with less distraction by the confounding influence of the foreignness of the given culture. Taxa (plural of taxon) allow for reconciliation of what are referred to as "orphan cases," in which typical presentations of culture-specific diagnoses occur in other cultures. Simons suggested the following taxa: genital retraction, sudden mass assault, running, fright, startle matching, sleep paralysis, and cannibal compulsion. By arranging the culture-specific diagnoses in this manner, scientists can better study etiology and underlying psychological processes in related disorders. In the future, this may also allow for the study of genetic or neuro-imaging data.

The World Health Organization's *International Classification of Diseases 10th edition* (ICD-10)'s Classification of Mental and Behavioural Disorders (World Health Organization, 1992), used by most European countries, does not include culture-specific diagnoses as diagnostic criteria. The authors instead cite the dwindling interest in a separate category for such diseases and the lack of "sound descriptive studies, preferably with an epidemiological basis." The authors go on to suggest that these disorders can be considered local variants of existing mental disorders within the ICD-10 and, therefore, should be coded accordingly with additional notation as to the nature of the culture-specific disorder involved and any feigning of symptoms or attention-seeking behaviors observed.

The Diagnostic and Statistical Manual – 4th Edition, Text Revision (*DSM-IV-TR*) (American Psychiatric Association, 2000) includes a glossary of culture-bound syndromes. In the introduction, the authors define culture-bound syndromes as "recurrent, locality-specific patterns of aberrant behavior and troubling experience that may or may not be linked to a particular DSM-IV-TR diagnostic category." The manual goes on to explain that culture-bound syndromes are localized to a specific society or culture and "frame coherent meanings for certain repetitive, patterned, and troubling sets of experiences." The DSM-IV-TR lists 25 of the most commonly encountered culture-bound syndromes in North American mental health practice.

Review of Culture-Specific Diagnoses

Over 200 disorders have been identified as being culturally specific. Many syndromes have multiple names in different languages, and there is a great degree of overlap between certain disorders (Simons & Hughes, 1993). Some disorders have fallen out of favor over the years. The following represents the most common and most studied culture-specific diagnoses arranged by geographic area.

Africa/Middle East

Baridi

Dr. Anitta Juntunen wrote in 2005 about the baridi syndrome among the Bena people of Tanzania (Juntunen, 2005). Through interviews with the local people, she was able to identify the signs and symptoms of this disorder as consisting of feelings of restlessness, fatigue, drowsiness, lack of appetite, and general feelings of illness. Advanced baridi was identified by joint deformity, extremity weakness, and mental disturbances. The Bena consider baridi to be caused by acting against the interests and norms of the tribe, being disobedient or critical of elders, neglectful in familial duties, using slanderous or insulting language, or breaking sexual taboos. Treatment is in the form of a return to cultural norms by apologies, gifts, and herbal remedies under the direction of a healer.

Boufée Délirante

The *DSM-IV-TR* defines boufée délirante as a French term used to refer to a sudden outburst of agitation seen in West Africa and Haiti (American Psychiatric Association, 2000). There is typically irritable behavior, confusion, and psychomotor agitation. Hallucinations and paranoia may be present, causing a presentation similar to the *DSM-IV-TR*'s Brief Psychotic Disorder (American Psychiatric Association).

Johnson-Sabine and his colleagues reviewed discharge diagnoses of all patients discharged over a 4-year period in a Paris psychiatric hospital (Johnson-Sabine et al., 1983). They found that boufée délirante represented between 2% and 12% of all diagnoses in the 30 cases which they reviewed. When they compared the individuals who had been diagnosed with boufée délirante with those diagnosed with affective psychosis or schizophrenia, they found that the boufée délirante group was more likely to have been born outside of France and of foreign parentage, and that 40% had lived in France for less than 5 years.

Brain Fag

Brain fag is listed in the *DSM-IV-TR* as a West African disorder typically affecting high school and university students (American Psychiatric Association, 2000). In response to academic pressures, students or others who work in academic fields experience an inability to concentrate, comprehend, read, or recall information, physical sensations of numbness or tingling, emotional presentations of sadness, irritability, or anxiety, or impaired sleep (Jegede, 1983). Individuals can have other somatic symptoms which focus on the head and neck and include muscle tension, pressure, pain, burning sensations, and blurry vision (American Psychiatric Association, 2000) or physiological disturbances of palpitations, tremor, weight loss, or breathing difficulties (Jegede, 1983).

Jegede studied 382 secondary school students in Ibadan, Nigeria, to see how common symptoms of brain fag were (Jegede, 1983). He found that the prevalence of symptoms ranged from 48.9% of boys and 45.6% of girls experiencing "heat in body" to 96.4% of boys experiencing headache and sleeping difficulties, and 98.9% of girls experiencing "crawling in body." In 231 third year university students, he found frequencies ranging from 7.36% of students experiencing headaches to 65.37% experiencing "crawling feeling in the body" and 67.53% experiencing "heat in the head." Jegede concluded that the symptoms commonly thought of as brain fag actually constitute not one disease entity, but multiple, with different etiological factors.

Zar

The *DSM-IV-TR* states that zar is a term used in several North African and Middle Eastern societies to refer to the possession of an individual by spirits (American Psychiatric Association, 2000). According to Grisaru, the word zar is Amharic and is a derivation of a pagan deity (Grisaru, Budowski, & Witztum, 1997). Women are particularly at risk for this condition which can be precipitated by physical ailments, infertility, or boredom. Individuals who have been affected typically present in a dissociative state. They may cry out, sing, laugh, shout or bang their heads. Longer possessions can be marked by withdrawal, and refusal to eat, drink, or carry out daily responsibilities (American Psychiatric Association). The village gathers in support of the afflicted and feasts and gifts are given to the possessing spirit to appease it. Many cultures do not see such behavior as abnormal. Grisaru found that some people experiencing zar actually find the experiences pleasurable and desirable (Grisaru et al., 1997).

Genital Retraction

Psychotic episodes of genital theft and retraction, similar to the Asian culture-bound syndrome koro, have been reported in Africa. Charles Mather (Mather, 2005) describes the case of an individual in Ghana who accused a stranger of genital theft. Cameroon, Nigeria, Gambia, and the Ivory Coast have all experienced mob lynchings of those suspected of removing men's genitalia. In some parts of West Africa, the victims have been females with perceived shrinkage of breasts and changing or sealing off of the vagina. There have been several mass hysteria-like episodes in which several people in the same village or town are affected and frequently take justice into their own hands through violence. Some explain these experiences as the impact of juju or witchcraft (Dzokoto & Adams, 2005).

Asia

Amok

Amok is a dissociative episode characterized by a period of brooding, followed by an outburst of violent, aggressive, or homicidal behavior directed at people and objects, according to the *DSM-IV-TR* (American Psychiatric Association, 2000). Episodes are also often accompanied by persecutory ideas, automatism, and amnesia. The violent acts are usually followed by exhaustion and a return to one's premorbid level of functioning. This disorder appears to come from Malaysia, but similar behaviors have also been observed throughout Southeast Asia. Countries including Indonesia, Laos, Philippines, Polynesia, Papua New Guinea, Singapore, Sumatra, and Thailand, all have documented cases of amok. The first documented case came from Captain Cook in 1770 when he toured the Malaysian archipelagos (Haque, 2008).

The term amok is a Malaysian word meaning to engage furiously in battle and is also known amongst the Malay as *matagelap,* which literally means black before the eyes (Gaw & Bernstein, 1992). It is also the origin of the English phrase "running amok" ("Culture-Bound Syndromes," n.d.). Some historians believe that amok dates back to ancient Indian warriors entering into a trance before battle. This hypnotic state allowed them to engage in combat without trepidation. These early warriors likely passed on their knowledge to the Malay people. Early Malay fighters would scream "amok" on the battlefield and with the knowledge of their predecessors they would fight without registering fear or pain. Malay fighters were instructed to engage in "fanatical charges, indiscriminant slaughter, and refusal to surrender" (Carr, 1978). Once Islam arrived to the islands, cases of amok were blamed on acts of religious fanaticism. Speculation exists that episodes were actually suicide attempts disguised as violence towards others. However, doubters argue that the Islamic faith opposes suicide and Malaysia is known to have one of the lowest suicide rates in the world. Nevertheless, one psychodynamic approach views amok as a projection of rage or an act against society instead of against oneself. Some of the folklore of Malaysia attributes cases of amok to evil spirits possessing an individual's body and forcing him or her to engage in violent acts. Other tales portray amok as a culturally sanctioned means of expression. It is a vehicle for aggression in a society that encourages social responsibility and repression of anger.

Currently, the typical sufferer of amok is a male who has suffered a loss or has undergone a perceived insult. He is young to middle aged, isolated from his family and home, poorly educated, and from a low socioeconomic class. Others often describe the afflicted as quiet and withdrawn, but not uncommonly there exists a history of behavior problems, including immaturity, impulsivity, mood lability, and lack of accountability. Although isolated cases exist, most cases occur following exposure to similar behavior in others. Some theorists describe amok as a "transmittable" illness and argue in favor of a social learning process as the necessary ingredient for manifestation. Epidemic patterns usually emerge during times of political, economic, or sociocultural discord. Previously, the Malay people viewed amok as a mental illness, and the *pengamok,* or perpetrator, was felt not to be responsible for his acts of violence. However, amok episodes are now considered crimes and carry the potential for punishment by death. Interestingly, when the Malay culture shifted political views and amok became a crime as opposed to a mental illness, the number of cases declined. Now amok is considered to be a rare phenomenon, even though documented cases do still exist.

Latah

According to the *DSM-IV-TR*, latah is a hypersensitivity to sudden fright (American Psychiatric Association, 2000). It is a trance-like syndrome characterized by an extreme response to startling stimuli which is often accompanied with echopraxia, echolalia, command obedience, and dissociative behavior. Latah usually affects middle-aged women of Malaysian descent. Although it is thought to have originated in Malaysia, this disorder has actually been identified in many parts of the world. A symptomatic individual will typically demonstrate hyperfocused attention, defensive posturing, coprolalia, mimicry, and an extreme suggestibility that generally absolves them of any responsibility for their actions. Any attempts to control them are usually met with resistance. When startled, these individuals will drop or throw objects held in the hand and often will start to utter obscenities. Onlookers frequently find the behaviors amusing and victims may be intentionally startled for the enjoyment of others. Many scholars do not consider latah to be an illness, but instead view it as a culture-specific reaction to the innate startle reflex.

Koro

The DSM-IV-TR (American Psychiatric Association, 2000) defines koro as an episode of sudden and intense fear that the penis (in females, the vulva or nipples) will retract into the body and possibly cause death. This syndrome is typically found in south and east Asia and is identified by a number of local terms. Despite the majority of cases being grouped in the East, there are documented cases in non-Asian patients as well, leading to controversy over the true nature of the disorder. Popular belief states that the word koro is derived from the Malay word for tortoise, *kuro,* since the tortoise can retract its head into its shell. Koro consists of perceptual, cognitive, and emotional disturbances (Buckle, Chuah, Fones, & Wong, 2007). The misperception that the body part is receding into the body and subsequent cognitive distortion that this will cause death, ultimately leads to intense feelings of anxiety and panic. Koro exists in both epidemic proportions and, more rarely, as isolated occurrences. One researcher compiled a list of cases and only uncovered 19 individual episodes in 15 years (Bernstein & Gaw, 1990). Nevertheless, given the ease of immigration and the ability to travel worldwide, solitary episodes and pockets of illness may occur more often in Western society.

Epidemics of koro are believed to stem from the cultural attitudes of the people living in any given region. Chinese mythology holds that ghosts of the dead have no male reproductive organs and will disguise themselves in order to steal penises from the living. The hysterical response to this folk belief has facilitated an epidemic of koro on more than one occasion. Traditional Chinese medicine views koro as an imbalance of Yin and Yang. Good health derives from the dual power of these two forces, and, in cases of koro, the equilibrium is upset by sexual indulgence. Excessive sexual activity is thought to deplete the sperm, cause retraction of the genitals, eventually resulting in death.

Early psychoanalysts postulated that koro represents a version of Freud's castration anxiety and that koro's clinical features stem from underlying sexual conflicts. The biomedical approach frequently describes koro as a symptom of a medical condition as opposed to being its own illness. Koro-like symptoms have been reported in individuals experiencing heroin withdrawal, brain tumors, epilepsy, strokes, and HIV. Psychiatry has classified koro as a body image disturbance, a sexual neurosis, an acute panic reaction, a hypochondriacal stress response, a somatoform disorder, a psychotic disorder, a depersonalization disorder and a conversion reaction. Some feel the belief in retraction is an overvalued idea while others consider it to be a delusion (Bark, 1991).

Research has actually shown that a perception of penile shrinkage may be associated with a reduction in penile circumference, suggesting that some cases of koro may have a physical basis. Given the multitude of potential diagnostic categories, Albert C. Gaw proposed a decision tree to help classify this disorder. Initially, a treating physician must determine whether the genital retraction is a primary psychiatric disorder or is due to a preexisting medical condition. Then a provider would need to frame the disorder in its specific cultural context, and determine whether the koro episode is an isolated case or is occurring in the context of an epidemic. Finally, a diagnosis of Genital Retraction Disorder, Culture-Specific single case versus epidemic or Genital Retraction Disorder, Not Culture-Specific may be rendered.

Dhat

According to the *DSM-IV-TR* (American Psychiatric Association, 2000), dhat is a folk diagnostic term used in India to refer to anxiety and hypochondriacal concerns associated with the discharge of semen. In colloquial terms, dhat is identified as a "neurosis of the Orient" (Sumathipala, Siribaddana, & Bhugra, 2004). Sufferers become severely preoccupied with the idea that they are losing semen in their urine and often present with associated feelings of fatigue and other vague somatic complaints. Open discussion about sexual issues is considered inappropriate in polite society, and those prone to overreaction may not have the necessary outlet in which to discuss misconceptions (Perme, Ranjith, Mohan, & Chandrasekaran, 2005). Innocent symptoms like fatigue may seem catastrophic when an individual simultaneously perceives his urine to be turbid or white in color. Cultural beliefs indicate semen loss is harmful to the body and, in a somatically preoccupied individual, any discoloration of the urine can lead to extreme health-related anxiety. The anxiety over semen loss traces back thousands of years to ancient Ayurvedic texts ("Culture-Bound Syndromes," n.d.). According to the writings, semen is the most precious body fluid, and the loss of even a single drop might completely destabilize a person.

Hwa-Byung

According to the *DSM-IV-TR* (American Psychiatric Association, 2000), hwa-byung is a Korean folk syndrome that translates into "anger syndrome." Symptoms are thought to result from anger suppression and include indigestion, anorexia, dyspnea, insomnia, fatigue, and generalized aches and pains. Perhaps the most classic symptom is the sensation of a mass in the epigastric area, "the upper abdomen-lower chest is consistently identified as the primary site of the pathology by the patients" (Lin, 1983). Inner conflicts develop into a "blood-muscle lump" known as *Hwa*, and its presence is felt in the abdomen, although no evidence of its presence is found on physical examination (Pang, 1990). Unfortunately, all of the somatic complaints are rather resistant to medical treatment, and the epigastric mass sensation has driven patients to surgical interventions with little relief. Hwa-byung is considered to be chronic; one study suggested the duration was, on average, 10 years from the onset of symptoms. The causative stress is frequently identified as an extramarital affair or strained in-law relationships, although financial hardship and separation from family and social supports also qualify as stressors. These domestic situations provoke anger which the victim suppresses. Eventually, the anger manifests itself as an epigastric mass sensation along with a myriad of other somatic complaints. Prevailing theories suggest hwa-byung is a "means of expressing misery and despair without stigma" (Park, Kim, Kang, & Kim, 2001). Many sufferers consider the illness to be their destiny and suppress their anger according to cultural norms, knowing their symptoms will be recognized by others as socially acceptable. The suppressed anger is projected onto a body organ or system, and the patient deals with the resulting symptoms with resignation and acceptance, although many will still try to alleviate some of their discomfort with medical treatments. Korean culture emphasizes restraint and temperance, and it is considered a virtue to endure life's misfortunes silently and without aggression, confrontation, or disobedience (Pang, 1990). Thus, sufferers view their illness as fate and translate their ire into physical problems that are culturally sanctioned.

Approximately 75% of hwa-byung cases are women. One survey found that the majority of female hwa-byung sufferers were of low socioeconomic status, lived in rural areas, used tobacco and alcohol, and were either divorced or separated from their spouse (Park et al., 2001). Many of those who were afflicted were aware that their illness was not necessarily physical, but were reluctant to view themselves as psychiatric patients. Sufferers retain insight as to the nature of their symptoms, but may prefer to utilize medical treatment alternatives rather than focusing on the emotional aspects of the illness.

Taijin Kyofusho

The *DSM-IV-TR* (American Psychiatric Association, 2000) defines Taijin kyofusho as a culturally distinct phobia in Japan that parallels the symptoms of Social Phobia in the West. Taijin means interpersonal, and kyofusho means fear. Taijin kyofusho together refers to an individual's intense fear that his or her body will somehow offend other people through appearance, odor, facial expression, or movement (Gaw, 2001). The dread of hurting or offending others typically takes one of four forms. *Sekimen-kyofu* is a phobia of blushing, *shubo-kyofu* is a phobia of a deformed body, *jikoshisen-kyofu* is a phobia of eye-to-eye contact, and *jikoshu-kyofu* is a phobia of foul body odor ("Culture-Bound Syndromes," n.d.). The syndrome typically afflicts young people, and symptoms are most salient during interpersonal situations. Included in the official Japanese diagnostic system for mental disorders, taijin kyofusho is likely fueled by a cultural emphasis on proper behavior in all social interactions. Due to the conviction that they are repulsing others, sufferers will take showers, brush their teeth, and change their clothes on a frequent basis, and may ultimately avoid public appearances (Suzuki et al., 2004).

Given the variability of its presentation, taijin kyofusho likely exists on a continuum from transient adolescent social anxiety to fixed delusions. Currently the most common form is a fear of blushing, which affects young males who are in the adolescent stage of self-consciousness and feelings of insecurity (Suzuki et al., 2004). Prognosis is uncertain, but generally symptoms will attenuate in the fourth decade of life (Russell, 1989). However, some cases progress and take on the characteristics of more debilitating illnesses such as schizophrenia. More mild cases of taijin kyofusho typically result in symptoms only when in the physical presence of others and are limited to encounters with "intermediate-level persons" such as classmates, coworkers, and neighbors. Complete strangers would not induce high levels of anxiety, nor would family or intimate friendships. Serious cases involve individuals not actually present and take on more of a delusional quality such as the belief that one is polluting the entire neighborhood and offending everyone within its borders. Strangers and intimates alike create fear and the victim may become housebound. Mild sufferers seek psychiatric help for their affliction; serious sufferers often lack insight into their condition and opt for more radical measures such as surgery to remove their offending physical flaws. Ultimately, individuals with taijin kyofusho pursue treatment out of concern that they are offending their fellow man. Theorists argue that this "altruistic" attempt to correct a weakness mirrors the Japanese values of maintaining quality interpersonal relationships.

Shenjing Shuairuo

The *DSM-IV-TR* (American Psychiatric Association, 2000) describes shenjing shuairuo as a Chinese condition characterized by mental and physical fatigue, dizziness, headaches, and impairments of sleep, concentration, and memory. Made famous by Arthur Kleinman, the symptoms are often synonymous with Western diagnoses of Mood or Anxiety Disorders (Hall, 2006). China recognizes shenjing shuairuo in the Chinese Classification of Mental Disorders, Second Edition, and the syndrome is also identified by the term Neurasthenia. Neurasthenia is a designation that was once recognized by the DSM as a part of Western medicine, but the disorder has been omitted in recent revisions. However, it is still recognized by the World Health Organization's ICD-10 (World Health Organization, 1992) classification system.

In translation, the term shenjing means "nervous system" and shuairuo means "weakness" (Gaw, 2001). It includes elements of depression and anxiety, and is frequently accompanied by gastrointestinal problems, sexual dysfunction, irritability, excitability, and other signs of autonomic dysfunction. At one time, it was the second most common diagnosis in Chinese psychiatric hospitals and one of the most common diagnoses overall. Neurasthenia, or "exhaustion of the nerves," (Parker, Gladstone, & Chee, 2001) once served as a mark of status since the upper class were considered more susceptible to these health problems in the same way that ulcers or high blood pressure might indicate a person of important occupational status today (Hall, 2006). Since neurasthenia was considered to be a diagnosis of the elite, members of upper-class society were treated by the most respected physicians, and these patients were not stigmatized as "mentally ill." Many neurasthenia patients are survivors of China's Cultural Revolution, a violent mass movement that began in 1966 and ended officially with Mao's death in 1976. The Cultural Revolution brought about widespread social, political, and economic upheaval. Many people developed symptoms of shenjing shuairuo in response to the economic chaos and massive social and political changes. Currently, the Chinese view the disturbance as a depletion of "qi," which translates into "energy flow" and is believed to constitute a fundamental part of every living thing. Symptoms of various illnesses are often believed to be the result of interrupted or blocked qi movement through the body's meridians, as well as deficiencies or imbalances of qi in multiple organ systems. The symptoms of shenjing shuairuo are not unique to China, and many societies across the globe have grouped similar symptoms together and label them according to their own cultural beliefs.

The Americas

Bilis and Colera

The *DSM-IV-TR* defines bilis and colera as a group of syndromes in which extreme anger results in disturbances between the spiritual and physical aspects of an individual (American Psychiatric Association, 2000). These disorders, which can also be referred to as muni, demonstrate the belief by many Latino cultures that anger is a strong and dangerous emotion. Individuals who have been afflicted by bilis or colera can present with nervous tension, headache, trembling, yelling out, GI disturbances, or fainting (American Psychiatric Association, 2000).

Coraje

Elizabeth Cartwright, Ph.D., identified coraje, a disorder similar to bilis and colera, during her time living among the Amuzgo Indians of Oaxaca, Mexico (Bender, 2003). While coraje has been translated as anger, this is an oversimplified Westernization of the disorder. The Amuzgo see coraje as a result of negative interactions and events in one's life. When coraje befalls an individual, it is believed to settle on a specific body region which will present symptoms of the illness

(Bender, 2003). For example, if it settles on one's head, the victim may have headaches, or if it settles in the limbs, it may cause pain or weakness. Coraje can move about the body. Extra care, including the wearing of special belts, is taken by the Amuzgo to prevent the migration of the disorder to the heart which they believe can result in death. One of the cardinal features of coraje is the fact that it can be contagious. The weak, elderly, and young are at particular risk. As a result the community is very careful to not become angry with one another or yell which could spread the disease (Bender, 2003). Curing this ailment is undertaken by a "curandera" who combines elements of traditional tribal beliefs with Roman Catholicism.

Nervios and Ataque De Nervios

Nervios translates as "nerves" and ataque de nervios as an "attack of nerves (American Psychiatric Association, 2000)." These disorders seen in people of Hispanic background have been described in the literature for over 40 years. Nervios is a more general chronic condition in which an individual suffers a constellation of somatic symptoms in response to ongoing stress. These symptoms can range from insomnia and headaches to heart palpitations, body aches, and chest pain. It is generally associated with overwhelming worry. Interpersonal stressors such as family and relationship difficulties are a frequent cause of nervios. Ataque de nervios is a more acute disorder with an abrupt onset in reaction to an intense stressor such as the death of a loved one, accident, war, or learning extremely bad news. The manifestations of such an attack can include dizziness, faintness, shaking or seizure-like activity, and palpitations. Aggression can also occur, frequently in the form of verbal threats, swearing, striking out at others, or harming oneself (American Psychiatric Association, 2000). Such episodes can serve an adaptive role within the community of bringing together an individual's family and friends for support in their time of need. Such brief and culturally accepted forms of ataque de nervios rarely necessitate the intervention of traditional or modern medical practitioners. It is only when the illness is long-lasting or atypical that help is typically sought.

Guarnaccia, Good, and Kleinman (1990) reviewed data suggesting that these nervous disorders presented with more numerous and more clinically significant symptoms amongst Puerto Ricans in New York City than other Hispanic groups. They found deficiencies in several of the prior studies, including the ways in which methodological differences and a lack of clear and consistent measures may have skewed results. Guarnaccia and his colleagues identified confounding factors that could increase the rate at which people of certain cultural backgrounds report mental and somatic symptoms, including the stigma associated with a given illness in the culture and the type of health care system an individual has been raised in (Guarnaccia et al., 1990). They also found that the immigrant role and its associated stresses may play a large part in the elevated rate of mental illness and severity of symptoms seen in Puerto Ricans in New York compared to native New Yorkers and Puerto Ricans who did not emigrate (Guarnaccia et al., 1990).

One of the major criticisms of the inclusion of nervios and ataque de nervios as distinct culture-specific diagnoses has always been their similarity to panic attacks and panic disorders. Meghan Keough and colleagues conducted a study in which more than 300 undergraduate students of different cultural and ethnic backgrounds were asked about their experiences of symptoms of panic attacks, ataque de nervios, and, as a test of reliability, koro (Keough, Timpano, & Schmidt, 2009). The names of the disorders were withheld to ensure the results were not confounded by an individual's familiarity with the diseases. Twenty-five percent of the sample reported a lifetime experience of at least one episode consistent with ataque de nervios, while only 17% endorsed symptoms of a panic attack, and none reported a history of koro symptoms. They found that only 9% of respondents reported a history of both ataque de nervios and panic attacks. Such a low co-occurrence rate supports a clinical distinction between these two disorders. They found that neither self-identification as Hispanic, nor rate of acculturation as measured by the Multigroup Ethnic Identity Measure (MEIM) or Psychological Acculturation Scale (PAS) correlated with the rate of ataque de nervios. This finding suggests that ataque de nervios may be more universal than previously believed.

In contrast to the low co-occurrence rate found by Keough, Ester Salmán and her colleagues found high rates of panic disorders in Hispanic individuals with a history of ataque de nervios (Salmám et al., 1998).

Salmán and her colleagues developed the Ataque de Nervios Questionnaire-Revised (ANQ-R) and administered it to 156 Hispanic individuals who had presented to a nonprofit anxiety disorder clinic in New York. Of those studied, 69.9% reported at least one episode of ataque de nervios. Of those who had a history of ataques, 41.3% also met criteria for panic disorder (with or without agoraphobia), 8.3% for generalized anxiety disorder, 4.6% for social phobia, and 8.3% for anxiety disorder not otherwise specified. They found no statistically significant difference in the specific ataque de nervios symptoms or coexisting psychiatric disorders between those respondents from Puerto Rico, Dominican Republic, or "other" Hispanic nationalities. The differences in co-occurrence rates in these two studies may be a function of the populations studied as Keough at al. interviewed a nonclinical sample of undergraduate students and Salmán et al. utilized individuals who had specifically presented for treatment at an anxiety clinic. Since individuals with "typical" ataque de nervios symptoms do not usually seek treatment, it would make sense that Salmán's sample had more coexisting pathology based on the fact that they had sought out treatment at an anxiety clinic.

Falling Out/Blacking Out

The *DSM-IV-TR* (American Psychiatric Association, 2000) defines episodes of falling out or blacking out as "a sudden collapse, which sometimes occurs without warning," but can be preceded by feelings of light headedness, dizziness, or a "swimming" feeling in the head. The person typically falls to the ground and feels unable to move. While their eyes are frequently open, they claim a lack of sight, though they can hear what is going on around them. Such episodes primarily occur in the southern United States and the Caribbean. The *DSM-IV-TR* comments that such episodes may correspond to a diagnosis of Conversion Disorder or Dissociative Disorder (American Psychiatric Association, 2000).

Weidman reviewed data collected from approximately 100 households comprised of various ethnic groups as part of a comparative study of health conditions, beliefs, and practices in inner-city Miami (Weidman, 1979). She found that 23% of the Bahamian sample reported instances of "blacking out," while 10% of the Southern African American sample reported "falling out." Weidman's colleague, Lefley, reviewed Miami Fire Department's "run reports" describing their emergency calls over an 8-month period (Lefley, 1979). She found that 12% of the 3,700 reports were for possible cases of falling-out. Of the possible falling-out cases African Americans represented over 49%, Latinos represented 21%, and non-Latin Caucasians represented 30%. They attributed the relatively low percentage of Latinos to their overall underrepresentation in total numbers of emergency service runs.

Locura

Locura is a "term used by Latinos in the United States and Latin America to refer to a severe form of chronic psychosis," according to the *DSM-IV-TR* (American Psychiatric Association, 2000). Individuals who are believed to be suffering from locura typically present with symptoms of incoherence, inability to function in society, hallucinations, aggression, impulsivity, and bizarre behavior that is outside of socially acceptable norms (American Psychiatric Association, 2000). Locura is believed to be caused by repeated stressors in life, a familial vulnerability to the disorder, or a combination of the two. Individuals who have been identified by family and friends as having locura would benefit from an evaluation for schizophrenia or other psychotic disorders.

Pinaeros and his colleagues reviewed an "outbreak" of nine cases locura in an indigenous Columbian population in their 1998 article (Pinaeros, Rosselli, & Calderon, 1998). They presented with bizarre behavior, headaches, convulsions, and visions. Trials of antipsychotic medications, religious healers, and herbal remedies were unsuccessful and individuals only responded to shamans of the same ethnic origin. They concluded that the presentation was a reaction to the psychosocial stress of culture changes in their community.

Rootwork

Rootwork, according to the *DSM-IV-TR*, is a belief in the ability of an individual to influence another's physical well-being with hexes, witchcraft, or sorcery (American Psychiatric Association, 2000). Physical symptoms can vary greatly and are believed to be the direct result of the type of supposed magic at work. Treatment is typically sought from a special healer or "root doctor." While rootwork is primarily seen in the Southern United States and the Carribean, similar versions referred to as *mal puesto* or *brujeria* are present in Latin cultures. This condition is also very similar to mal de ojo, a Mediterranean belief in the ability of those who wish someone ill to effectuate that wish through the use of magic, referred to as "the evil eye" (American Psychiatric Association, 2000). Those who have been affected may exhibit crying, fever, poor sleep, or gastrointestinal distress.

Mathews wrote extensively of the traditional medical practice of African Americans which he identified as having roots in the "slave culture of the antebellum South" (Mathews, 1987). She identified illnesses which are conceptualized as "natural" under this framework, including hypertension, anemia, and diabetes, in contrast to those thought of as "unnatural," including magical possession, fading, and magical poisoning. Natural illnesses are believed to be caused by blood imbalances that can be cured by natural substances, including food and herbs, while unnatural illnesses have their roots in magic and require treatment by a root doctor who can undo the harmful spells. She concludes by emphasizing that rootwork serves psychological and social needs which cannot be met by the general medical community and the importance of physicians to communicate with their patients in a culturally respectful manner.

Séizisman

According to Nicholas, DeSilva, and Grey (2006), séizisman or "seized-up-ness" is a disorder of Haitians in which an extreme emotion or unexpected event or situation brings on a physical reaction (Nicholas et al., 2006). The extreme emotion can be in the form of anger or joy and can be precipitated by learning of injury or death of a loved one or witnessing a fight. The physical consequences are believed to be a result of blood rushing to the head. This can result in difficulty breathing, weeping, confusion, or a state of paralysis. The effects can last from hours to days. Treatment is typically in the form of a rallying of social supports, massages, and herbal remedies. A particularly concerning form of Séizisman involves pregnant women and those who have recently delivered. In this group, an episode of Séizisman is believed to carry the risk of miscarriage, maternal death, premature delivery, deformations in the fetus, or tainted breast milk. As a result, it is common in this culture to delay the giving of bad news until after delivery, in an attempt to shield pregnant women from exposure to stress; special accommodations may be made if bad news or stress cannot be avoided.

Susto

The *DSM-IV-TR* states that susto is a disorder in which an extreme fright causes the soul to leave the body (American Psychiatric Association, 2000). Susto goes by many names, including espanto, pasmo, tripa ida, perdida del alma, and chibih, and is believed to affect Latinos in the Americas. The symptoms of susto are various and include sleep and appetite disturbances, pain, gastrointestinal disturbances, sadness, difficulty with social roles, or even death. There can be a delay between exposure to the stressor and the appearance of symptoms, and the illness can last for months or years. Treatment is often sought from indigenous healers who work to return the soul to the body and restore the balance between body and spirit.

Weller and her colleagues interviewed 200 subjects in a family medicine clinic in Guadalajara, Mexico, to determine if there was an association between a history of susto and current depressive symptoms (Weller, Baer, Garcia, & Rocha, 2008). Over 69% of the sample reported a past history of susto. They found that a history of susto was not significantly associated with age, marital status, educational level, income, or a rural background. Individuals who reported a history of susto had significantly higher levels of current stress and depressive symptoms than those who did not. Individuals with a prior episode of susto were twice as likely as those without it to have a high current likelihood of depression.

Arctic/Subarctic

Pibloktoq

First identified by Abraham Brill in 1913, pibloktoq has also been referred to as Arctic hysteria (Dick, 1995). Pibloktoq was first observed in the Inuit people of Greenland and later in other arctic and subarctic Eskimo communities. The *DSM-IV-TR* defines pibloktoq as "an abrupt dissociative episode accompanied by extreme excitement of up to 30 min duration"

(American Psychiatric Association, 2000). During the episode, the afflicted individual may shout obscenities, remove clothing, become aggressive, or eat feces. An episode may be preceded by social withdrawal or irritability. Following an attack, the individual may display convulsions and "coma" lasting up to 12 h. Seizure disorders should be ruled out in individuals who present with symptoms of pibloktoq as should excessive levels of vitamin A which can be found in high amounts in arctic marine life and mammals and which comprises a large part of many Eskimos' diet and can cause similar symptoms (Landy, 1985).

Religious Experiences and Culture-Specific Diagnoses

Historically, certain religious beliefs have been considered culture-specific diagnoses. While these beliefs can impact presentation and treatment of mental illnesses, they should not be confused with culture-specific diagnoses. The belief in spirit possession is one such example that can be seen in many different religions, including the Caribbean religion of Santería (Alonso & Jeffrey, 1988). Santería is a combination of African and Catholic rituals and beliefs. One aspect of Santería involves festivals during which participants try to be possessed by spirits of saints. In 1988, Drs. Alonso and Jeffrey discussed clinical cases in which four individuals' psychiatric presentation was confounded by their belief and practice of Santería. An important point made in their article is that while these beliefs are associated with culturally based religious practice, they are distinct from culture-specific diagnoses. Beliefs in ideas such as spirit possession and communication with the dead can represent a culturally and religiously accepted norm (Alonso & Jeffrey, 1988). The authors report that an examination of an individual's adaptive functioning can help distinguish those whose beliefs cross the threshold of accepted cultural belief into delusion. They suggest a review of the person's ability to carry out usual activities, to use good judgment, and to appreciate the limitations of their beliefs to aid in the assessment (Alonso & Jeffrey, 1988).

Erika Bourguignon's 1976 article, "Possession and Trance in Cross-Cultural Studies of Mental Health," further elaborates on the prominent role of trances in many cultures (Bourguignon, 1976). Dr. Bourguignon points out that, when reviewing trance states, it is important to look at not just the state of consciousness the person is in, but also the cultural significance of the experience and the beliefs and practices that surround attaining and interpreting it. She emphasizes that the dissociative state that is typical of both trances and possession is not pathological in itself, just as the dissociation induced by hypnosis or suggestion is not by itself a sign of psychopathology (Bourguignon, 1976). The cultural significance given to this dissociative state is frequently religious or sacred, and can deal with soul loss, spiritual possession, or spirit quests among other culturally significant concepts. Dr. Bourguignon defines a nonpossession trance as an intrapersonal event frequently involving hallucinations, which is knowable to others in the community only through the self-report of the individual. In contrast, a possession trance is a group event in which the possessed takes on the characteristics of the possessing animal or spirit and the audience or observers serve an important role (Bourguignon, 1976). In her 1972 review of 488 societies, she found that 90% recognized some form of trance or possession state within their culture (Bourguignon).

The *DMS-IV-TR* is also careful to point out that not all of the culture-bound syndromes it describes actually represent an illness; they can, instead, be a normal part of religious, spiritual, and cultural life (American Psychiatric Association, 2000). The authors point out that while "spells" or trance states in which individuals communicate with deceased relatives or other spirits may be misconstrued as a psychotic episode, they are not to be considered as medical events. The authors also point out that zar, which presents with spirit possession, is not considered pathological within the African culture. As a result, these states can only be understood within the context of the role they play within a given culture. These experiences warrant treatment only if they vary widely from the culturally accepted parameters of the experience or if they cause the individual some form of distress or impaired functioning.

Criticisms of Culture-Specific Diagnoses

During the past 3 decades, numerous criticisms have been leveled at the field of culture-specific diagnoses. Many of these began as there was a move toward greater respect and acceptance of the cultural practices of non-Westernized societies and an improved understanding of the impact that cultural differences have on all aspects of health care. These criticisms have grown so strong that many practitioners and even the World Health Organization have moved away from utilizing this category of diagnosis, instead applying mainstream or "typical" psychiatric diagnoses when clinically indicated, accompanied by a notation about cultural factors that are present.

One major criticism of culture-specific diagnoses is the fact that many of the beliefs and symptom clusters that make up these "disorders" are considered normal within their given culture. For example, many cultures have a strong belief in the supernatural and believe that spirits and witchcraft play a prominent role in the etiology of disease. Some Haitians have been found to believe that supernaturally induced illnesses are real and can result from a variety of sources including strained relationships with God, curses from angered individuals whether living or deceased, or retaliation from an offended lwa or spirit (Nicholas et al., 2006). These religious and supernatural issues are believed to cause illnesses directly or to be indirectly responsible for weakening the person and allowing illness to occur. These beliefs can serve as a lens through which genuine physical ailments are understood in this culture and can serve a useful role in rallying social and spiritual support as an individual battles illness. While some of these ideas may seem odd to Westerners, so too may the religious beliefs of Christianity or Judaism seem strange to other cultures. Respect must be given to cultural and religious practices. Acceptance of these beliefs and behaviors as normal for a given culture or religion can be undermined by naming them as syndromes or diseases.

Another key criticism of culture-specific diagnoses has been the overlap between many of these disorders and other DSM-IV-TR and ICD-10 diagnoses. Even the architects of the *DSM-IV-TR* note several likely overlaps between certain culture-bound syndromes and other diagnoses (American Psychiatric Association, 2000). They suggest that such falling-out spells may represent a form of dissociative disorder or conversion disorder and boufée delirante may represent brief psychotic disorders. One theory of why new culture-specific diagnoses were created when already existing psychiatric diagnoses could have been used to account for behaviors is a sort of "culture-shock" on the part of the clinicians visiting these foreign countries. It is possible that the differences of these newly studied societies in which culture-specific disorders were identified were so striking to the scientists that they were unable to appreciate the even more significant similarities, and, thus, "new" disorders were discovered (Hughes, 1993).

It is not surprising then that the vast majority of the culture-specific diagnoses are found within non-Western cultures or aboriginal groups that may reside within the borders of Westernized countries but whose cultural practices are nonetheless alien from the majority. Ronald Simons and Charles Hughes point out that Western diagnoses are also "bound" within the culture in which they were created, but are not distinguished as such because the cultural factors were not as visible to Western clinicians as were the cultural factors of "exotic" societies (Simons & Hughes, 1993). While knowledge of the impact of culture on a patient's presentation and illness course is important, so too is an accurate diagnosis and unnecessarily distinguishing disorders that could appropriately be grouped together can have negative consequences on patient care. With improvements in genetic studies of illness, brain imaging, and medications approved for specific diseases, accurately identifying the illness has become even more essential. It is important to keep in mind that even if a more traditional psychiatric illness can be diagnosed, there is always a need to appreciate and understand the individual's cultural background. Cultural awareness is essential in framing and explaining the diagnosis to the patient and his or her family and understanding reactions to treatment recommendations. Additionally, in some cases, it may also be useful to enlist the aid of cultural guides or indigenous healers and remedies just as one might enlist the assistance of a clergy member in the treatment of a patient with strong religious convictions (Guthrie & Szanton, 1976).

In the 1980s and 1990s, a backlash against the ethnocentric focus of the culture-specific diagnoses and an increased understanding and appreciation of the role of culture in diseases led to the characterization of several diseases in industrialized nations as culture-bound. One of the first diseases to be conceptualized in this way was anorexia nervosa, a mental illness that is, in part, defined by fears of gaining or maintaining an appropriate weight and distortions in the way one's body shape and size are perceived (Swartz, 1985). This disorder was first seen almost exclusively in countries in which food was abundant and there was a social preference for thinness (American Psychiatric Association, 2000). Cases of anorexia nervosa became increasingly more common in less affluent nations as exposure to this Westernized ideal of beauty became more widespread (Sing, 1996). The geographic creep of this illness demonstrates that as cultural norms shift, disorders thought to be culturally tied can become embedded in new regions.

In 1982, Cheryl Ritenbaugh took this argument one step further, demonstrating how even obesity could be thought of as a culture-bound syndrome within the United States (Ritenbaugh, 1982). In her article, "Obesity as a Culture-Bound Syndrome," she traces the history of cultural ideas about weight from positive associations with fertility to religious denouncements of gluttony, to the prominence of a more adolescent-appearing female figure in media. Around the same time that popular notions of beauty began favoring slim, athletic figures, the general public was becoming more aware of the negative health impacts of obesity. She finds support for her theory of obesity as a culture-bound disease in the prominence within the culture of the United States of diet-aids and health spas, and the amount of funds spent on treatment and research of obesity and obesity-related illnesses (Ritenbaugh, 1982). Several other conditions were briefly considered as Western culture-specific diagnoses, including premenstrual syndrome (PMS) (Johnson, 1987) and dissociative amnesia (Pope, Poliankoff, Parker, Boynes, & Hudson, 2007), before this movement was replaced by a more general understanding of the role that culture plays in all disorders.

Another major criticism of the field is the lack of consistency in the identification of diseases that constitute culture-specific diseases. Prince and Tcheng-Laroche delineated several potential pitfalls in assigning a constellation of symptoms the status of culture-specific disease or culture-bound syndrome (Prince & Tcheng-Laroche, 1987). These include the use of different names to refer to the same constellation of symptoms in different regions; the impact of different geographic factors on physiology, such as low iodine in the soil leading to similar disease manifestations; epidemiological differences such as gender distributions, age of onset, and frequency; and subtle differences in presentation between different cultural groups that do not inherently change the disease nature, duration, or course. All of these factors make it difficult to establish which conditions should be considered culture-specific diseases. Claire Cassidy (Cassidy, 1982) and her colleague Cheryl Ritenbaug (Ritenbaugh, 1982) sought to create a clear definition of culture-bound syndromes. They identified a culture-bound syndrome as "a constellation of symptoms which has been categorized as a dysfunction or disease," characterized by one or more of four factors: an inexorable connection to the associated culture or subculture, an etiology which reflects behavioral norms of the culture, a reliance on culture-specific ideology and technology to diagnose the illness, and the inability of a cultural outsider to accomplish successful treatment. While this is helpful in understanding how they conceptualize these disorders, it is not a concise definition and has not gained wide usage.

The lack of solid studies and empirical data on culture-specific diagnoses has been another criticism of the field. In 1990, Guarnaccia suggested that a major limitation of cross-cultural psychiatry was that studies were typically undertaken with Western diagnostic scales (Guarnaccia et al., 1990). They suggested that instruments should be developed to assess symptoms of local illnesses. The use of standardized instruments would allow more empirical studies which could help to differentiate culture-specific diagnoses from other DSM-IV-TR and ICD-10 recognized mental illness or provide firm data that no such difference actually exists. Guarnaccia and his colleagues further encouraged the inclusion of individuals who are knowledgeable about the local culture and are able to act as ethnographical interpreters in the design and implementation of such studies (Guarnaccia et al.).

Implications of Culture-Specific Diagnoses on Immigrants

Over the last several decades, countries outside the United States have been plagued by armed conflict, dictatorships, gender oppression, poverty, famine, and a myriad of other hardships. Their struggles have led to an increase in migrations worldwide. In 2000, the United Nations considered one out of every 135 living individuals to be a "refugee" (Pumariega, Rothe, & Pumariega, 2005). In the United States, "first and second generation immigrant children are the most rapidly growing segment of the American population, with the great majority of this population being of non-European origin" (Pumariega et al., 2005). Given the diversity of cultural backgrounds among immigrants to the United States and other countries, physician familiarity with identifying and treating culture-bound illnesses is essential. Older immigrants are especially likely to express distress in a pattern that is consistent with their own traditions and practices. However, older immigrants are less likely to seek medical care, in large part due to Western psychiatrists being unable to properly recognize and manage their symptoms. One study looked at Korean American immigrants and found that their mental health needs were not being addressed due to an underutilization of psychiatric services in the United States. Access to treatment barriers include "failure of mental health services to provide culturally relevant interventions," "an inadequate number of trained mental health workers, especially psychiatrists who are culturally sensitive," and a "belief in ethnic traditional medicine" (Lee, Hanner, Cho, Han, & Kim, 2008). Language barriers and the stigma many ethnic groups place on mental health conditions further reduce the chances of an immigrant population receiving appropriate psychiatric care.

In addition, immigrants remain a high-risk group given the complexity of their social situation. Many of them face separation from their families, detention in refugee camps, and discrimination once they arrive in their new country. They inhabit crime-filled inner-city neighborhoods and cannot afford health insurance, a quality education, or job security. Mental health treatment becomes a low priority, and those that seek care are faced with physicians who are ill-equipped to recognize their presenting symptoms. Given the growing ethnic and cultural diversity of the world, the challenges mental health care workers face in providing culturally competent care will continue to grow. Health care systems across the globe need to develop comprehensive research programs that will help address the complexity of culture-bound syndromes and allow psychiatrists to understand and treat foreign born populations who present with symptoms unique to their background (Guarnaccia & Rogler, 1999).

In summary, while the study of culture-specific diagnoses has helped to broaden mental health practitioners' understanding of some unique conditions, it has also been criticized for its apparent assumption that behaviors that differ from those that are common in one's own culture are a disease or disorder. In the last 20 years, there has been an improved effort to view all mental and physical disorders through the lens of culture awareness. This has led to an improved understanding of what is considered normal behavior within a given culture. Knowledge of culture-specific diagnoses is beneficial as it expands practitioners' familiarity with unique cultural experiences and symptom presentations. It is only through our understanding of culturally acceptable behavior that we will be able to identify and help those individuals whose presentation differs from the acceptable and treads into the pathological.

Health Determinants

M. David Low · Barbara J. Low
Management, Policy and Community Health, University of Texas School of Public Health, Houston, TX, USA

Introduction

Health determinants are often used to explain why some people become ill while others remain healthy. Specifically, a health determinant refers to a factor or event that influences human health throughout life. While professionals may seek reasons for health and illness based on their training, a wealth of evidence now supports the notion that the socioeconomic circumstances of individuals and groups are equally *or more* important to health status than medical care and personal health behaviors, such as smoking and eating patterns. The pathways from social experience to biological change are not fully established, but evidence is beginning to emerge.

Acute and chronic illness, injury, and even genetically mediated disorders develop because of social, economic, and environmental conditions that exist in the places where the person has lived, and as a result of the ways that a person has chosen, or been allowed to live his or her life. Through complex processes not fully understood, human beings incorporate environmental and social experiences into their biology, and they do so throughout their lives from conception to senility. Theoretically, human social experiences are received much like sensory stimuli and translated into biological signals that may strengthen resistance to illness or lead to disease that manifests clinically later in life. This *sociobiological translation* (Tarlov, 1996) may be the single most important macro- determinant of health for all individuals, and it should be clearly understood by those who may provide care for newcomers to any country.

The Public Health Agency of Canada (PHAC) offers a representative and widely articulated view of the factors influencing human health. The PHAC (2010) determinants include: early child development, income, income inequality, poverty, social status, education, literacy, employment and working conditions, gender, personal health practices and coping skills, social environments, social support, culture, physical environments, political and economic environments, genetic endowment and biology, medical care, and health services. None of these factors acts in isolation, and it is the combined influence of all of them *interacting across the life course* that ultimately determines health status. These principles are the foundation for the discussion of specific health determinants in this entry.

The Life Course Perspective

A life course perspective offered by Kuh and colleagues (2003) explains developmental factors acting across the life course that influence a broad range of outcomes, from general health to the ability to perform activities of daily living and to chronic disease. At an individual level, cumulative and programmed patterns mediate a complex array of regulatory processes such as psycho-neuroendocrine and immune function during critical and sensitive periods. The essential elements of such a framework assert that health is a consequence of multiple determinants operating in nested genetic, biological, behavioral, social, and economic contexts that change as a person develops. Health development is an adaptive process composed of multiple transactions between these contexts and the bio-behavioral regulatory systems that define human functions. Different health trajectories are the product of cumulative risk and protective factors and other influences that are programmed into bio-behavioral regulatory systems during critical and sensitive periods; and the timing and sequence of biological, psychological, cultural, and historical events and experiences will influence the health and development of both individuals and populations.

Health Determinants

Early Child Development

The nutritional and environmental conditions experienced by the infant during gestation are included

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

among the most important determinants of health because the conditions in which the fetus develops play a key role in regulating the function of its physiological systems later in life. This is sometimes referred to as intrauterine programming. Changes in the intrauterine availability of nutrients, oxygen, and hormones may program tissue development, and can lead to abnormalities in adult cardiovascular and metabolic function. The timing, duration, severity, and type of insult during gestation will determine the specific physiological outcome. Intrauterine programming occurs at the gene, cell, tissue, organ, and system levels and may cause permanent structural and functional changes that can lead to disease in adulthood.

As infants develop, they interact with their environment and in turn shape the experiences to which they must adapt mentally, physically, and socially. Through this process the child's behavior itself influences genetic expression. Stimulation and positive early experience in infancy and childhood have profound impacts not only on the development of those neural systems subserving cognitive, emotional, neuroendocrine, and neuroimmune functions but also on genetic expression of factors that modify the effects of stress hormone receptors, and therefore the individual's responses to stress, throughout life. Keating and Miller (1999) posit that as a result of this biological embedding, developmental trajectories are characterized by acquisition of competence and coping skills and by regulation of responses to new or challenging experiences. An example of the origin of such a trajectory is infant distress, integrating neurophysiological, behavioral, and social responses that help babies to regulate their emotions as well as to facilitate parental responses. Infants who are successfully able to regulate their attention, emotion, and social functions are better able to learn and to cope with new experiences and challenges. The quality of interpersonal relationships and social environment strongly influences infant developmental trajectories involving self-regulation, competence, and coping. These experiences set the stage for future competence in learning, formal education, and prosocial behaviors, although the mature brain continues to adapt to positive and negative environmental exposures throughout life.

Income, Income Inequality, Poverty, and Social Status

There is a connection between health and wealth, as a great deal of research demonstrates. Studies of income and mortality have shown lower mortality following higher incomes. Curiously, this relationship has only been demonstrated *within* societies; among the different countries in the OECD there is no relationship between per capita annual income and life expectancy beyond a threshold of about $US 5,000. There are significant exceptions to the rule that more income equals more health. In countries with the greatest income inequality, including the United States and the United Kingdom, health status and life expectancies are lower, even among the wealthy, than in countries where national income is lower but individual incomes are less unequal. For example, in Sweden, on average the poorest citizens live longer than the highest class of people in the United Kingdom. In some populations, notably among Hispanics of Mexican origin living in the United States, income appears to have less effect on health status than in the general population. Among them, life expectancies and other health indicators such as infant mortality tend to be better than expected given the level of material resources available. This so-called Hispanic paradox has been studied extensively in the United States (Franzini, Ribble, & Keddie, 2001).

A person's income is one of the principal determinants of both neighborhood of residence and housing quality, and several health indicators such as life expectancy are highly correlated with household welfare. These and other contextual factors influence health throughout an individual's life course. Among key determinants of population health such as social status, social affiliation, and stress, place matters. "Place refers to both geographical location and to group membership in terms of family, friends or age, and on the basis of class, ethnicity, residence, and gender that arise out of the (political), social and economic structure of society" (Kuh, Ben-Shlomo, Lynch, Hallqvist, & Power, 2003, p. 780).

Low socioeconomic status is one of the strongest predictors of poor health and development. Socioeconomic status (SES) is a measure of one's place in society variously based on income, education, occupation, and wealth. It is a relational concept that takes into account an individual's work environment, combined with their economic and social position relative to others. Beyond and in addition to the serious effects of material deprivation that those living in poverty experience, psychosocial factors may mediate many of the negative effects of relatively low socioeconomic status that are influenced by the neuroendocrine mechanisms of the stress response. Such psychobiological adaptation occurs at home and at work. It is demonstrated that stress harms health, particularly in the workplace, and that other psychological factors, mediated through social interaction may affect health either directly through conscious and direct individual-level processes, or indirectly by constraining behavior and lifestyle choices, although the interrelationships among these fundamentally significant processes are not fully understood.

Literacy, Health Literacy, and Education

There is an extensive literature dealing with literacy and various aspects of adaptation to society, such as functioning effectively in the general community and in the workplace. Health literacy is an important determinant both of health and social functioning. It must be regarded as a key issue for those individuals coming to the United States whose native language is not English, and also for the unfortunately large number of native-born Americans who have low literacy skills.

Whereas well-being and illness are influenced by biological, environmental, and social experiences that occur throughout the entire life span, the roots of learning, literacy, and the adaptive behaviors that sustain physical and mental health are established during the first few years of a child's life. These exert long-term influences on adult health and ultimately on community and societal function. Human learning and education are potentially critical mediators of the relationship between political, economic, and social factors, and health.

Recent evidence suggests that what an infant experiences during the first three or four years of life may be far more critical than previously realized in determining that child's ultimate intellectual capacity and its ability to cope with stress. An early environment rich with sensory stimulation and emotional nurturing greatly increases the likelihood of the child becoming a productive, emotionally stable, and resilient adult. There is a strong correlation between positive early life experience, *readiness to learn* on starting kindergarten, subsequent mathematics achievement and adult literacy.

Educational attainment is a powerful determinant of adult life experience through its probable influence on employment opportunity, earning capacity, personal mastery, social networks, and standard of living. Educational performance among immigrant youth may be influenced by their perception of family obligation (Kao & Tienda, 1995). In the United States, income and years of education are both strongly associated with adult health status. In particular, completion of high school education is significantly associated with reduction in adult mortality (Kaplan & Keil, 1993). The duration and quality of the educational experience also affect health and quality of life in adulthood through a variety of pathways (Ross & Mirowsky, 1999). Self-reported general health status has also been shown to be a good predictor of adult mortality and is positively associated with educational attainment (Idler & Benyamini, 1997). It seems that in many Western countries the longer you stay in school, the longer you will live. Immigrants, for example, deprived of economic and educational opportunities may suffer health consequences.

Employment and Working Conditions

The nature of employment and associated working conditions are powerful determinants of health since these are integral to economic security, social status, individual development, self-esteem, participation, relationships, work-life balance, protection from physical and psychosocial harm, and access to adequate health care services (World Health Organization [WHO], 2008). Primary concerns are: job and employment security; physical conditions at work; work pace, control (decision latitude) and stress; working time (duration, shift predictability, vacation time); opportunities for self-expression and individual development at work; participation and relationships at work; and work-life balance (Jackson & Polanyi, 2004).

Unemployed persons are at greatest risk for ill health due to economic strain and limited social support networks. Unskilled, temporary, and underemployed workers experience significantly higher mortality than permanent, skilled, or professional workers. Women and immigrants or migrant workers are most likely to be in the first three job categories. As well as forming a large part of the unskilled or temporary labor force, many immigrant noncitizens lack health insurance and receive little or no primary health care services.

A personal sense of control over one's life circumstances, particularly in the workplace, is a powerful determinant of health status. Marmot's Whitehall Study has demonstrated a steep gradient of mortality between the principal grades or job classifications in the British civil service. A man working in the trades or as a manual laborer is four times as likely to die in a given year as a man in an administrative position. Perhaps most striking is the fact that a male civil servant is twice as likely to die as his administrative boss. It appears as if one's position in the hierarchy in some way gets embedded in one's biology.

High rates of anxiety and depression affect many workers in North America, especially among those who are part-time, temporary, or lack a contract for employment. Work-related stress has been associated with reduced social support, unhealthy behaviors such as tobacco smoking and overuse of alcohol, and poor health outcomes such as a 50% excess risk of coronary heart disease (CHD).

Adverse conditions at work can contribute to physical and mental illness. Unsafe or unpleasant working conditions, especially in lower-status occupations, are likely to expose employees to health hazards. Blue-collar workers experience poorer health than their white-collar counterparts. Exposure to job strain incurs psychosocial stress associated with unpredictable shifts, long work hours, inadequate vacation time, high job demand and pace, low perception of control over decisions, low quality or level of work relationships, and discordance between effort and reward. Better employee health outcomes are associated with greater ability to shape working conditions, especially for safety. Overall, male workers are at greater risk for CHD but female workers may experience health problems due to work-life imbalance (i.e., the addition of household labor and care giving to their daily workload), particularly among low-income immigrant populations (Borrell, Muntaner, Sola, Artazcoz, Puigpinos, Benach, & Noh, 2008).

Employment status is a significant determinant of social status, economic well-being, access to health resources, and, ultimately, to health. Unemployment or working in unsafe conditions may cause poor health or disability, and poor health or disability may increase the likelihood of becoming unemployed, underemployed, or working in unhealthy environments.

Gender

Gender is a relational rather than a biological concept that is shaped by socially constructed roles for males and females within sociocultural groups. Appropriate personality traits, attitudes, attributes, values, and behavior are ascribed to women and men, and girls and boys. Depending on the social norms and economic well-being of a particular society, gender may be characterized by relative differences in opportunities and resources available to either sex. This may differentially affect the power of men and women to exercise human rights, to reduce exposure to health risks, and to access and use health information, care, and services. This role discordance may be associated with an imbalance between leisure time and paid or unpaid work, particularly among some ethnocultural or immigrant groups. Women are more likely than men to fulfill role-related responsibilities for domestic management and provision of care to family members while working outside the home. Chronic stress from this disparity may disproportionately affect women, contributing to ill health over time. Systematic inequalities are associated with gender-based social status and differences in health outcomes (WHO, 2002). On most socioeconomic gradients, women are more likely to be disadvantaged than men when race/ethnicity, low level of education, or single parenthood are factors that interact with gender.

In the United States, mortality for males and females has worsened since 1990 compared to all of Western Europe and several lower-income nations. In North America, women tend to outlive men due to lower rates of cancer, heart disease, fatal unintentional injury, and suicide. This is most apparent among 20–34-year-olds when rates of potential years of life lost before age 70 are almost three times as high for men than for women. While they are less likely than men to die prematurely, women experience greater morbidity such as anxiety, depression, chronic stress, autoimmune disorders, musculoskeletal dysfunction, allergies, and arthritis, as well as injuries and death due to family violence.

Personal Health Practices and Coping Skills

Beginning in childhood, personal health practices and coping skills allow people to enhance their ability to protect and promote their own health. This involves developing an adequate capacity for self-care, problem-solving and self-management skills, dealing effectively with stress, and making informed choices to prevent or reduce their experience of illness. An individual's health practices and coping skills reflect personal choices, which are influenced by socioeconomic environments that enhance or limit/prevent opportunities for healthy lifestyles and behaviors. Physiological and biochemical pathways also play an important role by linking individual social experience to adverse health events such as injury, cardiovascular conditions, HIV/AIDS, and cancer.

Factors that impact health behavior choices affect individuals within five domains as they live, learn, develop, work, and play. These are personal life skills; coping with stress; social relationships and belonging; and personal sense of control (PHAC, 2010). Personal life skills can be defined as an array of abilities required by all individuals to help them to thrive in everyday life. The most important are social skills that mediate the maintenance of healthy relationships, family interactions, and interpersonal communication. Personal skills may include self-reliance, discipline, self-organization, goal setting, respecting oneself and others, motivation, and managing performance outcomes. Application of these skills may assist an individual to cope with challenges that most human beings experience throughout the life course, permitting them to maintain a sense of well-being regardless of the level of stress they perceive.

Associated with trust and membership in a social group, a sense of belonging seems to be of particular importance as a protective factor across age, gender, race/ethnic, cultural, occupational, recreational, and socioeconomic groups. Underpinning the sense of self is one's perception of the locus of control, defined as the personal belief about what causes good or bad things to happen in one's life. From a health behavior perspective, an internal locus is associated with a sense of personal responsibility for health practice choices while an external locus (e.g., luck, fate, and other people's actions) suggests that other people or events are perceived to be responsible for health outcomes. A persistent external locus of control may contribute to poorer health.

Some health-risk behaviors are likely to contribute to illness or injury. Causes of premature morbidity and mortality vary by age, gender, and race/ethnic groups but Americans are most likely to die from heart disease, cancer, stroke, chronic lower respiratory disease, or accidents (unintentional injuries) (Centers for Disease Control [CDC], 2010). The risk to health increases when people engage in multiple behaviors associated with poor health outcomes, such as those experienced by individuals who combine alcohol or drug use with driving a motor vehicle, or with unprotected sexual activity.

Tobacco cigarette smoking poses one of the most significant health risks in the world, and is associated with up to one-quarter of all deaths among adults 35–84 years of age. Its effects are primarily on the cardiovascular, respiratory, and immune systems that lead to lung and other cancers, coronary heart disease, stroke, chronic respiratory disease, and other illness.

Other health-risk behaviors that contribute to preventable illness and mortality are poor nutritional practices, especially the intake of excessive dietary salt and *trans*-fatty acid and inadequate dietary omega-3 fatty acid, and a sedentary lifestyle associated with nearly 1 in 10 deaths from overweight and obesity and physical inactivity (Danaei, Ding, Mozaffarian, Taylor, Rehm, Murray, & Ezzati, 2009). Ranked 11th as a cause of mortality, suicide was cited as the cause of 33,000 deaths in 2006. This lethal form of intentional injury is closely linked to depression and other types of mental illness, substance abuse disorder, family history of suicide, family violence including physical and sexual abuse, marital separation and divorce, firearms in the home, and poor coping skills (National Institute of Mental Health [NIMH], 2009).

Ultimately, personal health practices and coping skills shape many individual health outcomes within the context of socioeconomic and physical environments throughout the life course. People's beliefs, attitudes, and skills influence their capacity to promote or adversely affect their own health as well as the health of other people around them.

Culture, Social Environments, and Social Support

The term *culture* implies a particular way of viewing social relationships that are established over time within specific groups of people who share common beliefs, values, and perceptions of normative behaviors and practices. Within one's perceived cultural sphere, an individual may choose to adopt health behaviors that are more or less risky to them and to others living and working in proximity. Strong social connections and networks, especially of others within one's culture, may serve to protect people from illness and harm.

The nature of the society in which we live matters greatly to our health. Social support is a significant factor in promoting and maintaining healthy lifestyles at an individual and population level, probably as important as risk factors such as hypertension, obesity, and smoking. Individual and community-level support offers practical and psychosocial resources to help people to cope with daily stress, illness, and many of life's challenges. Low levels of emotional support and social participation are associated with increased overall death rates.

A supportive society is one whose values and norms contribute to a variety of assets such as social stability, safety, positive working relationships, respect for diversity, and cohesive communities that reduce many potential risks and provide opportunities for healthy behavior choices. Such social cohesion and civic vitality depend on strong formal and informal social networks within a community, region, state, or nation through institutional, organizational, and individual support practices that share resources and strengthen interpersonal and group affiliations (PHAC, 2010). Life expectancy is greater in states and regions where there is broad participation in civic affairs and a high degree of social trust. States where there are high rates of volunteer activity report lower mortality rates and incidence of heart disease.

Lack of social support can also arise from lack of provision or access to social goods and services (e.g., language services for immigrants, housing for the homeless, and legal sanctions to prevent discriminatory practices). Without adequate opportunity for contributing to society, people may not be socially active or productive and they may face inadequate or unequal access to means of livelihood. Recent immigrants are often considered to be among the most marginalized groups in US society, encountering high risk for reduced earning capacity, increased poverty, unemployment or underemployment, discriminatory practices in the workplace, segregation due to lack of equal access to neighborhood housing, contact with the criminal justice system, reduced access to health care services and insurance, and poor experience of overall health. For example, many children living outside the United States may endure long-term separation from their migrating parents if they must remain in their country of origin, often with inadequate supervision that may lead to harmful consequences such as sexual abuse or neglect (Pottinger, 2005). Among Mexican-origin Latinos, the largest immigrant group in the United States, family support is positively associated with self-rated physical and mental health, while family cultural conflict may be negatively associated. This conflict may arise, in part, from different generations' culturally-related beliefs and behaviors and appears to be mediated by language, although the mechanism for this is not well understood. Although important for community cohesion, Latino neighborhood-level social cohesion may not be significantly related to self-rated physical or mental health when the effects of education, income, and other demographic measures are taken into account (Mulvaney-Day, Alegría, & Sribney, 2007). Overall, however, social networks and number of social contacts seem to matter to everyone's health, regardless of cultural background, age, or gender.

At the other end of the spectrum of social support and community cohesion, violent crimes pose serious threats to health. Worldwide, women and children are most likely to be exploited by human trafficking and transported to US destinations. In the United States, experience of family violence tends to follow race/ethnicity. From 2006 to 2008, the US child mortality rates due to assault, negligence, and maltreatment were the highest among all countries with reliable data – three times higher than other Organization for Economic Cooperation and Development (Organization for Economic Cooperation and Development [OECD], 2010) nations except for Mexico. Indirectly, an individual's health may be adversely affected over time through lost productivity or ability to work or attend school, increased need for mental health and medical care, as well as greater involvement with law enforcement and criminal justice systems.

Physical Environments

Aside from the importance of clean air and water, proper waste disposal, absence of toxins from the soil, and adequate control of disease vectors, the environment in which we live our daily lives has profound effects, especially on gestating mothers, infants, and children. North Americans on average now spend 90% of their time indoors, in their homes, schools, workplaces, recreational facilities, shops and malls, etc. The broader built environment of human settlements (villages, towns, suburbs, and cities) is also important, because these are not only physical environments, they are also social environments where people gather and relate to one another.

In addition to being safe and providing shelter, housing also should be hygienic. This means having clean water, sewage and solid waste removal, and clean food storage and preparation areas. These subjects have been at the core of traditional public health work for many decades. Housing should also support mental and social well-being – it should be attractive, pleasing, and well maintained, preferably with green space and play areas for children.

The quality of the urban built environment is also important to health. Outdoor air pollution comes from industry and from motor vehicles. Particularly in the summer months, nitrogen oxides and volatile organic carbons from these sources combine to form ground-level ozone, while particulate pollutants and acid emissions contribute to smog in summer or haze in winter. Motor vehicle accidents are a major cause of death and injury. Traffic noise is a major irritant, while large roads and highways impede access for pedestrians and isolate neighborhoods from each other. Urban settlements also contribute enormously to water pollution. Human wastes, industrial wastes, urban runoff from the streets and parking lots, pesticides and herbicides from parks, lawns, golf courses, and gardens – all end up in rivers, lakes and streams.

The design of urban environments also has an important influence on crime and violence. It is not just the violence, but the fear of violence that is debilitating. If people do not feel safe, they will not use their community's streets and facilities, and increasingly will wall themselves off in gated neighborhoods. This only serves to increase the isolation and the disparity between rich and poor, young and old, Black and White. Indeed, the social impacts of the urban environment are at least as important as the physical impacts. High-rise apartments, deserted streets, poor public transportation, gated communities, urban sprawl – these and other aspects of modern cities can contribute to isolation, lack of access for the disadvantaged, and alienation.

Housing quality is one of the principal determinants of children's health, both while they are children and later as adults. Persistent cold, dampness, mold, fungi, pesticides, lead-based paint, vermin, insects including mosquitoes, cockroach droppings, and a host of other household contaminants and agents all have negative effects on a growing child. Immigrants in rural and urban areas experience many of these conditions in the colonias, refugee camps and other locations where they may have to live. The health effects of negative exposures in childhood last a lifetime, even if the individual's economic status increases later in life.

Political and Economic Environments

Governments and their policies are important and can have profound effects on health. Aside from the obvious negative health effects of war and conflict in which civilian women and children always suffer the most, administrative decisions about resource allocation, taxation, income redistribution, education, provision of health services, infrastructure development, transportation, food and water supply, personal safety and security and social services all have some effect on the health status of many individuals in the population.

It has been clearly demonstrated that in some countries, income inequality itself is associated with poorer health for those at the lower end of the scale. These economic inequalities are not accidental. They result from decisions made about taxation policy, home ownership, business regulation, welfare and unemployment benefits, education funding and access, healthcare funding, etc. For example, market-generated child poverty in Sweden, the United States, and the United Kingdom is 23.4%, 26.7%, and 36.1%, respectively. Tax and transfer policies in Sweden reduce this child poverty burden to below 3%, while in the United Kingdom it is only reduced to about 19.8% and in the United States to 22.4%, and child poverty is a powerful determinant of health (Graham & Power, 2004). Among developing nations, the Indian state of Kerala has long been cited as a model of what can be accomplished with very little in the way of material resources. Average incomes there are very low, but inequalities are deliberately minimized in law and the people enjoy the highest rates of literacy and the longest average life expectancy on the Indian sub-continent. By contrast, in Britain, the economic reforms of the Thatcher era were followed by increasing death rates among the lower classes. As Nobel laureate Amartya Sen (2002) has said, "Health is an exquisite mirror of social circumstances."

Genetic Endowment

Genes determine many things about us, including normal biological characteristics such as eye and skin color, hair pattern, earlobe shape, blood type, and probably longevity. They are also responsible for a number of abnormal conditions and diseases. Because parents pass on their genes to their children, like certain aspects of physical appearance, some diseases tend to cluster in families. Comparing the genes of people affected by a disease with the genes of unaffected people has revealed genetic variations that substantially increase the risk of age-related macular degeneration, type 2 diabetes, Parkinson's disease, and heart disorders, for example.

Cell division involves a network of signals that work together to determine when and how often a cell will divide, and how errors can be fixed. Cancer occurs when cell division gets out of control. Mutations in one or more of the nodes in this network can trigger cancer, through exposure to some environmental factor (e.g., tobacco smoke) or because of an inherited predisposition, or both. With some exceptions, no single risk is sufficient to trigger the development of cancer. Many factors other than genes, including diet, exercise and environmental exposures will determine health and malignancy risk.

Biology and Disease

Ultimately, disease will manifest as some kind of disturbance of normal biological functioning. The nature, extent, and location of the disturbance will constitute a disease that can be labeled and understood in the western scientific tradition, but may be viewed very differently by those who follow the much more ancient traditions of China (Qi or Chi), India (Ayurveda), or Africa, for example. Caregivers should be aware that they may form the entire foundation of beliefs about health and disease of many newcomers to America and native-born citizens alike.

The top ten leading causes of death worldwide (according to western science) are heart disease, cerebrovascular disease, respiratory infections, HIV/AIDS, chronic pulmonary disease, perinatal conditions, diarrheal disease, tuberculosis, malaria, and respiratory tract cancers. Some of these, like HIV/AIDS and malaria are most prevalent in one region of the world or another, while others like heart disease and stroke are ubiquitous, and the prevalence of these chronic diseases is growing. Heart disease, stroke, cancer, chronic respiratory disease, mental illness, and diabetes together account for half of all deaths worldwide. Cardiovascular disease is now the leading cause of death in all regions of the world except sub-Saharan Africa. These chronic diseases are related to lifestyle and the environment, most particularly unhealthy diets, lack of physical activity, tobacco use, harmful alcohol use, certain infectious agents, and air and water pollution. Those conditions that contribute most to disease burden are poor sanitation, lack of potable water, little or no access to health care services, low levels of education, and undernutrition – all associated with poverty.

Infectious diseases previously considered under control are experiencing a major comeback, especially in those areas of the world where the climate is warm and damp. Infectious diseases may require an intermediary insect host or vector such as a mosquito or tick, or zoological hosts like swine or cattle. Some infections are spread through direct contact sexually or through contact with inanimate objects (fomites), contaminated food or water, blood products, or respiratory droplets.

Emerging and reemerging diseases are a growing concern, including HIV/AIDS, Ebola, severe acute respiratory syndrome (SARS), avian influenza, West Nile virus infection, malaria, and tuberculosis. Vector-borne diseases are reemerging for a number of reasons including resistance to pesticides, climate change and changes in agricultural practices. Malaria is the most important infectious disease worldwide, and ninety percent of cases occur in Africa. Among the sexually transmitted illnesses (STIs), 95% of those with HIV also live in developing countries, accounting for more than 25 million deaths since 1981 (Avert, 2010).

It should not be overlooked that while they are generally not killers, syphilis and gonorrhea are more common than HIV. The incidence, prevalence, and mortality due to STIs continue to increase. Finally, tuberculosis is a problem in every low-income country in the world and is a growing problem in the United States. One-third of the world's population is estimated to be infected, and successful treatment requires multiple medications to prevent the development of resistance.

Medical Care and Health Services

The saving of lives in acute life-threatening emergencies is an important contribution of medical care to health, but that is a small part of the total medical effort. Much larger efforts are devoted to preventive or curative measures, and an even greater proportion of the total is devoted to preventing or to minimizing the poor quality of life associated with chronic disease (i.e., to the relief of pain, disability, and disfigurement).

Since the 1960s, advances in medical technology and scientific knowledge have both contributed greatly to human well-being. Much of the benefit has been due to advances in dealing with newborn babies (notably the availability and use of surfactant) managing heart disease, particularly acute myocardial infarction, and prevention of stroke with TPA. According to John Bunker, one of the few investigators who have attempted to quantify the contributions of medical care to health, medical care is now the major determinant of life expectancy.

Health care is not available, accessible, and provided equitably to all people in many nations, including the United States. Research by the Institute of Medicine revealed that racial and ethnic minorities tend to receive a lower quality of health care than nonminorities, even when insurance status and income are controlled. Patients may not look for necessary care because they fear being misunderstood or disrespected, or may not adhere to medical advice because they do not understand or trust the provider. Language barriers have a negative impact on utilization, satisfaction, and compliance with prescribed care. Improving the quality of physician–patient communication and cultural sensitivity enhances outcomes.

Conclusion

All of these health determinants were summarized by Sir Michael Marmot (Wilkinson & Marmot, 2003), a pioneer in the field of population health research, who noted there are some "solid facts" that can be relied upon by caregivers and policy makers alike. Regardless of their country of origin, people's social and economic circumstances affect their health throughout life; stress harms health; the effects of early life experience last a lifetime; one's life context matters, including the family and neighborhood; functional literacy and education are major determinants of health and life success; social exclusion creates misery and costs lives; social support matters; stress in the workplace increases disease; a personal sense of control and reward for effort matter greatly; unemployment and job insecurity have powerful negative effects on health; dietary intake and food security are very important but the availability of healthy food is a major political issue in virtually all countries; and environmental degradation is dangerous to life and health. Many of these factors influence the health of immigrants who may experience life course events that disrupt their family and social networks, place them in impoverished environments exposed to health and safety risks, and compromise their basic food and nutrition sources. Education and health care are often inaccessible to them, while economic, language, and cultural barriers impede their healthy development. Understanding health determinants and their effects can lead to a more informed approach to health and social interventions in this vulnerable population.

Occupational and Environmental Health

Doug Brugge[1] · *C. Eduardo Siqueira*[2]

[2]Department of Community Health and Sustainability, School of Health and Environment, University of Massachusetts Lowell, Lowell, MA, USA

The Boundaries Between Occupational and Environmental Health and Safety

Occupational and environmental health are often considered together because they are largely similar and, in many ways, overlap or intersect with each other. Indeed, the boundaries are mostly social rather than scientific. In the USA, the same individual who is in a car crash while driving for work would be classified as an occupational injury, whereas if the crash occurred under identical circumstances off work time it would not be considered occupational. Likewise, a waiter who is exposed to secondhand smoke at the restaurant where he/she works has an occupational exposure, whereas if he/she were a customer in that same restaurant, his/her exposure would be environmental.

The political separation into occupational and environmental exposures has led to distinct regulatory approaches. Critically also, exposures at work often differ from those in the general populations both in form and intensity. While secondhand smoke exposure and car crashes may be similar in both spheres, in other instances workers may be exposed to much more intense repetitive strain injuries (meat cutting, for example) or more concentrated airborne pollutants due to being close to the source. In addition, susceptibility to harm may differ as the general population includes children, elderly people, and people too ill to work.

Thus, we accept the bifurcation into occupational and environmental categories and frame both this chapter and the entries in the encyclopedia along these lines.

Where Immigrants Live and Work

The International Organization for Migration estimates that there are 214 million international immigrants. The countries hosting the largest number of immigrants are the United States, the Russian Federation, and Germany. According to the International Organization for Migration (IOM), those sending the most immigrants are China, India, and the Philippines. Wikipedia reports that net immigration is mostly from low-income countries to high income countries (➲ *Fig. 1*).

Reasons for immigration may differ considerably and range from fleeing violence or political persecution to seeking economic opportunities, to following family members, among many other reasons. But the majority of immigrants move from lower-income settings to economies where they at least perceive that they can make economic gains. Thus, these immigrants are usually at or near the bottom of the economic ladder when they arrive. If they have a limited proficiency in the dominant language(s) of their new home, that might also hold back their advancement. These are important factors when thinking about environmental and occupational health as the housing, neighborhoods, and jobs that these people find are driven by their social situation. In general, recent immigrants will be concentrated in the worst living and working conditions, living in low-income or public housing that may be poorly maintained in neighborhoods with multiple social problems and working in jobs, often hazardous, that the higher income native populations are unwilling to take.

Environmental Health

Air Pollution

Ambient Air Pollution

There is a deep and growing literature that shows that ambient air pollutants, including particulate matter, ozone, oxides of nitrogen, carbon monoxide, sulfur oxides and others, adversely affect the health of people. While pollution levels are greatest for most contaminants in major cities in the developing world, Beijing or Mexico City for example, it is also clear that the relatively lower levels of pollution in North America and Europe are still sufficient to elicit adverse health outcomes, including increased mortality.

Most research on ambient air pollution has either not included or not separated out immigrants from nonimmigrants. This situation may be changing with studies such as the Multiethnic Study of Atherosclerosis air pollution sub-study which includes large numbers of Chinese and Hispanic Americans (Diez Roux et al., 2008). Critical to the case that immigrants might have different exposures to air pollutants is the fact that these pollutants vary across time and space so that some people will be exposed more than others, even within a single city. The ways that pollutants vary are complex and differ by type of pollution. For example, ozone is a regional pollutant that forms at a distance from the source of its precursors. Conversely, the smallest particulate pollution, ultrafine particulates, is elevated mostly within hundreds of yards of major traffic routes.

A small number of air pollution studies have reported analysis of air pollution data by immigration. One team of researchers looked at "air toxics" levels as reported by the US EPA in relation to multiple demographic factors, including immigration. One of their studies, which converted toxic air pollution levels in California into predicted cancer risk, found, after controlling for many possible factors, that census tracks with higher percentages of recent immigrants had a statistically significant association with cancer risk (Pastor et al., 2005). Another study by this team suggested that, again in California, Latino and Asian children had higher exposure to air pollutants and, consequently, higher "respiratory risk." Further, this analysis suggested a possible relationship to lower academic performance (Pastor et al., 2006). A third study in this series found that residential segregation was associated with estimated cancer risk for Asian and Hispanic populations across the USA (Morello-Frosch & Jesdale, 2006).

A second team, working with data from Phoenix, Arizona, found that Latino immigrants experience higher levels of carbon monoxide independent of their socioeconomic status (Grineski et al., 2007), but found no association of Latino immigrants with asthma hospitalizations in a separate analysis (Grineski, 2007). US inner city populations, which include many immigrants, have higher exposures to air pollution and may experience poorer health outcomes, especially cardiovascular and respiratory, as a result of those exposures.

Clearly the literature to date does not adequately answer the question of how different ambient air pollution exposures and risks are for immigrant communities compared to native-born communities. That the literature is US-based leaves a particularly large gap. But the findings, limited as they are, suggest greater exposures and health risks for immigrants.

Indoor Pollution

In developed countries, people spend a large percentage of their time indoors, including time inside their homes. Thus, in these countries indoor exposures, including infiltration of ambient pollutants, are more important than outdoor levels. Time spent indoors may be much less in developing countries, but sources of indoor pollution may be more extreme, for example, poorly ventilated smoke from solid fuel fires used for cooking. It is worth noting that this means that many immigrants who move from developing countries to developed countries experience dramatic changes in the nature of their indoor exposures.

Combustion is a significant source of indoor exposure via inhalation. Indoor combustion products, whether from a wood fire or a gas stove or from infiltration from outdoors, include particulate matter, polyaromatic hydrocarbons, carbon monoxide, oxides of nitrogen, and sulfur oxides. All are well known to be toxic and to cause or exacerbate health problems. For indoor combustion, exposure may be particularly high since dispersion of the pollutant is impaired by the enclosure of the building.

Other important indoor contaminants include products of biological organisms, pesticides, lead in paint, asbestos, and secondhand tobacco smoke, among others, some poorly studied or not well defined. Biological contaminants include cockroach, dust mite, cat, dog, and rodent antigens. In people who are immunologically sensitive, one or more of these antigens may contribute to allergies and asthma. Some of these exposures, cockroaches for example, may be more common in low-income housing more frequently occupied by immigrants, while others may be preferentially found in higher income suburban homes, such as dust mites.

Pesticides, often applied indoors to counter pest infestation, may accumulate and remain on surfaces for relatively long times and many are nerve toxins and/or carcinogens. Lead paint is found on indoor surfaces in countries, the USA, for example, that did not ban its use following early indications of its toxicity to children.

The difference in time spent indoors and in the sorts of exposures encountered indoors may be an important change for immigrants who move from developing to developed countries or from rural to urban settings in the course of immigration. For example, a report from Washington State in the USA found that a majority of carbon monoxide poisonings were among immigrant families during storm and power outages, and that burning charcoal indoors to stay warm was a common error on the part of these families (Gulati et al., 2009). A study from Boston, Massachusetts, found that pesticide residues in public housing often included restricted use pesticides that were not supposed to be applied in homes (Julien et al., 2007). Hispanic families were buying these pesticides at local bodegas and using them, undiluted and without training on their hazards, to counter cockroach infestations in their apartments.

Biomass (coal, wood, charcoal) is widely used as fuel for cooking and heating in much of the world. Burning biomass produces large quantities of smoke that is poorly dispersed in many indoor environments, exposing residents to particulate matter, oxides of nitrogen, carbon monoxide, and other combustion products. These pollutants have been associated with disease, including respiratory diseases, cancer, ear infections, and low birth weight. In 2000, as many as two million deaths may have resulted from this practice, perhaps half in children.

Assessing exposure to this form of indoor pollution is complicated by the fact that levels of smoke are variable, rising, for example, when fuel is added to a fire, and due to variability in proximity to the fire. However, it appears that women are exposed more than men. Well-defined dose-response relationships have been reported when careful assessment of exposure was undertaken, with an almost eightfold increased risk of acute respiratory infections at the highest exposure levels. Intervention programs aimed at reducing exposure and associated health impacts need to account for actual circumstances in the field, not just idealized performance of, for example, stoves designed to reduce exposure (Ezzati & Kammen, 2002).

Secondhand Smoke

Secondhand tobacco smoke (SHS) is a mixture of thousands of substances, both gasses and particulate matter, many of which are known or suspected carcinogens and have other toxicological properties, including effects on the cardiovascular system. SHS is produced both during inhalation by the smoker and while the resting cigarette (or other tobacco product) smolders. The smoke produced during active smoking is called “mainstream” smoke and that produced while smoldering is “sidestream” smoke. Because sidestream smoke burns at a lower temperature and achieves less complete combustion, it may contain more toxic substances.

Exposure to SHS has been linked to cardiovascular disease, lung cancer, asthma (both occurrence and exacerbation), middle ear infection, pneumonia, low birth weight, and sudden infant death syndrome. In the 1990s the strength of the science was contested in widespread public debates in the USA with the tobacco industry and restaurant associations being the main skeptics, but the evidence base is strong and broadly accepted in the scientific community and there is much less doubt among public and industry groups expressed today.

Internationally, the regulation of smoking indoors varies widely, with at least some countries on every continent enforcing strong bans. Some countries have weaker regulations and some have a patchwork of rules that are enacted for locations within the country, such as states, provinces, or cities (➲ *Fig. 2*).

There is no overarching federal regulation or law in the USA that restricts exposure to SHS at work, making the USA a prime example of a piecemeal approach to regulation. The US Occupational Safety and Health Administration would be the agency to issue such rules, but it has not done so despite the fact that SHS is present in greater amounts and is more toxic than many other occupational exposures that are regulated. Thus, municipal and state regulations vary considerably from jurisdiction to jurisdiction, ranging from nonexistent to bans on smoking, especially in restaurants (American Nonsmokers’ Rights Foundation, 2010).

Although also subject to considerable debate in the past, it is now widely accepted that ventilation cannot reduce SHS to acceptable levels. This is largely because the level of air exchange needed to dilute the tobacco smoke would be far too great to be practical or cost effective. One calculation found that there would need to be over 220 changes of the air per hour in a 100 m^2 office in which two cigarettes are smoked per hour (Repace & Lowrey, 1985).

Today the leading edge for control of SHS exposure in locations where workplaces have been or are largely restricted is in-home exposure. Of particular concern are children and nonsmoking spouses of smokers.

For immigrants the SHS issue will depend considerably on the regulatory framework, or lack thereof, in their country of origin and the framework (or again lack thereof) in the country to which they have moved. Thus, an individual immigrant or his or her family might have moved from little or no regulation of smoking to more strict regulation and enforcement. Or they might move from a place with strong bans to a place with none or limited enforcement. Or, it is also possible to make a lateral move where the acceptability of smoking does not change much.

A common circumstance is for immigrants to move from locations with few or no restrictions on smoking (much of Africa and Asia) to places that enforce bans (parts of Europe and North America). This circumstance puts recent immigrants in a position in which they have to learn a new cultural and legal norm. Because of what is often a rapid immersion into the social environment of their new country, these immigrants may not understand the rationale behind bans or restrictions that have been debated in their adopted country for years before they arrived.

One consequence may be that immigrant enclaves enforce smoking bans or restrictions less vigorously than in other locations. But it is also possible that in

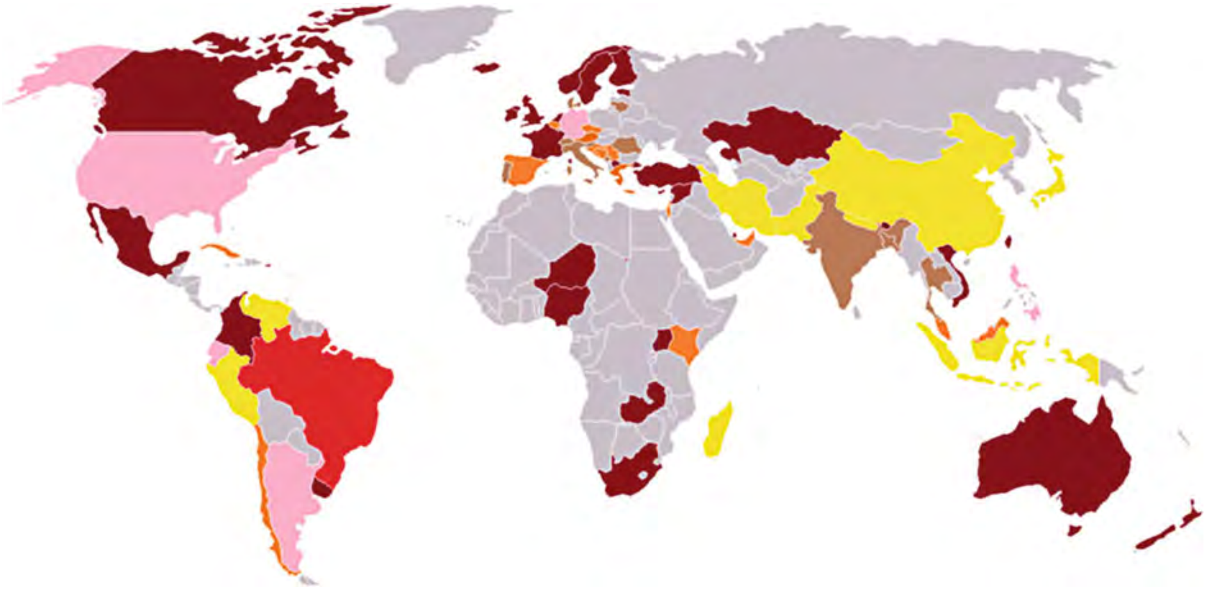

Fig. 2

Smoking bans worldwide as of Feb 8, 2010: ☐ no restrictions or no data; 🟨 patchy and incomplete bans, low enforcement; 🟪 no national ban, some localities have comprehensive indoor bans; 🟧 strong national ban in public areas except entertainment and restaurants, or weak enforcement in indoor entertainment areas; 🟥 strong national ban in public areas except entertainment and restaurants, some localities have comprehensive indoor bans; 🟫 strong national ban in all public indoor areas. Note: Countries with all subnational entities having a ban equates to a nationwide ban here, such as for Canada and Australia (http://en.wikipedia.org/wiki/List_of_smoking_bans)

countries with a patchwork of different smoking policies, immigrants are more likely to work around smokers because of "occupational segregation." That is, some jobs are less likely to have smoking bans than others. For example, a ban may be in place in restaurants, but not in all workplaces, leaving, again for example, warehouse workers free to smoke. Consistent with this, a 2009 study found that in a representative sample of the US population, persons of foreign birth were less likely to be covered by smoking bans than were US-born workers (Osypuk et al., 2009).

In what is perhaps a contrasting example, another 2009 study compared Mexican families living in two cities in Mexico or in one city in California. California has more strict smoking control programs than does Mexico. The study found that voluntary smoking bans were more common in the USA than in Mexico, while smoking prevalence was higher in Mexico. Importantly, smoking bans appeared to be more effective at reducing SHS exposure in the USA (Martinez-Donate et al., 2009).

In most legal jurisdictions with relatively strong programs aimed at reducing smoking and limiting exposure to SHS for nonsmokers, the extension of these programs to recent immigrant populations is in the early stages of development. Extending cessation programs and education about the need for and the legal prohibition on smoking to recent immigrant populations may entail both linguistic and cultural translation. Effective translation across both domains is not necessarily easy and certainly requires more than rote translation of words from one language to another. For example, Brugge et al. (2002a) developed message concepts for Vietnamese and Chinese immigrants living in Boston, Massachusetts. The approach was to understand better the values and concerns of the populations first through a series of focus groups and then to test messages derived from what was learned by showing them to people from the target populations. There is a need for more efforts not only to develop educational materials in this fashion, but also to assess their efficacy through empirical tests.

There may be wide variation of opinion among immigrants from different countries and living in different adoptive countries. However, a recent study (Osypuk & Acevedo-Garcia, 2010) found that immigrants in the USA were overall more supportive of smoking bans the more recently they had immigrated, with a gradient of decreasing support from first generation to third generation immigrants. While, as the authors suggest, this might be an opportunity to find allies to support tobacco control, it may also suggest that with time in the USA, and acculturation, their support for restrictions declines. Acculturation appears to be associated with being less likely to let people smoke in the home, at least among Asian immigrants in the Delaware valley. But the associations for acculturation variables were not statistically significant and stronger associations were seen for education, family size, current smoker in the household, and being Korean or Vietnamese (Ma et al., 2004). There is evidence, not surprising perhaps, that for Asian immigrants at least, social factors, including avoidance of conflict, contribute to attitudes toward smoking bans in ways that they might not for US-born residents.

Thus, it seems likely that we are only scratching the surface of what is a complex issue that deserves considerably more attention to be well understood.

Water Pollution

Infectious Diseases

Numerous infectious agents are transmitted through environmental exposure (in contrast to contagious organisms transmitted person to person, which we will not consider here). These environmental threats are often not as well known as diseases that are transmitted person to person, but they account for substantial morbidity and mortality worldwide. Among the most common of these diseases are:

- Helminthes, intestinal worms including Ascariasis, Trichuriasis, and Hookworm
- Schistosomiasis
- Elephantiasis
- Trachoma
- Onchocerciasis
- Leishmaniasis

Ascariasis is the most common, with prevalence above 800 million individuals infected, while other intestinal worms are not far behind with hundreds of millions of people infected. Schistosomiasis is also common with over 200 million cases. These diseases are usually contracted through unsanitary conditions, such as contact with human feces or water into which people have urinated. In some cases, the organisms pass through another species, as with Schistosomiasis and certain species of snails. In other cases, they pass through a soil phase and re-infect humans (Hotez, 2008).

These diseases are found mostly in rural, low-income populations in the developing world and are rarely present in cities where sewage systems, pavement, and shoes all interfere with their life cycles. They are chronic diseases that are rarely fatal, but can cause disability and disfigurement (Hotez, 2008). It is thought that these diseases have been with humans, and other vertebrates, for millions of years. Our coevolution probably explains the low-grade response to these infections. Indeed, the hygiene hypothesis suggests that infections such as these may modulate the immune system and that in their absence we acquire greater risk of immune system abnormalities, such as asthma and allergy or inflammatory bowel disease (Liu & Leung, 2006; Schaub et al., 2006).

For immigrants moving from developing countries, where these infections are common, especially in rural areas, to developed countries, the main effect will be that those who have been infected will lose their infection. There are undoubtedly positive consequences to this, such as reduced anemia due to intestinal worms. But these immigrants may also encounter new ailments to which they were previously unfamiliar, such as allergies. Research on immigrants to many developing countries has suggested, but is not yet conclusive, that allergies and asthma increase in populations following immigration (e.g., Brugge et al., 2008).

There is a need to better understand these “forgotten” diseases (Hotez, 2008), both to ameliorate the suffering and reduced productivity that they cause in people with the infections and to understand how these organisms might have affected our own evolution such that aberrations in immune function might develop more often in their absence.

Chemicals in Water

Chemical contamination in water is of many sorts and comes from many sources. Some well known and common contaminants include heavy metals, such as lead; transition metals, such as arsenic; or organic compounds, such as benzene or polychlorinated biphenyls. While there is natural contamination of surface and groundwater by some types of contaminants, activities undertaken by humans can either directly or indirectly increase chemical levels in water. They include sewage systems, especially in the absence of treatment plants or in instances where such plants do not effectively remove some chemicals. Also, direct discharge of industrial chemicals into water or onto soil, and from there into water may be better or less well regulated. Air pollution deposits on surfaces, including water, but also onto hard surfaces that then get rinsed by rainfall and end up in water.

In general, immigrants from low-income countries are likely to encounter improved water quality when they immigrate to high income countries. But there may be instances in which they move from relatively pristine rural areas to urban centers were water pollution is more of a problem.

Nonoccupational Injuries

Evidence to date suggests that immigrants to Europe and the United States experience less nonoccupational unintentional injuries than native-born persons. For example, a study found that both boys and girls of foreign-born mothers in Denmark had lower rates of injury (Laursen & Moller, 2009). A study in the USA reported lower percentages of reported injuries in the past year for Black, Hispanic, and Asian American immigrant children in comparison to US-born children, all of whom were low-income as they were recruited from Head Start programs (Schwebel et al., 2005). Apparently this trend extends to very narrow sub-groups of immigrants, as a study in California had similar findings for fatalities from injuries comparing Hmong to non-Hispanic Whites (Yang et al., 2009). There is some evidence counter to the dominant findings, for example, a study in Italy found that immigrant men, but not women, had higher rates of acute care and hospitalization for injuries than did native Italians (Baglio et al., 2010).

Road traffic injuries are more common in developing than developed countries (Donroe et al., 2008). But in developed countries the evidence is mixed with regard to whether immigrants experience higher risk of such injuries. Using nationwide data, a US study found that transportation-related injuries were more common among immigrants, despite overall injury prevalence being lower for immigrants (Sinclaire et al., 2006). On the other hand, a study in Sweden found that socioeconomic differences increased risk of traffic injuries, but that being an immigrant did not. Notably, most of the immigrants in the Swedish study were from Finland, which might suggest modest cultural differences.

There has been little research aimed at understanding why immigrants might experience injuries less often than nonimmigrants. One study produced evidence that language acculturation, learning English, was associated with increased injuries (Schwebel & Brezausek, 2009). Another paper by the same group raised the possibility that immigration might select for "well-adjusted and healthy children" (Schwebel et al., 2005, p. 505). Another concern with the studies to date is that they do not address well enough the possibility that there is differential reporting of injuries, including differential assessment of the level of severity that requires medical care. There are programs aimed at addressing injuries in immigrant communities, including a participatory program in Birmingham, England (Kimberlee, 2008), and an effort to address local planning to reduce traffic-related injuries in Boston Chinatown (Brugge et al., 2002b).

Occupational Health

Chemical Hazards

Immigrant hired farmworkers are commonly exposed to a variety of pesticides in fruit and nut, vegetable, horticultural, or field crops. There were over a million hired crop farmworkers in the USA in 2006, about a third of an estimated three million people employed in agriculture. Almost half of hired farmworkers lack authorization to work (Kandel, 2008), and 80% are males (Das et al., 2001). California alone has as an estimated 36% of the nation's farmworkers; almost all of them are Hispanic (99%) and most are born in Mexico (96%) (Aguirre International, 2005). In the last 10 years in California and Oregon there has been significant growth of indigenous farmworkers from Mexico (Mixtecs, Zapotecs, and Triquis) and Guatemala, who may not speak Spanish, (Bacon, 2006; Farquhar et al., 2008).

Das et al. (2001) analyzed California pesticide illness surveillance data and found that the most common causes of pesticide-illness cases in 1998–1999 in California were organophosphates and N-methyl carbamates (20.2%), followed by inorganic compounds such as sulfur and copper compounds (13.6%) and pyrethroids (8%). The most common illnesses reported were dermatologic symptoms and signs (44.2%), followed by those affecting the nervous (38.7%), gastrointestinal (38.1%), ocular (32.5%), and respiratory (23.7%) systems. These illnesses occurred mostly while farmworkers performed routine activities in the fields (64.4%), followed by exposures while mixing, loading, or applying pesticides (28.6%). The most prevalent exposure routes were dermal (41.3%), inhalation (24.2%), and ocular (11.3%). Though California has the oldest and most comprehensive surveillance system in the country, the authors note that there is significant underreporting of pesticide illnesses due to a variety of weaknesses and difficulties facing the surveillance system.

Strong et al. (2004) studied a sample of 211 farmworkers in Eastern Washington state, 92% of whom were born in Mexico, and found that exposure to organophosphate pesticides was common. They reported that health symptoms or signs such as headaches, pain in muscles, joints or bones, burning eyes, rash or itchy skin, blurred vision, stomach aches, and shortness of breath were the most common. Burning eyes and shortness of breath were weakly associated with detectable samples of azynphos-methyl, methyl-paration, and phosmet in house and vehicle dust. Azynphos-methyl and phosmet as well as captan (a fungicide) residues have also been found in migrant farmworker homes in Oregon (McCauley et al., 2001).

Villarejo & McCurdy (2008) reported pesticide exposure and illness data from the California Agricultural Workers Health Survey (CAWHS), which was a cross-sectional random household survey of 970 hired farmworkers, including workers in dairy, poultry, and other types of livestock production. Twelve percent of males and 7% of females self-reported direct contact with pesticides from being sprayed or drifted upon in the previous 12 months. Direct contact with pesticides from being sprayed or drifted upon among both males and females was associated with multiple self-reported work-related health conditions such as irritated, itchy, or watery eyes; blurry or clouded vision; skin irritations; and headaches.

Another newly studied but very common chemical exposure for many Asian and Latino workers in the USA is exposure to solvents in nail salons. For example, California has over 300,000 workers licensed to perform nail care services. Nail care products may contain methylene chloride, benzene, formaldehyde (which can cause cancer), toluene, and dibutyl phthalates (endocrine disruptors). A study with a sample of mostly female Vietnamese nail salon workers in California found that 47% reported symptoms that may be associated with solvent exposures, such as skin irritation, breathing problems, numbness, and eye and throat irritation. Most of these symptoms began after they started working in the industry (Quach et al., 2008).

A similar study in Boston surveyed 71 Vietnamese nail technicians exposed to nail polishers, nail polish removers, artificial nail products, nail tip adhesives, artificial nail removers, and disinfectants. It found that almost one-third of those surveyed reported a respiratory symptom that got better when they were away from work; 43% of these reported respiratory irritation only, 31% reported skin problems, and 18% experienced difficulty breathing (Roelofs et al., 2008). Though both of the nail salon studies had small samples and design limitations, they suggest that there are potentially serious health problems emerging in urban, small service sector businesses owned and staffed by recent immigrants.

Vietnamese hardwood floor finishing workers are exposed to flammable liquids such as lacquer sealers and organic solvents. There were 11 fatal injuries of workers in the floor laying/other floor work business in the USA resulting from fire and explosions between 1992 and 2001; five of them occurred in wood floor sanding. In September 2004, two Vietnamese floor finishers burned to death in a Somerville, Massachusetts, house fire when refinishing wood floors. In July 2005, another Vietnamese floor finisher died in another house fire in Massachusetts (Azaroff et al., 2006).

Immigrant janitors and housecleaners are routinely exposed to a variety of toxic chemicals such as chlorine, ammonia, alkylphenol ethoxylates, and 2 butoxyethanol diethylene glycol monoethyl ether, among others (Gute et al., 2010; Pechter et al., 2009). Exposures to toxic cleaning agents at work may cause respiratory problems, such as asthma; irritation of throat, nose, and eyes; dermatitis; and allergies from sensitizing ingredients.

The meat and poultry industry is a good example of a manufacturing industry where immigrant workers are exposed to a variety of chemical hazards. In 2003, 42% of workers in this industry were Hispanic/Latino and about 2% were Asians or other Pacific Islanders. About 26% of all workers in the industry were foreign-born noncitizens, while 38% of production and sanitation workers in this industry were foreign-born noncitizens (GAO, 2005). Workers in the industry may be exposed to hazardous chemicals such as nitrogen sulfide gas, carbon dioxide, and methane in manure pits or manure waste "lagoons," liquid ammonia and freon, used to keep production lines cold, and disinfectants.

Exposure to inorganic lead in construction remains a problem for immigrant workers throughout the USA, especially recent immigrants. For example, blood level screenings conducted in Boston, Massachusetts, in 2008 indicate that Brazilian immigrant residential painters were overexposed to lead at work (Siqueira, 2008). Lead poisoning can cause acute and chronic adverse effects in multiple organs, such as reduced sperm counts, memory loss, kidney problems, fatigue, and miscarriages.

Physical Hazards

Immigrant workers who work outdoors are at higher risk of exposure to extreme hot or cold temperatures and ultraviolet (UV) radiation. Extreme heat conditions are usually seen in the summer in the South and Southwest of the United States. Farmworkers in these areas may suffer from heat cramps, heat stroke, heat exhaustion, and heat rash, among other problems. Heat cramps usually occur after workers sweat profusely during arduous activity. Symptoms include muscle spasms in the abdomen, legs, or arms. Heat stroke is the most serious form of heat stress. Symptoms include hot and dry skin, chills, high body temperature, confusion, dizziness, hallucination, and a throbbing headache. Symptoms of heat exhaustion result from loss of water and salt, and include heavy sweating, extreme weakness or fatigue, nausea, clammy or moist skin, dizziness, and confusion. Immigrant workers in the restaurant industry also often complain of hot work environments in kitchens (Restaurant Opportunities Center of New York, 2005).

Extreme cold conditions usually in the Northeast, Midwest, and North may cause frostbite, hypothermia, and other conditions in construction workers at construction worksites without good climate control (for example, road construction). UV radiation may cause skin cancer and sunburn. Laborers and roofers may also be struck by lightning.

Workers in meat and poultry plants may be exposed to very hot temperatures, used to cook or cure meat, or to very cold temperatures used to preserve meat and facilitate processing. Even colder temperatures are required for production of frozen meat and poultry (GAO, 2005).

Electromagnetic fields (EMFs) produced by power lines, electric wiring, and electric equipment may also be hazardous to immigrant workers, who may be exposed to high magnetic fields if working near electrical systems that use large amounts of electric power, such as large electric motors, generators, or the power supply or electric cables of a building (NIOSH, 1996). There is evidence linking exposures to EMFs and leukemia and other cancers, but no consensus exists regarding EMFs as their cause. Therefore, EMFs are not considered a proven workplace hazard by USA government agencies.

Particulates

Immigrant workers in construction may be exposed to asbestos and dust in demolitions of buildings that contain asbestos, residential and commercial renovations, performance of building maintenance activities, and asbestos abatement projects. Although exposures to asbestos decreased in the last decades due to significant reduction of its use in the USA, immigrant laborers may still be exposed to it as a result of lack of training and compliance with health and safety standards to protect workers. Asbestos-containing materials are usually found in insulation and fireproofing materials, cement and wallboard materials, and automotive breaks and textile products. Exposure to asbestos fibers may cause lung cancer, mesothelioma, and asbestosis. Acute symptoms include shortness of breath, chest or abdominal pain, and irritation of the skin and mucous membranes. Chronic symptoms include reduced pulmonary function, breathing difficulty, and dry cough, among others.

Unusual but important exposures of immigrant workers to particulates and asbestos may also occur. For example, Malievskaya et al. (2002) reported immigrant worker exposure to fiberglass, alkaline concrete dust, crushed glass, and other pulverized construction material during the clean-up of contaminated offices and residential buildings near Ground Zero (the World Trade Center site). Clinical exams were conducted in a nonrandom sample of 418 immigrant building clean-up workers, mostly immigrants from Colombia and Ecuador. Almost all workers examined suffered from either irritation of the airways (cough, sore throat, nasal congestion, and chest tightness) or systemic symptoms, such as headache, fatigue, dizziness, and sleep disturbances.

Exposure to silica dust may occur in construction jobs that involve concrete cutting, surface grinding, tuck-point grinding, sacking and patching concrete, concrete floor sanding, and sandblasting. Diseases caused by exposure to silica include silicosis, lung cancer, pulmonary tuberculosis, and airway diseases (NIOSH, 2010a).

Psychosocial Hazards

Almost all occupational health and safety studies that asked immigrant workers to identify their most important job hazards found stress as one of the major hazards experienced by these workers in the hotel industry (Buchanan et al., 2010), the restaurant industry (Tsai & Salazar, 2007), the health care industry (NIOSH, 2009), the meat and poultry manufacturing industry (GAO, 2005), the textile industry (Lashuay et al., 2002), and the electronics and computer assembly industry (Azaroff et al., 2004), among others. The main reasons for the pervasiveness of high levels of stress in many jobs held by immigrants is that they tend to work in high physical demand and low worker control jobs or in low wage and insecure informal jobs with high turnover, often subject to poor working conditions. In addition, undocumented immigrants may be exposed to racial/ethnic discrimination at work; they may have language barriers, receive poor or no safety and health training, and suffer abuse from employers who have no accountability for failing to protect them against hazardous exposures (AFL-CIO, 2005). Therefore, a broad array of symptoms and diseases has been found in immigrant workers that are associated with stress at work: depression, sleep disorders, neurotic disorders, anxiety, musculoskeletal pain, angina, gastrointestinal disorders, and heart disease, among others.

For example, a survey of 200 Latino workers, almost all immigrants, in poultry processing plants in North Carolina found that management practices, such as poor commitment to safety and abusive supervision, and indicators of job design, such as psychological workload, repetitive movements, frequent awkward posture, task variety, and authority, were associated with risks of self-reported injury/illness, and musculoskeletal and respiratory problems (Marín et al., 2009). de Castro et al. (2006) described how work organization affected immigrant workers in Chicago according to worker rights cases collected by the Chicago Interfaith Workers' Rights Center. This study found that immigrant workers reported racial and ethnic discrimination on the job, as well as discrimination based on immigration status. de Castro et al. (2008) also found that job-related stressors are associated with chronic health outcomes (a composite of a number of chronic conditions such as asthma, diabetes, high blood pressure, back problems, etc.) among Filipino immigrants, and that this association was stronger for recent immigrants.

Infectious Diseases

Immigrant workers are exposed to infectious diseases in a variety of workplaces, such as health care facilities, meat and poultry plants, and farms. There were 1.1 million immigrants employed in health care occupations in 2000, representing 12.9% of the healthcare workforce. They were 25% of all physicians; 17% of nursing, psychiatric, and nursing aides; 16% of all clinical technicians; and 11% of registered nurses (RNs). Asians were the largest immigrant group in the industry, with Filipino nurses the largest immigrant group of RNs and Mexicans the largest immigrant group within nursing aides, followed by Jamaicans and Haitians. Immigrants made up a large proportion of home health aides as well (Lowell & Gerova, 2004). Since there is not much evidence to show disparities in worker exposures in health care settings, one may conclude that immigrant health care workers may be exposed to the same infectious disease hazards faced by the native workforce. Thus, as RNs and nursing or home health aides, they may be exposed to bloodborne pathogens, such as hepatitis B/C and HIV from percutaneous injuries from needlesticks and sharps, mucous membranes, and skin exposures (NIOSH, 2009). Immigrant health care workers may be routinely exposed to common viral respiratory infections, such as the influenza or flu viruses, and also to particular strains of viruses that have caused major epidemics, including the corona virus that caused the epidemic of severe acute respiratory syndrome (SARS) in 2003, and the H1N1 influenza virus that caused the 2009–2010 flu epidemic (NIOSH, 2010b).

In meat and poultry plants immigrant workers may become ill by contact with virus and bacteria in animal tissues and bodily fluids from carcasses, blood and fat, as well as feces. As a result, they may have fever, diarrhea, nausea, or vomiting, all related to acute infections (GAO, 2005). Poultry workers may also be exposed to the avian flu virus (NIOSH, 2010b). Immigrant hired farmworkers may have a high prevalence of parasitic diseases and tuberculosis, and have also been found to have sexually transmitted diseases (e.g., syphilis and AIDS) (Villarejo & McCurdy, 2008).

Ergonomics and Occupational Safety

Musculoskeletal Disorders

Hispanics or Latinos (native and immigrant) accounted in 2008 for 10.5% of all musculoskeletal disorders (MSDs) (Bureau of Labor Statistics, 2009), which included a wide variety of illnesses and injuries such as sprains, strains, carpal tunnel syndrome, and back pain. Asians (native and immigrant) accounted for only 1.5% of MSDs. A qualitative study with a sample of 75 immigrant workers from Latin America and Asia who worked in the restaurant, housecleaning, homecare, apparel, and hotel industries in the Los Angeles area found a high prevalence of self-reported musculoskeletal injuries (Brown et al., 2002). According to a report on workplace injuries experienced by predominantly Chinese immigrant workers in the garment industry in San Francisco, 99% of patients who attended a free clinic for garment workers had one or more diagnosed work-related conditions such as back, neck, or shoulder sprains or strains (Lashuay et al., 2002). A participatory action study conducted with unionized hotel room cleaners in Las Vegas, 85% of whom were immigrants, found that 75% of those surveyed experienced work-related pain, and worked while in pain in the 12 months prior to the survey. Repetitive physical tasks may explain most of the pain reported by such workers (Scherzer et al., 2005).

The meat and poultry industry has one of the highest rates of musculoskeletal injuries compared to other manufacturing industries. These injuries are associated with the meat and poultry production process, such as cutting motions in production lines. In 2001, the carpal tunnel injury rate was 6.8 cases/10,000 full-time workers, while the rate of sprains and strains was 51.9/10,000 and the tendonitis rate was 3.5/10,000. The rate of repetitive motion injuries in the industry in 2002 (22.2/10,000) was fifty percent higher than the rate (14.7/10,000) for all US manufacturing (GAO, 2005).

Hired farm laborers in California reported high levels of musculoskeletal pain: 41% of men and 40% of women surveyed in the California Agricultural Workers Health Survey experienced persistent pain in their backs, necks, knees, shoulders, hands, feet, or multiple parts of the body. The longer the number of years as hired farm workers, the larger the number of body parts which experienced pain (Villarejo & McCurdy, 2008).

Fatal Occupational Injuries and Nonfatal Occupational Injuries and Illnesses

The fatality rate for immigrant workers in 2001 was 5.7 per 100,000 workers, compared to 4.3 per 100,000 workers for all US workers. Analysis of Census of Fatal Occupational Injuries (CFOI) data from 1996 to 2001 shows that foreign-born workers accounted for 13.6% of all fatal occupational injuries recorded in the US. Workers from Latin American countries were responsible for 61% of fatal injuries – two-thirds were

Mexican. Asians were the second largest group, with 21% of foreign-born worker fatalities. Workers born in Europe were the third group, with 12.5% of fatal injuries, followed by workers born in Africa (3.2%) (Loh & Richardson, 2004). The four occupational groups with the largest fatality rates were transportation and material moving occupations; handlers, equipment cleaners, helpers, and laborers; protective services; and construction trades. Private construction, retail trade, and transportation and public utilities were the three most common industries for foreign-born worker fatal injuries. Workplace homicide was responsible for one in four fatal injuries of immigrants, followed by falls to a lower level, and highway incidents. Immigrant workers had a higher fatality rate than native-born workers in retail sales and as handlers, equipment cleaners, helpers, and laborers. The southern region of the USA had the largest share of fatalities, due to its proximity to Mexico and Cuba, while the West had the second largest due to its large share of agricultural, fishing, and forestry immigrant workers.

According to the most recent statistics collected by the Bureau of Labor Statistics, Hispanics or Latinos suffered 13.5% of all nonfatal occupational injuries and illnesses involving one or more days away from work, compared to 1.4% for Asians (Bureau of Labor Statistics, 2009). One study estimated that immigrants have an excess of 16,380 nonfatal injuries involving at least 1 day away from work and an excess of about 61,720 nonfatal injuries annually. It concluded that immigrants work in riskier jobs mainly because of a lack of English literacy and low levels of education (Orrenius & Zavodny, 2009).

Most available literature about immigrant workers' injuries and illnesses focuses on Latino workers, which include a significant proportion of recent immigrants from Mexico and Central America. For example, a national day laborer study with 2,660 day laborers, mostly Mexican and Central American immigrants, found that one in five workers surveyed experienced an injury on the job and two-thirds missed work due to an injury. Although many of these workers were construction workers who worked in a known, dangerous industry, the high rates of injuries reported reflected their poor working conditions, lack of training, and lack of enforcement of safety and health laws and regulations (Seixas et al., 2008; Valenzuela et al., 2006). The poultry processing industry, where many Hispanic/Latino immigrants work, had a nonfatal injury rate of 5.5/100 workers and an illness rate of 2.3/100 workers in 2005 (Marín et al., 2009). A recent study of Occupational Safety and Health Administration (OSHA) 300 logs of injuries in hotel housekeepers, largely females, found that housekeepers had the highest injury rate, 7.9/100 workers. Hispanic (immigrant and nonimmigrant) housekeepers had a higher rate of injuries than other ethnic/racial groups (Buchanan et al., 2010).

Summary

In summary, immigrants are exposed to significant occupational and environmental health risks, resulting in an increased burden of disease and, all too often, mortality. While there are numerous areas noted above that clearly require greater study, it is clear that there are also many hazards that are well documented and affect immigrants disproportionately. The development of culturally and linguistically adapted programs to reduce the burden of these illnesses and injuries in immigrant populations is critically needed. Commensurate with intervention programs there also needs to be better enforcement of existing laws and regulations and, in some cases, development of new policy to provide adequate protections.

Methodological Issues in Immigrant Health Research

Patrick J. M. Murphy · Irin Rachel Allen · Mo-Kyung Sin
College of Nursing, Seattle University, Seattle, WA, USA

Immigrants have particular health needs and concerns that may not be framed well in the context of the culture from which they left, nor in their new surroundings. The way in which research is conducted with immigrant cultures impacts how effectively the broader community can address significant healthcare needs. The analysis and interpretation of immigrant health research affects our understanding of how to best optimize health for all groups within a population. This chapter highlights some of the most notable methods and methodological issues arising from conducting immigrant health research. Particular attention is given to describing and comparing specific research approaches that have been successfully used in researching issues related to immigrant health.

Special Considerations for Conducting Immigrant Health Research

Role of Language Translation and Cross-Cultural Boundaries

One complicating factor that has the potential to arise while conducting research with immigrant populations is the need for language and cultural translation, be it literal or metaphorical. Healthcare interpreters and translators may be used to facilitate communication across cultural boundaries, and it is important to note translation involves conveying complex ideas and connotations as much as providing a word-for-word conversion between two languages. Most commonly, translators are used for facilitating written communication and interpreters are used for oral communication. Both translators and interpreters may play important roles in assisting the investigator with the design, implementation, and analysis of a research project (de Chesnay, Murphy, Harrison, & Taualii, 2008).

Investigators have previously noted the importance of conducting research requiring translation in the field of immigrant health. Limited representation of non-English-speaking immigrants in health research has been speculated to adversely effect evidence-based health and human services policy (Garrett, Dickson, Whelan, & Whyte, 2010). The language barrier between immigrants and those in the healthcare profession has been shown to adversely affect health services access, health outcomes, and patient satisfaction among immigrant groups, and patient satisfaction with different interpreter methods provides insight into potential applications for research study design (Gany et al., 2007).

Legal and Ethical Protection of the Rights of Human Participants

Several factors may directly contribute to the classification of immigrant groups as vulnerable populations in need of special protections when they are involved in healthcare research. Cultural barriers, language differences, and legal status may all present challenges to effectual communication about – not to mention access to – needed health care. Academic institutions and clinical sites involved in healthcare research most commonly have a designated institutional review board (IRB), sometimes referred to as an independent ethics committee or ethical review board, that is charged with protecting the rights of human subject research participants and evaluating the risks associated with all aspects of a proposed research study.

The IRB is responsible for ensuring an investigator has developed adequate mechanisms for obtaining *informed consent* from all research participants prior to their involvement with the study. Informed consent requires that participants voluntarily agree to participate in the study and that they understand (1) what is

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

being asked of them and (2) the purpose of the study and any reasonably foreseeable risks to them associated with their participation (Belmont, 1979). The researcher must disclose any potential conflicts of interest between himself/herself and their role in the project. They must clearly identify to the participants the extent to which their privacy and confidentiality are being protected and maintained. It is of particular note that research participants have the right to withdraw informed consent at before, during, or after the research study has been conducted, and the investigator has an obligation to honor this right at all times, including after data have already been collected (Belmont, 1979).

In the process of conducting immigrant health research, there are numerous ways in which ethical responsibilities and cultural understandings intersect. For example, investigators conducting a recent study on elderly Korean immigrants observed participants were reluctant to answer questions about mental health and depression due, in part, to a cultural predisposition to not share openly what was regarded as a private family matter (Sin, Choe, Kim, Chae, & Jeon, 2010). Another research group conducting qualitative research on cervical cancer screening among diverse groups of immigrant women identified the need to utilize "flexible and innovative approaches," such as including members of the participating cultural groups in the research team, in order to involve multiple cultural groups in their study (Karwalajtys et al., 2010). Developing trust with the immigrant community and individual participants and explaining the extent to which participant confidentiality was to be maintained were essential to the success of these studies.

Selection of Study Designs for Immigrant Health Research

There are many factors to consider in the selection of an appropriate study design that will address issues of immigrant health. The selection of a specific research methodology to be used will be affected by the individual characteristics of the immigrant group to be researched, as well as the nature of any health assessments that may be performed as part of the research process. The purpose and potential applications of the study should be identified to aid in the selection of a beneficial study design. Research that focuses on health needs of immigrants is often used to assist in distribution of aid or resources. If this is an aim, measurable outcomes may be a key factor in the design of the study, and a more comprehensive view of the health needs of the entire community may also need to be addressed. When looking at existing programs in relation to immigrant health issues, taking the participants' self-identified needs into consideration may be one of the most important factors and may encourage a participant-driven type of study. If a deeper understanding of cultural values is desired, the researcher may need to consider how they can build a deeper relationship with persons from that culture. If a large-scale collection of data is needed, the researcher may need to focus efforts on the development of culturally appropriate methods of obtaining sufficient data, while taking a more distant role in the actual collection of data.

Significance of Investigator–Participant Relationship in Immigrant Health Research

What differentiates studies of immigrant health research from other health research is the relationship between the immigrant group and the dominant culture, as there may be a differential in power relationships. In the case that an individual from an immigrant group feels to be of powerless social standing, the role of an interviewer or researcher must be examined for ethical integrity (Green & Thorogood, 2009). When addressing health needs of an immigrant group within a dominant culture, the perspective of the researcher is paramount. A researcher, whether from the immigrant culture being studied or from another cultural group, may choose a research design that respects this potential differential by examining his or her own perspective on the research process. Understanding the desired research relationship between the researcher and the issue or group being studied can aid in selecting the most effective research design. While some immigrant cultures may be celebrated or honored, others may be discriminated against or denied rights. How these cultural groups relate to the dominant culture affects their access to health resources. In a similar manner, the relationship between the researcher and the researched group will impact how data are collected and analyzed. Because each immigrant group differs by culture and country of origin, careful examination of how the researcher relates to the culture being studied and the theoretical issues addressed through the study is useful in order to develop a greater perspective on immigrant health.

Use of Investigator–Participant Relationship to Provide a General Taxonomy to Research Methodologies

The following methods for conducting immigrant health research are organized based on relationships between the researchers and the researched immigrant groups, as illustrated in ➲ *Fig. 1*. This conceptual model represents a nonexclusive taxonomy intended to assist a novice investigator discerning among commonly used approaches to studying immigrant health research.

We describe five approaches to study design, organized according to their population focus.

- Research designs that are *directly focused on the individual or group participants* are subject to limited input or influence by the researcher. An example of this method is a longitudinal study following a specific group of immigrants within the first few years of their arrival in a country.
- Designs may have a *direct focus at the population level*. An example of a study design with this type of focus is the US Census, which collects demographic data for the national population.
- *Participant-generated methods* are studies in which the population being studied plays an active role alongside the researcher in the production of data and the direction of study. An example is

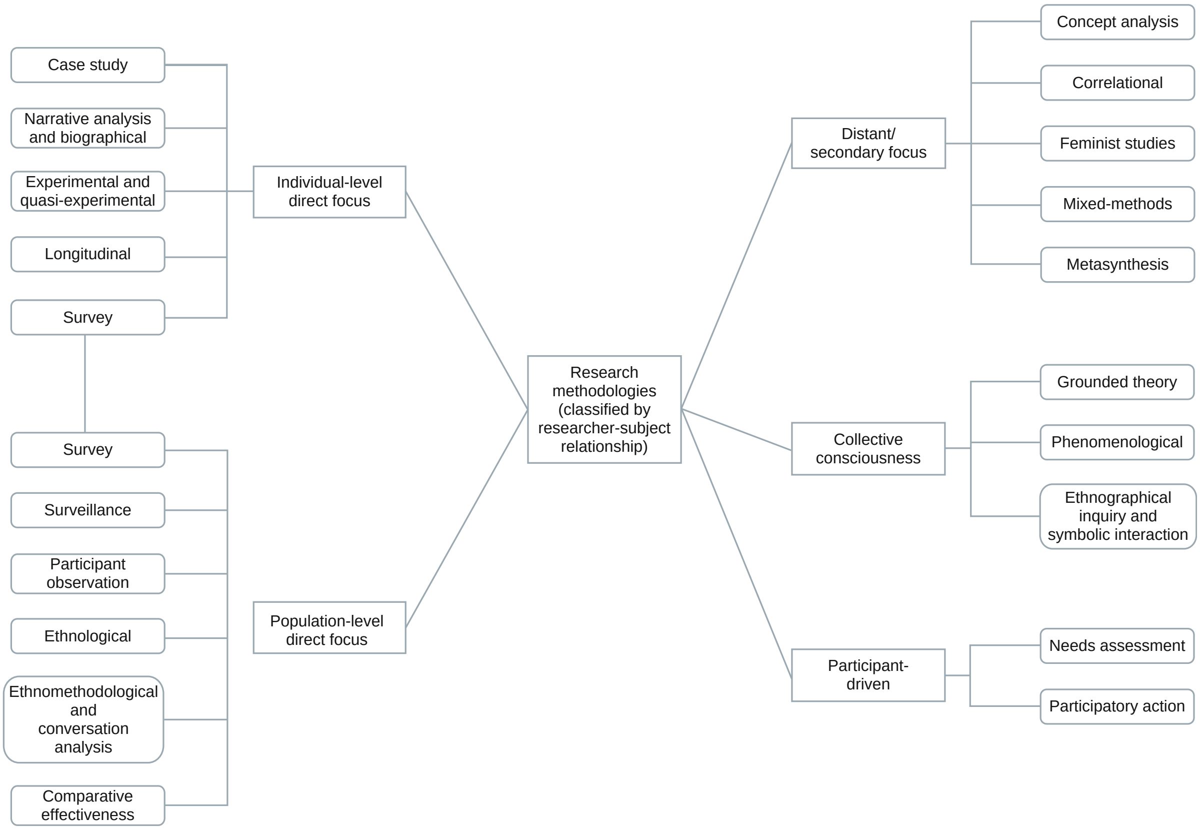

Fig. 1

Illustration of research methodologies commonly used in studying immigrant health, classified by the investigator–participant relationship

a participatory action design to improve healthcare access among immigrant groups in a city, in which community members generate the interventions and outcomes through focus groups, education about resources, and community building training.

- Research methodologies may focus on *defining a collective consciousness* and evaluating theoretical constructs relating to the issue or population studied. An example of this research design is a grounded theory evaluation of the experience and descriptions of depression in an immigrant community in which in-depth interviews are used to synthesize a theory that encapsulates the essence of the experience.
- The research approach may have a *secondary analysis or distant focus* in which previous knowledge is evaluated, revised with a new perspective, or synthesized to generate new knowledge or theories. An example is a systematic review of the experiences of immigrant nurses in Western countries, and barriers they encounter. Through the process of secondary analysis of existing studies, results can be applied to increase understanding as well as establish evidence-based best practice for healthcare managers working with these individuals.

Examples of Research Methodologies Used in the Study of Immigrant Health

Individual-Level Direct Focus Research Methods

Many types of studies have a direct focus on one immigrant group, a collection of individuals, or a specific time frame. These studies tend to allow detailed analysis and insight into a particular group of persons or events, but may not be broadly generalizable. In these studies, the focus is on the person or persons being observed, and the researcher is a discrete variable. Ideally, the same data are collected from each participant, with minimal personal influence or interference from the researcher. If interviews are included in the methodology, the focus is on the participant, rather than the interactive process. These studies also share a common theme in that they may go into depth about an individual or group, but are not broadly generalizable. Studies with a direct focus are useful when the group of participants is limited in scope, or when the health issue is highly specific. These types of research designs include, but are not limited to, biographical and narrative analyzes, case studies, experimental and quasi-experimental designs, longitudinal studies, and surveys.

In choosing a direct focus research relationship for the evaluation of immigrant health issues, some benefits include the ability to generate detailed data on an issue, or to create depth of knowledge relating to a particular group. A direct focus may also promote the minimization of bias or subjective interpretation between the researcher and the group of persons being studied, as the focus is more on the data than on theoretical or subjective analysis. Such types of studies are often foundational, such as a case study that provides an insight to trigger further investigation or a survey that provides accurate numbers with which to evaluate use of health status among immigrant communities. By expanding the direct focus research design to the population level, there is greater potential to use the data for distribution of resources, as well as evaluations and comparisons of ethnic groups within a larger community.

Case Study

A *case study* is an intensive focus on one individual, one group, or a social unit, often over a period of time (Polit & Beck, 2009). Case studies provide detailed observations of a particular program, project, or group of individuals. Case study research asks how and why events occur but does not attempt to control any behaviors, and thus differs from experimental study designs (Yin, 2003). The benefits of case studies include the ability to generate depth of inquiry and observe natural human occurrences (Green & Thorogood, 2009). One potential limitation of conducting case study–based research is that the conclusions from the analysis cannot be generalized well to an ethnic subcommunity, a larger immigrant group, or to the greater population (Green & Thorogood, 2009). A case study may be used to develop a new theory or hypothesis or to find meaning in phenomena that are infrequently seen or poorly understood, and they may lead to new avenues for research.

When using a case study design for immigrant health research, the availability of sources, access to translators, and the desired application of the data are key considerations. There are not specific methodologies for all types of case studies, as the category of research is broad, and may refer more to the sample selected than the method of research (Green & Thorogood, 2009). Documentation and archival records, as well as physical artifacts, such as objective observations and data on a house or apartment building in a case study that relates to housing conditions, can be conducive for accurate documentation of an analysis of data within a case study (Yin, 2003). This information may be difficult to obtain from the country of origin if working with immigrants in a new host country. Interviews and direct observation provide accessible firsthand data, which may have a powerful impact on the reader; however, obtaining this information may become time-consuming for the researcher (Yin, 2003). Using as many sources of data as possible to link and describe phenomena will substantially strengthen the external validity of a case study (Yin, 2003).

Narrative Analysis

Narrative analysis examines how individuals construct and tell stories as a way of making sense of the world and their own existence (Green & Thorogood, 2009). This term does not refer to particular methods for research, but applies to numerous methods that focus on how stories are told (Green & Thorogood, 2009). *Biographical* research may stand alone as a study design, or may serve as the basis of data within the construct of a narrative analysis. In comparison to narrative analysis, biographical studies focus more on content than context. Biographical research methods, which may be done as interviews when the focus is on the life experience of an individual, emphasize the participant's reports of events and experiences in their own life. The emphasis is on the relationship between the experiences and the telling of the experience (Green & Thorogood, 2009). Benefits to narrative analysis are the abilities to include detail and depth about experiences and to promote representation of individuals within a population (Green & Thorogood, 2009). Disadvantages for using narrative analysis for immigrant health research include decreased generalizability and limited ability to examine how human experiences are told in natural social settings, if the data are gathered from interviews (Green & Thorogood, 2009). Applications for biographical and narrative analyzes are focused on understanding and creating the basis for comparison of cultural constructs.

An example of narrative analysis is a study by De Fina (2003) on the accounts of Mexican immigrants living in Maryland, in the northeastern USA. De Fina informed participants of her intent to learn about the life experiences of Mexican immigrants, thus employing a biographical approach to collecting data, but did not reveal that her analysis was on the narrative process itself. Key methods for obtaining data include full transcription of interviews for reference and analysis and building trust with the participants by earning a positive reputation among other members of the community (De Fina, 2003). De Fina's study used a "snowballing method" to recruit subjects, in which new participants for the study are recruited based on referrals from other participants (Polit & Beck, 2009). This method allowed for the collection of narrative accounts from an extended family and social circle within one community. De Fina used her personal identity as an immigrant to America and a previous Mexican resident to build trust and understanding (De Fina, 2003). In this regard, the researchers' personal views and cultural identity are intrinsic to the research process. This helps to create a stronger foundation upon which to develop hypotheses and interpret the narrative discourse, but introduces the possibility of personal or cultural bias in analysis of the data. De Fina's exploration also draws heavily on linguistics and how implicit choices in grammatical and narrative construction reflect on the immigrants' orientation within the society (De Fina, 2003).

Experimental and Quasi-Experiment Design

Experimental studies have an intervention (treatment) with an experimental and a control group based on random assignment (Polit & Beck, 2009). Quasi-experimental studies have similar characteristics as experimental studies but lack a control group based on random assignment. Even if a quasi-experimental study has a control group, that is not based on random assignment that limits causal assumption (Polit & Beck, 2009). The benefits of experimental research study designs include the ability to evaluate new medical treatments or interventions and to control for extrinsic factors that may interfere with the ability to examine cause-and-effect relationships of treatments (Loue, 1999). A disadvantage of attempting experimental designs in an immigrant health context is the difficulty in effectively matching a target population with a control group (Loue, 1999). In a health study of a diverse immigrant or migrant group, it may be difficult or even impractical to control most social variables except through policy or allotment of resources. The benefit of choosing a quasi-experimental design in social settings is the ability to compare multiple groups without the need for randomization (Loue, 1999). Applications of this type of quasi-experimental study may focus on program evaluation, evaluating health effects of a performed intervention, or to test hypotheses on the development and spread of a disease within a community.

As an example of quasi-experimental research design, an immigrant settlement policy in Sweden was evaluated in regard to the success of immigrants relative to where they were placed after arrival (Edin, Fredriksson, & Åslund, 2004). In the context of an experimental design, an independent variable, or proposed cause, has an impact on the dependent variable, or proposed effect. In the study from Sweden, the independent experimental variable was the placement of immigrants away from regions where many immigrants already lived, in accordance with a new policy; the control group consisted of the immigrants placed in cities with existing concentrations of immigrant communities (Edin et al., 2004). Because these experimental and control conditions were not assigned based on randomization, the study is classified as quasi-experimental. Over time, the research showed significant losses in employment and earnings potential for those affected by the new policy, and an increase in welfare dependence (Edin et al.). This indicates that the new policy was not an effective intervention in encouraging successful outcomes for the participants. Further study of these immigrant populations may relate to evaluations of healthcare access and utilization by groups in different geographical locations, and further investigation of the factors that contributed to variable economic success for different immigrant groups.

Longitudinal Studies

Longitudinal studies follow groups of participants for an extended period of time. Examples of these types of inquiries are trend studies, cohort studies, panel studies, and follow-up studies. The benefits of longitudinal study designs include the evaluation of trends over time and the ability to follow up with a particular subset of individuals. Potential drawbacks of conducting longitudinal studies with immigrant populations include high attrition rates if participants are lost to follow-up contact attempts, and an investment of resources to collect data at multiple points in time (Polit & Beck, 2009). The benefit of a large-scale longitudinal study in immigrant health research is the ability to see progress and trends of information over a key period in time, such as the first few years after immigrants' arrival. Results can be used for future policy development and to create more successful programs for new immigrants.

One example of a longitudinal study is the Longitudinal Survey of Immigrants to Canada (Statistics Canada, 2004). The Longitudinal Survey of Immigrants to Canada was established in 2000 as a large-scale evaluation of new arrivals and their process of adjustment. Participants were interviewed at set intervals over the course of four years, through face-to-face or telephone interviews, using a standard questionnaire (Statistics Canada, 2004). Nearly 20,000 participants were initially selected for the survey, and data were collected and analyzed by governmental employees. Though the participants were a randomized sample, governmental data on immigrants were limited to those who were legally registered and thus likely missed workers who were in the country without documentation. Follow-up of participants is a concern with longitudinal studies and of particular concern for newly arrived immigrants, who may change addresses and jobs between interviews. This study used access to national registries to trace individuals who changed their location, in order to reduce attrition rates of the original participants (Statistics Canada, 2004). This particular study was large in scope, but other studies may direct their focus on a much smaller group of immigrants. The applications from the data collected can be used for further research on healthcare utilization in the initial months after arrival, and how orientation programs for new immigrants can be improved to address needs revealed in this longitudinal study.

Surveys

Surveys rely on self-report of information by participants to examine trends and relationships within a population, either as a sample survey or census (Polit & Beck, 2009). They are limiting in that they tend to be topical in scope, but have the potential to reach a broad spectrum within a population, such as with a national census. A benefit of obtaining survey data is the ability to determine prevalence, distribution, and relationships of variables among a population, and the potential to evaluate opinions and knowledge across a spectrum of individuals (Polit & Beck, 2009). Potential disadvantages of conducting surveys with immigrant populations include language barriers, cultural misunderstandings relating to questions asked, and intense time commitments if surveys are done in person (Polit & Beck, 2009). For immigrant health research, the need for interpreters for interviews or written translations may affect the choice of data collection methods or the scope of the population targeted.

Some survey collection methods are personal interviews, telephone interviews, mixed-mode methods, or questionnaires (Polit & Beck, 2009). Though postal mail is a simple way to distribute surveys, and e-mail surveys are less costly to create and distribute, return rates are variable for both methods. E-mail surveys are effective when participants have access to the Internet and are computer literate (Kaplowitz, Hadlock, & Levine, 2004). However, computer literacy cannot be assumed when working with diverse groups of immigrants, particularly if groups of persons are coming from less-developed countries. Telephone surveys may not be effective for low-income individuals, possibly including newly arrived immigrants, who may not have telephones (Polit & Beck, 2009). Surveys done with non-English speakers may need to be recorded, translated, or dictated. Some surveys use a mixed-mode strategy, in which multiple methods may be used in an attempt to collect data if one method initially fails, such as for an individual who cannot read a written survey or does not have a telephone for an interview (Polit & Beck, 2009).

The Mexican Migration Project, developed as a partnership between researchers at Princeton University and the University of Guadalajara, utilizes an ethnosurvey method (Durand & Massey, 2004). The ethnosurvey is designed specifically to evaluate experiences of migrants, with attention to multimethod data collection and multisite sampling for the collection of social and demographic data. In addition, the survey includes detailed personal histories, as well as details about all of the participants' experiences with migration between Mexico and the USA (Durand & Massey, 2004). The sampling methods are done with extensive knowledge of how and where particular groups of workers migrate between the USA and Mexico, and these groups are studied over the course of years to generate consistent sources of data on previously undocumented communities (Durand & Massey, 2004). The design of the survey utilizes human migration patterns and sociocultural factors as integral aspects to the survey design. The data from the Mexican Migration Project is used to evaluate use of health resources, to identify migration patterns, and to inform public policy regarding binational migration (Durand & Massey, 2004).

A key survey database that uses survey methods to specifically count foreign-born citizens in the USA is the Current Population Survey, which does not ask participants about their legal status (US Census Bureau, 2009). This survey generates data about the number and distribution of groups of foreign-born residents, as well as evaluating use of welfare funds and work patterns among families across the country.

Population-Level Direct Focus Research Methods

As with the methods outlined in the section above describing individual-level direct focus research, some larger scale studies at the population level also maintain a direct focus with the researcher examining a group, issue, or set of events. Data collection is central, as is the ability of the researcher to analyze and interpret significance from these data. Some methods, like surveys, are easy to administer in small populations but become more labor intensive when applied to a large population. In comparison to the objectives for the study methods involving individual-level studies described above, population-level studies describe more characteristics of an entire ethnic group or subset of a population, and less about personal needs or individual experiences. Larger studies can also be more applicable for purposes of resource allocation as well as evaluations of healthcare accessibility and efficacy. Several studies at the population level, including ethnological and ethnomethodological studies, have a specific focus on ethnicity and cultural identity, and are well suited to research with immigrant groups (Polit & Beck, 2009). These research methods may be useful for gathering demographic data as well as for evaluating immigrant groups compared to a larger population. Types of immigrant health research designs with a direct focus at the population level include surveys, surveillance, participant observation, ethnological design, ethnomethodology and conversation analysis, and comparative effectiveness.

Surveys

As described with individual-level studies, surveys rely on self-report in order to collect information from individuals to represent trends and commonalities. Sample surveys that target smaller subsets or groups of individuals are typically simple to administer and reflect the needs of a subset of the population. A census type of survey attempts to gather information from every individual within a group, and may be conducted at a national population level. Additional benefits of surveys for population-level research include the generation of national statistics and the ability to use collected demographic data to compare with other variables (Green & Thorogood, 2009). Potential disadvantages of conducting surveys with immigrant populations include the potential for exclusion of nonlegal residents from governmental surveys and miscommunication in written or spoken survey formats when working with speakers of other languages (Green & Thorogood, 2009).

One example of population-level direct focus research is the US Census. This survey attempts to count every person living in the USA regardless of legal status. However, it is difficult to ensure that immigrants, migrants, minorities, and non-English speakers are fully represented. According to the National Association of Latino Elected and Appointed Officials (NALEO), undocumented workers and new immigrants are likely to be undercounted in the census or may be unwilling to provide personal data when asked, thus reducing the accuracy of the data (NALEO, 2010). However, there is an increased focus on population-level research methods to include vulnerable persons in national surveys, such as the *Ya Es Hora* ("It's time") campaign to increase mail response to the US Census among Latino communities across the country (NALEO, 2010). Methods to increase participation include media promotion of the benefits of participation, such as allocation of funding to Latino communities so that communities desire to participate (NALEO, 2010). The campaign also promotes participation in surveys by building partnerships between community organizations and Latino media outlets, including Spanish-language television networks. Much of the effort in growing Latino communities, particularly for migrant workers and those newly arrived to the USA, is to provide assurance that there will be no negative ramifications to the person or their family with participation in the census, and that the information will not be used to inform immigration officials about the presence of undocumented workers (NALEO, 2010).

Once data have been collected through a census survey, the data can be used for evaluation and analysis of health trends, particularly between minority and majority groups within the entire population. A study by Oza-Frank and Narayan (2010) used national survey data to evaluate the potential for diabetes prevention programs within different ethnic immigrant groups in the USA. Several populous immigrant groups in the USA were compared in regards to body-mass index and prevalence of diabetes (Oza-Frank & Narayan, 2010). This study required access to a large sample size of nearly 35,000 individuals, which included both immigrants and nonimmigrant control groups. The respondents were surveyed through the National Health Interview Survey, which utilizes data from the US Census. The analysis of survey data showed that immigrants from the Indian subcontinent were more likely to have diabetes than European immigrants regardless of whether they were overweight. In contrast, immigrants from Central America, Mexico, and the Caribbean were more likely to have diabetes as well as be overweight, when compared to European immigrants (Oza-Frank & Narayan, 2010).

Surveillance

Another common tool used in public health research is *surveillance*, in which departments of health or other organizations collect and analyze outcome-specific data continuously. This may include mandated reporting of information on diseases, prevalence of disease within a region, or the utilization of prevention programs. Surveillance methods do not incorporate interventions to improve conditions, but rather monitor and evaluate compilations of data at a population level (CDC, 2010). Passive surveillance methods use data already collected by public health offices, whereas active surveillance methods reach out to community members for evaluation of events such as disease outbreaks. Sentinel surveillance samples a part of the larger population. Special systems surveillance methods are for evaluation of population trends that cannot be monitored by other methods (CDC, 2010).

Benefits of utilizing surveillance tools in research include evaluating disease and wellness trends in subset of the population, by geography, or by other demographic characteristics. Within immigrant populations, surveillance data can be useful for examining the spread of disease and identifying population groups that may be in need of health interventions. Potential disadvantages of utilizing surveillance tools with immigrant populations include limitations of available data for nonlegal residents of a country and a topical focus on health issues. The collected data can be used to improve education about health resources, or may be used for future studies to evaluate community strengths that may contribute to favorable health outcomes among these groups of immigrants. Smaller scale surveillance designs may be used by local public health departments, such as to monitor use of health resources, disease reports, and emergency room visits among newly arrived immigrants.

A Canadian surveillance program used two decades of comprehensive data from national databases to evaluate health resource utilization by immigrants as well as mortality rates (DesMeules et al., 2004). The study found that immigrant populations had a favorably low mortality rate compared to the national rates for most causes of death, with the exception of infectious and parasitic diseases. Surveillance data also showed sharp increases in health utilization resources approximately 3 months after immigrants arrived in Canada (DesMeules et al., 2004). This knowledge can be particularly useful to healthcare providers working with immigrant populations to identify strengths within the patient population, and to be aware of highly prevalent diseases.

Participant Observation

Participant observation involves the researcher's immersion in the culture or group being studied, and his or her development of a role within the order or structure of the group itself. Participant observation is generally unstructured and time-intensive, with the intent of the researcher to observe firsthand how people exist and interact in their natural environment. Though the researcher is engaged in the social group, there is no attempt to perform any interventions (Green & Thorogood, 2009). Participant observation is based on study frameworks pioneered in the early twentieth century, focusing on urban sociology. Benefits of utilizing participant observation include a deeper understanding of cultures, evaluations of cultural norms, and the ability for a researcher to approach an "insider's" perspective (Polit & Beck, 2009). Potential disadvantages of utilizing participant observation with immigrant populations include the potential for observer bias, emotional involvement that reduces objectivity, and influence of the observer on their surroundings (Polit & Beck, 2009). Ethnographical research often uses the same methods as a participant observation study, but ethnography studies also focus on the interplay of the gathered observations and theoretical constructs as part of the analytical process.

A foundational study of participant observation methods in immigrant research, Thomas and Znaniecki's *The Polish Peasant in Europe and America*, was first published in 1918 during a period of mass immigration of Eastern Europeans to the USA (Bulmer, 1984). The book utilized personal documents, data, and theoretical constructs about culture and sociology to create a more holistic portrait of the immigrant experience, as well as set the foundations for empirical research about immigrants (Bulmer, 1984). The style of research from this early study integrated the roles of Thomas, an American, and Znaniecki, a Polish national, as researchers, both participating in participatory observational research on immigrants. They also incorporated evaluations of migration patterns in the USA and Poland (Bulmer, 1984). Observational research was conducted on two continents over the course of two decades with significant funding from private donors (Bulmer, 1984). From such foundational methods in immigrant research, in which theories were developed from observations of immigrant social groups, the researchers involved with this study developed urban sociology constructs that encouraged subsequent research and exploration of vulnerable communities.

Ethnological Inquiry

Ethnological inquiry is used to compare and contrast cultures, particularly in regards to language, origins, social structure, and characteristics. It is an anthropological construct and allows one to make conjectures about different cultures. It is linked to ethnography, which focuses on interpretations of human behaviors in cultural groups (Polit & Beck, 2009). Additional benefits of ethnological inquiry in population-level research include the ability to examine similarities and differences between diverse subsets within a population, and an examination of behaviors that have an effect on health and disease (Polit & Beck, 2009). Potential disadvantages of ethnological inquiry with immigrant populations include a researcher's potential inability to separate his or her own cultural biases in order to create a balanced interpretation (Polit & Beck, 2009).

An example of a use of this type of approach is an Australian ethnological project, the Mothers in a New Country Study (Small, Rice, Yelland, & Lumley, 1999). This study explores views of maternity within three immigrant groups: Turkish, Vietnamese, and Filipino. When dealing with non-English speaking immigrant communities, research considerations include effective sampling, recruitment, retention, and representativeness (Small et al., 1999). The study found that investing in the training and support of the interviewers to increase cultural awareness and sensitivity yielded a more successful process and greater confidence in the study by participants (Small et al.). As ethnology focuses on comparison of different cultures, all of the bicultural interpreters needed assurance of equal training and support in order to improve success within the study and allow for effective comparison between groups. In this respect, the ethnic and cultural identities of the research assistants were incorporated into the evaluation of the efficacy of data collection methods and validity (Small et al.). This increased cultural competence for the research interpreters, and was an effective method to increase the success of data collection.

Ethnomethodology

Another type of inquiry focused on cultural identity, *ethnomethodology*, is the study of methods that individuals use to communicate and make rational decisions within their cultural group, and how individuals comprehend social relationships (Green & Thorogood, 2009). The researcher is aware of methods employed through his or her observation of the study participants, even though the individuals being researched may not be aware of the process. This raises potential ethical concerns due to the power imbalance and level of cultural awareness that may develop between researcher and participants, and ethical safeguards protecting participants of ethnomethodological studies should be established. This theory is often used in sociology and developed from a phenomenological viewpoint. Phenomenology focuses on how humans describe and interpret experiences through the experience of being conscious in the world (Green & Thorogood, 2009).

Within ethnomethodology, two key concepts are indexicality and reflexivity. Indexicality is the assumption that the meaning of words and language relies on the social context in which they are employed (Garfinkel, 1967). Reflexivity is the assumption that researchers, observers, and participants bring their own identity into the social situation, and cannot be separated from the social relationship, regardless of their role in the study (Garfinkel, 1967). In regards to indexicality, ethnomethodological studies should be considered as they happen in a natural environment, with context playing a role in analysis along with the content of what is said. Reflexivity, which is a component of many other types of studies, allows the researcher to actively analyze how his or her own views and human presence may affect data content or the data collection process.

Additional benefits of using ethnomethodology for population-level research include increased comprehension of complex social interactions and an ability to evaluate interpersonal communication within healthcare settings (Green & Thorogood, 2009). Potential disadvantages of using ethnomethodology with immigrant populations include an overt focus on small interactions without attention to greater social structures (Green & Thorogood, 2009). This type of approach within immigrant health research could be used to evaluate how providers interact and communicate in their office with members of an immigrant group who are not English speakers.

A variant of ethnomethodology is *conversation analysis*, in which recorded and transcribed conversations form the data source for processing and evaluation (Polit & Beck, 2009). Benefits of using conversation analysis for population-level research include the ability to evaluate discourse between patients and providers within healthcare settings, and the potential to observe modes of therapeutic and nontherapeutic communication in real settings (Green & Thorogood, 2009). Potential disadvantages of using this technique in immigrant health research include the potential for misinterpretation or altered translations when working with speakers of other languages (Green & Thorogood, 2009). Conversation analysis can be used for evaluation of public opinion within the context of immigration policies, such as in an Australian study of the discourse used by lawmakers. The study evaluated the effects and ramifications of using terms such as “illegals” when referring to asylum seekers, and other language constructs that portray migrants negatively (Every & Augoustinos, 2007). In regards to these findings, other countries may also choose to consider how the language used affects laws and policies relating to immigration, as well as impacting public support or nonsupport for issues.

Comparative Effectiveness

Comparative effectiveness studies examine different treatments or interventions in regards to their advantages and successful outcomes. Through this research, costs and benefits, or benefits and risks, may be weighed in order to educate providers about when and how to recommend particular treatments. It can also be used to incorporate research into practice (AHRQ, 2010). Advantages for utilizing this type of research include the ability to develop guidelines for providers and for determining cost-effective methods of healthcare funding distribution. Applications for use in immigrant healthcare research may include efficacy of preventive and maintenance treatment of diseases for newly arrived immigrants and cost-effective views of insurance coverage for temporary or migrant workers. In the USA, the National Institutes of Health, Agency for Healthcare Research and Quality, and other major governmental agencies consistently utilize this method to evaluate costs and benefits of medical interventions, new treatments, and health assistance programs such as Medicare and Medicaid (ECRI Institute, 2009). Comparative effectiveness can be useful to dispel myths about how medical funds are used, and in particular can shed light on resources used by immigrants compared with permanent residents.

Current attention to comparative effectiveness in the USA addresses costs and benefits of the potential federal healthcare plan, and how it will affect those who are privately insured, those who are uninsured, and those who are currently covered through government programs. A study in 2005 analyzed data from both the Medical Expenditure Panel Survey and the National Health Interview Survey to compare health costs incurred by immigrants and nonimmigrants (Mohanty et al., 2005). The study found that immigrants who were on public assistance or were uninsured utilized half as many federal dollars in health care as US-born residents with the same insurance status (AHRQ, 2010). In addition, immigrants had 55% lower healthcare expenditures than nonimmigrants, despite public opinion surveys that indicated a majority of people believed immigrants to utilize more public healthcare funds than nonimmigrants (AHRQ, 2010). The assessment of health outcomes in immigrant populations as well as the implications of providing healthcare access to legal and illegal immigrants is another issue to be addressed through comparative effectiveness research (AHRQ, 2010).

Participant-Driven Research Methodologies

In comparison to the methods outlined in the sections above describing individual-level and population-level direct focus research, which focus directly on populations and issues, methods outlined in the following section emphasize collaboration between the researchers and participants in the planning of the research process as well as the generation of data and interventions (Polit & Beck, 2004). In these research designs, the goal of the researcher is to act as a facilitator in order to generate response and analysis from a community. For immigrant groups that occupy a unique role within the dominant society, this method can be highly appropriate for assessing health needs and self-reflexively seeking solutions to health disparities. Drawbacks to these participant-driven methods include a decreased ability to produce results on a set timeframe, as well as the risk of participant inaction or incompletion of the project. These types of participatory methods are particularly useful for interdisciplinary studies, for building community programs, and for building relationships between healthcare providers and healthcare researchers (Green & Thorogood, 2009). These participant-driven methods include needs assessments and participatory action research.

Needs Assessment

Needs assessments evaluate the necessity for a particular type of intervention or program within a community (Polit & Beck, 2009). Needs assessments are central to public health evaluations within a community and are often done in the form of surveys. Another method is a key informant approach, in which specific individuals are targeted to illuminate the needs of the community. An indicators approach uses records and statistics to make an assessment (Polit & Beck, 2009). Needs assessment reports may be self-contained, in which the assessment is the only outcome. They may be the first step in a more comprehensive research study such as a participatory action model. Assessments may also be intended for education within a community. However, the most important reason for conducting a needs assessment is for prioritization of needs, so that recommendations for action can be developed and implemented (Polit & Beck, 2009). Additional outcomes of needs assessments are to be used in funding proposals or secondary research. Additional benefits of conducting needs assessments on a population include evaluating the needs of groups that may be powerless or suffer from negative health disparities (Polit & Beck, 2009). Potential disadvantages of conducting assessment surveys with immigrant populations are that the assessments methods alone do not confer action for change.

There are a variety of methods that can be used for needs assessments, including observations, interviews, focus groups, community forums, oral surveys, questionnaires, analyzes of existing data, and community resource inventories (Minnesota DOH, 2010). Other types of needs assessments include the PRECEDE–PROCEED model. PRECEDE (Predisposing, Reinforcing, and Enabling Constructs in Educational/Environmental Diagnosis and Evaluation) is an acronym to represent the assessment phase. PROCEED (Policy, Regulatory, and Organizational Constructs in Educational and Environmental Development) represents the developmental and implementation stages, and may manifest as action research or secondary analysis (Li et al., 2009). By first conducting an assessment, any subsequent interventions using this knowledge will be grounded in evidence about what a community needs most. A needs assessment using this model seeks to identify health issues, behavioral and environmental influences, and community resources for health promotion (Li et al., 2009).

Participatory Action Research

Participatory action is a voice-centered relational method in which researcher and participant act together during all stages. The voices of the participants are central to the development and outcome of the project. The collaborative relationship between the researchers and participants is needed for the development and revision of methods and goals, which may be revised as new perspectives arise. This method is designed for groups that may be subject to control or discrimination by another culture or group (Polit & Beck, 2009). It was developed from action research. Action research was developed in the 1940s as a research method intended to enable change and improve stakeholder practices within the community – rather than have the researcher passively observe or act as a detached bystander (Green & Thorogood, 2009). Participatory action research is more of an approach than a specific type of research methodology, in that it may be framed within qualitative, quantitative, or mixed-methods designs (Khanlou & Peter, 2005). As such, methodological issues and ethical considerations may look different with a participatory action design than in other types of studies. It may be difficult to ascertain approval for the use of human subjects in a standard ethical board review, as the subjects are truly coinvestigators (Khanlou & Peter, 2005). Investigators may also need to focus on a risk-benefit ratio during the planning stages of study, considering that action research with vulnerable populations may create situations of community unrest and real or perceived danger to participants within their communities (Khanlou & Peter, 2005).

Participatory action is well-tailored to address health concerns within immigrant populations that are oppressed by dominant cultures and likely to suffer negatively from health disparities (Khanlou & Peter, 2005). Furthermore, participatory action research encourages a relationship of balance in power and knowledge between the investigators and participants, thus helping to facilitate empowerment and equality (Polit & Beck, 2009). This approach entails four components: participation, the attainment of knowledge, empowerment, and social change.

Through the process of participation, the community members are conducting the research, since they are the ones capable of engendering social change to reduce inequities (Baum, MacDougall, & Smith, 2006). Potential disadvantages of conducting participatory action projects with immigrant groups include limited generalizability between settings and less attention to the development of theoretical knowledge through this research process (Green & Thorogood, 2009).

Reciprocity, also referred to as reciprocal exposure, is an aspect of research that concerns the exchange between the investigators and participants (Harrison, MacGibbon, & Morton, 2001) and is a factor to consider when conducting participatory action research. It also implies the right of the participants to question researchers as an intrinsic component of the research process (Maiter, Simich, Jacobson, & Wise, 2008). This may be especially pertinent in ethno-studies in which the researcher is immersed in a different cultural group, or when participant action is the focus of the discovery process. As an issue of ethics, the process of reciprocal exposure and power sharing in community-based participatory action research is a necessary component (Maiter et al., 2008). An additional benefit of reciprocal exposure includes input about costs and gains for both participants and researchers (Maiter et al.). Potential disadvantages of reciprocal exposure with immigrant populations include investigator maintenance of the role of facilitator while simultaneously maintaining a power-sharing dynamic with participants (Maiter et al.). An example of this approach is provided by an investigation in Canada that was designed to improve the success of participatory action methods among immigrant groups. The investigators focused on improving access to mental health resources among several immigrant communities. The goal was to link community members to existing services and empowering them to promote access to groups and individuals in need within their cultural communities (van der Velde, Williamson, & Ogilvie, 2009).

Participants defined themselves into five ethnocultural groups, which included Chinese, Somali, Southeast Asian, Spanish-speaking, and Vietnamese. Focus group interviews were conducted, with questions relating to perceptions of mental health issues and access to community-based mental health programs. These focus group sessions were transcribed and recorded, and used for thematic analysis. Strong initial participation and maintaining activity by members in the focus groups was a key intervention in the success of the study, as the other components of participatory action research flow from this foundation (van der Velde et al., 2009). An analysis of program efficacy found that a multiethnic approach for developing programs was effective, but the reasons that many individuals chose to participate and continue with the health projects were culturally unique (van der Velde et al.). Reasons for participating included a desire to support community members, to influence healthcare policy, and to learn about health resources in the community. For other immigrant groups involved in participatory action research, an increased understanding of the cultural reasons for participation may increase retention and involvement.

Collective Consciousness Research Methodologies

More theoretical products of health research include the knowledge derived from interpretations of human experiences and the processes by which a group's identity is formed and described (Green & Thorogood, 2009). From these interpretations, theories can be developed about collective consciousness, which implies commonalities that exist in experiences across diverse groups of individuals. The goals of these methods are not to only observe and record, but to understand generalities about experiences particular to the groups being observed. The emphasis of collective consciousness or group identity research is on how the researchers' interpretations of data build on other theories and insights. Examples of research with an emphasis on collective consciousness include grounded theory, phenomenology, and ethnography.

Collective consciousness research designs will be effective in addressing particular study aims, but anticipating the uses and applications for the study will help to determine whether it is an appropriate methodology. For example, if a researcher wanted to collect incidence and prevalence rates of HIV infection in a particular immigrant group, utilizing surveillance data and health records would be an appropriate method for research, but a study of group identity would not be appropriate. If the goal was to understand the experiences of a few individuals with the disease, a case study method with a direct focus on a small group may be used. If the goal was to interpret the meaning of how humans experience the disease, a mode of study such as phenomenology may be most appropriate.

Though the particular data and demographic representation of certain immigrant groups may be vastly different, an evaluation that utilizes a collective consciousness approach emphasizes similarities. The drawbacks to these types of studies are they may be time-intensive, and the results may not be considered to be as useful for cost-benefit analysis or other issues that use outcomes of research for allocation of funding (Green & Thorogood, 2009). However, ethnography and related studies have tangible applications to health research and public health improvement, and are used in government-funded studies in the USA. The US Government Accountability Office (GAO) describes the value of ethnographic studies for the allocation of federal funding, particularly in regards to immigrants and vulnerable populations. The US Census Bureau has used ethnography to uncover why minority subgroups are underrepresented in the national count, and is applying that knowledge to the 2010 count, to increase success (GAO, 2003). The Center for Disease Control and Prevention also applied ethnographic methods in outbreak studies of sexually transmitted diseases, with a focus on the factors that spread disease within communities (GAO, 2003). Research that utilizes theories of collective consciousness produces data that are more subjective, and may seem less tangible in regards to healthcare knowledge or interventions. But, it can create bridges between diverse groups relating to health in vulnerable communities in order to identify similar experiences and needs.

Grounded Theory

Grounded theory focuses on describing social processes that form an essence of a phenomenon or an aspect of human consciousness (Polit & Beck, 2009). Using an inductive process, in which data are gathered through observation, researchers develop theories about behaviors (Green & Thorogood, 2009). The data are initially collected and analyzed, and theories are developed from these data. The theories are tested with newly collected data and continually evaluated in a cyclical fashion until a point of "saturation," when no new interpretations arise from the data (Green & Thorogood, 2009). Additional benefits of grounded theory in immigrant health research include the development of deeply analyzed theories about human experiences through systematic methods (Green & Thorogood, 2009) Potential disadvantages of using grounded theory with immigrant populations include time constraints, as grounded theory is often a time-intensive pursuit, and difficulty predicting when the saturation point will be reached, if at all (Green & Thorogood, 2009).

A study on depression in Vietnamese Americans used a grounded theory approach to discover and interpret trends and commonalities among the experiences of individuals in a shared cultural group (Fancher, Ton, Le Meyer, Ho, & Paterniti, 2010). Common themes of depression were explored within an ethnic group in order to develop culturally appropriate strategies to be used by healthcare providers. Methods particular to this study included employing a native Vietnamese speaker as an interviewer who was trained by mental health professionals for this project. Sampling was completed with a nonrandom snowballing method in which each participant referred potential new participants through their own social contacts. The researchers conducted semi-structured interviews, which followed a guide on the topic being addressed, but did not follow a set script. All interviews were transcribed, and coded, which is a system for categorization in which recurring themes were identified and noted where they occurred in each transcript (Green & Thorogood, 2009). Four common themes were identified from the participants' discussions of depression: the stigma of mental illness, the role of family, views on medications and traditional healing, and issues of culture and language (Fancher et al., 2010). By utilizing the grounded theory approach, the investigators began the research study with knowledge of the nature of the issue, but used the observation process to inform the development of the research process.

Phenomenology

A framework related to grounded theory, phenomenology, uses a similar foundation and research structure to uncover the meaning of human experiences. *Phenomenology* seeks to describe the essence of human experiences and ascribe essential meaning to these experiences (Polit & Beck, 2009). Phenomenological studies are often based on interviews and personal accounts. Methods in a phenomenological study are similar to grounded theory, including the use of personal, semi-structured interviews, and the employment of interpreters as needed when working with diverse cultural groups. Benefits of phenomenology research include the ability to develop a greater understanding of how unique human experiences can be described and interpreted, and attention to concepts of human experience that are not well understood. This approach is well-suited to use in nursing practice. Potential disadvantages of conducting phenomenology research with immigrant populations include the time-intensive nature of interviews and data collection, the need for the researcher to have deep knowledge about the participants' culture and social constructs, and limited generalizability to other groups.

A phenomenological investigation of experiences with depression among Nigerian-born female immigrants to the USA found that the women were unable to distinguish depression from other mental illnesses (Ezeobele, Malecha, Landrum, & Symes, 2009). Furthermore, the essence of the experiences with depression was linked to perceptions of "craziness" or "curses by spirits," with clergy being the preferred care providers for depressive symptoms rather than healthcare providers. Other essential themes surrounding depression related to social isolation, rejection by family members, and relationship problems (Ezeobele et al., 2009). Data for this study were coded and analyzed through stepwise guidelines for phenomenological inquiry, which helped the investigators identify these themes (Ezeobele et al., 2009).

Descriptive phenomenology focuses on the meaning of the experience itself, as was the case in the study with Nigerian-born women and depression, mentioned above. Researchers using this format may follow a sequence of bracketing (examining one's own biases), intuiting, analyzing, and describing, in order to uncover essential meaning (Polit & Beck, 2009). Another variation, *interpretative* phenomenology, based on the philosophical views of Heidegger, is focused on why and how these experiences are understood. Components of lived experience can be divided into themes of spatiality, corporeality, temporality, and relationality, and how individuals' worldview relate to their own relationship with these themes throughout their life (Polit & Beck, 2009). A study with elderly Iranian immigrants in Sweden used an interpretative phenomenological framework to examine perceptions of mental health and wellness in a vulnerable subset of an immigrant population (Emami, Benner, Lipson, & Ekman, 2000). Interviews were not structured, but participants were guided to talk about their impressions of health, illness, and disease. Data analysis included recordings and transcriptions of the interviews, and the interviews were analyzed in their entirety as well as in parts for comparison. Key themes generated by the interviews were evaluated through thematic analysis, and compared with the original interviews. Themes uncovered in this interpretative phenomenological study revolved around the role of social functioning for health, the concept of health and wellness as continuity within one's life, and illness as a type of disruption to that continuity (Emami et al., 2000). Goals with such a study were to build understanding about human experiences within this community, and allow care providers insight for more therapeutic interactions.

Ethnographical Inquiry and Symbolic Interaction

Ethnographical inquiry is a holistic method based on detailed observations derived from immersion or participation in cultural group studied over a period of time (Polit & Beck, 2009). Ethnographical inquiry is commonly used in anthropology, and can be highly relevant to studies of immigrant health. The relationship between researcher and researched group becomes intertwined over time, which places greater responsibility on the researcher to truly understand and respect the immigrant culture being studied. The outcome of research is generally through written text by the researcher, with an emphasis on what can be learned from the relationships of behaviors within the group (Loue, 1999).

Ethnographies may be viewed at the macro level, to examine large populations groups, or at the micro level, to examine a small community or group of individuals. Ethnography is different from an observational study because of the emphasis on understanding both the emic and etic perspectives of the society. An *emic* perspective represents the members' view, and represents how an "insider" describes their social environment. An *etic* perspective represents the view of the observer, or the one doing the analysis (Green & Thorogood, 2009). In ethnography, the interrelationship between the emic and etic viewpoints drives the creation of theory about the culture and how humans understand their world (Green & Thorogood, 2009). Additional benefits of ethnographies include their holistic approach and diversity in techniques for data collection. Potential disadvantages of conducting ethnographies with immigrant populations include the time-intensive nature, and how the role of an observer affects the culture being studied.

A type of study related to ethnography and undertaken from a sociological perspective is *symbolic interaction*. Symbolic interaction assumes that behavior of individuals is a result of human relationships and experiences with one another (Polit & Beck, 2009). Behavior is thus understood only within the context of the community or cultural group. The meaning of social symbols, which includes language, signs that carry information, and objects, are based on the process of interpretation by each individual within their social world (Polit & Beck, 2009). Benefits of symbolic interaction include an increased understanding of how individuals interpret social cues, such as language (Polit & Beck, 2009). Disadvantages of using symbolic interaction with immigrant groups are the potential for misinterpretation if the analysts are working with a culture outside of their own, and the potential for observer bias.

In an exploration of the perceptions of health of adolescent immigrants from Mexico, both ethnography and symbolic interaction frameworks were used to form the structure of the inquiry (Garcia & Saewyc, 2007). Specific methodological techniques in working with this population included waiving written consent by the students or their parents, owing to the possibility that families might not have had legal status to reside in the USA and would be afraid to sign their name for the study process. The Institutional Review Board accepted oral assent from students. Students also chose an alias for the study to further preserve confidentiality (Garcia & Saewyc, 2007). The methods included an initial, guided interview about the adolescents' views on health and access to services in the USA; these initial interviews were followed by both participant photo journaling of their views of health and follow-up interviews (Garcia & Saewyc, 2007). The analysts were actively immersed in the cultural setting, an American high school, for a period of time. Other techniques used for data collection in the study included participant observation, journaling, and field notes.

In the analytic phase of the study, the theories of symbolic interaction influenced how the data were interpreted. The investigators showed through their interpretation how the students' worldviews were inextricably tied to their cultural and ethnic identities. This relationship affected their perceptions of health, as evidenced by the ethnographical analysis and interpretation of data in a symbolic interaction framework.

Distant/Secondary Focus Research Methodologies

A final set of methods takes a more distant perspective, with the researcher using a theoretical approach to research, examining a large set of studies, or using a retrospective approach to examine or reinterpret studies over time. Meta-interpretative studies imply a secondary analysis of existing studies. Other studies with a distant focus seek to describe correlational relationships between factors, such as potential risk factors in the development of a disease. Research studies identified in this section include concept analysis, correlational studies, historical analysis, feminist studies, mixed-methods, and metasynthesis.

Concept Analysis

Concept analysis is an examination of the characteristics associated with a particular set of phenomena. Concept analysis is useful for deeper understanding of abstract terms that may be commonly used but poorly understood, or for exploration of lesser-known, concepts (Polit & Beck, 2009). Examples of concepts that may be analyzed in health research include stress, caring, or health literacy. If concepts are the "building blocks" for the development of theory (Polit & Beck, 2009), then an analysis of these building blocks addresses the foundation upon which all other research is built. Within the field of health care, benefits of applications from concept analysis may include the development of culturally sensitive models of care and the development of new tools for screening or evaluation (Polit & Beck, 2009). It may encourage the development of new theories or challenge existing theories of a concept. A disadvantage of using concept analysis in immigrant health research is the difficulty of translating findings into practice (Polit & Beck, 2009). Concept analysis studies are generally analytical and exploratory, and may share data collection methods with that of a literature review.

Choi (2001) used the conceptual analysis method to explore the idea of "cultural marginality" in an adolescent immigrant population. Using a framework for analysis developed by Walker and Avant (1995), the study examined a specific concept and its attributes, antecedents, and consequences within a particular population. Choi first established the significance of specialized care of this group. The concept "cultural marginality" was defined by the author, with an exploration of the historical development and related terminology, as well as a literature review relating to the concept. Four attributes, or characteristics, were identified from their repeated mention in the relevant literature. Antecedents, which are necessary factors in the development of cultural marginality, included the immersion of an individual in two distinct cultures. Consequences, which are expected outcomes from one's experience with cultural marginality, were identified as the successful and unsuccessful modes of negotiation between cultures (Choi, 2001). Applications from this study include a greater understanding of cultural marginality for care providers of immigrant adolescents, so that they can provide more sensitive care.

Correlational Studies

Correlational research focuses on the relationship between variables, such as potential risk factors in the development of a disease. Unlike experimental designs, the independent variable is not controlled, and no interventions are performed through this type of analysis. These studies are also called *ex post facto* ("after the fact"), as they may use data already collected from existing studies (Polit & Beck, 2009). Correlational studies can be beneficial for finding previously unknown or unstudied relationships, or for strengthening existing theories. Some correlational studies use a cross-sectional method to look at particular variables as they relate to one another at a moment in time. Other studies use a longitudinal approach to view data over a period of time (Polit & Beck, 2009). Benefits to this type of study include the ability to illuminate previously unknown relationships and to develop hypotheses. Disadvantages to its use in immigrant health research include the inability to establish causality between variables and the potential for misinterpretation of relationships.

A systematic review of research on breast cancer used a correlational model to examine possible disease risk factors and protective characteristics across diverse immigrant populations (Andreeva, Unger, & Pentz, 2007). A systematic review method was chosen in order to examine a wide scope of knowledge and research and seek potential commonalities in groups that differed in age, ethnicity, and culture (Andreeva et al., 2007). In addition, the study was designed to challenge an existing theory on migration and disease, the acculturation-based risk transition model. The research encompassed 79 different studies on breast cancer that spanned a period of 35 years; this permitted an examination of historical trends and relationships in research on the disease. For this study, an extensive collection of data sources was used, particularly cancer registries, public health surveillance databases, and catalogues of academic literature. Inclusion and exclusion criteria were established. The data analysis phase focused on identifying modifiable factors exhibited by women in the pre-migration and post-migration phases and creating a model that can be used for interventions. By using a correlational framework for evaluation, the researchers were able to evaluate a range of contributing risk factors and develop a new model that included the diverse interplay of these factors, without attributing causality to any of them. This model was suggested for use in interventions among Eastern European Jewish immigrants, who have the highest breast cancer prevalence rates in the world (Andreeva et al., 2007).

Historical Analysis

Historical analysis studies are to describe, analyze, and interpret past events. The goal in historical studies is accuracy and impartial interpretation of events as they relate to the research topic, such as the role of illness and physical health in a societal history (Green & Thorogood, 2009). Historical research may depend on documents or recorded accounts of those who were alive during the time period of interest. Documents that are publicly available may be easier to procure than those held privately and can also reduce the amount of resources needed to collect data (Green & Thorogood, 2009). Benefits of a historical analysis include the ability to examine how immigrant groups have moved and adjusted to events over time and how health indicators or conditions have changed. Disadvantages to using historical analysis approaches in immigrant health research include potential limitations of sufficient documentation and the inability to control how past data were collected (Green & Thorogood, 2009).

Feminist Studies

Feminist research uses gender as a tool to examine social processes, knowledge, and power, with emphasis on experiences of women within a male-dominated societal hierarchy. An assumption within feminist theory is that knowledge generated from a male-dominated societal sphere is not objective, and therefore only reflects a masculine worldview (Green & Thorogood, 2009). Specific categories may include feminist empiricism, feminist standpoint research, and feminist postmodernism. Each different approach of feminist research will generate different aims and research questions (Green & Thorogood, 2009). Advantages of using feminist approaches include the ability to examine why marginalized groups of persons, such as women within an already-marginalized ethnic group, do not access health services, or why their needs are not as well addressed. Disadvantages in using this approach in immigrant health research include an intense focus on gender and assumptions about the differences in human experiences by men and women.

A feminist study about immigrant women in Canada evaluated how women tell their stories, particularly focusing on their work, health, and perceptions of identity as female immigrants. By using a feminist approach, the researchers evaluated how sociopolitical forces affected each woman's experiences as well as her telling of the experiences (Dyck & McLaren, 2004). An initial stage of this study consisted of focus groups with educators and community leaders, where impressions of immigrants and immigration issues were discussed. Seventeen women, all immigrants to Canada in the past 5 years, were recruited by the community leaders and interviewed in English or through a translator (Dyck & McLaren, 2004). Though the topics of the interviews were set forth as femininity and family, and how they are affected by immigration, the women directed the discussions. They often focused on economic pressures, inability to find work, and the negative effects of immigration on their personal health (Dyck & McLaren, 2004). All interviews were recorded and transcribed and evaluated along with the researchers' field notes (Dyck & McLaren, 2004). How the women felt they are perceived as immigrants, as well as the socioeconomic pressures they encounter, affected their ability to find work, take control of their health, and succeed in their new surroundings. The researchers described how feminism reframing may not just be beneficial, but also necessary in order to improve research and provide more accurate social representations of female immigrants (Dyck & McLaren, 2004).

Mixed Methods

Mixed-methods studies integrate qualitative and quantitative methods of data collection and analysis. A component design keeps the qualitative and quantitative parts separate for the purpose of data collection and analysis (Polit & Beck, 2009). These types of designs may be used to address one research question build on the results of the other design type, or address separate questions (Polit & Beck, 2009). An integrated design uses both qualitative and quantitative aspects throughout the entire process (Polit & Beck, 2009). These designs blend the qualitative and quantitative data sources throughout the research process, and are more useful for developing and testing theories than component designs (Polit & Beck, 2009). Benefits of utilizing mixed-methods designs include the ability to use nearly any combination of research methodologies and to evaluate multiple within the same study. A disadvantage to mixed-method designs in immigrant health research is that some health issues in research are only suited to either qualitative or qualitative inquiry (Polit & Beck, 2009).

An evaluation of acculturation and food acquisition among Somali refugees to the USA used a mixed-methods approach in order to examine five interrelated hypotheses. The study focused on the effects of food and diet, the geography of where refugees were placed, economics, and access to food stamps on immigrants' dietary choices (Patil et al., 2009). The methodology for this study included data analysis, surveys, and interviews of refugees and caseworkers. The mixed-method approach did not permit the identification of causal links between these factors, dietary changes and poor health outcomes, but did permit the description of many facets of the complex issues surrounding diet, nutrition, and food acquisition in refugee populations (Patil, Hadley, & Nahayo, 2009).

Another mixed-methods study of African refugees incorporated multiple data collection strategies to enhance a community-based participatory action program. The researchers focused on female genital cutting within particular ethnic communities in the USA (Johnson, Ali, & Shipp, 2009). Methods for this study included surveys, interviews of individuals from the refugee community as well as healthcare providers, and focus groups. Through the use of a community-based participatory action design, the investigators were able to engage community members throughout the research process. Participatory action was a particularly important methodological approach to use in this situation since the practice being investigated was not commonly seen among nonimmigrant populations in the USA. An intended application from this research approach was to increase the development and utilization of culturally competent care within this population (Johnson et al., 2009).

Metasynthesis

Metasynthesis is a secondary analysis of a comprehensive group of existing studies from which new theories and interpretations can be developed (Polit & Beck, 2009). Rather than a summary, *meta*-studies seek to develop new theories and interpretations about a collection of separate but linked inquiries (Polit & Beck, 2009). For example, meta-ethnographical studies are used to synthesize conclusions from a range of ethnographical studies, using interpretation of existing data rather than newly collected observations. Considerations for metasynthesis designs include the determination and application of inclusion criteria, publication bias, and an emphasis on the quality, rather than the quantity, of studies to be included. Advantages to utilizing metasynthesis include the ability to integrate studies and knowledge from multiple disciplines and the ability to use the findings as the basis of evidence-based practice. Disadvantages include the potential lack of depth in interpretations and overgeneralization (Polit & Beck, 2009).

Researchers conducting a metasynthesis of studies relating to Asian immigrant nurses working in Western countries used a metasynthesis approach in an effort to improve clinical and communication practices, build on nursing knowledge, and develop policy (Xu, 2007). Studies were collected from an extensive literature search of qualitative research, and inclusion criteria were established. The researchers identified four themes relating to the experiences of Asian immigrant nurses: communication as a barrier, clinical practice differentials, discrimination, and differences in culture (Xu, 2007). The process of gathering and interpreting multiple existing data sources both facilitated the development of theories and thematic conclusions and broadened relevant knowledge beyond what would have been possible through a literature review (Xu, 2008).

Conclusions

A wide array of research methodologies are available to assist investigators in the study of immigrant health. The roles of language translation, cross-cultural boundaries, as well as legal and ethical protections must be carefully considered in research study design and implementation. Of equal significance is the consideration of the relationship between the researcher, research participants, and immigrant community being studied. Selection of the most appropriate methodological approach to studying issues of immigrant health increases the scientific validity of the research findings. Careful attention to methodological issues further ensures the investigator's ethical responsibility to accurately represent the research participants and cultures being studied and to clearly disseminate the research findings to the scientific community and beyond. As immigrant health research may illuminate health disparities and call attention to previously unidentified needs of underserved and vulnerable populations, it is reasonable to regard the well-designed research method as not only as a tool for information gathering and critical analysis, but as a vehicle for social justice.

Ethical Issues in Research with Immigrants and Refugees

Sana Loue
Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Introduction

Migration has been construed as:

- The physical transition of an individual or a group from one society to another. This transition usually involves abandoning one social setting and entering a different one (Eisenstadt, 1955, p. 1)

  A relatively permanent moving away of ... migrants, from one geographical location to another, preceded by decision-making on the part of the migrants on the basis of a hierarchically ordered set of values or valued ends and resulting in changes in the interactional set of migrants (Mangalam, 1968, p. 8)

  A permanent or semipermanent change of residence (Lee, 1966, p. 49)

  The process of social change whereby an individual moves from one cultural setting to another for the purpose of settling down either permanently or for a prolonged period (Bhugra & Jones, 2001, p. 216).

These varied constructions indicate that the concept of migration encompasses both movement within and across national borders. This includes both internal migrants, such as agricultural workers and persons who have been displaced as the result of natural disasters or civil conflict, and those who cross international borders, regardless of the manner or legality of their entry. Importantly, the concept of migration captures the continuum of time during which movement and transition occur, from the premigration phase, when individuals may be only contemplating movement; through the perimigration phase, during which movement is effectuated from one locale to another; and through the postmigration phase, following the individual's arrival at a place of temporary or permanent refuge or residence (Loue & Galea, 2007).

Approximately 175 million people, or 2.9% of the world's population, live either permanently or temporarily outside of their countries of origin (International Organization for Migration, 2003). In 1990, migrants accounted for 15% of the population of 52 countries (Council of Europe, 2000). The International Organization for Migration has estimated that currently one in every 35 people in the world is an international migrant (International Organization for Migration, 2003) and that by the year 2050, the number of international migrants will approach 250 million (International Labour Office, International Organization for Migration, & the Office of the United Nations High Commissioner for Human Rights [ILO, IOM, OHCHR], 2001). These figures include migrant workers, permanent immigrants, and those who are seeking asylum or refugee status; it does not include individuals who migrate across borders illegally, who are known variously as "illegal," "undocumented," or "irregular" (World Health Organization, 2003). These individuals may migrate themselves; may be trafficked, a process that involves coercion or deception; or be smuggled, meaning that their entry has been facilitated by others for profit (ILO, IOM, & OHCHR, 2001). Consequently, these figures represent underestimates of the magnitude of migration and its demographic impact in various regions of the world (Council of Europe, 2000).

Individuals may migrate from one area to another for any number of reasons. Circumstances at the point of origin that may "push" individuals to leave include poverty, unemployment, persecution, internal civil strife, a change in government or regime, and/or natural disasters, such as a hurricane. Refugees, in particular, migrate due to "push" factors. The 1951 United Nations Convention on Refugees, as modified by the 1967 Protocol Relating to the Status of Refugees, describes a refugee as a person who:

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

- owing to well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group or political opinion, is outside the country of his nationality and is unable or, owing to such fear, is unwilling to avail himself of the protection of that country; or who, not having a nationality and being outside of his former habitual residence as a result of such events, is unable, or owing to such fear, is unwilling to return to it.

Individuals may also migrate because they feel a "pull" toward the intended destination as a result of perceived employment prospects, the ability to reunify with other family members, expectations of a better economic and/or political situation, freedom from persecution, and/or a safe haven from the ravages of man-made or natural disasters. Distinctions have accordingly been made between those immigrants who are "voluntary," such as students, tourists, and migrant workers, and those who are "forced" to migrate as the result of displacement due to internal conflict, environmental disaster, famine, or development projects (Loughna, n.d.).

The various circumstances surrounding immigration and, in particular, those involving trafficked persons and refugees fleeing persecution, may leave persons particularly vulnerable, meaning that they "are relatively (or absolutely) incapable of protecting their own interests" due to insufficient power, education resources, strength, or other requisite attributes (Council for International Organizations of Medical Sciences, 2002, Guideline 13). Vulnerabilities may be cumulative, resulting in what is essentially compounded powerlessness. As an example, a minor child who is fleeing from individuals who have bought and sold him or her into prostitution is vulnerable as a function of both age and sex. This chapter explores the ethical issues that arise in the context of conducting health-related research, whether of a biomedical, epidemiological, or social science nature, with such individuals and communities during their experience of such movement.

The Impact of Migration

Asylum Seekers and Refugees

Numerous studies have reported that refugees and asylum seekers may suffer from posttraumatic stress disorder (PTSD) and other mental illness. In order to be diagnosed with PTSD, the individual must have experienced, witnessed, or been confronted with a traumatic event or a series of events that involved actual death or serious injury or the threat of death or serious injury. As a result of these events, the individual experienced feelings of intense fear, horror, and/or helplessness (American Psychiatric Association, 2000). Additionally, for a period of at least 1 month, the individual reexperiences the event (s), avoids stimuli that are associated with the trauma, and experiences numbing of general responsiveness and increased arousal, resulting in clinically significant distress or impairment in one or more important areas of functioning, such as family life or work. Individuals may attempt to avoid any feelings or thoughts associated with the trauma and, consequently, may suffer "emotional anesthesia" and/or experience amnesia with respect to the triggering event(s) (American Psychiatric Association, 2000). Not surprisingly in view of these symptoms, many individuals suffering from PTSD may experience difficulty with one or more important functions of daily living.

Data suggest that two out of every three asylum seekers (the equivalent of a pending application for refugee status) in the European Union have experienced some mental problems (Burnett & Peel, 2001) and that up to 40% of all refugees have been tortured (Steel, Frommer, & Silove, 2004). In a study of ten detained asylum seekers in the United Kingdom, it was found that six had suffered torture, all ten were suffering from depression, four were suicidal, and two had attempted suicide while in detention (Bracken & Gorst-Unsworth, 1991). More than 50% in a sample of 33 asylum seekers in Sydney, Australia, reported having been physically tortured (Sultan & O'Sullivan, 2001). A review of 20 studies providing results for 6,743 adults from 7 countries and 5 surveys of 260 refugee children from 3 countries reported that among the adults, 9% suffered from PTSD, 4% had generalized anxiety disorder, and 5% had major depression, while 11% of the children were diagnosed with PTSD (Fazel, Wheeler, & Danesh, 2005). The authors concluded that refugees are ten times as likely to have PTSD compared to age-matched individuals in the native populations of the countries surveyed.

High rates of PTSD have also been reported among refugee children. Almost all of the children in a sample of internally displaced Bosnian children were diagnosed with PTSD (Goldstein, Wampler, & Wise, 1997). Among children who had experienced war in Cambodia and the former Yugoslavia and had migrated to the United States, almost one-half suffered from symptoms of PTSD (Mollica, Poole, Son, Murray, & Tor, 1997; Sack, Clarke, & Seeley, 1996; Weine et al., 1995). A study of refugee children ages 8–16 in London found that greater severity of PTSD was associated with premigration experiences including the violent death of family members and an unstable or insecure status following migration (Heptinstall, Sethna, & Taylor, 2004). Similar findings were reported from a study involving 87 children and adolescents who sought refuge in the United States from Cuba and had been held in refugee camps for up to 8 months prior to arrival in the United States (Rothe et al., 2002). More than half of the children (57%) evidenced symptoms of PTSD. Age and having witnessed violence in the camps were associated with PTSD. Consistent with findings from other studies (Chung, 1994; Chung & Kagawa-Singer, 1993; Steel, Silove, Phan, & Bauman, 2002), a dose–effect relationship was noted between the number of stressors and the severity of self-reported symptoms.

Exposure to war and/or political unrest may also heighten the risk of PTSD. A study comparing 258 immigrants from Central America and Mexico to the United States and 329 US-born Mexican Americans and Anglo Americans (non-Hispanic Whites) found that 52% of the Central Americans who had migrated because of war and political violence experienced symptoms of PTSD, compared with 49% of Central Americans who had migrated for other reasons and 25% of Mexican immigrants (Cervantes, Salgado de Snyder, & Padilla, 1989).

Refugees who were subjected to torture may also be at increased risk of developing both PTSD and another psychiatric disorder. A study of ethnically Nepalese, religiously Hindu refugees from Bhutan who sought refuge in refugee camps in Nepal found that those who had been tortured were 5 times as likely to develop PTSD as those who had not been tortured, and 1.6 times as likely to have any psychiatric disorder (Van Ommerren et al., 2001). The 12-month prevalence of any psychiatric disorder was 74.4% among those refugees who had been tortured, compared to 48% among those who had not. The impact of torture on mental health may be alleviated by the presence of family and social support from the immigrant community after arrival in the receiving country (Başoğlu & Paker, 1995; Schweitzer, Melville, Steel, & Lacherez, 2006).

Research findings also indicate that individuals who are placed in detention facilities following their arrival at their destination country may suffer both retraumatization and a worsening of their mental health in comparison with those who are not detained (Becker & Silove, 1993; Bracken & Gorts-Unsworth, 1991; Steel & Silove, 2001; Thompson & McGorry, 1998). In the previously mentioned study of 33 asylum seekers in Sydney, Australia, researchers noted a progressive deterioration in the mental health of the asylum seekers, who had been held in detention for an average period of 2 years (Sultan & O'Sullivan, 2001). The research team found that many of these individuals were

> ► dominated by paranoid tendencies, leaving them in a chronic state of fear and apprehension and a feeling that no one, including other detainees, can be trusted. Long periods of time are spent alone and some develop frankly psychotic symptoms, such as delusions, ideas of reference and auditory hallucinations (Sultan & O'Sullivan, 2001, p. 595).

This deterioration of mental status while in detention is also seen in refugee children. Their distress may be exacerbated as a result of observing parental distress and suffering, interviewing by immigration officials, witnessing displays of violence and self-harm, being separated from their parents with or without warning, and experiencing instability due to lengthy delays in processing their claims for refugee status (Zwi, Herzberg, Dossetor, & Field, 2003).

Confronting the New

At a minimum, immigrants to a new country of temporary or permanent residence may experience what is known as "culture shock." The term "culture shock" was introduced by Kalvero Oberg in 1954 to refer to an "abrupt loss of the familiar" or the "shock of the new."

> ► [It] is precipitated by the anxiety that results from losing all familiar signs and symbols of social

> intercourse. These signs are the thousand and one ways in which we orient ourselves to the situations of daily life: when to shake hands, when and how to be gracious and appropriate . . . when to accept invitations, how to take statements seriously . . .. (Oberg, 1954, p. 1).

As a result, individuals may experience feelings of inadequacy, vulnerability, anger, resentment, and irritability. They may find that they are unable to solve even simple problems because of their lack of familiarity with the new environment. As a result, they may lack self-confidence and have a tendency to blame others for any difficulties.

Culture shock occurs in various stages or phases, which have been variously termed incubation, crisis, recovery, and full recovery (Oberg, 1954, 1960); elation, depression, recovery, and acculturation (Richardson, 1974); and contact, disintegration, reintegration, autonomy, and independence (Adler, 1975). The first stage of elation is characterized by feelings of excitement, which may last for hours, days, weeks, or months. These feelings gradually dissipate, as the individual becomes increasingly aware of the differences that exist between her previous and current environments. This second phase of disintegration is marked by practical problems, an increase in misunderstandings and associated feelings of frustration, a sense of loneliness and uneasiness, and a decrease in self-confidence. During the third stage of culture shock, the individual begins to reintegrate into the new environment or reject her new situation, blaming others and adopting negative coping mechanisms, such as substance use and self-isolation. During the final stage of recovery, the individual may gradually adjust and adapt to the new environment, experiencing a greater sense of control, autonomy, and belonging (reintegration).

Significant variation exists between individuals in their experience of culture shock. The sequence and rate through which they pass through the various stages may differ as a function of their mental state, personality, familiarity with language, family and social support system, religious beliefs, level of education, socioeconomic condition, sex and gender, and past experiences with travel. Some individuals may experience great difficulties, depending upon their age, sex, health status, migration experiences, and the nature of their reception in their destination country.

Ethical Issues in the Context of Research

Immigrants as a Vulnerable Population

The ethical principles of respect for persons and beneficence, derived from the Nuremberg Code (1949), demand that we as researchers assess the risks and benefits to prospective participants prior to the initiation of an investigation, in order to determine whether the investigation should even be pursued. In general, special justification is need for the conduct of research with vulnerable participants (CIOMS, 2002, Guideline 13). Accordingly, one must first ask whether immigrants as a group constitute a vulnerable population within the context of research involving human participants.

As indicated previously, vulnerability refers to those persons who are relatively or absolutely unable to protect their own interests because "they have insufficient power, prowess, intelligence, resources, strength, or other needed attributes to protect their own interests through negotiation for informed consent" (Levine, 1988, p. 72). Application of this definition to the situation confronting many immigrants argues in favor of a determination of vulnerability. Many, if not the majority, of immigrants often do not speak the language of the country to which they are relocating. They may have little access to medical care or knowledge of the health care system. At a minimum, they are likely experiencing some degree of culture shock; some individuals, such as refugees and asylees, may also be suffering from the effects of trauma, severe depression, and physical injury. As a politically and often socially and economically marginalized group, individuals may not perceive their participation in research as voluntary (Barsdorf & Wassenaar, 2005).

Although the principles of respect for persons and beneficence would suggest that these circumstances disallow the participation of immigrants in research, the inquiry cannot stop. The exclusion of immigrants from participation based on such factors alone may well constitute a paternalistic overemphasis on the principle of autonomy, which provides for individual decision making, and the principle of justice, which dictates that the benefits and burdens of research be accessible across populations (Beauchamp, Jennings, Kinney, & Levine, 2002; Erlen, Sauder, & Mellors, 1999; cf. Roberts, Geppert, & Brody, 2004; Stanley B., Stanley M., Lautin, Kane, & Schwartz, 1981). Depending upon the health care system of the receiving country, participation in research may represent for many immigrants the only means by which they can obtain needed health information and care; this may be particularly true for undocumented adults and children. As an example, US law provides that even legal immigrants who are residing permanently in the United States are barred in all but very limited circumstances from receiving health care through publicly funded sources (Personal Responsibility and Work Opportunity Reconciliation Act of 1996). Accordingly, immigrants should be provided with the opportunity to participate in research protocols for which the risks and benefits of participation have been carefully assessed and special protections implemented (CIOMS, 2002, Guideline 13).

Funding Source and Participant Risk

Researchers do not generally consider the possibility that the source of their funding for a study may jeopardize in some way the situation of their research participants. Consider, however, the following hypothetical case.

Recently, a US citizen who had emigrated from Pakistan attempted to car bomb an area of Times Square in New York (Moore, 2010). A law enforcement agency might decide to fund research to understand better the circumstances that might compel an individual in his circumstances to engage in acts of terrorism. The researcher owes the participants of his or her research confidentiality to the extent possible. Yet in such circumstances, the law enforcement entity may feel entitled to all of the data based on its national security concerns. The source of the funding has created potential risk for the participants and the larger participant community; as a result of the fact of the study or its findings, the community as a whole may be subject to increased surveillance, or other measures, which may prove later to have been unwarranted. The community may also be stigmatized as a result of the increased attention from law enforcement authorities.

It is critical that in such circumstances, the researcher negotiate with the finding source the extent to which each party will have access to the data and control its use. The outcome of such negotiations must be made clear to prospective participants so that they can knowledgeably consent to or decline to participate.

Sampling and Recruitment

Immigrants and refugees may face particular risks even during the process of research study recruitment, prior to enrollment, which must be balanced against whatever benefits they may derive, if any, from their participation in the proposed research. First, efforts to recruit individuals that are premised on a designation of membership in a particular group or subgroup or disease status may have the unintended effect of focusing increased attention on a group that may be marginalized and/or stigmatized within not only the larger population, but also within the individuals' immediate milieu. As an example, recruitment to research relating to HIV/AIDS or mental illness that is conducted within a refugee camp, which is often characterized by close quarters and a lack of privacy, may inadvertently result in the identification of individuals with the disease or illness and their consequent marginalization and/or victimization within the camp. A similar consequence may result with respect to research related to any number of diseases, depending upon the sensitivities of a particular group or culture (Leaning, 2001). Accordingly, it is incumbent upon the researcher to understand the dynamics and perceptions of the community prior to the initiation of recruitment efforts, in order to fine-tune the recruitment procedures and language so as to minimize such risks.

Genetic research poses unique ethical issues. The meaning of kinship is known to vary widely across cultures; the meaning may determine issues of politics, economics, inheritance, property rights, succession, and access to power (Kissell, 2005). A redefinition of kinship by a research team to examine what are considered by researchers to constitute familial relationships may have the unintended effect of disrupting the individual's sense of his or her place in the world and reorganizing individual and group responsibilities and obligations, leaving individuals feeling – or being – isolated and dislocated. The worst-case scenario may find individuals expelled from their kinship group and community as the result of such redefinition, with attendant emotional, social, psychological, and economic losses.

Second, depending upon how inclusion and exclusion criteria for a particular study are framed, some individuals illegally present in a particular country may be eligible to participate in the study. Targeting a particular geographic area of a city or town may focus unwanted attention on the immigrants' presence, thereby unintentionally increasing both their vulnerability to political processes and their risks of deportation and/or violent victimization by vigilante groups and/or unethical government agents. Additionally, as Loue and Sajatovic (2008) found in their study of the cultural context of HIV risk among Mexican and Puerto Rican women with severe mental illness, an increase in law enforcement efforts that occurs independently of the researchers' recruitment efforts may increase the difficulty of recruiting and retaining study participants.

The conduct of research with immigrants confined to detention centers raises other ethical issues. When official approval is required to conduct such research and the screening and selection of eligible detainees is determined by those in charge of the facility themselves, the possibility of coercion in selection or nonselection remains ever present. Research conducted without official approval or through the use of deception may ultimately place the detainees at risk of harm and threaten the credibility of the investigators and their research (Kirmayer, Rousseau, & Crepeau, 2004). The close quarters that are characteristic of many detention facilities may limit privacy and confidentiality, potentially placing the participating detainees at increased risk from authorities and/or others who are detained. Nevertheless, some scholars have argued that researchers have a moral responsibility "to address actions of violence or neglect, perpetrated by the state on their behalf that brings suffering and hardship to others" (Kirmayer et al., 2004, pp. 85–86). Others have asserted that even when there exists a conflict of interest between researchers and those in authority in a detention situation, there exists "a legitimate moral imperative . . . for clinical researchers to breach the walls of enforced silence and give a voice to those who are afflicted" (Steel & Silove, 2004, p. 93).

Third, the mechanism used for sampling and/or recruitment may potentially subject immigrants to coercion and duress. Snowball sampling and respondent-driven sampling (RDS), both commonly used in conducting research with populations that are considered hard-to-reach, involve the recruitment of individuals to the study by an already-enrolled participant. The researcher may be unaware of the power dynamics that exist within a specific network or community, or the nature of the relationship between the respondent-recruiter and those that he or she recruits to the study. This can potentially lead to the coercive recruitment of individuals when conducting research with immigrants and refugees specifically because of their relative powerlessness as immigrants and refugees.

Recruitment through a gatekeeper or community leader raises similar concerns of coercion and duress. The leader or gatekeeper may be able to exert influence or pressure on community members because of his or her relative power within the group; this may be particularly true where the individual possesses greater education, wealth, or political connections relative to others, or is a member of a subgroup that has historically held greater power. As with recruitment conducted through already-enrolled participants, recruitment of individuals through a perceived leader has the potential to exacerbate intragroup or intergroup tensions of which the researcher may be unaware, and lead to further oppression, humiliation, or persecution of individuals. Where that individual receives resources, such as cash or transport, from the researcher in exchange for their assistance with recruitment, the researcher may unknowingly be legitimizing the individual's presence and authority to the detriment of those who will be participants (Jacobsen & Landau, 2003).

Enrollment and Participation

Informed Consent

The informed consent process is inherently complex, requiring an assessment of the prospective study participant's capacity to provide informed consent, his or her understanding of the information provided about the study, and the extent to which the individual's agreement to participate is voluntary and free of coercion or duress. The complexity of this process may be compounded with immigrants and refugees due to differences in language, lack of familiarity with the new culture generally and with research specifically, power differentials between the researcher and the participant and, in some cases, a history of trauma, and/or a fear of violence and/or discovery.

Language. The language in which information about the study is conveyed to the participant should be the language that he or she understands as, for example, to present the information in Romanian to Romanian-speaking participants. However, the language that is used must be accessible to and understandable by prospective participants if their consent is to be truly informed. It is unlikely, for instance, that individuals with little or no formal education would understand medical terms used by physicians in a case presentation during Grand Rounds.

In addition, the demographic characteristics of the translators (addressing the written transformation from one language to the other) and interpreters (addressing the oral transformation from one language to the other) may affect the translation/interpretation and, consequently, the accuracy of the information provided to the prospective participant and/or the information that the participant wishes to convey to the researcher. In the context of back translation, one translator will translate the consent form from its original language to that of the prospective participants and a second translator will "back translate" the translated version to the original language to maximize accuracy and reduce ambiguity or confusion. Variations between the translators in terms of their age, social standing, level of education, socioeconomic status, and even place of origin may impact on the dynamics between them, leading one to defer to the other out of respect, even where such deference may lead to less-than-optimal results with the translation (Yick & Berthold, 2005). Similarly, the existence of such differences between the prospective participant and the interpreter assisting with the informed consent process may affect the dynamics of the informed consent process, resulting in reticence on the part of the prospective participant to ask questions or to disagree. It is important that the research team consider such possibilities and take steps to minimize them.

Personhood and Self-in-Context. Unlike the cultures of many industrialized countries, many cultures define personhood as a person-in-context, that is, as a function of the many and varied relationships and roles for which the individual may be responsible. A woman, for example, would not be considered an autonomous individual with sole decision-making authority for herself, but would rather be conceived of as a daughter, a wife, and a mother, with obligations to those persons for whom she plays these roles. Accordingly, consent to participate in a study may require consultation with those to whom she is responsible (Loue, Okello, & Kawuma, 1996). In such situations, researchers may wish to provide for a waiting period between the provision of information to the prospective participant and the completion of the informed consent process, in order to allow the participant adequate time to consult with others of their choosing. Ultimately, however, the decision to participate must be an individual one.

In some cultures, consent must be obtained from a tribal chief or community leader prior to seeking consent from individuals for their participation (Dawson & Kass, 2005; Molyneux, Wassenaar, Peshu, & Marsh, 2005). This necessarily raises issues as to who can legitimately speak for the community and the extent to which that individual is respected by and reflective of or distanced and mistrusted by the community (Marshall & Batten, 2004).

Power Differentials. There is inherently a power differential between the research team members and the immigrant participants because of the difference in roles; this may be accentuated due to differences in sex, education level, professional status, or socioeconomic status. Researchers may believe that reliance on research assistants from the same country or area as the research participants may enhance both recruitment efforts and communication with participants because of their similarity to the participants. However, the researcher may inadvertently transgress political, social, or economic fault lines that exist within the group by unknowingly employing individuals who are members of a subgroup that has historically been hated by or has hated and persecuted those of other subgroups within the country (Jacobsen & Landau, 2003).

Discovery. Prospective participants may fear discovery for any number of reasons. A study focusing on family violence may raise fears of prospective participants that they will be subjected to further violence should their abusive family member discover their participation. Individuals who have been persecuted and/or tortured by the governments or agents of their governments from which they fled may be concerned that their disclosure of any information may incur the wrath of some unknown and unidentified "other," who will seek them out for punishment. Trafficked persons may fear that their traffickers may find them, recapture them, and once again subject them to threats or violence. Still others may be concerned that, if discovered, they will face deportation to their country of origin, where they will once again face whatever drove them to leave. As a consequence, individuals may be reluctant to sign any paper signifying their participation in or association with the research (Langford, 2000).

In such circumstances, it may be advisable to implement informed consent procedures that require only oral consent from the participant (Cwikel & Hoban, 2005). This may be supplemented by a statement signed by a second research staff person, confirming that the participant was provided orally with all of the information necessary to make an informed decision regarding participation and that the individual did, indeed, provide consent to participate. Where circumstances permit, a written information sheet describing the study and the requirements of participation can be provided to the participant.

These safety concerns underscore the need to ensure confidentiality (referring to information) and privacy (referring to the individual) even during the enrollment process, before any data are collected. The possibility of breaches of confidentiality may be reduced by putting passwords on computers; limiting access to data linked to individually identifying information, such as names and addresses, to those persons who truly need such information; maintaining any hard copies of the data in locked file cabinets in enclosed and locked offices; and requiring that all personnel involved with the study sign confidentiality agreements that advise them of the severity of a breach and the likelihood that disciplinary action will be taken if a breach were to occur. Mailings should not be sent to the participant or messages left on a voicemail recording without the prior consent of the individual and assurances that his or her safety will not be threatened as a result of the communication. In the United States, data collected within the boundaries of the United States may receive additional protection through the issuance of a certificate of confidentiality from the National Institutes of Health after application by the researcher and his or her institution (United States Department of Health & Human Services, 2009). Privacy may be enhanced by conducting all interviews and telephone conversations in enclosed office space or, where such space is unavailable, conducting the interviews and conversations out of sight and hearing range of others.

Continuing Consent. Circumstances may change during the course of the study which may impact an individual's willingness or ability to continue with his or her participation and, consequently, require the re-consenting of the individual to assure ongoing validity of his or her consent to participate. As one example, an individual suffering from posttraumatic stress disorder may experience an exacerbation of his or her symptoms that may or may not be related to the focus of the study, but that make it increasingly difficult to continue as a participant. Changes in external circumstances may also render it more difficult for an individual to continue participation. An increase in immigration law enforcement activities in the geographic area in which the study is being conducted may cause a shift in the balance of risks and benefits to the individuals participating (Loue & Sajatovic, 2008). The increase in participants' risk of discovery may outweigh any direct benefits that they had identified at the time of their initial consent to participate.

Special Protections

Community Advisory Boards (CABs). CABs consisting of members of the relevant community have been instrumental in the conduct of research with immigrant communities (Kobetz et al., 2009). Importantly, CAB members who are familiar with and connected to the immigrant community can provide advice to the research team regarding culturally sensitive mechanisms to reduce participants' risks and maximize participants' benefits from the research. CAB members may provide critical input in the development of the research protocol, recruitment and enrollment efforts, and the interpretation of the collected data.

The establishment of a CAB and the training of its members is consistent with ethical principle of beneficence (to maximize good) and with the provisions of Guideline 20 of CIOMS' *International Guidelines for Biomedical Research Involving Human Subjects*, which urges researchers to strengthen capacity for ethical and scientific review and biomedical research, including "educating the community from which research subjects will be drawn." The formation and successful operation of a CAB in partnership with the research team may (1) increase the capacity of the community and its members to understand scientific research, (2) increase community knowledge of a particular disease and its prevention and treatment (Morin et al., 2008), (3) increase access to needed resources and services through the development of linkages between community members and biomedical institutions, and (4) increase community members' knowledge and experience with organizational development and management (Cox, Rouff, Svendsen, Markowitz, & Abrams, 1998).

Researcher Intervention and Referral. During the course of the research, members of the research team may witness acts of violence or other abuse perpetrated against the immigrant respondent. This may occur, in particular, in the context of research involving trafficked persons (Cwikel & Hoban, 2005). Intervention without participant consent to do so may actually exacerbate, rather than ameliorate, the participant's situation by bringing about increased violence or abuse, transport of the participant by the traffickers to a less visible and findable location, and/or the individual's deportation.

Some, but not all, immigrant/refugee participants may have suffered trauma, as a result of events leading up to their departures from their countries of origin and/or their experiences in transit to their destination. It is critical that researchers working with immigrant and refugee populations be aware of this possibility and have appropriate resources and/or referrals available to the participants who may be in need of such services. It is also possible that some of the participants may be suffering from severe depression or may be suicidal. In order to reduce the risk of harm to the participants, appropriate protocols to address such situations must be developed and staff trained on their use prior to the commencement of the study.

Close-Out: Post-Study Dilemmas

Access and Abandonment

Guideline 19 of the *International Guidelines for Biomedical Research Involving Human Subjects* advises that investigators should ensure that participants who are injured as a result of their participation receive free medical treatment for any such injury and that they receive appropriate compensation for any resulting impairment, disability, or handicap. In general, this may be problematic for a number of reasons. First, funders of research, such as the National Institutes of Health in the United States, do not provide funding to compensate research participants for such injuries. Consequently, any such payment is at the expense of the investigator, his or her institution, and/or the industry sponsor of the research, if there is one. Second, there is often no existing legal mechanism to facilitate such recovery, such as a legal regulation requiring such compensation as a condition of conducting the research. As a result, individuals who believe that they are so injured must seek compensation through the court system.

Additional barriers confront immigrants and refugees in such situations. If they are in the country illegally, they may not wish to make their presence easily known for fear of deportation. They may also lack sufficient funds to pursue a lawsuit, with all of the costs that attend it, such as court filing fees, attorney's fees, medical evaluations, etc. The exclusion of immigrants and refugees from proposed research that entails risk of injury may contravene the ethical principles of both distributive justice and respect for persons, but their inclusion might violate the principle of beneficence, requiring that the investigator maximize benefit, and nonmaleficence, requiring that the investigator minimize harm.

Commentary to Guideline 21 of CIOMS' *International Guidelines for Biomedical Research Involving Human Subjects* suggests that researchers should provide referrals to study participants for the diagnosis and treatment of diseases not related to the focus of the research or advise the participants to obtain necessary treatment. This raises issues of access for immigrants and refugees, who may be unable to avail themselves of government-funded health care services because of limitations imposed by those governments on the receipt of such services and/or may be unable to access privately funded health care due to insufficient personal funds. Where eligibility screening for inclusion or exclusion from a study reveals the existence of a serious health problem, one must query whether the researcher's ethical obligation does not at least extend to assisting the individual to obtain the necessary care, particularly in circumstances where the immigrant/refugee faces additional barriers due to language, culture, and unfamiliarity with the country's health care system.

Dissemination of Findings

How the data derived from studies of immigrant or refugee groups are interpreted and disseminated may have serious implications for members of that group. First, the theoretical framework utilized for the development of the protocol and the conduct of the study provides the basis for the direction of the research and, often, the interpretation of the findings. However, reliance on a single theory may bring about a situation in which the researchers are able to see – and consequently are able to convey – only a portion of the real picture, much as each blind man in Saxe's poem about the blind men and the elephant was unable to understand the totality of the elephant because he could feel ("see") only one part of the elephant. Because immigration is often a controversial and highly contested political issue, an unintentionally biased portrayal of the immigrants' situations may result in adverse political consequences to that group (cf. Liamputtong, 2007; Schweitzer & Steel, 2008).

Similarly, a less-than-careful interpretation and portrayal of the study findings may subject an entire immigrant community to stigmatization and marginalization. Such was the case, for example, with the labeling of Haitians by the United States Centers for Disease Control and Prevention as a risk group for HIV/AIDS during the early years of the epidemic (Schiller, Crystal, & Lewellen, 1994).

Conclusion

Significant issues may arise in the context of doing research with participants who are immigrants or refugees. Although a number of these issues are common across research endeavors, they are particularly challenging in this context because of immigrants' and refugees' heightened vulnerability as research participants. Foremost among these are issues relating to the source of the study funding; to sampling and recruitment procedures; the informed consent process; the safeguarding of participants' privacy, confidentiality, and safety during the course of and following the cessation of the study; access to and availability of the benefits of the study following its termination; compensation for study related injury; and the content and mechanism for the dissemination of the study findings. Inadequate attention to the development of appropriate safeguards with respect to these issues may inadvertently result in stigmatization, victimization, marginalization, economic hardship, and/or deportation.

Ethical Issues in the Clinical Context

Beatrice Gabriela Ioan
Department of Legal Medicine, Medical Deontology and Bioethics, University of Medicine and Pharmacy “Gr. T. Popa”, Iasi, Romania

Introduction

Immigration is not new phenomenon. In recent years, however, it has become more complex as the groups of immigrants became more heterogeneous, with varying determinants of health status, health needs, and levels of vulnerability (World Health Organization, 2010). The importance of migration is highlighted by the 2007 EU Portuguese Presidency identification of the challenges occurring with immigration. In connection with the health of immigrants, the goal was to “develop a common vision for immigration and health, based on common values and principles of the EU.” The conclusion was that a starting point to achieve this goal would be increased funding of research in the field. This would include efforts to develop research techniques, increase collaboration between research centers in Europe, and increase attention to methodological barriers in order to include data on immigrants in health surveys in Europe and at national level.

It is estimated that there are about 200 million international immigrants, consisting of workers, students, illegal immigrants, or immigrants not registered with authorities. About 70% of individuals are migrating from developing to developed countries. The remaining migration is taking place between developing countries or between developed countries (United Nations Development Program, 2009).

In the EU countries, international immigration is increasing, due to economic and social opportunities. This places increasing challenges on the host countries (Herm, 2008). The migration rate in EU countries in 2008 was three times higher than the natural growth of population in these countries (Vasileva, 2009). Currently it is estimated that in Europe there are about 35–40 million immigrants (Mladovsky, 2007). Approximately 75% of these immigrants in the EU live in Germany, Spain, UK, France, and Italy (Vasileva, 2009). In the USA in 2000, there were 28.4 million immigrants, with 43% more than in 1990 and three times more than in 1970. Immigration has become one of the main determinants of US population growth. From 1990 to 2000, 70% of US population growth was immigrants (Camarota, 2001). In New Zealand, it is estimated that one in five citizens of this country is born in another country (Merwood, 2006).

Because of the heterogeneity of immigrant groups, their degree of vulnerability to health problems varies widely. The health of migrants and the health problems associated with migration are important issues for public health and impose difficult challenges for the governments of the host countries, which must find solutions to integrate the particular needs of immigrants in national health policies, taking into account the rights of immigrants, including their right to health (World Health Organization, 2010).

This chapter addresses the ethical issues that may arise in the clinical context of health care provided to immigrants. While far from being the “last word” on ethical issues in immigrant health, the author’s intention is to highlight some of the issues of this sensitive and extremely large subject, and to foster discussion on this topic. I will first discuss health and disease as social constructs that are largely culture dependent and that influence access to formal health services and adherence to treatment. Next I will discuss various aspects of the concept of individual autonomy (typical for western medicine) in the context of multiculturalism. This will include patient preferences for disclosure of information and obtaining informed consent, detailing the communication barriers that create problems in doctor–patient interaction. I will discuss the barriers that stand in the way of accessing health services by immigrants, with a particular focus on how access to health care is reflected in the welfare of immigrants. Finally I will discuss the necessity of providing culturally appropriate healthcare services for

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

immigrant populations in order to increase access and quality of healthcare services and further to improve the health of immigrants, whatever their legal status.

Concepts of Health and Illness: A Multicultural Perspective

In Western medicine, physical and mental health concepts have been mainly defined by the medical model of disease (Palmer & Kaufman, 2003) In Western medicine, the concept of health is divided into physical and mental health, these two being located at the extremes of a continuum. Health may, however, be conceptualized differently in other cultures.

As an example, the concept of *holistic health* has been identified among Iranian immigrants. In Iranian culture, health is seen as a sphere formed outside the physical (body) and the inner spirit (*ruh*). Seen in this way, health is equivalent to a state of balance in life, the best combination of physical, mental/emotional, and spiritual, and represented by a social functioning (Martin, 2009). Disease is regarded as lack of balance in diet, social, physical, mental, spiritual, and emotional health, a loss of self-identity and loss of appetite for life. In this culture, pain is described in terms of suffering rather than pain being located in a particular area. Pain thus is a much larger entity, which affects multiple aspects of a patient's life. This conceptualization is consistent with the holistic approach on health and disease (Martin, 2009). Being culture-dependent constructs, the concepts and categories used by immigrants to explain health problems may differ significantly from typical Western understanding (Mladovsky, 2007). For example, in Iranian culture, the disease called *Evil Eye* occurs when an envious person sends negative energy to another person (Martin, 2009).

There are mental or somatic disorders that are recognized in some cultures that have no corollary in Western culture. This makes diagnostic and therapeutic methods characteristic of Western medicine ineffective for treatment. For example, in Japan, *Taijin kyofusho* is a disease characterized by a morbid fear that physical or behavioral abnormality will cause inconvenience, embarrassment, or will offend the others (Palmer & Kaufman, 2003). In India, the Philippines, Taiwan, and Latin America the condition called *Susto* ("sudden fear") is manifested clinically by tremor, sweating, tachycardia, and depression. *Susto* is considered to result from problems with a person's two components: organic and spiritual. The latter can be detached from the body through a traumatic event or an intense fear (Palmer & Kaufman, 2003). Among Latino immigrants (especially Puerto Ricans), *ataques de nervios* represents the clinical manifestation of stress caused by dislocations produced in the family or a social response to a given situation. This condition is manifested clinically by uncontrolled behavior with anger, crying, shaking, heart palpitations, seizures, or unconsciousness. *Ataques de nervios* might be diagnosed by Western medicine as hysteria, psychosis, or suicidal ideation. Because it is not an accepted psychiatric disorder, drugs used in Western medicine are not often helpful for this condition, which can be cured by family, social, and spiritual support (Palmer & Kaufman, 2003).

Perception and acceptance or rejection of certain diseases in society impact on how an individual suffering from a certain disease is seen by the members of society and may affect his/her willingness to seek medical help or support from family or the community. Cultural factors can lead to stigmatization and marginalization of people who suffer from a disease that is considered to bring shame. For this reason, patients from certain cultures may avoid contacting a doctor, fearing that they will be judged for suffering from a certain disease and for violating social norms (e.g., abortion, contraception, sexually transmitted diseases, infertility, and HIV/AIDS).

Tuberculosis is a highly stigmatizing disease in some countries. For instance, in Vietnam women suffering from tuberculosis may be stigmatized in family and society. As a consequence stigma is one of the main barriers to compliance with treatment among Vietnamese women (Johansson et al., 1999).

In a study on Chinese immigrants to Canada who suffered from chronic fatigue and physical weakness, it was found that their main concern about disclosure of their condition to the family and community was related to the risk of stigmatization. According to Chinese culture it is not appropriate to disclose personal failures and disgrace. In addition, disclosure can also be hindered for other reasons, such as fear that others will not understand the real cause of their condition and will consider that their allegations are motivated by laziness or character flaw. Disclosure could decrease marriage opportunities or cause damage to family life. Individuals may fear they will become a burden for their partners or they will not be able to provide for their family. When the family members learn the diagnosis they may try to keep it a family secret, because according to Chinese social values family shame should not be exposed. This may impede the family's reporting of the patient's condition. Patients may thus prefer to seek treatment with traditional Chinese medicine before they seek a Western physician (Lee, Rodin, Devins, & Weiss, 2001).

Some patients may decide not to disclose certain medical symptoms that could be essential for establishing the correct diagnosis and treatment, such as sexually transmitted infections or pain in order to avoid being punished or judged by the physician or because of beliefs about what is appropriate to discuss with the doctor. A number of studies indicate that in certain cultures there are sex-related norms regarding the acceptability of patient complaints related to pain. Nondisclosure of certain symptoms is more common when the patient is treated by a doctor of the opposite sex, but this can also happen if the doctor is the same sex as the patient (Govender & Penn-Kekana, 2007).

Mental health problems are perceived differently in different cultures. In some cultures mental illness places significant stigma on the sick person who may consequently avoid seeking medical help or may avoid divulging psychological or psychiatric symptoms (Lee et al., 2001).

In some countries, there are only a few medical units for treating the mentally ill and the existing ones are associated with significant social stigma. Countries that have traditionally faced the problem of migration have developed models to address mental health problems of migrants and health professionals have been trained with appropriate cultural and linguistic skills. Examples include the Multicultural Mental Health Plan 2008–2012 in New South Wales, Australia, or the centers for "Refugees as Survivors" (RAS) of New Zealand (http://www.portaldasaude.pt).

The quality of healthcare services is assessed by patients according to their expectations, the latter being strongly influenced by specific cultural norms and beliefs. There are patients who primarily value the physician's medical knowledge and experience, while others mostly value the interpersonal relationship established between the physician and patient. For example, Iranian immigrants assess the quality of health care largely depending on the time spent with their doctors as a prerequisite for building trust and proper communication (Martin, 2009). Russian immigrants consider that physicians need to "have soul" in addition to technical knowledge. They frequently complain that Western medicine focuses on examination based on various devices, to the detriment of clinical examination. Part of this expectation may be because they come from a country with limited technical equipment and are consequently accustomed to diagnosis mainly by clinical methods (Dohan & Levintova, 2007).

Iranian immigrants who emphasize holistic patient care consider that a good doctor is one who, in addition to professional knowledge, has the ability to inspire the patient with hope and optimism. Diet plays an important role in the lives of the Iranians mainly by facilitating social interactions. As a consequence, Iranian immigrants consider that a good treatment should combine drug therapy with appropriate dietary prescriptions, criticizing the fact that most times Western medicine ignores the role of diet in treatment (Martin, 2009). Two studies conducted in Oslo in non-Western immigrants (the Oslo Health Study and the Oslo Immigrant Health Study) have found that satisfaction with medical services received may be directly proportional to the degree of integration in the host country (acculturation) (Lien et al., 2008).

Immigrants may exhibit behaviors that do not conform to Western standards of behavior. Some reports note that some Russian immigrants may present to be seen by a doctor without an appointment, request that the examination be conducted by only a senior physician, and display emotional outbursts in emergency waiting rooms. Some of them might complain of certain symptoms that they do not actually have, perhaps due to past experiences of extreme medical shortage and in order to be examined (Dohan & Levintova, 2007).

The Concept of Individual Autonomy in a Multicultural Environment

Disclosure of Information to the Patient

Individual autonomy represents the right of a person to decide for himself/herself, independently of any influence from other people. In Western medicine, respect for the patient's autonomous decision is a mandatory requirement for all the members of the medical staff, while for patients autonomy is a right (Beauchamp & Childress, 2001). Disclosure of health information to the patient is a central element of Western medicine (Palmer & Kaufman, 2003) that allows for an appropriate choice (Beauchamp & Childress, 2001), expressed through informed consent for diagnostic procedures and treatment.

Attitudes toward disclosure of information, the quantity of information that can be provided, and the circumstances of disclosure depend largely on the culture from which the patients come. Studies have shown that immigrants from countries where disclosure to the patient of a severe diagnosis is not common maintain this preference in the host country (Berkman & Ko, 2009). A study of elderly patients of different ethnic backgrounds (Korean-Americans, Mexican-Americans, European-Americans, and African-Americans) found that ethnicity was the main factor correlated with attitudes toward disclosure of diagnosis and prognosis of terminal illness and to decisions to end life. Korean-Americans and Mexican-Americans considered to a lesser extent than European-Americans and African-Americans that a patient should find out the diagnosis of terminal illness and should make decisions on the use of life support, believing that family members should make decisions in this regard. Thus the principle of individual autonomy is not universally accepted (Beauchamp & Childress, 2001; Palmer & Kaufman, 2003). In the Asian cultures, for example, the focus is placed especially on the principles of nonharm and benefit (Berkman & Ko, 2009). There are communities in which the family-centered model for decision making is considered more appropriate based on the idea that the patient is part of a network of family relationships and the smooth functioning of the family is more valuable than the individual autonomy (Beauchamp & Childress, 2001; Palmer & Kaufman, 2003).

Preferences toward disclosure of information to patients can be greatly influenced by cultural beliefs toward disease, causes of illness, and patients' or their families' fear that disclosing a diagnosis of serious disease may harm the patients. Navajo Indians may believe that thinking and language have power to influence reality and control events, and disclosure of negative information can be potentially harmful. Navajo Indians believe that positive language promotes and even allows healing (Beauchamp & Childress, 2001; Palmer & Kaufman, 2003).

Some Latin-American and Hispanic populations consider it inhumane to burden a person with information about disease (Palmer & Kaufman, 2003). Some ethnic groups prefer to learn only the minimum or ambiguous information about the disease they are suffering, such as elderly Koreans, Mexicans, Native Americans, and Bosnian immigrants in the USA and other countries (Berkman & Ko, 2009). In Asian countries, there may be belief that disclosure of a diagnosis of serious disease destroys hope and condemns the patient to death (Berkman & Ko, 2009).

Russian immigrant families may prefer to spare family members knowledge of bad news about their health. This creates dilemmas related to disclosure of diagnosis and prognosis. In the Russian immigrants' opinion, the diagnosis of cancer is interpreted as a "death sentence," especially since Russian therapeutic resources are limited, even nonexistent in comparison with the USA. Disclosure of diagnosis of cancer to the patients, especially elderly, is equivalent to "taking hope and spirit." Following disclosure of the diagnosis of cancer, patients may become depressed with a diminished power and desire to survive. In discussions with these patients even the word "cancer" should be avoided. A possible solution for such a sensitive case is the creation of support groups for Russian immigrants and their families, who can facilitate the use of curative or preventive medical services and can inspire the patient toward an optimistic vision of the possibilities for treatment (Dohan & Levintova, 2007).

A number of studies indicate that preferences of immigrants regarding the disclosure of a serious diagnosis may be influenced by the time spent in the host country and the degree of acculturation. Research suggests that more acculturated Korean immigrants in the USA receive more information about the disease from which they are suffering, compared to those who are less acculturated (Berkman & Ko, 2009). Russian immigrants in the USA are more willing to work with physicians and accept the disclosure of cancer diagnosis, especially after spending more time in the host country, and become more optimistic about the chances of treatment and recovery in this disease (Dohan & Levintova, 2007).

Disclosure of Information to the Patient's Family

The extent to which patients agree to share information about their health status with family members depends largely on their culture of origin, because individual values and cultural norms are closely linked to attitudes toward disclosure of serious illness (Berkman & Ko, 2009). Family involvement in decisions about health care must take into account the negative impact that the disclosure of a certain diagnosis can have on the patient's family and the community in which the patient lives.

As an example, research findings indicate that among Asian immigrants, the main barrier to disclosure to family members of some diagnoses, such as HIV infection, involves the collectivist nature of Asian culture, in which an individual's behavior is seen in the context of his/her entire family. Harmony and the avoidance of conflicts are particularly appreciated values in the Asian culture. Asian cultures generally discourage discussing personal issues or taboo topics such as sexual orientation, in order to avoid embarrassment to the family/community. Homosexuality and bisexuality are considered deviant, contrary to family values, and evidence of moral weakness. Given that many individuals infected with HIV are gay, individuals may assume that the disclosure of HIV infection is also a disclosure of sexual orientation. In these circumstances individuals may choose not to disclose a diagnosis of HIV infection in order to protect their families from stigma and discrimination. Avoiding disclosure also minimizes family material and emotional burdens arising from the obligation to help. Asian immigrants with HIV infection often seek support from friends, especially those with the same sexual orientation who may also be HIV infected. Healthcare professionals must keep in mind that Asian immigrants need support both in the disclosure of HIV diagnosis and after disclosure. To facilitate communication between Asian patients infected with HIV and their families, healthcare facilities should provide written information materials in their preferred language. This will minimize language barriers and misunderstandings or incorrect perceptions about HIV infection. Patients' isolation due to language barrier, fear of intolerance, or of exclusion from family could be minimized with language and culture-specific education (Yoshioka & Schustack, 2001), enabling the patients to receive appropriate medical care and prevention from the spreading of infection among the population at large.

Patients have the right to request not to be informed of their illness. This is accomplished via a *waiver* (Palmer & Kaufman, 2003), indicating the person who should be informed and who is designated to make healthcare decisions on the behalf of the patient. A patient's decision to delegate the right to decide to another person becomes a manifestation of his/her autonomy (Beauchamp & Childress, 2001).

When the patient delegates his/her right to know and to decide, his/her opinion should be respected, provided that there is no reason to suspect coercion, abuse, or neglect (Ho, 2006). Health professionals must be sensitive to cultural values in addition to conducting an assessment of the patient's communication style and relationships with his/her family. The clinician should understand the decision-making process in the patient's family, why the patient wants to delegate the right to be informed, and why the family members want to make decisions for the patient. It is essential that the patient knows that he/she has the right to receive health information, that he/she has freedom of choice, and that family members know the patient's preferences. The patient may be in a subordinate relationship with the rest of the family, may not believe that he/she is entitled to decide, or may fear that the rest of the family or community may ostracize him/her. In this situation, delegation of right to choose is the result of indoctrination or manipulation and is not a real autonomous desire.

Analysis and appropriate communication with the patient and his/her family allow the clinician to understand the patient's family situation. Clinicians should respect the delegation of decision making by families when it is in full harmony with the patient and in accordance with patient values and preferences. If family decisions do not promote the best interest of the patient, the doctor may discuss the issue with the patient or exclude the family members from the decision-making process. If it is not clear that the family is in harmony with the patient, the clinician should respect the patient's expressed wishes, but also monitor the family dynamics. It is important for the clinician to establish good communication with the patient and inform him/her that he/she has the right to decide autonomously (Ho, 2006).

Often, however, it is difficult for clinicians to evaluate the dynamics of the patient's family. This may be due to minimal interaction with the family or because the patient is not willing to discuss his/her family with the clinician. This may be a particular issue when there are language barriers or if the patient feels that the doctor is not sensitive to the values of the culture from which the patient originates (Ho, 2006).

Although specific cultural values may be characteristic of various immigrant populations, and health professionals should be aware of these features to provide patient-centered and culturally sensitive care, they must also recognize that not all immigrants from a particular community adhere to the community's characteristic practices and values. Healthcare professionals should not assume a priori that if the patient belongs to a certain community, he/she shares the values and beliefs of that community (Beauchamp & Childress, 2001; Berkman & Ko, 2009). Therefore, healthcare professionals must determine on the one hand what, how, and when patients wish to be informed, and on the other hand, what, how, and when they wish to disclose to the family members.

Disclosure of information and informed consent process must be flexible, must be adapted to each patient rather than applying a rigidly individualistic or family-centered decision-making model (Berkman & Ko, 2009; Ho, 2006), and be nonviolative of patient autonomy. Again, autonomy may be operationalized in a variety of ways depending upon the specific circumstances, for example, by individual decision, in collaboration with his/her family members, or delegating his/her right to decide to the family.

Although the decision-making model is largely influenced by cultural values, the preferences of patients from the same culture can vary depending on income, education, religious affiliation, and fluency in English while in the host country. Young immigrant patients with a high degree of acculturation and high health education or those who had been patients before often prefer an individualistic model of obtaining informed consent. It is therefore not correct for the medical staff to assume that if a patient comes from a culture where the focus is on family and close family relationships, he/she would prefer family involvement in his/her healthcare decision (Ho, 2006).

Informed Consent in Multicultural Clinical Settings

Informed consent is considered central to Western medicine in providing ethical, safe, legal, and patient-centered care (Schenker, Wang, Selig, Ng, & Fernandez, 2007). The doctrine of informed consent reflects Western beliefs that mind, body, and soul are separate entities, and that man has an intrinsic value and ability to self-update (Palmer & Kaufman, 2003). However, individual autonomy promoted by Western medicine is not universally accepted. Many US immigrants come from non-Western cultures, where emphasis is placed on strong intergenerational family relationships and the family is considered as the basic unit of society (Ho, 2006). Immigrants from Japan, China, Laos, and Pakistan may live together in extended families, often under the same roof or close to each other. They value family harmony and personal identity is not viewed independently, but in the context of relation to family. Family members are typically involved in important decisions. Many immigrants may not accept the individualistic model of decision making, especially when the decisions they make can have great impact on the lives of entire family. They may prefer the model of informed consent based on the inclusion of family ("family-facilitated approach") (Ho, 2006).

Exclusion of family members in treatment decisions may be more difficult with involuntary migrants (those who do not voluntarily choose to leave their culture and whose family is their main support) and elderly immigrants, especially those who do not speak English fluently, and who may prefer family members to communicate with doctors or assume responsibility for decisions (Ho, 2006). Isolation from family members may inadversely affect these individuals' well-being and can induce a state of anxiety (Ho, 2006).

Immigrants coming from countries where medicine is predominantly paternalistic may wrongly interpret the physician's efforts to inform them. For example, Russian immigrants in the USA may interpret a physician's provision of information as hesitation on the part of the physician and may become skeptical about the ability of the physician to treat them (Dohan & Levintova, 2007).

Communication Barriers in Informing the Patient

Barriers in communication between physician and patient can be related to language barriers or to differences in communication of emotions in different cultures. Level of education and limited knowledge of the language of the host country are the most important factors that affect access to health services by immigrants (Mladovsky, 2007; www.portaldasaude.pt). Language barriers hamper the provision of care to patients from different cultures (National School of Public Health, 2010) in several aspects. Language barriers are also an obstacle to adherence to the treatment and treatment referral (www.portaldasaude.pt). Language differences can create problems in physician–patient communication (Dohan & Levintova, 2007) and more time between patient and clinician is needed for the clinician to ensure full and correct understanding of the information provided (Schenker et al., 2007). When accessing medical services, immigrants may have difficulty in communicating symptoms or misunderstand instructions given by the medical team. The situation is often complicated by the lack of familiarity with a formal healthcare system (National School of Public Health, 2010).

Cumbersome and often poor communication due to language barriers has a negative impact on many aspects of patient care including patient satisfaction, interpersonal care processes, comprehension, and length of hospitalization (Schenker et al., 2007). In addition, misunderstanding of symptoms by the clinician may lead to delayed treatment, medical errors, and even death (National School of Public Health, 2010). From the perspective of ethics and human rights, proper communication is essential to obtain informed consent for medical interventions and to ensure confidentiality of medical information (National School of Public Health, 2010). A first step to facilitate communication between physicians and patients in clinical settings and thus to improve the care of immigrants is the provision of an interpreter (Schenker et al., 2007; National School of Public Health, 2010). Written materials should be provided in the preferred language of immigrants (National School of Public Health, 2010).

Often in clinics members of the patient's family are used as interpreters between the physician and the patient. This is not the best option because family members do not know medical terminology (Schenker et al., 2007) and may unintentionally impede the exchange of information between the patient and the clinicians (Patridge & Proano, 2010). Besides the possibility of inadequate interpretation, it may be difficult for family members, placed in the position of translators, to bear the emotional burden of disclosure of a serious diagnosis for their beloved (Schenker et al., 2007). In addition, reliance on family members as interpreters may infringe on the patient's privacy (Mladovsky, 2007). During the communication process between physician and patient, information may be transmitted that the patient might not want to reveal to his/her family.

Ideally, when physician and patient do not speak the same language, they should involve professional interpreters (Schenker et al., 2007). A study on pediatric populations showed that lay interpreters commit more errors than the professional ones (Flores et al., 2003; Patridge & Proano, 2010). Professional interpreters can act both as translators and as cultural facilitators to get the best results in communicating with patients. They can help clinicians in adapting to cultural differences in the disclosure of the diagnosis – especially in case of a serious diagnosis – and to social differences in treatment expectations (Patridge & Proano, 2010). Professional interpreters adapt their way of communication according to cultural norms of the patient. The clinical objectivity that is characteristic of information disclosure in Western medicine is not suitable for all cultures. For example, Russian immigrants have to be approached "like talking to your own parents" (Dohan & Levintova, 2007).

A professional interpreter is accountable for the work he/she does including signing for the translation made (Schenker et al., 2007). Involving professional interpreters in the process of communication between patient and physician has beneficial effects on the utilization of healthcare services, clinical outcomes, and patient satisfaction with medical care received (Patridge & Proano, 2010).

In some cases, standard disclosure practices can create professional and personal dilemmas for professional interpreters, because on the one hand they have to do their job and translate what is being told, and on the other hand they realize that disclosure could harm the patient. Anticipating this kind of dilemma some interpreters prefer to use a milder disclosure ("soft disclosure") or to preemptively inform the physician about the patient's cultural background. Some physicians accept terms of a more gentle translation, while others require interpreters to literally interpret their words irrespective of patient's cultural particularities (Dohan & Levintova, 2007). Given the clear benefits of their activity, an increasing number of hospitals in countries experiencing high migration rates (particularly in the USA and UK) include professional interpreters in the medical teams (National School of Public Health, 2010).

Unfortunately, many physicians and patients who confront the language barrier do not have access to professional interpreters. Even when professional interpreters are available, they are often underutilized (Schenker et al., 2007). This may be because nonprofessional interpreters, such as family members and medical staff members, could be preferred by some patients or clinicians, extra time is needed to work with interpreters, and the costs of professional interpreters are higher (Patridge & Proano, 2010).

A US survey showed that medical training in the use of professional interpreters in clinical settings has lead to their increased involvement. Low use of professional interpreters in healthcare settings may be partly a consequence of lack of physician training in this direction (Schenker et al., 2007). The US Civil Rights Act of 1964 prohibits discrimination based on national origin or because of limited knowledge of English. In 2000, public and private hospitals that receive federal funds were mandated to provide services for professional interpretation (Patridge & Proano, 2010).

Means of Communication of Emotions

People's emotional experiences and expressions are not universal, but are shaped by culture according to construction of the self. In the Euro-American culture, individuals have an independent, autonomous, and auto-limited sense of the self. Emotions are considered in the context of the needs, desires, and goals of the individual. Emotional expression is a way of showing who one is ("ego-focused emotions"). Emotions like anger and frustration may be considered expressions of individual needs. In East Asian cultures, self is not constructed as a separate entity, but is defined in a relational context. The Asian sense of self is "collectivist" or "interdependent." The self is fluid, changing depending on the environment in which individuals live and function. Emotions are focused on the needs and responses of others, making the individual's emotions less important in determining his/her actions ("other focused emotions"). In the East Asian culture, the prevailing collective meaning of the self suggests that people expect to understand each other without expressing emotions and needs. In Chinese culture, for example, "excess" emotion, whether positive or negative, is considered harmful to the health and spirit of the individual. The ability to regulate emotions and maintain a state of harmony with oneself is crucial to the well-being of the individual. East Asian immigrants do not typically openly express emotions, especially happiness, which can challenge interaction with them in the clinical settings. Chinese individuals may express anxiety with repetitive questions or repeated complaints regarding their physical condition or personal dilemmas. It may not be suitable for healthcare professionals to ask Asian immigrants to openly express their emotions (Shibusawa & Chung, 2009). This attitude is totally opposite to Western cultures in which open expression of emotions is encouraged.

Barriers to Access to Health Care for Immigrants: A Coin with Two Faces

Access to health care and providing health care are problematic issues related to migration. Studies indicate that, regardless of cause/barriers (social, structural, financial), immigrants do not use health services in a host country that ideally enables them to maintain optimal health. A study on health and social situation of newborns in two communities of Portuguese emigrants found high levels of morbidity for mothers and children, and extensive use of emergency services instead of primary care. This suggests a need to provide immigrants with information regarding the appropriate and timely use of health services (National School of Public Health, 2010). Availability and access to medical services have a major impact on health (World Health Organization, 2008b).

Limited access to healthcare services may lead to delays in care (Mladovsky, 2007), negative repercussions on health status (Leclere, Jensen, & Biddlecom, 1997), more expensive treatments later, and poorer outcomes (Mladovsky, 2007; World Health Organization, 2008b). A study from the Netherlands showed a higher rate of preventable mortality among immigrants than among native Dutch (Mladovsky, 2007).

Access and appropriate use of medical services by immigrants is limited by a number of specific factors.

Limited financial resources are a significant impediment to accessing healthcare services especially in the period immediately following migration, when immigrants are often faced with economic problems and poverty (Leclere et al., 1997). Availability and appropriate use of healthcare services by immigrants are often hampered by lack of familiarity with the operation of the healthcare system (National School of Public Health, 2010). There is a need to create orientation services and publishing guidance materials for immigrants (Mladovsky, 2007).

Access to health care is also limited by the *lack of cognitive resources* represented by *limited education* and *language barriers*. Lack of fluency in the language of the host country prevents access to healthcare services (Leclere et al., 1997).

Deterrence from treatment by medical staff could limit the access of immigrants to healthcare services (National School of Public Health, 2010). Despite the fact that primary care services should be the first to assist immigrants, they often discourage immigrants from seeking medical help. This is because general practitioners are often unfamiliar with the epidemiological profile of migrant groups and may feel unprepared to address the complex psychosocial issues affecting immigrants. For this reason, immigrants may choose to use the community services that are often provided by NGOs and take into account the cultural particularities of the community (www.portaldasaude.pt).

The social environment in the host country may affect the access of immigrants to information and health services. *Families* of the immigrants are "social bridges" between the individuals and the medical system. Family members or friends who previously immigrated can help immigrants to more readily acquire information on the healthcare system in the host country. At the same time family members and friends can act as substitutes for formal care (Leclere et al., 1997), leading to reduced use of healthcare services in the host country.

Distrust of Western medical system is an important barrier to accessing formal healthcare services by immigrants (Mladovsky, 2007). For example, many elderly Iranian immigrants resort to traditional medicine because they do not trust Western medicine and because they believe that diseases have certain causes that are not recognized and cannot be treated by the Western medicine (Martin, 2009).

Gender/Sex Issues in Patient–Physician Relationship in Multicultural Clinical Settings

Cultural differences between clinicians and patients, and practices that are considered usual in Western medicine may lead to dissatisfaction among some immigrants who interact with the medical system in the host country. For example, for some immigrant women, lack of access to a female physician can be a barrier to accessing health services (Mladovsky, 2007). Sex differences may create problems in the physician–patient relationship, which can range from mistrust and lack of adherence to treatment, to refusal of medical examination. Reasons for this perspective are varied, and often are culturally dependent. Patients themselves and/or their families may find it unacceptable to be examined by physicians of the opposite sex. Refusing to see a physician of the opposite sex is especially common in gynecology for patients coming from strong patriarchal societies, where the social, cultural, and religious norms and practices require a clear demarcation of sex-related social roles and limit the social and physical contact between men and women (Govender & Penn-Kekana, 2007). A study that examined the experiences of women in Cuba, Thailand, Saudi Arabia, and Argentina who sought antenatal care found that women in Saudi Arabia and Thailand prefer female physicians. In Saudi

Arabia women can be examined by male physicians, in the presence of nurses. However, the women felt uncomfortable with the idea of examination by male physicians, especially for pelvic examinations. Thai women preferred to be examined and assisted by midwives, believing that they can more easily relate with them emotionally. Cuban women accepted examination by male physicians but stated that before examination they must cover their bodies in order not to arouse physician curiosity (Nigenda et al., 2003; Govender & Penn-Kekana, 2007).

In some countries, women prefer a female physician for reproductive problems because treatment and examination of a woman by a male physician is seen as dishonoring the woman and her family (World Health Organization, 2008a). In China, women are reluctant to address a male physician for reproductive problems, and follow-up of women who undergo a surgical sterilization by male physicians rarely happens because it is considered inappropriate for a man to visit the wife of another man. A study in the Yunnan province of China found that women are reluctant to discuss physical and contraception issues with male physicians and the latter, in turn, are reluctant to provide medical care for reproductive issues in women (World Health Organization, 2008a). In contrast, women in Western societies display only a slight preference for their physician on the basis of his/her sex and, instead, base their preference on professional performance and communication style (Govender & Penn-Kekana, 2007; Howell, Gardiner, & Concato, 2002; Plunkett, Plunkett, Kohli, & Milad, 2002; Zuckerman, Navizedeh, Feldman, McCalla, & Minkoff, 2002).

The quality of interaction between physician and patient may also be influenced by sex differences, particularly with respect to the patient's trust in the physician's capacity to treat, and the patient's adherence to prescribed treatment. There are patients who do not take seriously the prescriptions made by nurses, who are mostly women, but follow the prescriptions made by male physicians. The reverse situation is also possible (Govender & Penn-Kekana, 2007).

Studies show that immigrants in the period immediately following migration have a better health status than the population in the host country. This may be due to the selective migration of healthier people (Ronellenfitsch & Razum, 2004) that results from legal barriers against immigration in some countries for people with impaired health (Leclere et al., 1997). This phenomenon is called "the healthy migrant effect." The weakness in this argument is that it does not evaluate the health of the population in the immigrants' home country (Ronellenfitsch & Razum, 2004). Putting aside the difference between the initial health status of immigrants and native populations, immigrants may have greater morbidity than natives due to differences in the prevalence of certain diseases in their home countries (Leclere et al., 1997). Immigrants may develop particular health problems such as communicable diseases (National School of Public Health, 2010) or problems caused by psychological and somatic distress related to migration and adaptation to their new physical and social environment in the host country (Leclere et al., 1997). Many immigrants face, at least in the initial period of life in the host country, a number of difficulties such as greater sacrifices than those estimated before migration, lack of training and work experience recognition, and acceptance of a job below their level of training. All of these factors may lead to depletion of emotional, spiritual, and physical resources (Lee et al., 2001).

Currently immigrants from Eastern European countries represent more than 5% of the total population in Germany (Ronellenfitsch & Razum, 2004). A study on health satisfaction among immigrants from Eastern Europe to Germany indicated that satisfaction was less compared to native Germans, despite substantial improvements in indicators related to socioeconomic status. Decline in health satisfaction can be attributed, on the one hand, to adverse health conditions and increased prevalence of risk factors in immigrants from Eastern Europe in their home countries (e.g., increased prevalence of smoking, hypertension, deficits in antioxidants due to low fruit and vegetable consumption, and frequent alcohol consumption) and, on the other hand, to certain issues pertaining to immigrant status (such as discrimination, psychological stress, and lack of informal support networks). Rapid deterioration of health status among Eastern European immigrants in Germany, irrespective of improving their socioeconomic status, is a concern for public health services and health policies in the host country.

Similar results were obtained in two studies on Russian immigrants in Israel, a country that received about 775,000 Jewish immigrants from the former Soviet Union during the period from 1989 to 1998. Russian Jewish immigrants reported less satisfaction with their health compared with native Jews; chronic diseases were most commonly reported. Recent immigrants more frequently reported low satisfaction with their health than those who immigrated previously. Those expressing satisfaction with their health status were younger and healthier and immigrated at the beginning of the wave of migration from former Soviet Union in Israel (Ronellenfitsch & Razum, 2004).

Given the particular dynamics of the immigrants' health status, it is desirable to create mechanisms to facilitate their access to information and healthcare services (National School of Public Health, 2010). The International Organization for Migration (IOM) estimates that in the near future 3–5 million people will migrate from Eastern European countries, indicating the need to identify specific points of vulnerability and to develop public health policies in the host countries (Ronellenfitsch & Razum, 2004).

Particular Problems of Illegal Immigrants

Access to health care becomes more complicated and difficult for illegal immigrants due to both legal and financial barriers, as well as the fear of being referred to the authorities and deported to their home country (Mladovsky, 2007; National School of Public Health, 2010). Studies show that illegal immigrants, regardless of origin, linguistic fluency, and length of residence in the host country, access fewer formal healthcare services than legal immigrants (Leclere et al., 1997). To improve the level of access to health services it becomes mandatory for the host country to ensure that illegal immigrants be given the right to privacy and that healthcare policies be completely separate from immigration policies (Médecins du Monde, 2009).

In September 2009, Médicins du Monde, a nongovernmental organization, published a report on access to health care for illegal immigrants from 11 European countries (Belgium, France, Germany, Greece, Italy, the Netherlands, Portugal, Spain, Sweden, Switzerland, and UK), based on 1,218 interviews. The report shows that access to health care of illegal immigrants is uneven among European countries, but is very restrictive overall (Médecins du Monde, 2009). The report shows that 72% of the health problems of illegal immigrants are inadequately resolved. The status of illegal immigrants represents a significant barrier to access to healthcare services although the need for medical care in illegal immigrants is very high. They suffer most frequently from arthritis, gastrointestinal ulcer, diabetes, hypertension, and psychological disorders (insomnia, anxiety broadcast, and psychosis). It is estimated that in about 16% of the cases the prognosis is unfavorable without treatment (Médecins du Monde, 2009). Illegal immigrants have poor living conditions and are more sick than the native populations. The situation is aggravated by the difficulties encountered by illegal immigrants when they need health care. According to the report, 45% of illegal immigrants who have health problems declare that they are not examined and receive no treatment. Even when the law of the host country provides medical care free of charge, only one third of respondents say that immigrants really have access. Fourteen percent of respondents stated that they were denied medical care when they were sick.

These difficulties also impact the children of illegal immigrants, although the International Convention on Children's Rights obliges signatory states to provide children the best care possible (Médecins du Monde, 2009). Antenatal care, delivery, and postnatal care in illegal immigrant women are also precarious. Only one out of every two pregnant women stated that they received medical care during pregnancy. Many illegal immigrant women give birth in emergency hospitals that were not suitable for this purpose, and were discharged immediately after the birth of their child (Médecins du Monde, 2009).

Culturally Sensitive Practices in Treatment Provided to Immigrants

Before the 1960s, immigrants in host countries were approached in the context of the *assimilation* perspective, which states that newcomers in a culture will comply and integrate into the lifestyle of the dominant culture. At the end of 1960s, following the disastrous results of this approach, immigrants began to be considered with the *multicultural diversity* perspective. Professionals give more importance to culture and its influence on identifying and defining health problems and on the ways to seek medical help in order to solve them. Most care providers now recognize the importance of respecting the values and experiences of all members of society, starting from the premise that diversity and difference means that the views, experiences, and different perspectives deserve to be heard and valued (Maiter, 2009).

McPhatter defined cultural competence in social work as the ability to transform knowledge and cultural awareness in medical or psychosocial interventions that support normal functioning of the client–system relationship in an appropriate cultural context.

In 1999, Barker stated that *culturally sensitive practices* are ways of professional intervention that take into account both the unique and common features of the clients/patients in terms of different racial, ethnic, religious, economic status; age; sex; or sexual orientation. Culturally sensitive practices are based on elements resulting from exploration of the practices and beliefs of patients on symptoms, disease, death, and other human experiences (Palmer & Kaufman, 2003). Culturally sensitive practices recognize that people with different backgrounds may experience different problems, so that social and medical interventions must be appropriate for members of different ethnic groups. Healthcare professionals must take into account cultural factors that might influence immigrants' help seeking behavior and their adherence to medical treatment. For example, Iranian immigrants in the USA prefer to not seek formal medical help because they have a sense of pride and do not want to become a burden to others. They may think that American physicians do not understand them (Martin, 2009).

Understanding cultural values is crucial in providing adequate medical care to populations of diverse cultural and ethnic background (www.portaldasaude.pt). In order to understand cultural norms and values of their patients, healthcare professionals should make a careful assessment of the patients' cultural features, in order to protect the patients from cultural generalization and stereotypes. A solution for the improvement of quality of the medical services provided to the immigrants is the involvement of *cultural brokers.* They are consultants (social worker, community leaders, etc.) from various ethnic populations, who may provide information regarding beliefs about health, appropriate methods of communicating with members of certain communities (e.g., to show respect for the elderly), and problematic aspects in the interaction between the medical system and immigrants. Using cultural brokers is particularly useful when working with elderly immigrants, who have more health problems and rely more on traditional medicine that may not be compatible with norms in the host country (Martin, 2009).

To provide culturally competent/culturally sensitive care, healthcare professionals must take into account their own cultural background, biases, cultural and professional norms, and incorporate relevant knowledge and interpersonal skills related to the care of patients who have a different cultural background. In providing health care to immigrants it is also necessary that health professionals be familiar with their specific health problems and social characteristics and understand that there are many important cultural, religious, social, gender factors that may arise in the negotiation and implementation of a therapeutic plan for various conditions, such as reproductive health, childcare, management of chronic diseases, aging, and end of life (www.portaldasaude.pt).

Healthcare professionals may be confronted by particular issues that affect immigrant populations such as female genital mutilation. Female genital mutilation, also known as genital cutting and female circumcision, was defined by the World Health Organization in 1998 as: "all procedures involving partial or total removal of external female genitalia for cultural, religious or other non-therapeutic reasons." Female genital mutilation currently affects about 130 million girls and women worldwide; the highest prevalence is in some African countries (Little, 2003; Taylor, 2003). Ethical and legal issues raised in the clinical context of patients who are victims of genital mutilation may be serious.

Female genital mutilation has become an issue for healthcare professionals in countries where this practice is culturally, socially, and legally rejected but is practiced by groups of immigrants. This occurs in Europe, America, and Australia (Hopkins, 1999; Thompson Ortiz, 1998). It is estimated that about 7,000 women who are at risk of genital mutilation arrive each year in the USA. Although female genital mutilation is illegal in the UK, it is practiced in some communities of immigrants coming from Eritrea, Somalia, and Yemen (Hopkins, 1999). About 15,000 children in immigrant communities in UK are at risk of being subjected to genital mutilation, due to the desire of parents to maintain their cultural identity (Taylor, 2003). This widely accepted social and cultural practice in some societies often leads to serious short- and long-term complications (Brady, 1999; Little, 2003). Advocates for this practice assert that female genital mutilation is an important cultural tradition with ancient roots and motivations, one that is motivated by the norms and beliefs of certain societies (Little, 2003). Frequently, female genital mutilation is performed under unsanitary conditions, often by older women in the community (Little, 2003). Recent years have seen an increased "medicalization" of female genital mutilation, that is, families of higher economic status seek medical help to practice genital mutilation of their daughters in order to avoid short-term complications. The issue of healthcare professionals performing a surgical intervention that has no medical benefit and may lead to harm raises difficult ethical issues given the fact that the leading principle of practicing medicine all over the world is "do not harm" (World Health Organization, 2001).

The USA, UK, Canada, Sweden, Australia, Belgium, Switzerland, Denmark, France, and the Netherlands prohibit female genital mutilation and reinfibulation after giving birth with or without the consent of the woman (Hopkins, 1999). However, despite these legal prohibitions, female genital mutilation is still practiced. The great danger of passing repressive legislation is that of moving the practice underground and fostering reluctance to seek for medical help in case of complications, which, ultimately, affects the victims of genital mutilation (Hopkins, 1999).

In the context of international human rights, female genital mutilation is considered to be physical and mental abuse of female children. This practice is being banned by several international bodies (World Health Organization, 2001). However, international human rights laws are difficult to apply because of arguments based on cultural relativism. What is considered to be a violation of the rights of individuals in one culture might be considered morally right in another. Rigid imposition of such laws can lead to accusations of racism or attempts to impose Western values on people from other cultures (Hopkins, 1999).

It is now clear that female genital mutilation cannot be eradicated by legal means alone, but extinction of the practice may occur if it is more widely recognized that this practice is harmful to women's health (Taylor, 2003). Healthcare professionals can play an important role by educating men and women from affected communities so that they understand the dangers and short- and long-term disabilities induced by female genital mutilation. In addition, the girls and women who do not undergo genital mutilation should not be ostracized in their communities. For instance, the French government currently supports a multi-pronged strategy designed to reduce the prevalence of female genital mutilation among girls living in France. One of the central elements of this strategy is based on providing culturally sensitive information and discussion with the girls and their families (Wu & Martinez, 2006).

The key factor in building a healthcare system based on cultural competence is community involvement from the outset and during the planning and implementation stages (in the form of focus groups, advisory committees, or board representation). Community involvement facilitates the understanding of patient needs and the effective allocation of resources and establishes a monitoring system for provision of quality healthcare services to the community members. In this way healthcare services can be provided efficiently, leading to increased patient satisfaction and improvement in the quality of care. In addition, good relationships between the community and healthcare facility support the healthcare services provided to the community (Wu & Martinez, 2006).

Studies indicate that the effectiveness of efforts focused on health promotion, illness prevention, and intervention for disease depend on the creation of medical assistance programs consonant with the linguistic and cultural characteristics and education of the population to whom they assist. The most successful programs are those aimed at a specific target population that ensures participation in the program design, implementation, and evaluation. For example, the Innvadiab project, which aims to reduce the development of type 2 diabetes in Pakistani women living in Oslo, Norway, demonstrated that culturally tailored education has the potential to change women's intentions and behavior related to a healthy diet (www.portaldasaude.pt).

Low level of acculturation reduces the addressability of the immigrants to the healthcare system in the host country. Age at time of immigration and acculturation level has an inverse relationship. For example, elderly Iranian immigrants in Sweden, even if they emigrated many years previously, continue to have difficulty speaking and feel isolated and largely dependent on their children (Martin, 2009). In these circumstances, it is essential that immigrants receive adequate care in a culturally sensitive environment. Organizations serving immigrant communities that can provide assistance with immigrants' needs may help in this regard (National School of Public Health, 2010).

An efficient model that directly addresses the linguistic and cultural problems of immigrants is based on using a *team of cultural support*, which works with both medical staff and community members. Members of this team, called intercultural mediators, are appointed as community health workers or patient navigators; they often originate from the immigrant community. In Hamburg, Germany, intercultural mediation teams plan and carry out activities in immigrant communities in order to familiarize their members with the German healthcare system. Belgium has introduced a program of 80 intercultural mediators in 62 hospitals in Brussels, to provide translation services and patient support activities (www.portaldasaude.pt).

A culturally competent approach must be integrated into all aspects and structures of healthcare. This approach eliminates the tendency to abandon efforts to build cultural competence when a healthcare system is faced with problems, such as the financial ones. Changes in the functioning of the healthcare system due to introduction of the cultural competence approach should be assessed regularly and carefully, both in terms of success and limitations (Wu & Martinez, 2006).

Continuous training of staff is essential for the staff members to understand why changes are needed and to accept them. For example, if staff members understand the usefulness of a professional interpreter, then they will not feel uncomfortable when patients require an interpreter and are more likely to facilitate access (Wu & Martinez, 2006). Medical staff should be trained to respond effectively to the sociocultural needs of the immigrants by "Cultural Competence Training." In Qatar, for example, Weill Cornell Medical College, in association with Hamad Medical Corporation, has implemented a program of Cultural Competence Training for medical students. In New Zealand, the Health Professional Competency Assurance Act of 2003 requires that professional organizations establish standards of cultural competence, clinical competence, and ethical standards to approach immigrant populations and ensure that these standards are met. US medical students must demonstrate that they understand health needs, beliefs, and communication needs of diverse populations. Six states already implemented continuing medical education programs in cultural competence (www.portaldasaude.pt).

Besides cultural factors, race and race-related issues faced by some people, especially those of color, are important aspects in interaction with the patient and his/her family in healthcare settings. It is important for healthcare professionals to take into account the racial differences and the consequences that being a member of a particular race has on the patient's family life. In 1998, Dei launched the so-called antiracist approach that takes into account the social effects of race. Significant social effects of race in White-dominated societies are evident in the experiences of minority groups. This framework can be useful in analyzing complex problems faced by families belonging to racial minorities, analyzing the situation of social services, developing clinical intervention strategies, and conducting research on diversity (Maiter, 2009).

Healthcare systems must systematically incorporate all aspects of immigrant health into service delivery. There are several models that illustrate such an approach, from the single-site intervention, up to comprehensive national policy (National School of Public Health, 2010).

In 2008, the World Health Assembly issued a resolution dedicated to health concerns of migrants (Sixty-first World Health Assembly, 2008), which mainly requires Member States to engage in the creation of *migrant-sensitive health policies and practices*, with the purpose of promoting and protecting the health of immigrants (World Health Organization, 2010). The concept of *migrant-sensitive health services* starts from the need to understand and respond effectively to the needs of immigrants and indigenous communities worldwide. Medical models based on this concept respond adequately to linguistic, cultural, social, religious, and health status differences, which affect the ability of immigrants to properly use the formal healthcare system of the host country. Many of the factors influencing the social status of immigrants and the use of healthcare services by immigrants relate to their social circumstances, which is why multiculturalism is linked to social determinants of health (National School of Public Health, 2010).

Immigrant-sensitive health systems are designed to meet the needs of migrants related to medical services, from basic recognition of the right of immigrants to health care to adaptation of healthcare systems and strategies for service delivery according to the needs of immigrants. Such services already exist in countries with historically high rates of immigration, such as Canada, Australia, New Zealand, the USA, and the UK, and are beginning to be implemented in countries recently experiencing high rates of migration (Fortier, 2010).

How health problems are related to immigration status depends largely on the type of immigration in each country, but also on the level of national social care system (Mladovsky, 2007). Between EU countries there is significant variability in the approach to health problems of immigrants. Healthcare politics for immigrants were developed in Italy since the 1990s. However, it is not clear to what extent the Italian government has successfully managed their implementation. Spain has recently developed national and regional plans for integration of immigrants (Mladovsky, 2007). In the Catalan region of Spain, the program *Migrant-Friendly Health Centres* was implemented by a NGO, in partnership with 33 hospitals of the Catalan public health system. Its purpose is to offer intercultural mediation services (www.portaldasaude.pt). Holland pays sustained and systematic attention to the health problems of immigrants (Mladovsky, 2007). In Norway, the *migrant-friendly hospital network* addresses a series of issues including language barriers in the interaction between patients and healthcare professionals, staff education, and multireligious assistance in the hospitals (www.portaldasaude.pt).

In 2000, the United States Department of Health and Human Services developed national standards to ensure culturally and linguistically adequate care (culturally and linguistically appropriate health services – CLAS). These standards address the practices of medical institutions with respect to the interaction between healthcare professionals and patients, the training of team members, community involvement, data collection, and administrative aspects (www.portaldasaude.pt).

Part 2

Immigrant Health Topics A–Z

Access to Care

Charles Edward Begley
School of Public Health, University of Texas Health
Science Center, Houston, TX, USA

Access to care is defined for an individual or population as the ability to obtain preventive, primary, and tertiary healthcare as needed for optimal health. The US Institute of Medicine Committee on Monitoring Access to medical care defined access as: the timely use of personal health services to achieve the best possible health outcomes. Access to care is measured through population surveys or statistical data that relate actual healthcare use to various need and other personal, health system, and environmental factors that tend to reduce or enhance healthcare seeking behavior.

In understanding access to healthcare and social services, it is useful to consider the variety of different predisposing, enabling, and need factors that act independently and together to influence patterns of use and outcomes. Predisposing factors include environmental and patient characteristics such as age, gender, race/ethnicity, marital status, education, occupation, environmental risk factors, and health attitudes and beliefs. These factors affect a person's healthcare seeking behavior.

Enabling factors refer to individual and healthcare system and service characteristics that affect the means for obtaining healthcare. They include personal characteristics facilitating access to care such as personal income, health insurance coverage, transportation, and language proficiency. They also include healthcare system characteristics such as the availability of resources and the training and practice styles of providers, which may vary on a regional basis or over time. These factors are often targeted by health policies and programs aimed at improving access.

The third component of access is the combination of professional and patient perceptions of need which drive health care demand. Perceived need is based on the recognition and severity of illness, the recognition and severity of comorbidities, and the desire for a high quality of life. Together with enabling factors, need perceptions determine the extent to which an individual will actually obtain healthcare.

Recognizing the diversity of factors that influence access to care is the basis for measuring access as the relationship between the use of healthcare and the environmental, socioeconomic, behavioral, and need characteristics of individuals and populations.

For more than 3 decades, health services researchers have studied these relationships to understand the determinants of access to care for different populations and predict healthcare use. Initially, access models contained only individual-level variables to explain the variation in access to care across populations. Recently, contextual variables reflecting the social, economic, structural, and public policy environment have been added to the access model.

Contextual variables for a defined geographic area (e.g., country, county, metropolitan statistical area, or state) measure the environment or milieu in which access occurs. Community variables capture the social, economic, structural, and public policy environment in which access occurs. Specifically, these variables include the characteristics of the population (insured and uninsured), public policy support for low-income and safety-net populations, and the structure of the health care market and safety-net services within that market. Other contextual variables that can be considered in the framework include the number of hospitals and hospital beds per 1,000 population, the number of physicians per 1,000 population, and economic measures, such as the unemployment rate in a geographic area.

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

Access Measures

Population surveys or administrative databases are used to describe potential and actual measures of healthcare access and associated access factors. Potential access is measured by the presence of enabling variables such as having a regular source of medical care or having insurance coverage. Realized access can be measured in positive terms such as regular visits to a physician and early initiation of prenatal care or negative terms such as delays in seeking or obtaining treatment, and late or no prenatal care.

Access outcomes measure the extent to which effective and efficient access is achieved once the individual enters the healthcare system. This measure combines the use of a specific type of healthcare for a specific health condition. Examples include preventable hospitalization rates for ambulatory care sensitive conditions, visits to hospital emergency rooms for non-urgent conditions, and hospital use for high-risk and complicated deliveries.

In countries with limited resources and lack of epidemiologic data, a common measure of access that combines a number of dimensions of the access model is the treatment gap. The treatment gap is used to measure the difference between the number of people with a given medical condition and the number being appropriately diagnosed and receiving treated. Direct measures of the treatment gap involve population surveys using adequate methods of case ascertainment, representative sampling, and a valid screening questionnaire. Information regarding treatment should be recorded with standardized questions that provide sufficient details on the type and quantity of treatments. Indirect methods, which can be applied when data are scarce, involve comparing hypothetical estimates of prevalence based on data from comparable countries to the number of people in treatment. For example, the drug treatment gap could be estimated by dividing the amount of drugs sold in a country by the defined daily dose of the drug and compared to the estimated number of people in the country who need the drug. Such estimates are subject to numerous biases and should only be used as broad indicators of access problems. A major limitation of the treatment gap as a measure of access is that it reveals little about the alternative factors that may be causing a gap. The researcher should also attempt to investigate the possible causes of the treatment gap in order to point to the strategies needed for improving access to care.

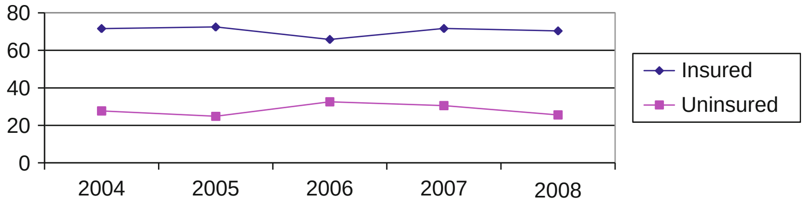
There are two broad approaches used in estimating health care access: empirical and hypothetical. In the former, estimates of the frequency and type of health services, social support services, and family member resources used by individuals with a condition are derived from prospective or retrospective studies of cases. In the latter, the estimates are based on hypothetical information provided by expert panels and/or related literature. Major concerns in both types of studies are the temporal perspective that is adopted (incidence perspective focusing on prognosis of new cases versus prevalence focusing on the current experience of all cases), case definition, the measures of use that are addressed, the generalizability of the estimates, and the attribution of services in patients with comorbid conditions.

Recent Trends in Access to Care in the US State of Texas

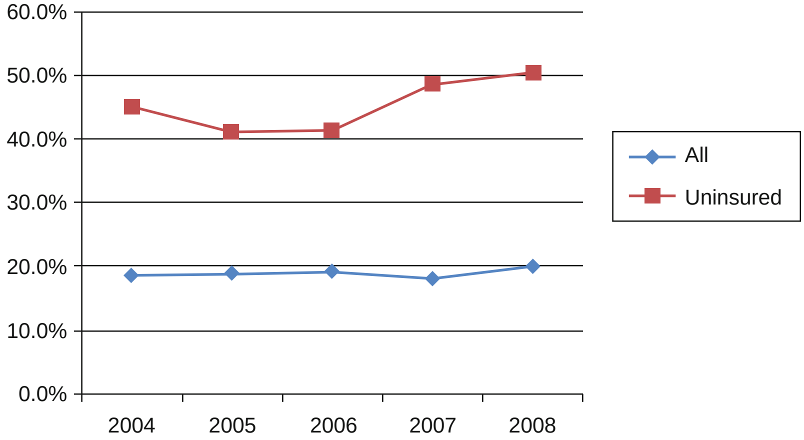
The state of Texas has 3.7 million foreign-born immigrant residents, the third largest number of immigrant residents among the states (after California and New York) and provides a useful example of access issues for immigrants. In Houston, Texas, the largest city in the state, there has been a sharp rise in the percentage of noncitizen residents, many of whom are uninsured. This is a concern because immigrants in the USA, particularly recent immigrants, are much less likely to be insured, and to have a personal source of care than US born individuals. They are also more likely to delay seeking medical care, less likely to receive appropriate care, have a higher rate of disabilities and death, and tend to rely more on Emergency Medicaid funding.

Immigrants in Texas are much more likely to be uninsured than are native-born residents. Well over half (60%) of the 2.6 million foreign-born residents of Texas who are not citizens (legal permanent residents, undocumented, and other foreign-born residents) are uninsured. Compared to other states with similar characteristics, Texas has the largest percentage of children of immigrants (40%) without health insurance.

With respect to potential access, there was a significant gap between the uninsured and the general population in Houston in terms of having a regular source of care (Fig. 1). The uninsured are about half as



Access to Care. Fig. 1 Disparity in potential access: percent with personal doctor or healthcare provider



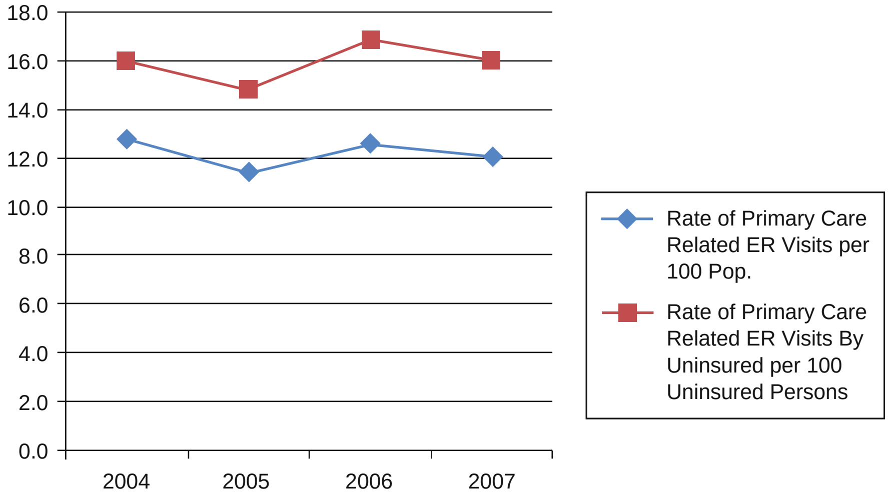
Access to Care. Fig. 2 Disparity in actual access: percent delayed a doctor visit in last 12 months due to cost

likely as the general population to indicate that they have a regular source of care (30% versus 60%). Similarly, with respect to realized access, the uninsured are about twice as likely as the general population to have delayed going to the doctor due to cost (Fig. 2). The gap increased over the last 5 years as the number reported delayed care increased somewhat for the uninsured while remaining constant for the general population. The rate of primary care–related hospital ER visits was between 12 and 13 per 100 population over the last 5 years, but for the uninsured, it ranged from 15 to 17 per 100 (Fig. 3). The gap between the two remained about the same over the period. Similarly, the percentage of total hospitalizations that were preventable was higher for the uninsured than for the general population (about 7% for the general population versus 10–11% for the uninsured) (Fig. 4). The gap between the two increased during the last 5 years.

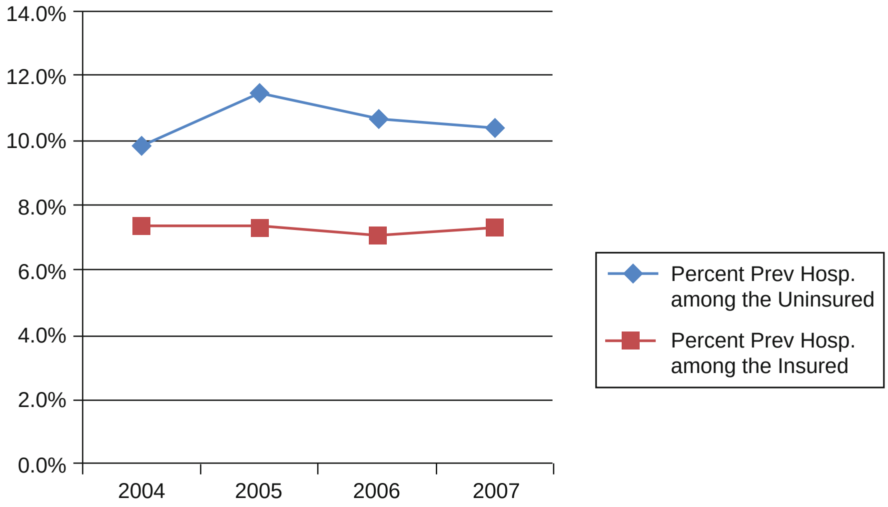
Conclusion

Access to care studies are important in identifying the need for resources, coverage, and or behavioral interventions to improve access and/or reduce the treatment gap. Problems are identified by the extent to which factors other than need determine who gets care or whether there is a significant gap between the need for and availability of care. In order for access studies to be useful, they must provide specific details regarding the barriers to access or the factors that cause the treatment gap. Immigrants in the USA and internationally experience multiple factors that impact their access to appropriate care. Researchers contribute to the understanding of healthcare seeking behavior and health outcomes. Their findings are instrumental in developing programs and policies that insure access for vulnerable populations such as immigrants and address the population-specific nature of access issues.

Immigrant noncitizen adults in Texas have the highest uninsurance rates of any group and face substantial barriers in access to care. In Houston, Texas, they are much less likely than people with health insurance to have a usual source of care, an important facilitator of access to healthcare. They are more likely to delay seeing a doctor because of cost, a measure of



Access to Care. Fig. 3 Disparity in access outcomes: primary care–related emergency room visit rate



Access to Care. Fig. 4 Access outcomes: preventable hospitalizations as percent of all hospitalizations

realized access, and they have higher rates of primary care–related hospital emergency room visits and preventable hospitalizations, both measures of access outcomes.

Acculturation

Amy Kerivan Marks, Bridgid M. Conn
Department of Psychology, Suffolk University,
Boston, MA, USA

The term “acculturation” is used to define a set of changes, both at the psychological and social level, which immigrants usually experience in order to facilitate their own settlement to host societies. At the individual level, the term acculturation denotes a complex series of psychological and interpersonal changes that occur when an immigrant experiences a first-hand encounter with a new culture. These encounters may precipitate psychological adaptations (e.g., changes in behaviors and beliefs, identities, values and attitudes) that are made in order to thrive in the new cultural environment.

Contextual immigration factors may facilitate a healthy and smooth adaptation process at times, while the individual may experience great stress and difficulty in acculturating at other times. As a result, immigrants also appear to have varying levels of health and wellness disparities, which are influenced by the stress involved with the acculturation experience. For new immigrants, access to health care, mental health support, and culturally sensitive services may provide a healthy new beginning and opportunities for growth. On the other hand, immigrants who experience greater disparity in access to services may also suffer from segregation and discrimination. Therefore, they may endure high levels of stress that end up leading to poorer health outcomes and fewer opportunities for a healthy development.

Numerous theoretical perspectives are used by researchers and practitioners to understand how context and acculturation might impact immigrant health. Contemporary bidirectional perspectives on acculturation differ quite dramatically from the early straight-line “assimilation” models that dominated the health and social sciences literature several decades ago. These “assimilation” and “melting-pot” models posited that immigrants can – and should – completely assume the values, customs, identities, languages, and behaviors of the new host country, by leaving their old cultural orientations and traditions behind. Such assimilation into the new host culture was thought to be ideal for promoting rapid social integration into the recipient society through a process that would, in the end, yield optimal social and health outcomes. Despite the popularity of these models before and during the 1960s, the USA’s post-1965 immigration era challenged these views along with the unprecedented diversity of culture, language, and racial origins brought by recent immigrant waves. The new immigrants’ diversity questioned the simplistic models of acculturation as a path toward a predominantly European-based White cultural majority, which has been the mainstream belief until not long ago.

In contrast to simplistic acculturation models, more recent theorists have proposed a multicultural approach to acculturation, in which distinct ethnic milieus can be created and sustained, serving as independent and autonomous cultural living environments. For some immigrant groups in the USA, this may result in the development of ethnic and cultural enclaves, which provide much needed support and security in the new society. Proponents of the multicultural perspective claim that optimal development in the new society might be achieved through immigrants’ immersion in traditional family cultural practices, within a culturally congruent community environment. Individual development within an ethnic enclave may provide stability and support without having to experience interethnic conflict and distress, which may be the case among children who have to navigate both their own cultural system and the one of the host country.

Further, immigrants' introduction to American cultural values and practices may lead to the birth of new "hybrid" cultural groups that hold diverse cultural values, behaviors, and identities. For example, the Latino ethnic group is comprised of individuals of Hispanic or Latin American origin. Many Latino subgroups identify themselves as a distinct aggregate that share both common and distinctive ethnic characteristics. As a result, ethnic, racial, and cultural diversity in today's US communities, schools, and families is more commonplace than exceptional. Importantly, alongside this new cultural diversity came a growing spectrum of theoretical and political perspectives on the ways immigrants and their children could and should "become Americans."

Unfortunately, although multicultural environments can support positive ethnic identities and favorable out-group understanding among minority groups, they may also lead to stereotyping immigrants, thereby placing them and their children at risk for psychological distress and poor developmental outcomes. For immigrants in these situations, there may be greater exposure to discrimination, which can lead to negative mental health outcomes as well as to barriers for receiving adequate and timely health services. Given the shortcomings of either a purely assimilationist or a purely multicultural model, today's research and health practice perspectives emphasize Berry's bidirectional acculturation model, to which we now turn.

The Bidirectional Model and Acculturation Styles

The bidirectional model describes acculturation as a function of the degree to which immigrants strive to maintain their cultural heritage and identity, vis-à-vis the extent to which they become immersed with a new cultural environment. Therefore, immigrants' social and psychological incorporation into a new culture can be understood as a combination of the adaptations made between two cultural frameworks – the culture of origin and the host culture. In examining immigrants' patterns of psychological adaptation, research has found support for four strategies or styles.

The first type of acculturation style, called "assimilation," describes the scenario wherein individuals who do not wish to maintain their original cultural traditions forego them and completely assume the beliefs and practices of the host culture. These individuals learn the new language quickly, usually by making an effort to stop speaking their old language. They are likely to adopt new cultural traditions (e.g., holidays) and practice their household activities (e.g., cooking) according to the new country's cultural norms. The second style, "separation," occurs when an individual strongly adheres to his or her traditional cultural practices, and avoids contact with the cultural institutions of the host country. Immigrants ascribing to the separation style are reticent to adopt new cultural customs, including learning new languages or seeking social relationships outside their communities of belonging.

The acculturation style described as "integrated" refers to immigrants' allegiance to their old ethnic ways, while, at the same time, adopting the new language, values, and traditions prevalent in the host culture. This style, oftentimes is seen as an ideal balance between old and new practices, and is also referred to as biculturalism. "Marginalization" is the final acculturation style stemming from the bidirectional model. This is widely considered as the most deleterious of the four styles, as it indicates a lack of engagement with either culture, and is strongly associated with poor psychological and emotional outcomes (e.g., depression, anxiety).

Acculturation, Context, and Child Development

From a developmental stance, the nuances of the acculturation process are central for understanding its impact on immigrants' overall health throughout the life span. For instance, as the fastest growing segment of the US population, immigrant youth acculturate in ways that usually vary dramatically from their parents or co-ethnic adults. Studies from the last two decades have demonstrated that children adapt to life in the USA differently from their parents', particularly given their different contexts of acculturation (i.e., school vs. work).

Certainly, parents tend to retain more traditional values and practices as they have less exposure to both the majority culture and to the "agents" of cultural change (i.e., teachers and native-born peers). This is especially true if the immigrant family lives and works within an ethnic enclave. Children in these families are more often exposed to mainstream agents, such as schools and native peers, so they will have more opportunities for cross-cultural exploration. As a result, immigrant children appear to acculturate more quickly than their parents, and tend to assume unique family roles during the acculturation process (e.g., translation/interpreter roles for parents). Numerous studies have shown that children and adolescents born in the USA to foreign-born parents have more intercultural social contacts, and are less socially segregated than their parents. Importantly, the implications of these family dynamics are profound. Differential acculturation rates, styles, and strategies between parents and their children have been linked to higher levels of parent–child conflict and distance.

Further, children who immigrate at younger ages (particularly before the age of ten) have been found to experience less stress related to acculturation compared to children who immigrate at older ages, as the first demonstrate less difficulty in acculturating and in adopting the practices and values of the host country. However, these children have also been found to engage in more intergenerational conflict with their families and elders resulting from differences in acculturation rates, amid incongruence of values and behaviors across cultural contexts. In contrast, children who immigrate later may experience greater synergy with their parents, due to the fact that they may be strongly attached to their cultures of origin. However, unlike their peers who immigrated at younger ages, these older children may experience similar acculturative stress as their parents. Furthermore, the acculturation-related struggles taking place within the family are highly influenced by the qualities of the receiving community in which immigrant parents and their children live.

Generally, most immigrants will continue to experience changes in cultural adaptation throughout their lifespan, although their individual responses amid their contexts of belonging will vary. In describing the influence of culture on adjustment, specifically within the school environment, Ogbu proposed three types of cultural discontinuities, which capture the process of how individuals make unique adaptations to new cultural institutions, such as the school system. In the "universal" type of cultural discontinuity, all children must learn to adjust to new school environments, for example, by adapting to novel classroom organization, new social norms, and daily routines. In the "primary" discontinuity model, immigrant children must adapt to new cultural concepts (e.g., American conceptualizations of "liberty" and "rights"), as well as to new learning styles, language, and idiomatic forms, and even basic mathematical concepts such as length and time. Finally, within the "secondary" discontinuity model, populations that are highly stratified and have a long history of social subjugation (e.g., racial minorities) must learn to adapt to the host country's "collective struggles" toward seeking specific religious, political, and legal rights.

Immigrant children are often faced with contradictions between school/peer cultures (which may challenge ideals of upward social mobility), and the beliefs espoused by their parents based on the importance of education as a means for social integration and upward mobility. Additionally, adult immigrants may suffer from the dissonance between their individual expectations and the realities presented to them as either "lower class" individuals or as "minority" members. Particularly with respect to recent immigration policy changes, the psychological and emotional stress experienced by some immigrant groups can be further strained as they fight for their rights, particularly when trying to obtain basic health and social services for their families. Finally, the discontinuity theories discussed in this section highlight the importance of understanding the larger social structures and stratification systems in place during the acculturation process.

Stress and Change

The saliency of the acculturation styles explained earlier can be seen in their association with different health and mental health outcomes. For example, immigrants experiencing either an integrated or a bicultural style of acculturation are also likely to present overall positive health outcomes that include lower levels of worry, stress, and anxiety. At the other end of the continuum, immigrants that ascribe to a marginalized acculturation style are more often exposed to social and structural barriers, such as poverty and racial discrimination. In addition, an internalized feeling of marginalization has been found to result in greater behavioral problems for children, adolescents, and young adults who may also suffer from higher levels of psychological distress.

As a result of the dynamic processes of acculturation, research has found evidence that support a specific psychological outcome, which has been termed as "acculturative stress." Historically linked to "culture shock," acculturative stress refers to the negative emotional reactions that immigrants may suffer during acculturation. As individuals come into contact with a new culture, they may experience fear and emotional threats to their traditional ways of life. They can also suffer from feelings of isolation or discomfort as they try to adapt to a new environment, while being overwhelmed by the challenges presented by the host society (i.e., entering school, finding a job, joining new social networks). Other syndromes that immigrants may experience include anxiety, depression, increased psychosomatic issues, and identity confusion.

Similar to acculturation itself, acculturative stress is a continuous and dynamic process that can be extended over time. Therefore, it is critical to count on services able to help immigrants deal with their physical and psychological difficulties, and which provide coping resources aimed at promoting health and well-being. Immigrants who present higher levels of acculturative stress have been found to experience negative outcomes in the social, emotional, academic, and health realms. Acculturative stress can also have a serious impact on the well-being of immigrants, by increasing their physical health ailments (i.e., chronic pain, heart conditions). Furthermore, recent research has demonstrated the existence of a powerful link between immigrants' experiences of discrimination and marginalization on the one hand, and deleterious health outcomes on the other. Finally, the endurance of acculturative stress increases the likelihood of developing mental health problems, particularly depression and anxiety.

The Immigrant Paradox

There are some acculturation-related health patterns that have been observed among immigrants in the USA, and that are collectively summarized in the notion of the *immigrant paradox*. According to this phenomenon, more highly acculturated groups of individuals will show *less favorable* health and education outcomes than their less-acculturated peers. Particularly among recent immigrant streams (i.e., Latino and Asian groups in the USA), the immigrant paradox suggests that these individuals will have significantly better health and education outcomes than both their native counterparts and those whose families have lived in the USA for generations (i.e., second generation). This troubling health pattern has been documented across a wide array of physical health (e.g., obesity, heart disease, smoking behaviors, sexual health), mental health (e.g., delinquency, internalizing problems), and educational (e.g., high school and college degree attainment) outcomes.

One way to disentangle these seemingly contradictory patterns, is to acknowledge the role structural factors play in shaping immigrants' acculturation experiences. Upon arrival to the USA, immigrants often encounter few upward mobility ladders and meager opportunities for economic advancement. Furthermore, they are typically exposed to grueling living conditions, which along with progressive and deep changes in their life styles can have a negative effect on both their physical and mental health outcomes. Lifestyle changes often include radical modifications in daily eating practices (e.g., drinking alcohol and eating unhealthy foods), working long hours and having little time for resting and socializing with peers. Therefore, it is not surprising to find that the longer immigrants have resided in communities that present high levels of poverty and social marginalization, the worse their physical and mental health outcomes and education possibilities may be. Further research is needed to fully explore the contextual, social, and intrapersonal factors underlying the immigrant paradox.

Final Remarks

The notion of individual acculturation encompasses a diverse set of experiences, which have profound implications for immigrants' health. Importantly, the types of acculturation patterns discussed earlier must be interpreted within the larger social contexts in which immigrants reside. Social barriers, such as poverty and discrimination, greatly influence immigrants' specific acculturation styles which, in the end, will greatly impact their health and developmental outcomes. Furthermore, many immigrant groups may continue to experience stigma and fear when seeking help for both physical and emotional issues.

Finally, less acculturated immigrants may have more difficulty understanding and utilizing Western models of medicine, and may insist on adhering to their healing beliefs. The respect for immigrants' traditional healing methods can actually increase their trust in biomedicine, and may lead to implementing successful multicultural approaches to health care.

The concept of acculturation refers to the cultural and psychological changes that groups and individuals undergo when they come into contact with another culture. Acculturative stress is stress that directly results from and has its source in the acculturative process, often resulting in a particular set of stress behaviors that include anxiety, depression, feelings of marginality and alienation, heightened psychosomatic symptoms, and identity confusion. Acculturative stress may underlie a reduction in the health status of individuals, including physical, psychological, and social health.

People have long been emigrating to better their lives for a variety of reasons, including seeking a safer environment, greater food sources, and personal freedom. In the last few decades, people have migrated more than ever before. Civil wars in Africa, the fall of the Soviet Union, natural disasters, and human-made disasters have instigated the relocation of several million people. While immigrant groups may be seen as having a large number of practical stressors as a result of relocation, such as economic or housing issues, stress related to acculturation also involves problems unique to immigrants, such as difficulties with language and varying customs. The types and intensity of acculturative stress depend on many factors including the similarities and differences between the host culture and that of the immigrants' country of origin, sex, age, language, race, motivation for the relocation, level of education, socioeconomic status, and the host country's political and social attitudes, especially toward immigrant groups.

The influence of gender on the acculturation process and related stressors differs in part due to variation in gender roles ideology across cultures. Females have been reported by a number of researchers to have greater difficulty in adapting to a new culture, with either fewer opportunities to acculturate while remaining in the home, or stressed by demands of employment coupled with a traditional division of labor, resulting in a heavy workload overall. Also, women are often more willing than men to accept low-wage and unskilled positions, sometimes becoming the wage earner in the family and creating stress with their male partners who may be unemployed and feel threatened by power shifts in the relationship and family structure.

Age at the time of immigration often appears to be negatively related to adjustment in the acculturation process. Studies have shown that a younger age at the time of immigration predicted higher levels of acculturation and greater life satisfaction. In addition, elderly people who immigrate with their extended families tend to do more poorly than their younger relatives, due to feelings of isolation being overwhelmed by the differences between the host country and country of origin.

Another factor of acculturative stress is the motivation behind the relocation itself, as it can be voluntary or involuntary. Some individuals have been motivated to move in order to seek educational or occupational opportunities; in other cases, individuals may perceive themselves as having less choice in the decision to leave their home county. Those immigrants with a history of mistreatment, such as refugees, may perceive themselves as threatened or treated unfairly by those in the mainstream group, and thus may feel less inclined to identify with that group.

Other major stressors include changes in socioeconomic status, level of education, and language proficiency in the host country. Immigrants' entry status into the larger society may be lower than their departure status from their country of origin. In addition, the inability to communicate proficiently in the host country's language may result in unemployment or having to accept a position of lower status than the one held in the country of origin.

Provision of social and economical support to immigrants may ease the transition to their new country and may play a vital role in lessening the effects of acculturative stress.

Acquired Immune Deficiency Syndrome

Daniel J. O'Shea
HIV, STD and Hepatitis Branch, Public Health Services, County of San Diego, San Diego, CA, USA

Acquired Immune Deficiency Syndrome (AIDS) is a medical diagnosis by a physician of a set of symptoms or conditions based on specific criteria established by the US Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO). These criteria include infection with Human Immunodeficiency Virus (HIV) *and* either the presence of one or more defined AIDS indicator diseases or other indicators of a suppressed immune system based on certain blood tests (CD4+ counts). The "opportunistic" diseases associated with AIDS occur following the depression of an individual's immune system, allowing susceptibility to unusual infections or malignancies.

AIDS, the end stage of HIV disease, is caused by the infection and spread of HIV within the body. A positive HIV test result alone does not mean that a person has AIDS, only that HIV infection has occurred. HIV destroys CD4+ T blood cells which are crucial to the normal function of the human immune system. Most HIV-infected people carry the virus for years before the immune system is damaged enough for AIDS to develop. There is a direct correlation between the amount of HIV in the blood, the decline in CD4+ T cell numbers, and the onset of AIDS. Progression from initial HIV infection to AIDS may take 10 years or more, but varies greatly depending on many factors, including a person's health status and his or her health-related behaviors. Reducing the amount of virus in the body with anti-HIV drugs can slow down the rate at which HIV weakens and destroys the immune system. The natural history of HIV infection is well documented in the medical literature. Information on HIV transmission, testing, and care and treatment may be found in the entry for "Human immunodeficiency virus (HIV)" in this encyclopedia.

State of the HIV/AIDS Epidemic and the Impact of Migration and Immigration

Worldwide, the United Nations AIDS program (UNAIDS) and WHO estimated that 33.4 million people were living with HIV/AIDS at the end of 2008 (31.3 million adults and 2.1 million children), 20% higher than in 2000 and three times higher than in 1990. During 2008, an estimated 2.7 million people became infected with HIV, and two million individuals died from AIDS. Dramatic advances have been made in understanding the natural history of HIV disease and in development of effective antiretroviral (ARV) therapies that significantly extend survival, allowing many years of healthy life. Nevertheless, the HIV/AIDS epidemic continues to grow with some disturbing trends. ARV drugs remain largely unavailable to many infected individuals in the developing world, and HIV/AIDS morbidity and mortality increasingly impacts the poor, the disenfranchised, and the young.

The International Organization for Migration reported that approximately 191 million people (3% of the world's population) were international migrants in 2005. Migration and immigration, while not HIV risk factors themselves, may create circumstances that increase one's risk of infection. UNAIDS data on HIV transmission and risks indicate that migrant and mobile populations, including labor migrants, refugees, asylum seekers and immigrants, newly arriving or resettling in a new country, are at greater risk for HIV infection than the local general populations in the new country of arrival or resettlement. UNAIDS attributes this to several issues and challenges ranging from financial and environmental conditions to cultural and language barriers, stigma, discrimination, exploitation, and difficulty accessing HIV education, prevention or health services. Patterns of migration are driven by political tensions, war, and economic and environmental crises which exacerbate instability and stress for the population on the move.

The majority of people with HIV/AIDS live in the developing world, two-thirds in Sub-Saharan Africa followed by 14% in East, South, and Southeast Asia. On the other hand, in the developed, high-income regions (United States, Canada, Western and Central Europe and Australia), the number of people living with HIV/AIDS continues to rise due to continued high rates of new HIV infections and widespread access to life-extending ARV therapy. Extended life expectancy with ARV increases the pool of HIV-infected people who are able to transmit the virus to others. HIV prevention activities in some high-income countries are not keeping pace with the spread of HIV or are falling behind, as evidenced by HIV increasing among marginalized groups, including drug users, immigrants, and refugees.

Sub-Saharan Africa contains just over 10% of the world's population and 67% of all people living with HIV/AIDS. Approximately 1.4 million people in this region died from AIDS in 2008. Average survival without treatment is around 10 years after infection. ARV drugs which dramatically extend survival are unavailable to most Africans. In contrast to other regions of the world, Sub-Saharan African women are 1.4 times more likely to be HIV-infected than men, due to both greater effectiveness of male-to-female HIV transmission through sex and the younger age at initial infection. As a generalized epidemic, defined as that in which HIV has spread beyond those engaged in high-risk behaviors to the general population with prevalence rates of 5% or more in urban areas, HIV affects all social and economic groups within Sub-Saharan Africa.

Regional migration, including work-related mobility, within Sub-Saharan Africa is an important factor for HIV transmission in that it encourages increased sexual risk behavior. Examples include increased infection among women who traveled away from home five or more times per year in the United Republic of Tanzania; among individuals residing in close proximity to a primary road in rural KwaZulu-Natal province in South Africa; among long-distance truck drivers and migrant mine workers, who are more likely to engage in high-risk or commercial sex; and among couples in Lesotho separated as a result of labor migration, resulting in a high rate of multiple concurrent partnerships.

In *Eastern Europe and Central Asia*, the HIV/AIDS epidemic is rapidly expanding, with 110,000 people infected with HIV in 2008, bringing the total number of people living with the virus to around 1.5 million. Very few have access to ARV therapy, resulting in around 87,000 deaths from AIDS in 2008, higher than it might otherwise be. Most impacted are the Russian Federation, Ukraine, Estonia, Latvia, and Lithuania. Around 940,000 people are living with HIV in the Russian Federation. Migration in this region has been significantly exacerbated by political tensions, war, economics, disintegration of the former Soviet Union, and recent enlargements of the European Union, all increasing instability with and potential susceptibility to HIV infection.

UNAIDS and WHO estimated approximately 310,000 people living with HIV/AIDs in *North Africa and the Middle East*, with 35,000 new infections and 20,000 deaths from AIDS in 2008. Long believed to have sidestepped the global epidemic possibly due to strict rules governing sexual behavior, the epidemic continues to grow here as well. Timely and reliable epidemiological and behavioral data have been extremely limited for this region, hindering a clear understanding of HIV-related dynamics and trends, including any impact of migration to or within the region.

In 2008, around 4.7 million people were estimated living with HIV/AIDS in *East, South, and Southeast Asia*, with 350,000 new infections and 330,000 AIDS-related deaths in that year. Comprising 60% of the world's population, East, South, and Southeast Asia is second in the number of people living with HIV, with India accounting for roughly half. Other countries with large numbers of people living with HIV include China (700,000), Thailand (610,000), and VietNam (290,000). Although adult prevalence was below 1% in most countries in this region, the national averages may obscure serious epidemics in some smaller provinces and states within larger countries.

Nearly 50 million people in the East, South, Southeast Asia and Pacific region are not living in their country of birth. Even so, this is significantly less than the number of people who migrate internally, particularly within larger countries such as China. Much of the latter is generated by migration for work to urban areas; China's so-called floating population is close to 150 million people. Among these rural-to-urban migrants, frequent substance use, intoxication, and elevated rates of sexually transmitted infections are reported. Cross-border migration among sexual and drug-using networks in some areas, including the India–Nepal border, appears to be contributing to two-way HIV transmission. Migrants are often excluded from basic health services in the areas to which they have migrated and more likely to delay seeking treatment.

UNAIDS and WHO estimated approximately 59,000 people living with HIV/AIDS in *Oceania*, with 3,900 new infections and 2,000 AIDS-related deaths in 2008. Oceania, comprised of Australia, New Zealand, Papua New Guinea, and numerous island nations and dependent territories within the Southern Pacific regions of Melanesia, Micronesia, and Polynesia, generally has a very low HIV prevalence rate compared with other regions, well below 0.1% for the small island nations that make up most countries in the region. Australia, with an estimated HIV prevalence of 0.2%, is also considerably less severely affected than other high-income countries. Monitoring epidemiological trends in the region is limited by weak HIV surveillance systems in many countries. Consequently, the impact of regional migration on epidemiological trends cannot be measured, or whether the epidemic in one country is affecting neighboring countries.

In Australia, the impact of immigration from outside of the region is clearly demonstrated in a per capita rate of HIV diagnosis more than eight times higher among immigrants from Sub-Saharan Africa than among Australian-born persons. Fifty-nine percent of the relatively small percentage of heterosexually acquired cases of HIV infection reported in Australia between 2004 and 2008 were among individuals born in Sub-Saharan Africa or among individuals with sexual partners born in a high-prevalence country.

An estimated 2.24 million people are living with HIV in *Latin America and the Caribbean*, including the estimated 190,000 who became infected during 2008. Around 89,000 people died of AIDS in the same year. Five Latin American countries have an adult HIV prevalence greater than 2%, higher than anywhere outside Sub-Saharan Africa. Although the largest epidemic is in Brazil, with 730,000 people living with HIV, the death rate has fallen there due to widespread access to treatment.

Large-scale migration occurs between countries in Latin America due to civil conflicts, political and socioeconomic conditions, and the high pace of urbanization. Recent studies have linked this movement of people to the spread of HIV in Latin America. Factors which exacerbate risk for HIV infection for immigrants from Latin America include poverty, violence, few available health services, increased risk-taking, rape, loneliness, and contact with large numbers of sex workers. Recent research indicates that the vast majority of migrants do not protect themselves during sexual intercourse, and 10% of female migrants had experienced forced, unprotected sexual intercourse. Migrants sometimes engage in high-risk behaviors, such as sex work, in order to survive day-to-day in a new and unfamiliar area.

Mexico's HIV/AIDS epidemic may be considerably impacted by US/Mexico cross-border migration. According to a survey of more than 1,500 Mexicans who had spent time in the USA, migrants had more sexual partners and used more non-injecting drugs than non-migrants, but migrants also reported higher rates of condom use and HIV testing. More than 20% of individuals with AIDS in the southern Mexican states of Michoacán and Zacatecas had previously resided in the USA. Male injecting drug users (IDUs) in Tijuana who had been deported from the USA were more than four times more likely to be HIV-positive than non-deportee IDUs. Close to 50% of men who have sex with men (MSM) in Tijuana reported having male partners from the USA.

UNAIDS and WHO estimated approximately 2.3 million people living with HIV/AIDs in *North America (north of Mexico) and Western and Central Europe*, with 75,000 new infections in 2008. Within this region, the rate of new HIV infection is highest in the USA. Even with the rate of AIDS-related deaths substantially reduced in this region through access to ARV medicines, AIDS claimed approximately 38,000 lives in the North America and Western and Central Europe region in 2008. In the USA, the CDC estimated that approximately 1,106,400 people were living with HIV or AIDS at the end of 2006, with an estimated 56,300 new HIV infections in that year. The CDC projects that 21% of those infected with HIV are unaware of their status, posing an even higher risk for transmission of HIV to others.

The epidemics in North America and Western and Central Europe are concentrated in higher risk populations, especially MSM, IDUs, and immigrants. Immigrants who acquired HIV infection in their countries of origin before migrating to these areas constitute a sizable share of the epidemic in many of these countries. Migrant populations, particularly from Sub-Saharan Africa, appear to represent a considerable and growing proportion of both HIV infections and AIDS cases reported in the European Union between 1999 and 2006. Individuals who migrated from countries with a generalized epidemic comprised approximately 17% of new HIV diagnoses in Europe in 2007. Several European countries have reported increasing proportions of heterosexually acquired HIV, some associated with migrants from high-prevalence countries; 77% of people newly diagnosed with HIV in the United Kingdom (UK) in 2007 who acquired the virus through heterosexual contact were likely infected outside the UK. The proportion of Sub-Saharan migrants among heterosexual and mother-to-child transmission cases is very high in Europe, and increasingly contributing to the epidemic in Europe, particularly among females. Public health services in North America and Western and Central Europe are challenged to access and provide culturally sensitive HIV prevention programs, care, and treatment to the infusion of immigrants, migrants, and refugees from diverse areas of the world with high HIV infection rates and generalized epidemics.

Cross-border migration between Mexico and the USA creates additional challenges, with concerns that Mexican and other Latin American migrant and recent immigrant populations in the USA are at increased risk for HIV. While relatively little is known about the extent of the HIV/AIDS epidemic among these populations, several factors point to high risk for HIV/AIDS within these populations. These include constant mobility; cultural beliefs; cultural, linguistic, and geographic barriers to HIV testing and health care services; immigration attitudes and legislation, resulting in fear of deportation; change in sexual practices, including higher likelihood to engage in high-risk sexual practices; limited education, including education about HIV transmission and prevention or safer sex; psychosocial factors; isolation; discrimination; poverty; episodic employment and chronic underemployment; and substandard housing. Change in sexual practices can be attributed to a need to seek companionship to compensate for the alienating aspects of migration, fewer restraints or social controls on behavior, exposure to previously unknown or unacceptable sexual, drug-using, or other risky behaviors and practices, or unstable economics that compel some to exchange sexual services for food, lodging, or money.

Future projections of the course and extent of the worldwide HIV/AIDS epidemic cannot be made with any accuracy. Although there are promising signs that the epidemic is abating in some areas, major challenges remain in terms of universal access to prevention, screening, treatment, and care, particularly among many migrant populations. WHO predicts that AIDS will continue to be a leading cause of death throughout the world for the foreseeable future.

Acupressure

Gary Edmunds
Center for Minority Public Health, Case Western Reserve University, Cleveland, OH, USA

Many Chinese immigrants in the USA have accessed both Western style biomedicine and traditional Chinese medicine (TCM), which includes acupuncture, acupressure, dietary therapy, massage, and therapeutic mind/body practice. Traditional Chinese medicine is a healthcare delivery system that has a professional class of physicians and its own diagnostic system. Individuals may access both TCM and Western conventional medicine.

Acupressure is a form of acupuncture that is performed without the use of needles; it involves only the contact (or touch) of the patient's body through massage. Finger pressure is applied to specific spots known as acupoints; these follow rivers of energy throughout the body that are known as meridians. It is believed that illness occurs when these energies become unbalanced or blocked and that stimulation of the acupoints restores the balance of these energy flows and alleviates illness. Pressure and small circulatory movements with the thumb or index finger are used at the acupoint, and percussion is used along the line of the meridian. Randomized controlled trials suggest that acupressure may be effective in reducing nausea during pregnancy, postoperatively, and following chemotherapy. Its effectiveness in treating motion sickness has not been established.

Studies have found that many Chinese immigrants may prefer Western medicine for acute symptom relief and life-threatening illnesses and prefer TCM for more chronic conditions, especially if they have tried Western medicine and found it to be ineffective or if they have experienced side effects. Conditions such as stress, fatigue, and digestive difficulties are often treated with TCM. TCM may also be utilized because of family traditions or family pressure to do so.

Research also suggests that a decision to use TCM is not influenced by educational level or acculturation level. However, use of TCM may be influenced by socioeconomic status. In the USA, for example, visits to physicians are often covered by health insurance, but visits to TCM providers are generally not covered by insurance. TCM treatment plans may also require more practitioner visits than would be required by Western medical care. As a result, Chinese immigrants may find that TCM care is more expensive than Western-based medical care and that the cost of TCM is prohibitive because of the lack of insurance coverage.

Acupuncture

Brandy L. Johnson
Rynearson, Suess, Schnurbusch & Champion, L.L.C.,
St. Louis, MO, USA

Acupuncture is an ancient healing practice that can trace its history back thousands of years to its apparent origin in China. It eventually spread to Japan, Korea, Vietnam, and East Asia. In the 1970s, the practice finally gained attention in the USA.

Classical Chinese acupuncture is based upon naturalist and Taoist thought. Traditional Chinese Medicine is a form of acupuncture that strives to keep the body in balance. Under Traditional Chinese Medicine, *qi* regulates a person's spiritual, emotional, and physical well-being. A person's *qi* is believed to be affected by two polar compliments: yin and yang. Yin represents negative energy or passive principle. Conversely, yang represents positive energy or active principle.

An imbalance of yin and yang leads to a blockage of the vital energy, or *qi*, along pathways called meridians and results in illness. It is thought there are more than 2,000 points on the human body that connect with 12 main and eight secondary meridians. Through acupuncture, which involves the placement of hair-thin, solid, metal needles at the various points of the body that connect with meridians, the blocked pathways can be cleared. It is believed the use of the needles to manipulate the ability of *qi* to flow allows yin and yang to be brought back into balance.

While Traditional Chinese Medicine is still practiced, another form of acupuncture has emerged: medical acupuncture. Medical acupuncture is often practiced, in Western cultures, by doctors other than health care professionals with medical/health science training. While Traditional Chinese Medicine is highly individualized, medical acupuncture treats the patient's symptoms using a corresponding group of points. Rather than imbalances in the body, it is based more on biomedical diagnoses, anatomy, physiology, and biochemistry.

There are several biomedical theories for how acupuncture works. It has been proposed acupuncture stimulates points that relay electromagnetic signals. This would cause the signals to be sent at a faster rate, triggering the flow of pain killing biochemicals, like endorphins, and sending immune system cells to the injury/diseased site. Another proposition is that acupuncture results in opiates being released into the central nervous system. A third theory is that a patient's brain chemistry may be changed, through acupuncture, due to the release of neurotransmitters and neurohormones in a positive manner.

Acupuncture can be used to treat a variety of conditions. According to the 2007 National Health Interview Survey, 1.4% of respondents, representing approximately 3.1 million US adults and 150,000 children, indicated they had undergone acupuncture the previous year. An earlier National Health Survey Interview revealed pain or musculoskeletal complaints accounted for seven out of the top ten conditions for which people underwent acupuncture. The most common condition was back pain. Other commonly cited conditions included joint pain, neck pain, migraine/ headache, and recurring pain. Acupuncture has also been used to treat conditions like fibromyalgia, menstrual cramps, labor pain, chemotherapy-induced nausea and vomiting, epicondylitis, osteoarthritis, postoperative dental related pain, carpal tunnel syndrome, and myofascial (trigger point) pain.

The Alternative Health/Complementary and Alternative Medicine Supplement portion of the 2002 National Health Interview Survey reported 62.1% of the US population had used some form of complementary and alternative medicine. In 2002, 1.1% of the population had used acupuncture in the prior 12 months. The 2007 National Health Interview Survey revealed the proportion of US citizens that used acupuncture in the prior 12 months increased to 1.4%.

The National Health Interview Survey also examined the ethnicity/race of the respondents. In 2002, of the respondents who used alternative medical systems, which includes acupuncture, 2.4% were Hispanic, 2.8% were White, 1.4% were African-American, and 4.5% were Asian. In 2007, of the respondents who used alternative medical systems 3% were Hispanic, 3.7% were White, 1.4% were African-American, and 5.4% were Asian. Females and those who are between the ages of 40 and 60 were more likely to use treatment like acupuncture. Additionally, individuals in the Western USA as compared to other regions of the USA were more likely to use treatment such as acupuncture.

Asian immigrants to the USA, especially older individuals, may be more familiar and comfortable with treatments like acupuncture and may view these approaches as consistent with their homeland's customs, rituals, cultures, and beliefs. Moreover, language barriers might also prevent immigrants from seeking conventional medical care from physicians.

The effectiveness of acupuncture is subject to debate. As studies use different acupuncture techniques, controls, and outcome measures, the results of the studies can be difficult to compare and draw conclusions from overall. However, there is some evidence that a person's attitude about acupuncture can have an effect on their perceived outcome. While most agree more research is needed, acupuncture is gaining acceptance as a promising alternative for some pain conditions and is covered by some insurance companies.

Potential risks of acupuncture include infection, internal organ injury, soreness, bruising, and bleeding. To lower the risks associated with acupuncture, some countries impose regulations on the practice. In the USA, for example, the Food and Drug Administration regulates acupuncture needle use by licensed practitioners. It is also recommended the patient research the practitioner's qualifications and reputation prior to submitting to treatment.

Acupuncture, like many other types of complementary and alternative medicines, has been growing in popularity and acceptance. Although there is debate as to the effectiveness of acupuncture, it is generally deemed relatively safe when performed by a competently trained professional.

Addiction and Substance Abuse

M. Barton Laws
Department of Health Services Policy and Practice,
Brown University, Providence, RI, USA

Discussion of so-called substance abuse and addiction is vexed by ambiguity and disputes over vocabulary, which is caught up in equally vexing disputes about ideology and values. People may distinguish among substance use, misuse, abuse, abuse disorder, dependence, and addiction, but not necessarily in consistent ways.

The American Psychiatric Association defined drug abuse in 1932 as "the illegal, nonmedical use of a limited number of substances, most of them drugs, which have properties of altering the mental state..." Note the oddity that not all drugs are drugs – the second sense meaning therapeutic compounds. This double meaning creates additional confusion. The definition went on to establish as essential conditions violation of cultural acceptability, social norms, or statute; drug abuse was predominantly framed as moral transgression. This moral lens has continued to influence views of substance abuse, but the formulation of addiction or substance dependency as a disease has grown more influential.

As the disease model does not distinguish between licit and illicit behaviors, while the term "drugs" has not generally been understood to include alcohol and tobacco, "substance abuse" is now preferred. Some question the concept of a substance abuse disorder or addiction entirely, claiming that these cannot be distinguished from other categories of voluntary behavior which may have consequences that most people would view as negative. A contrary movement has extended the concepts of behavioral dependence and addiction beyond the use of psychoactive chemicals, to encompass behaviors ranging from gambling to eating to sex to surfing the Internet.

For the disease model of substance use disorders the authoritative texts are the *Diagnostic and Statistical Manual of Mental Disorders IV, Text Revision, (DSM)* issued by the American Psychiatric Association; and the World Health Organization *International Statistical Classification of Diseases and Related Health Problems*, 10th Revision (*ICD10*). Neither uses the term "addiction." The *ICD10* focuses on harm to the individual from overuse of psychoactive substances, with difficulty controlling use and continued use in spite of harm defining "Dependence Syndrome." The *DSM* uses a similar definition for "substance dependence." However, its definition of substance abuse does not focus on damage to health, but rather on psychosocial problems such as failure to fulfill role obligations, and legal consequences. In this respect, the moral lens persists.

In the vernacular, "addiction" may refer to any habitual overindulgence, but in neuropsychiatry it refers specifically to alterations in the brain's dopamine signaling system centering on the nucleus acumbens region. This circuit is believed to provide rewards for behaviors associated with evolutionary success, such as sexual intercourse and eating. Addictive drugs increase the level of dopamine in this system, resulting initially in behavioral reward. Chronic overstimulation of dopamine receptors results in needing the drug in order to feel any behavioral reward and overwhelming other motivations. Note that the "reward" for using the drug is not necessarily euphoria or even pleasure, but merely the relief of craving. Additional accommodations by the body to chronic use of an addictive substance may result in various other physical or mental symptoms when the drug is withdrawn, creating an additional short-term challenge to cessation. However, craving may persist long after these acute withdrawal symptoms have ended.

Chemicals that affect this neural circuit include opioids, nicotine, alcohol, amphetamines, and cocaine, although the effects of these compounds are otherwise dissimilar. Hallucinogens are considered drugs of abuse, but are not habituating. Cannabis (marijuana) targets a different class of neuroreceptors and is less habituating than chemicals that target the dopamine pathway.

Epidemiology of Substance Use Disorders

Any estimate of the prevalence of substance use disorders (SUDs) in any given region or population group depends on how these disorders are defined and ascertained. Some studies count any person who reports having used an illicit drug during some prior period – which could range from the past week to the past year; others require respondents to meet criteria regarding frequency, compulsivity, or social harms. Some count alcohol use exceeding some criteria of frequency and quantity, and/or social harms, usually referred to in this context as "problem drinking," or any tobacco use. Others depend on admissions for treatment for acute complications, or for detoxification or cessation services.

Studies generally find that onset of SUDs peaks sharply at around age 20. Acquiring an SUD in later life is unusual. The World Health Organization estimates there are 76.3 million people worldwide with a diagnosable alcohol use disorder. However, it acknowledges that data from various countries are not readily comparable and not always reliable. WHO finds age adjusted per capita alcohol consumption to be highest in Europe, by a large margin; second highest in the Americas; and lowest in the predominantly Muslim eastern Mediterranean region, and in Southeast Asia. (Islam proscribes any use of alcohol, but alcohol may be legally sold in some predominantly Muslim countries.) However, consumption in Europe has been falling in recent decades. The WHO estimates there are more than one billion smokers in the world – about one-third of the population 15 years of age and older. Use of illicit opioids, notably heroin, has principally been a problem in Europe and North America but is increasingly seen in Afghanistan – the primary producing country – and parts of Southeast Asia and southern China. Cocaine is produced in South America and principally consumed in the USA. (Traditional cocaine use in the Andes, where leaves are chewed rather than refined into pure cocaine, causes little harm.) The WHO publishes detailed reports on substance use and dependence in individual countries, but it is difficult to develop summary comparisons from the diverse forms of available data. (For more information about epidemiology and etiology of SUDs among international migrants, see the entries on "Drug Abuse" and "Substance Use" in this Encyclopedia).

Harm from Substance Use and Abuse

Habitual tobacco use is very harmful to health over the long term, dramatically raising the risk of lung cancer and some other cancers, heart disease, stroke, chronic obstructive pulmonary disease, and associated mortality. Tobacco use is considered the leading preventable cause of death in the USA and most of the wealthy countries. However, as tobacco is fully legal and does not produce acute impairment, other social harms associated with tobacco are minimal.

The example of tobacco supports a plausible argument that the harms associated with opioid dependency principally result from legal prohibition. Dependent users can be maintained with doses that do not produce euphoria but eliminate craving, with minimal consequences to health, and lead fully functional lives. However, as nonprescription opioids are very expensive and their sale and possession is subject to severe legal sanctions, habitual users must devote most of their waking hours to obtaining them or the money with which to buy them, often through illegal activity. They commonly self-inject to obtain maximum effect from small amounts, leading to risk of acquiring HIV and Hepatitis C virus from shared equipment, and injection site infections. They cannot count on the concentration or purity of the product they acquire, and may accidentally overdose or inject dangerous contaminants. They are subject to marginal existence, homelessness, and incarceration.

The harm reduction movement argues for a nonpunitive approach to drug dependence which "Accepts, for better and for worse, that licit and illicit drug use is part of our world and chooses to work to minimize its harmful effects rather than simply ignore or condemn them." Preferred harm reduction policies include providing clean needles, teaching safer injection practices, and mandating users who commit nonviolent crimes to treatment rather than jail.

The harm reduction approach is on weaker ground when it comes to amphetamine and cocaine abuse, as these substances have more profound inherent health and behavioral consequences. There is no medically safe maintenance approach to these chemicals. However, the social harm of prohibition extends beyond the users to the economy of illicit drug trafficking. Since drug traffickers obviously cannot call upon the authorities to enforce contracts and honest trading, the illicit drug industry is controlled by criminal organizations that use violence to control territory and settle disputes.

The case of alcohol is quite different. Alcohol used in moderation – typically defined as no more than two ounces of ethanol per day for men – may have health benefits; whereas excessive consumption and dependency have many negative health and social consequences. Prohibition of alcohol in the USA during the 1920s failed to control alcohol use and abuse, but spawned violent crime syndicates. Most now agree that the social harm associated with alcohol is less under a regime of regulated, legal production and sale than it was under prohibition. In some Islamic countries with no cultural tradition of alcohol use, however, prohibition appears to be successful.

In the USA and Western Europe there is increasing support for decriminalization of cannabis (marijuana), which is held to be at worst comparable to alcohol in potential for harm. Cannabis prohibition is very costly in law enforcement, the incarceration of otherwise law abiding people, and the promotion of criminal activity. However, research in recent decades indicates that cannabis use in adolescence may slightly elevate the risk of later diagnosis with schizophrenia. Cannabis is held by many to have potential benefits for palliation of symptoms of many diseases and side effects of chemotherapy for cancer, so the movement in some states has taken the form of legalizing cannabis for medical use only.

Opioid drugs are a double edged sword of another sort. They are indispensable for relief of pain and are widely prescribed in short courses after dental procedures or surgery. Such use rarely produces dependency. People with chronic pain may be prescribed maintenance regimens of opioids, which can be managed at a level which does not impair functioning. However, some people do develop dependency which continues after their prescription is withdrawn, or crave dosages larger than they are prescribed. This can lead to purchasing illicit supplies, or "doctor shopping" to obtain excessive prescriptions. Furthermore, diversion of prescription opioids to the illicit market is a principal means by which people in the USA are initiated into opioid abuse.

Etiology of Dependency

Nicotine may be the most powerfully addictive substance, which quickly produces dependence and craving in almost anyone who starts to use it. For other potentially addictive substances, some people likely have a genetic predisposition to become dependent. However, the social and cultural environment is important in determining whether use becomes abuse or dependence.

People with limited education who struggle in school and have difficulty getting established in the job market are at elevated risk for dependency. Many college students and young professionals have used illicit drugs, but with enticing life prospects or comparatively rewarding jobs, and a motivation to get to work on Monday morning, this use is less likely to end up as dependency.

But the causal story may not be so simple. In the USA, young African Americans and Latinos are no more likely to use illicit drugs than their White, non-Hispanic counterparts. White youth who come into contact with the police due to illegal drug use or underaged drinking are likely to be diverted into counseling, or simply given a lecture and released. However, minority youth are far more likely to encounter a punitive response, including institutional confinement. This is highly counterproductive, damages their school and career prospects, and immediately labels them as outlaws and failures.

The prison population in the USA overwhelmingly consists of people with substance use disorders – some estimates are as high as 80% – with limited education and erratic work histories, and disproportionately African American and Latino, including Latino immigrants. Most are confined for drug related offenses. They may experience limited access to treatment services while incarcerated, limited support for reentry, and face great difficulty finding jobs or housing. A return to a life of drug abuse and petty crime often results.

Substance abuse disorders have a high prevalence of comorbidity with other diagnosed mental disorders. This probably in part reflects attempts at self-medication, and perhaps also the limited career prospects and social marginalization of people with severe mental illness.

As the onset of substance abuse disorders seldom occurs in adulthood, prevention efforts largely target youth. The evidence base for primary prevention is thin. Many programs continue to receive funding despite limited evidence of effectiveness, and even affirmative evidence that they are ineffective. It is difficult to prove the effectiveness of social programs, but a credible school of thought holds that prevention should not focus excessively on substance abuse per se, but rather take a comprehensive approach to young people's social development including addressing school failure, family problems, self-esteem, and mental health.

Initiation into the use of substances that have potential for abuse and dependency requires a cultural milieu that supports use, and availability of the substance. Where the former exists, restricting the latter has proved to be very difficult.

Substance Abuse Treatment

Chemical dependency is a relapsing/remitting disorder. Many people succeed in long term abstinence only after several attempts. In the USA, "detoxification" means a short-term, inpatient course in which acute withdrawal symptoms are managed. Follow-up services are necessary or relapse is almost inevitable. For people with severe alcoholism, opioid or stimulant dependence, the most effective treatment modality may be a 3–6 month residential program, followed by ongoing outpatient counseling. Residential treatment takes people out of the milieu of dependency and provides a highly structured environment which includes intensive counseling.

Outpatient counseling, without preceding residential treatment, may succeed for people with less severe dependency or who have relatively stable lives and a naturally supportive milieu. Many people participate in so-called "12 Step" peer support programs, Alcoholics Anonymous, and others modeled on it. Although these are very widely accepted, there is little scientific evidence to support them, as participants are largely self-selected.

For people with opioid dependence, maintenance using the long-acting opioids methadone and buprenorphine is standard in some US states and parts of western Europe, but is severely restricted or unavailable in most of the world. Nicotine replacement is used for smoking cessation. Antidepressant medication is sometimes used to facilitate smoking cessation, and there are newer drugs specifically for this purpose. They do have side effects, and seem to have limited effectiveness. Naltrexone blocks the euphoric effects of alcohol and opioids, but its usefulness as a cessation aid is limited since people can simply stop taking it.

People who receive treatment are more likely to remain abstinent, or at least to have shorter periods of relapse and longer periods of remittance, than those who do not. However, health insurance generally provides limited benefits for treatment, if any, and access to publicly funded treatment is greatly insufficient to meet the demand in the USA. The availability of treatment programs, and their underlying philosophy, varies widely around the world. For the most part, the approach to addiction is punitive.

Adherence

Scott D. Rhodes
Division of Public Health Sciences; Section on Infectious Diseases, Department of Social Sciences and Health Policy, Wake Forest University School of Medicine, Winston-Salem, NC, USA

According to Rhodes and colleagues, is the extent to which a therapeutic regimen is correctly taken. Patients with high adherence take their medication as prescribed by their health care providers; patients with low adherence do not take their medication as prescribed by their health care providers. Adherence is particularly low for immigrants given higher rates of poverty, decreased access to health care, and inexperience with and/or mistrust of the US health care system. The lack of bilingual and bicultural service provision and limited provider knowledge of traditional medicine also lead to reduced adherence among immigrants.

Rates of adherence for individual patients are reported as the percentage of prescribed doses taken by the patient as indicated over a specific time period. Calculating this rate requires assessing whether medications were taken on time and according to the prescribed dosage. Poor adherence to therapeutic regimens accounts for worsened health, more rapid disease progression and even death, increased drug resistance, and higher health care costs. Osterberg and Blaschke reported that of all medication-related hospital admissions in the United States, 33–69% are attributable to poor adherence with the resulting cost of $100 billion per year. Rhodes found that for immigrants, adherence rates are much lower given the added layer of barriers to health screening, care, and treatment.

Generally, adherence is typically higher among patients with acute conditions compared to those with chronic conditions. In fact, adherence rates among patients with chronic conditions may drop dangerously low after the first six months of therapy, jeopardizing medication effectiveness and promoting drug resistance due to suboptimal drug levels. There is no standard for what constitutes "adequate adherence." In fact, adequate adherence may differ by medication. For example, most HIV medications require at least 95% adherence in order to ensure effectiveness, while rates between 50% and 80% may promote drug resistance due to ongoing viral replication.

In addition to adherence to therapeutic regimens, such as taking blood pressure medication, adherence to health-promoting and disease-preventing behaviors also can be challenging for individuals. Maintaining an exercise regimen, using condoms consistently, and seeking regular mammography are examples of behaviors to which some individuals are recommended to adhere. Adherence rates can be calculated for these types of behaviors.

The ability of health care providers to measure and assess adherence is limited. Common measures include directly observed therapy (DOT); measurement of the level of medicine or metabolite, or biologic marker in the blood; patient self-report; counting pills or weighing tubes; rates of prescription refills; patient clinical response (e.g., improved health); electronic medication monitors (e.g., medication bottle cap with an embedded microchip to record bottle openings); daily patient diaries; and caregiver report. Combining approaches may maximize measurement accuracy. However, these approaches require an individual to have access to health care services; immigrants often lack access.

Barriers to adherence to therapeutic regimens among immigrants can be categorized into six major domains. These domains include (1) demographics (e.g., low level of educational attainment, homelessness, unstable housing, and decreased income); (2) cognitive and psychological factors (e.g., little knowledge about how to take prescribed medications or lack of confidence in following guidelines such as condom use, depression, doubting the efficacy of evidence-based medicine, seeing initial positive results of taking medications and thinking that adherence is no longer necessary, and asymptomatic disease); (3) behavioral factors (e.g., alcohol and illicit drug use); (4) provider characteristics (e.g., poor provider–patient relationships, perceived and real prejudice and discrimination by providers, and mistrust of providers and health care system); (5) social factors (e.g., lack of social support, isolation, and stigma associated with illness and disease); and (6) treatment factors (e.g., complexity dosing or behavior, timing, cost, side effects, and food requirements).

Interventions designed to overcome these barriers and improve adherence have had mixed results. Interventions to improve adherence among immigrants may include social marketing to reach and educate them about available services for which they are eligible; reducing fears about eligibility, confidentiality, the privacy of medical records, and costs; patient and family education; improved dosing schedules that are simple and supported by cues to action; increased provider hours and shorter wait times; improved transportation to services; and improved communication between providers and patients.

Low adherence to therapeutic regimens is common, and immigrants are at increased risk of low adherence because of the multi-level barriers they often face. Improving adherence can have a profound impact on reducing disease, death, and health care costs.

Administration on Aging

Diane L. Munson
The Institute for Palliative Medicine at San Diego Hospice, San Diego, CA, USA

In 1965, the US Congress passed the Older Americans Act (OAA) (PL. 89–73) in response to a lack of community social services for older persons. The legislation established and granted the Administration on Aging authority for administering grants to States for community planning and social services, research and development projects, and personnel training in the field of aging. The Administration on Aging (AoA) serves as the federal focal point on matters concerning older persons and implements the new provisions contained in the Older Americans Act Amendments of 2006. Currently, the AoA is one of the nation's largest home and community care programs for the elderly and their caregivers.

AoA is an Operating Division of the US Department of Health and Human Services (HHS), reporting to the Assistant Secretary and assisting HHS in all matters pertaining to opportunities and challenges for elderly. Nine regional offices located across the USA provide support to the AoA's mission "to develop a comprehensive, coordinated, and cost-effective system of home and community-based services that help elderly individuals maintain their health and independence in their homes and communities."

AoA Activities

- Advocates for and advises on the characteristics, circumstances, and needs of older persons in program planning and policy development within HHS and with other Federal agencies
- Administers grants to States to establish State and community programs for older persons, including grants for older Native Americans, Alaskan Natives, and Native Hawaiians
- Provides policy and procedural direction, advice and assistance to grantees
- Disseminates consumer information and conducts public education activities, especially surrounding disease and disability prevention and emergency preparedness and response for older people

AoA Funded Services

AoA funds six primary services for elders and their caregivers including nutrition, the National Caregiver Support Program, preventive health services, supportive services, protection of elder rights, and services for Native Americans. Selected examples include:

- The *Aging Services Network* serves over seven million people as it promotes the development of a comprehensive and coordinated system of home and community-based services for older people and their family caregivers.
- The *Alzheimer's Disease Supportive Services Program* supports state efforts to expand the availability of community-level supportive services for persons with Alzheimer's.
- The *Lifespan Respite Care Program* coordinates community-based respite care services for family caregivers.
- The *National Long-Term-Care Ombudsman Program* advocates for the health, safety, welfare, and rights of older residents of long-term-care facilities.
- The *Older American Act Nutrition Program* provides meal service and nutrition education to elders in their communities and homes.
- State *Aging and Disability Resource Center Programs* provide streamlined access to health and long-term-care programs for the elderly.
- The *Hispanic Elders Project* supports community efforts to improve the health of Hispanic elders, especially around prevalent chronic diseases such as diabetes, heart disease, and arthritis.

As the federal focal point for older Americans and their caregivers, the AoA plays a vital role in information exchange on aging issues with other countries, and in collaborating with international organizations to enhance aging programs and policies worldwide. AoA actively supports the United Nations' *Madrid International Plan of Action on Ageing*, and has implemented projects in the areas of work and aging, transportation and aging, housing and aging, advancing health and well-being into old age, and volunteerism for and by the elderly. Aging is a global issue that impacts the global economy, labor force, trade migration, international relations, and national security – and AoA has been a leading supporter of international exchanges, conferences, and publications such as the American Association of Retired Persons' (AARP) Global Aging Program. Information provided by the AoA is helpful in determining what services in their communities are available for immigrant elders, who may be particularly vulnerable and need special services or advocacy.

Adolescent Health

TRISTAN E. GUARINI, AMY KERIVAN MARKS
Department of Psychology, Suffolk University,
Boston, MA, USA

Approximately 14 million children and adolescents in the United States are immigrants or have immigrant parents. The population of children and adolescents in immigrant families grew by almost 50% during the 1990s, almost seven times faster than the population of children with US-born parents. The majority of adolescents in immigrant families are of Hispanic or Asian origin, but a growing population of immigrant adolescents includes recently arrived refugees from Eastern Europe and Africa. Adolescents in immigrant families are more likely than native-born adolescents to be poor, live in crowded houses, to be uninsured, to lack a usual source for health care, and to be in fair or poor health.

In 2007, 34.3% of the US Latino population was comprised of individuals under the age of 18. Latino immigrant adolescent health is often influenced by factors including language/cultural barriers and lack of access to preventive health care and health insurance. Some of the leading causes of illness and death in the Latino community include cancer, heart disease, stroke, and diabetes. Other health conditions that significantly impact Latinos include asthma, chronic obstructive pulmonary disease (COPD), HIV/AIDS, obesity, suicide, and liver disease.

In 2002, 33% of the Black population in the United States was made up of individuals under the age of 18. The Black community is most affected by the following health-related conditions: heart disease, stroke, cancer, asthma, influenza and pneumonia, diabetes, HIV/AIDS, and homicide.

In 2004, 23% of the Asian community was made up of individuals under the age of 18. Asian immigrant adolescents in the United States contend with many factors which may threaten their health. Some factors that influence health care service utilization in this population include infrequent medical visits due to fear of deportation, language/cultural barriers, and lack of health insurance. Asians are most at risk for diabetes, heart disease, cancer, and stroke. The Asian community also has a high prevalence of chronic obstructive pulmonary disease, smoking, tuberculosis, HIV/AIDS, hepatitis B, and liver disease. While there is notable disease among this population, it is also important to note that Asian American women have the highest life expectancy in the United States (85.8 years).

Immigrant Health Paradox

Immigrant adolescents differ on many health-related outcomes as compared to their native-born counterparts. The degree to which this difference occurs often depends on the generational or acculturative status of the immigrant adolescent. Often, first generation, less-acculturated adolescents demonstrate less risk in health-related behavior than more acculturated or US-born adolescents. This phenomenon is called the "immigrant paradox." This phenomenon is progressive, wherein each generation presents more health-risk than the one before. The immigrant paradox has been documented most abundantly in Latino and Asian immigrant populations, but has also been documented in Black immigrant adolescent populations. The disparity in health-related outcomes remains even when differences in family income and parental education are taken into consideration.

One theory that helps to explain this disparity in health-related outcomes in immigrant adolescent populations is the operant theory of acculturation. According to this theory, behaviors in the adolescent's country of origin that were not reinforced, or were punished, will increase in prevalence during acculturation if the same punishers are not present post-migration. For example, in many Asian countries, healthy eating practices are reinforced, but in the United States, less strict dietary practices are the norm. Therefore, as Asian adolescents acculturate to the United States, it would be expected that their diets would become less healthy. This same theory can be applied to all health-related behaviors to explain why certain health-related behaviors become more problematic as adolescents acculturate to the United States.

Obesity, Diet, and Exercise

Adolescent obesity is a primary public health concern and has health, social, and economic consequences for the adolescent. A study examining the impact of immigrant generation and ethnicity on obesity found that 24.2% of White non-Hispanic adolescents were obese as compared to 30.9% of Black adolescents, 30.4% of Hispanic adolescents, and 20.6% of Asian adolescents. Chinese (15.3%) and Filipino (18.5%) adolescents demonstrated significantly lower obesity rates than White non-Hispanic adolescents. Both Asian and Latino male adolescents showed more obesity than their female counterparts. This was not true for the Black community, in which females demonstrated a higher rate of obesity than males. Important differences by immigrant generation were also found, such that Asian American and Hispanic adolescents born in the United States were more than twice as likely to be obese than first generation Asian and Latino adolescents. Additionally, low levels of physical activity, an important determinant of obesity, tend to be high in US-born Latinos when compared to foreign-born Latinos. There are few data on the dietary practices of Latino immigrants, but data do indicate that foreign-born Latinos generally have healthier diets than US-born Latinos. A study examining the impact of acculturation on dietary practices in Mexican Americans found that first generation Mexican Americans consumed more from the four basic food groups than did US-born Mexican Americans.

Another study examining the difference among Whites, Asians, and Latino adolescents on preventive health behaviors (bicycle helmet use, seat belt use, and sunscreen use), physical activity, time spent watching television or playing video games, and nutrition (fruit, vegetable, milk, and soda consumption) demonstrated interesting trends across immigrant generations. First generation Asian adolescents displayed lower participation in prevention health behaviors, less physical activity, and more television viewing and video game playing that White adolescents. This effect diminished across generations. For the same behaviors, first generation Latino adolescents were similar or worse than Whites, but did not show improvement over successive generations. First generation Asian and Latino adolescents did report having healthier diets than Whites, with higher fruit and vegetable consumption and lower soda consumption. Second and third generation Asian adolescents similarly had better dietary practices than Whites. However, for Latino adolescents, fruit and vegetable consumption decreased across generations and soda consumption increased so that by the third generation, Latinos’ nutrition was poorer than Whites’.

Tobacco and Substance Use

Cigarette smoking is the leading cause of morbidity and mortality in the United States. An estimated 20% of the adolescent population in the United States reports smoking cigarettes regularly. Studies routinely demonstrated that African American adolescents are less likely to smoke regularly than White and Latino adolescents. Studies have indicated that White and Latino adolescents are two to four times more likely to smoke than African American adolescents. Furthermore, studies have consistently demonstrated that White high-school students have significantly higher rates of smoking than African American, Latino, and Asian adolescents.

Studies examining the impact of immigrant generation on substance use have found that native-born adolescents often demonstrate higher levels of substance use than immigrants who were not born in the United States. A study looking at alcohol, marijuana, and illicit drug use indicated that use of alcohol and marijuana over the lifetime, in the past year, and in the last 30 days was higher among native-born adolescents than among immigrants who were not born in the United States. Differences in illicit drug use were not found by immigrant generation. Additionally, native-born adolescents are more likely to report recent alcohol and marijuana use and the intention to use these substances in the coming year than were first- and second generation immigrant adolescents.

Sexual Activity

Although sexual risk behavior is seen in persons of all ages, the 13–19 age group demonstrates the fastest growing group of new HIV cases. Overall, 50% of high-school seniors report having sexual intercourse and 20% report having four or more lifetime sexual partners. Of adolescents who reported having sex in a previous 3-month period, only 58% reported using a condom during sexual intercourse. Latinos appear to be at a heightened risk for contracting HIV overall which is concerning given the growing population of Latino adolescents in the United States. The Latino adolescent population is therefore a concentration of research surrounding sexual risk behavior and immigrant health.

Studies examining the impact of immigrant-generational status on sexual activity provide more mixed findings than those of any other health-related domain. Many studies of adolescent immigrant sexual behavior focus on the reproductive health of Latino adolescents as they have the highest fertility rate of any population in the United States. One such study found that Mexican-born adolescents had their first sexual intercourse at a later age than adolescents born in the United States. Foreign-born Mexican adolescents also had fewer lifetime sexual partners than Mexican Americans born in the United States. The same study found no difference by immigrant generation on age of first sexual intercourse.

In a study examining the impact of immigrant status on sexual activity rates, first generation Latinos were found to be more likely to abstain from sex, followed by second generation Latinos, and then by third generation Latinos. The converse was found to be true for unintended pregnancies, wherein less acculturated Latinas has significantly higher rates of unintended pregnancies compared to more acculturated Latinas.

Other studies have attempted to document the impact of immigrant-generational status on Black, Asian, and Hispanic adolescent immigrants. Findings indicate that overall Asian and Hispanic adolescent females had lower sexual intercourse risk than White adolescents. Black adolescent girls had higher rates of sexual intercourse risk than White adolescent girls. Latino adolescent males had a similar level of sexual intercourse risk to White adolescent males, while Black adolescent males had a higher sexual intercourse risk relative to White adolescent males. Asian adolescent males had a considerably lower level of sexual intercourse risk than did White adolescent males. These overall patterns of sexual risk were found to depend on immigrant generation. The decreased sexual intercourse risk among Asian and Latina adolescent females only applied to second generation adolescents. For adolescent males, third generation Latino males were found to have a sexual intercourse risk level about that of White adolescent males. Asian adolescent males had a lower sexual intercourse risk only if they were first or second generation immigrants.

One of the few studies examining sexual risk behavior in European immigrant adolescents found that levels of sexual risk behavior varied by acculturation status in a group of adolescents girls who were recent immigrants from the former Soviet Union. Results indicated that a higher level of acculturation to American culture was associated with increased risk for unplanned pregnancy of HIV infection.

Sexual behavior varies widely by ethnicity and culture, and therefore displays diverse outcomes for immigrant adolescents corresponding to differences in these factors as well as acculturation. Sexual behavior is influenced by differences in cultural norms and expectations as well as by gender. For this reason, more effort is necessary to develop appropriate prevention and intervention strategies corresponding to sexual health practices in immigrant adolescent populations.

Mental Health

Research suggests that first generation immigrants, overall, have lower rates of mental illness than second- and third generation immigrants. This pattern has been replicated in some studies of immigrant adolescents. In one study, Latino adolescent immigrants were found to have a lower prevalence of mental disorders than US-born adolescents. Similarly, Mexican adolescents born in the United States were found to have higher rates of psychological distress and suicidal ideation than Mexican-born adolescents. In examining depression and psychological well-being in adolescent immigrants, one researcher found that first generation immigrants reported less depression and more positive psychological well-being than their third generation counterparts. Second generation immigrants were found to have similar levels of depression and psychological well-being to third generation immigrant adolescents. Many factors were found to be related to first generation adolescents' heightened level of psychological well-being and decreased level of depression in comparison to their more acculturated counterparts. These factors include parental supervision, reduced parent–child conflict, religious practices, and social support.

Refugees, as a smaller subset of the overall immigrant population, are considered to be at particular risk for psychological distress because of the likelihood of exposure to traumatic events prior to immigrating. Studies of refugees in the United States show increased rates of PTSD, depression, and anxiety. Adolescent refugees in particular, because of the other demands of the adolescent developmental period, should receive targeted prevention efforts to ensure the stability of their mental health as they settle in the United States.

Health Care Access and Utilization

Due to policy in many states surrounding health care coverage for immigrants, many immigrant adolescents are uninsured and therefore have poorer access to medical care. Immigrant children and adolescents are less likely to have a usual source of health care, to see a physician, and to receive dental care than are nonimmigrant adolescents. Immigrant adolescents are also more likely to rely on public or nonprofit health clinics and hospitals that offer uncompensated care for uninsured patients.

Like many other health-related domains, health care utilization rates have also been linked to immigrant-generational status. A study of Latino adolescents demonstrated that 39% of first generation adolescents received routine health care compared to 54.9% of third generation adolescents. The difference in rates of routine health care access decreased after insurance status, parental education, and poverty were taken into consideration. In the same study, 16% of first generation adolescent immigrants reported not seeking health care when they thought they should compared to 22.5% of third generation adolescents.

Role of Context

Contextual factors have been examined to attempt to explain the disparities between immigrant ethnic groups and between generations of individuals of the same ethnic group. Of those factors, many appear to be relevant. Stressful working environments and lack of social support may impact the amount of time that parents can spend with their adolescent children. The lack of parental contact and supervision at home, parental monitoring, has been demonstrated to be related to the levels of health risk behaviors seen in immigrant adolescents. Parental monitoring of adolescent activities has been shown to be protective against adolescents engaging in sexual risk behavior. Language barriers between immigrant parents and adolescents may also lead to marginalization and isolation of immigrant parents from their neighbors. This isolation may further complicate parents' efforts to be involved with their adolescent children's lives due to lack of social support.

Interactions between the parent and the immigrant adolescent may also be related to the level and rate of health-risk behavior seen in various immigrant subgroups. Immigrant adolescents are exposed to American culture at school, through their peers, and through society in general. Parents of immigrant adolescents may hold traditional values which may contradict the American behaviors, attitudes, and values that adolescents are exposed to regularly. This phenomenon is known as *differential acculturation*, wherein parents continue to hold on to traditional values while their adolescent children adopt the values and norms of American culture. Normal parent–child conflict during adolescence may be exacerbated for immigrant adolescents and their parents, further decreasing the likelihood that parents will be able to monitor their children to reduce the chance that they engage in health-risk behaviors.

Other Factors

Many factors that may be precursors to future high risk behavior have been found to be elevated in immigrant adolescent populations as compared to native-born adolescents. Adolescents residing in the United States for less than 6 years reported more peer pressure for substance abuse, sexual activity, and violent behavior and delinquency than did their more acculturated adolescent peers. They also reported less parental disapproval of substance use, sexual activity, and violent behavior than their more acculturated counterparts. Less acculturated immigrant adolescents also reported less self-efficacy and confidence in being able to refuse substances that might be offered by friends.

Immigrant Paradox in Canada and Europe

Although a majority of published work examining the immigrant paradox in adolescent health has studied immigrants in the United States, researchers in Canada and Europe are working to document the immigrant paradox in their immigrant populations. The paradox has been documented in immigrants to Canada as well as in immigrants to European nations, but further research needs to be done in order to determine whether patterns are similar to those found in the United States.

Future of Immigrant Adolescent Health

Because of the increasing size of immigrant adolescent populations in the United States and other nations, it is surprising that little research has been done to examine the impact of immigrant generation and acculturation on health-related behaviors in this population. Many differences have been documented corresponding to ethnicity, but few studies have explicitly examined the differences in health-related domains according to time spent in the United States despite the extant literature which states that acculturation does impact health in adolescent immigrant populations. More research is necessary to document the links between acculturation and health-related behaviors in adolescent immigrant populations around the world.

Adoption

Eva Winsjansen Holsinger[1], Anna Mandalakas[2]
[1]Department of Pediatrics, Case Western Reserve University School of Medicine, Cleveland, OH, USA
[2]Global Child Health, Department of Pediatrics, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Overview

Adoption is an increasingly familiar phenomenon in many countries with declining birth rates. The 2000 Census estimated that there were over two million adopted children living in the USA, including step-parent, child welfare, private and international adoptees. Since 1990, Americans have adopted roughly 280,000 children from overseas. Although the background of domestically and internationally adopted children may vary greatly, the growing body of literature suggests that children in these two groups have many common characteristics and needs.

Before 1990, children typically came from Korea, India, the Philippines, and Latin America. Since 1990, children have been primarily adopted from China, Korea, Russia, and Guatemala. International adoption is fueled by a variety of social, economic, political, and cultural pressures. Many children originate from countries in transition. As these countries regain equilibrium, they may strengthen child welfare systems, moving from permitting large numbers of children to be adopted internationally to increasing domestic foster care/adoption programs. Government policies limiting family size, cultural values favoring male children, poverty, and natural or manmade disasters may also lead to more intercountry adoptions. The Hague Convention on International Adoption is an international agreement to safeguard and provide standards of practice in intercountry adoptions.

Effects of Deprivation and Neglect Early in Life on Children

Deprivation and neglect early in life delays emotional, social, sensory, and physical development, leading to learning problems, deficits in intellectual function, and various behavior problems. The likelihood that emotional and behavioral problems will persist is directly correlated with length of institutionalization. Similar findings have been described in children within the US child welfare system. Adopted children are at increased risk for psychological and learning disabilities making them eligible for special education services.

Studies show that children's functioning in these domains is positively affected by their adoptive families. Recovery depends heavily on family environment and parents' willingness to devote a significant amount of time to their children. In addition, the quality of resiliency – the ability to recover from adverse experiences – has also been shown to depend partly on genetic factors. It is critical that adoption professionals and mental health practitioners characterize the early history of the adoptee, recognize the potential impact of their experiences, as well as provide appropriate support and resources.

Health and Medical Care

The quality of care received by children prior to adoption varies. Many international adoptees have lived in crowded and resource-poor institutional settings with limited access to medical care. Malnutrition, infectious diseases (i.e., hepatitis, tuberculosis, syphilis, parasites, skin infections), and psychosocial deprivation are often noted. Children in the US child welfare system may also experience undiagnosed illnesses and delays in treatment of chronic conditions due to lapses in medical care. In addition, hearing, vision, and dental problems as well as birth defects are common. Adoption specialty clinics can provide enhanced care for children who have been adopted, and specific practice guidelines are in place to address the many needs of children who are adopted or are in foster care.

Development

During the first half of gestation through the first 3 years of life, brain development occurs that is crucial to focusing attention and inhibition – skills important for planning, problem solving, and sound critical judgment. Adoptees are at risk for exposure to many hazards to early brain development including malnutrition, lead poisoning, hypothyroidism, infectious diseases, and prenatal alcohol and drug exposure. They are also at increased risk of severe abuse and deprivation, which have been linked to poor brain development and decreased cognitive function.

Research suggests that modifications in the quality of care may dramatically improve developmental outcomes. Removal from a deprived and/or neglectful setting has a positive effect on gross and fine motor skills, as well as social and cognitive development. Factors that modify developmental outcomes include the length of deprivation and/or institutionalization, and quality of the pre- and post-adoptive environments.

Attachment and Psychosocial Functioning

Adverse pre-adoptive experiences have a direct impact on the psychosocial development of children.

Challenges in the attachment process and formation of healthy relationships are associated with a higher risk of later behavior problems. Conversely, sensitive responsiveness (the ability to observe and respond to a baby's signals adequately, appropriately, and promptly) is one of the key determinants of a secure attachment relationship. Adopted children who are more securely attached to their parents have been shown to attain better social and cognitive outcomes.

Supporting Adoptive Families

Adoption is a lifelong process. Families adopting internationally and domestically benefit from enhanced pre-adoption preparation, post-adoption supports, and access to professionals aware of the unique needs of these children. To optimize long-term outcomes, families should be prepared for possible challenges and have realistic expectations. While many complicated issues exist, adoption offers a tremendous number of rewards. Most adoptions are successful, most children recover, and the quality of children's lives improve dramatically as a result of gaining a family.

Affidavit of Support

Kathrin Mautino
Mautino & Mautino, San Diego, CA, USA

The affidavit of support is provided primarily as part of the permanent resident application process, although occasionally it is used in the nonimmigrant visa context. Its purpose is to overcome the "public charge" exclusion ground contained in Immigration and Nationality Act § 212(a)(4). All temporary visitors and intending immigrants must show that they are not likely to become a public charge while in the United States.

An individual can be considered to be a public charge if he/she relies solely on government-provided benefits in order to live. Individuals can be considered to be public charges if they are institutionalized for a mental or physical health reason and the costs are fully borne by the federal government. Individuals who receive emergency health care, food stamps, unemployment benefits, or medical benefits to pay for prenatal care and the birth of a child do not fall under the public charge provisions.

Prior to 2002, the affidavit of support was an unenforceable promise by an individual to support a foreign visitor or potential immigrant. Form I-134 was completed by any individual who was physically present within the United States who had assets, including a regular salary that could be used to support the foreign visitor or potential immigrant. There was no requirement that the individual be a United States citizen or lawful permanent resident or that the individual provide extensive proof of the asset claimed. In addition, intending immigrants could use their own assets to overcome the public charge provisions. There was no minimum income or asset requirement; in effect, the I-134 was a persuasive, rather than a probative document.

This situation changed with the Family Sponsor Immigration Act of 2002, Act of Mar 13, 2002, Pub. L. No. 107–150, 116 Stat. 74 (2002 Act). The 2002 Act changed the affidavit form and made its use mandatory in many situations. Individuals petitioning for family members are now required to use the new form I-864 even if they are not working and have no assets. In addition, companies whose owners are relatives of an intending immigrant sponsored by the company must also complete an I-864. The new I-864 is intended to be a legally enforceable contract between the individual completing the I-864 (the sponsor) and the United States government. In theory, if a beneficiary of the I-864 uses public benefits, the federal government can request reimbursement from the sponsor. To date, the federal government has not attempted to recover monies spent on beneficiaries from the sponsor. However, some divorce courts are using the existence of an I-864 as evidence to support spousal support determinations.

The I-864 now requires that the sponsor be a United States citizen or lawful permanent resident. The sponsor must be resident in the United States and generally must earn above 125% of the federal poverty guidelines for the household size plus the immigrants to be sponsored (Individuals who are on active duty military service must meet 100% of the poverty guidelines.). For example, a married United States citizen with two children has a household size of four. If she is sponsoring the immigration of a brother who is married and has two children, the sponsor must earn above 125% of the poverty guidelines for a family of eight. Other immigrants sponsored are also counted as part of the household unless the affidavit of support obligation ends. Proof of income and assets must be provided. Individuals are limited to the income reported to the IRS on their federal income tax.

The obligations of the sponsor continue until (1) the sponsor or the beneficiary dies, (2) the beneficiary becomes a United States citizen, (3) the beneficiary formally abandons his/her residence in the United States, or (4) the beneficiary can be credited with 40 quarters of work under Social Security Act. Note that divorce does not end the I-864 obligation, nor does a child reaching adulthood.

If an individual who is required to complete an I-864 does not have the income or assets to satisfy the poverty guideline requirements, a cosponsor willing to accept the I-864 obligations can be used. The cosponsor must meet all requirements independently of the sponsor; the income cannot be commingled.

A sponsor who does not have sufficient income can use the value of an asset to augment the income. Generally, the value of the asset must equal five times the amount lacking. For example, if a sponsor's income as reported to the IRS is $5,000 below the required amount, but the sponsor has a savings account that regularly has $25,000 in it, then the sponsor can use that asset and no cosponsor is required. Assets overseas can be used as long as the government officer reviewing the I-864 is satisfied that the asset could be converted to cash within a reasonable amount of time.

Individuals residing overseas generally cannot complete the I-864. Sponsors must be subject to the jurisdiction of United States courts. The Department of State has allowed an exception for individuals who intend to reside in the United States as soon as the sponsored immigrant receives an immigrant visa. However, evidence of an intent to reside in the United States immediately is required and rigorously enforced.

The I-864 is not required where a child will immediately receive United States citizenship under the Child Citizenship Act of 2000, where an individual is immigrating under the Violence Against Women Act, where the individual can be credited with 40 quarters of work or for certain widows/widowers of United States citizens. Such individuals file the I-864W.

The I-134 affidavit continues to exist and be used. Individuals immigrating through employment use it to show that their accompanying family members will not become a public charge. In addition, individuals wishing to show that a potential visitor will not be a public charge can still use the I-134.

Africa and Immigrant Health

Africa is both the second largest and second most populated continent in the world. Recent 2009 figures indicate that the population of the continent has surpassed one billion. Africa is comprised of 54 countries and over 1,000 spoken languages. It is rich in culture and natural resources. However, it remains one of the poorest continents in the world. This poverty is driven in part by ineffective government; despotism (dictatorship or tyranny); frequent military, tribal, political, and religious conflicts and war; as well as natural disasters. Such conditions are inextricably linked to outcomes such as malnutrition, inadequate water supply and sanitation, high prevalence rates of human immunodeficiency virus and acquired immune deficiency syndrome (HIV/AIDS), and infectious and parasitic diseases. These outcomes, in turn, negatively impact health and strain already weak health care systems. The combination of rich culture, abundant natural resources, and high levels of poverty and disease has resulted in both immigration to Africa and emigration from Africa.

Immigration to Africa

Individuals may choose to immigrate to Africa for a variety of reasons. Some may come seeking opportunities for missionary work in impoverished regions, while others come to study disease or conduct other scientific research. Individuals may also choose to immigrate to Africa as a result of job relocation to resource-rich regions such as Nigeria, Ghana, the Ivory Coast, and South Africa, where foreign companies may build affiliate offices. Others may simply immigrate for the sake of the cultural experience. Regardless of the reasons behind relocation to Africa, immigrants to the region will have to deal with many of the same health concerns.

Environmental health issues such as industrial waste, air pollution (indoor and outdoor), and unsafe and insufficient water supplies are issues of immediate concern. In addition, inadequate sanitation (i.e., waste removal and hygiene practices) is directly linked to poor food preparation hygiene and subsequent food and water borne illnesses such as cholera, typhoid, diarrhea, and increased exposure to disease-causing parasites. Diarrhea remains one of the leading causes of death in Africa. Less than half of Sub-Saharan Africa has access to adequate sanitation facilities and roughly half of the region has access to a safe water supply.

Further, food safety issues continue to be a health concern in various rural and urban regions of Africa. Unsafe water, poor food handling, poor refrigeration, and food storage jeopardize food safety. Likewise, failure to disinfect surfaces and utensils that come into contact with animal blood and waste, and the exposure of food to insects (known vectors of disease) jeopardize food safety. This is particularly an issue in areas where street food vendors are popular sources of meals and snacks. Poor handling and preparation of food leads to the spread of Salmonella, *Escherichia coli*, and Hepatitis A virus.

Immigrants to Africa are also at risk for infectious diseases common to the region. HIV/AIDS, tuberculosis, and malaria remain leading causes of death in Africa. According to various reports of the World Health Organization, Africa accounts for an overwhelmingly large portion of the disease burden for HIV/AIDS and malaria. Commercial sex (e.g., sex workers), lack of education, and unsafe practices have helped to accelerate the spread of HIV/AIDS. Examples of unsafe practices include: unprotected sex; sharing knives, razors, or similar implements for traditional ceremonies (i.e., cutting of tribal marks on the face and body, body piercings); and genital mutilation. Immigrants to the region are at risk, should they choose to engage in risky sexual behavior, or come into direct contact with blood, in a region that is known to have one of the highest numbers of HIV/AIDS cases in the world.

Many individuals affected by HIV/AIDS are also coinfected with tuberculosis as a result of weakened immune systems. A shortage of health care workers, underdiagnosis of the disease, unavailability of medication, and poor adherence to treatment regimens continue to serve as obstacles to the management and treatment of tuberculosis. The hot and humid climate of Africa coupled with its geography also help to spread various infectious diseases, including mosquito-borne illnesses such as malaria. An abundance of standing water and drug-resistant malaria parasites, in addition to the use of counterfeit malaria drugs, makes it difficult to reduce the burden of this disease in African nations.

Immigration to Africa has both its risks and benefits. It is important that immigrants to the region are aware of the potential health risks involved with relocation and take necessary measures to minimize such risks, where possible.

Emigration from Africa

The unfavorable conditions found in many regions of Africa have resulted in both voluntary and involuntary emigration from the continent. A large number of voluntary African emigrants are highly skilled workers such as doctors, professors, engineers, and scientists who are seeking higher pay and better working and living conditions for themselves and their families. This departure of highly skilled Africans is often referred to as the “brain drain.” Others leave Africa in pursuit of higher education, reunification with family members, or access to better medical care. Involuntary emigrants such as refugees and asylum seekers leave Africa to escape war, religious persecution, and genocide. Most African emigrants relocate to North American regions (i.e., the United States and Canada) and other developed regions of the world such as Europe (e.g., United Kingdom) and Australia.

African immigrants are a rapidly growing segment of both the immigrant and total Black populations residing in the United States and other developed countries. Most African immigrants come from the Sub-Saharan region of Africa (the region that lies south of the Sahara Desert in the continent of Africa). Historically, immigrants from the Sub-Saharan region have been from West African (i.e., Nigeria and Ghana) and East African (i.e., Ethiopia and Somalia) nations.

Upon relocation to host countries, these immigrants undergo many environmental, lifestyle, and cultural changes; some changes may be positive (e.g., better educational opportunities) while others may be negative (i.e., poor diet or sedentary lifestyle). This process of acculturation can be overwhelming and has the potential to produce negative health outcomes. The stress associated with acculturation is known as acculturative stress. Many immigrants live below the poverty level and are forced to deal with poor living conditions and malnutrition as they struggle to adjust to the culture of their host country. Such factors may compromise their health and safety. Chronic diseases (i.e., diabetes, hypertension, and cancer) are increasing among immigrants.

The increased prevalence of chronic diseases may be partially attributed to the nutritional transition experienced by African immigrants. The drastic change from undernutrition in Africa to an abundance of processed foods, and foods rich in animal fats and sugars in the host countries, may place immigrants at increased risk for diet-related chronic diseases. Further, the low cost and accessibility of fast foods may be especially appealing for immigrants who are living below poverty level.

Untreated infectious and parasitic diseases also continue to pose a problem for immigrants in their host country. The stigma associated with diseases such as HIV/AIDS and/or the lack of experience of health care workers in treating diseases specific to tropical regions such as Africa may hinder proper treatment and management of disease.

Recent African immigrants are less likely to be from English-speaking African countries such as Ghana, Nigeria, and South Africa. Immigrants who are not proficient in the language of their host country face difficulties in accessing health care resources and communicating effectively with health care providers. This problem is further compounded by a lack of culturally competent health care providers and culturally relevant health screening and intervention information for African immigrants.

For example, immigrants may have different cultural beliefs and meanings regarding the causes and treatment of disease and/or may prefer traditional medicine and healing practices (i.e., herbal medicine, native doctors, or special diets), which may not be recognized by health care providers in the host country. In addition, cultural issues related to gender may affect how immigrants interact with health care providers. This is illustrated by situations in which female African immigrants may prefer to be seen only by female health care providers or may not feel comfortable discussing certain symptoms or health issues due to cultural inhibitions.

Further, immigrants may delay coming forward to receive care as a result of language or cultural barriers and possibly fear of deportation. This, in turn, may limit the availability of treatment options if their medical condition is at an advanced stage. Additionally, African immigrants may have difficulty providing necessary medical history to health care workers as a result of language or cultural barriers. For example, diseases may be known by different names or descriptions in an immigrant's host country versus their native country in Africa. In addition, it may be virtually impossible for health care workers to acquire disease history and treatment or family history of disease from African immigrants, simply because such information is not recorded in the immigrant's native country.

Over time, the acculturative stress and the lack of sufficient resources may result in social isolation, depression, and poor lifestyle choices among African immigrants. Refugees and asylum seekers are particularly at risk for negative health outcomes as a result of the psychological stress of involuntary displacement from their native country and the process of acculturation.

Elderly immigrants also represent a vulnerable subpopulation of African immigrants at risk for negative health outcomes. Elderly immigrants may have more difficulty with the acculturation process than younger immigrants for a variety of reasons. First, they have been exposed to their native culture and values for a longer period of time than younger immigrants and therefore may be much slower to adopt the culture and values of another country. Second, age-related physiological changes (i.e., cognitive decline, decreased memory, and limited mobility) may simply prevent them from moving through the process of acculturation at a more rapid pace. Third, they are less likely to be proficient in the language of their host country and may not be willing or able to master a new language. Collectively, these factors may increase the health care barriers they face in their host country.

Relocating to another country does not necessarily mean that African immigrants will invariably face deterioration in their health. African immigrants may be afforded opportunities that were not available to them in their native country. For example, they may have better access to health education and preventive services (i.e., mammograms and prostate cancer screening), which can positively affect health. Likewise, they may have better access to health care and medication, which can result in better treatment and management of disease. Some countries that have socialized medicine or universal health care systems extend health care benefits to immigrants regardless of whether they are legal or permanent residents.

In addition, access to higher paying jobs and better educational opportunities can positively impact health, both directly and indirectly. Increased wages can help immigrants purchase healthy foods and afford living conditions that are better than what was available to them in their native country. Nutrition and living environment both affect health. Higher wages and better education can also enable immigrants to support family members and friends back home in their native country. This in turn can help foster positive mental health outcomes among immigrants who did not have the means necessary to support family members and friends in their native country.

AIDS

▶ Acquired immune deficiency syndrome

AIDS Knowledge

Daniel J. O'Shea
HIV, STD and Hepatitis Branch, Public Health Services, County of San Diego, San Diego, CA, USA

Acquired immune deficiency syndrome, or AIDS, is the deadly late stage of infection by human immunodeficiency virus (HIV) infection, when a person's immune system is severely damaged and has difficulty in fighting diseases and certain cancers. There is no cure for HIV disease, despite major advances in diagnosis and treatment. HIV is a preventable disease, and widespread understanding of transmission routes, associated high-risk behaviors, and how to protect oneself from contracting the virus is critical to control the spread of HIV/AIDS. Lower levels of HIV/AIDS knowledge are associated with a lower likelihood of safer sex or injection practices. Additionally, individuals who are unaware they are infected with HIV are 3.5 times more likely to transmit the virus to others than those who know about their infection; alarmingly, the proportion of people living with HIV who are estimated to be unaware of their status ranges from over 80% in

Kenya and Burundi to 67% in China to 21% in the USA. Additional information on AIDS, HIV transmission, testing, care and treatment, and the impact of the worldwide HIV/AIDS epidemic can be found in the entries for "Acquired immune deficiency syndrome" and "Human immunodeficiency virus" in this encyclopedia.

The spread of the worldwide HIV/AIDS epidemic has been facilitated in part by internal and international migration in terms of migrants bringing HIV into a host area or country, migrants at greater risk for acquiring HIV and transmitting the virus within the host country or to their home areas or countries upon return, and migrants often being medically underserved with limited access to services and information. As a mechanism for HIV prevention, HIV/AIDS knowledge among migrant and immigrant populations is of particular concern in this regard. Population movement, culture, language, geography, limited education, psychosocial factors, isolation, separation from families, discrimination, and poverty present significant barriers for these groups to accessing HIV/AIDS knowledge. Immigrant status, national origin, conflict situations, family connectedness, provider trust, and various demographic and social characteristics have also been found to be important factors related to HIV/AIDS knowledge.

Knowledge is an important first step to acquiring skills necessary for behavior change to ensure HIV prevention measures. In addition to perception, individuals must be committed to change and taking action. The fact remains that some individuals with high levels of HIV/AIDS knowledge often fail to follow safer sex or injection practices. Several studies among immigrants throughout the world, some of which are highlighted here, have been conducted to gain a better understanding of the level of knowledge of HIV/AIDS and how to tailor education programs to the specific needs of immigrant and migrant populations.

Immigrants from 20 African nations in Houston, Texas reported a high level of HIV/AIDS knowledge, but lower levels of safer sex behaviors and lower levels of perception of risk. Similarly, young migrants with HIV/AIDS in Denmark revealed a high level of understanding of the true ways of HIV transmission, but had knowledge gaps in false ways of transmission and safer sex practices. Another study of Somali and Sudanese immigrants in Denmark indicated low levels of HIV/AIDS knowledge, highlighting the need for targeted, culturally sensitive HIV/AIDS information and counseling. HIV-positive sub-Saharan African refugees in Canada indicated that family separation, continued exposure by family members to violence and fear, financial uncertainty, social isolation due to stigma, and poor nutrition interfered with their ability to engage in health-promoting behaviors. A study of immigrants in Germany concluded that HIV/AIDS educational messages are not reaching immigrants as effectively as German citizens. Within Thailand, 86% of immigrants from Cambodia and Myanmar had become fairly knowledgeable about HIV risk factors. Even so, gaps in knowledge remained for women, persons with less than five years of education, seafarers, and agricultural workers.

Research conducted with South Asian immigrants in the USA indicated a medium level of HIV/AIDS knowledge with some serious gaps, particularly for older immigrants. Both cultural and structural barriers were identified to accessing information. The former included denial, stigma, and patriarchy; the latter encompassed high health care costs, lack of insurance, mistrust of government, and fear that information sharing will negatively impact immigration-related issues. Immigrants of Latino origin, including migrant farmworkers and injection drug users, tend to have misconceptions and a lower level of knowledge of HIV/AIDS than other ethnic groups, frequently associated with low educational attainment and limited bilingual (English/Spanish) language exposure or understanding.

Gender may also play a significant role. Female Mexican, Cambodian, and Myanmar migrants appear to be far less knowledgeable than their male counterparts. Among women in the USA who recently emigrated from Jamaica, most were knowledgeable about HIV/AIDS but religious beliefs and cultural practices created barriers to safer sex behaviors. Many could not be certain their husband or partner was monogamous, yet discussion of sexual issues was considered taboo and the cultural gender imbalance often left women powerless to negotiate condom use or to refuse sex without a condom.

To effectively target information and education programs, public health services must not only know which populations are at risk, but also the gaps in knowledge and barriers to practicing HIV prevention measures for each risk group. Countries must ground their strategies in an understanding of the substantial diversity, inclusive of immigrant and migrant populations, that makes up their local HIV/AIDS epidemics, tailoring and disseminating culturally, linguistically, and educationally appropriate information and other interventions.

Air Pollution

Christina Hemphill Fuller
Department of Environmental Health, Harvard School of Public Health, Boston, MA, USA

Introduction

Air pollution is produced when chemicals, particulate matter, or gasses are introduced into the air and cause harm or discomfort to humans or other living organisms. The components of air pollution can be divided into primary and secondary pollutants. Primary pollutants are those that are released directly into the air by a process such as combustion. Main primary pollutants include carbon monoxide (CO), nitric oxide (NO) and nitrogen dioxide (NO_2) (jointly they are NO_x), sulfur oxides (SO_x), particulate matter (PM), volatile organic hydrocarbons (VOCs), and metals (such as lead). Secondary pollutants are created by the interaction of primary pollutants through chemical processes or agglomeration. An important secondary pollutant is ground level ozone, which is formed from NO_x and VOCs in the presence of sunlight. Some pollutants, such as NO_2, are both primary and secondary pollutants.

Although there are natural sources of outdoor (ambient) air pollution such as volcanic eruptions and wildfires, the most significant contributions come from human activity. Main sources of air pollution are manufacturing; the burning of fossil fuels for energy production, like coal-burning power plants; gasoline and diesel fuel combustion for vehicles; and methane production from cattle farms and landfills. It is estimated that the majority of ambient air pollution (52%) comes from industry, 27% from transportation, 10% from agriculture, 8% from consumer and commercial products, 1% from commercial and residential heating, and 2% from other sources. Air pollution can also be present indoors. Indoor air pollution is characterized by the presence of particulate matter from cleaning and cooking activities; NO_2 from gas stoves; off-gassing of chemicals from furniture and carpets; CO from wood burning; particulates and chemicals from cigarettes; and biological contaminants such as pet dander, cockroach allergen, and mold spores.

Distribution of Air Pollution

Ambient air pollution is present worldwide, and there is variation in pollutant levels by country, region, and city. Developing nations, including many countries in Asia and sub-Saharan Africa, shoulder a higher proportion of air pollution over industrialized countries. High pollution levels are a product of the complex interconnected processes governed by both economic and political development.

Within countries, there is significant variation in air pollution on a regional scale with urban areas carrying the highest burden of pollutant levels. In the USA, air pollution is higher in the Northeast and Midwest as compared to the South and West, with the exception of California, which has high levels. The regional gradient in pollution level is a function of industrial sources, population density, and meteorological conditions. Predominant westerly winds transport air pollution from industry in the Midwest eastward. Although transport plays a significant role in ambient air pollution, the main source of air pollution in the Northeast and other urban areas is vehicle exhaust. This source is also referred to as mobile emissions, which vary significantly on a local scale based on the location of roadways and public transit. Levels of most primary air pollutants, such as PM, NO, NO_2, and VOCs are higher close to major roadways of highways. However, a small number of secondary pollutants, such as ozone, are lower near highways due to the processes necessary for their development.

Similarly there is a range of indoor air pollution levels that are a function of ambient air pollution, housing type, building condition, behavior (such as secondhand smoke) and the time of year. In developing nations, a significant contributor to indoor air pollution is biomass fuel burning, such as wood, coal, and animal dung. The boundary between the indoor and ambient environments may also be a factor in levels of indoor air pollution. In many developing countries, the design of residential compounds and homes may result in fluid interchange between ambient and indoor air, especially in warm climates. In other countries, such as the USA, the boundary is more defined and the indoor and ambient environments are usually well separated.

Demographic factors regularly govern the distribution and magnitude of air pollution often due to socioeconomic status (a measure of an individual or household's social position based on income, occupation, and education) and race/ethnicity. The siting of polluting facilities has been the subject of environmental justice struggles for almost 30 years in the USA. Research has documented that poor communities and minority neighborhoods have a higher proportion of noxious facilities such as power plants, diesel bus depots, and hazardous waste facilities than higher income or White communities. Many communities comprised of a high proportion of new immigrants fall into one of these categories resulting in similar exposures.

Health Outcomes of Air Pollution Exposure

Exposure to air pollution has been linked to increases in death and illness and is supported by research in the USA, Europe, and other locations across the globe. A study on the global burden of disease estimates that 2.4 million people worldwide die each year from air pollution, a majority of those, 1.6 million, from indoor air pollution. In addition to increased mortality, air pollution has been linked to asthma symptoms, lung cancer, chronic obstructive pulmonary disease, deep vein thrombosis, cardiovascular disease, and an increase in infectious disease in children. The route of exposure to air pollution is the lungs, which explains some of the associations with respiratory illness. However, the majority of deaths from air pollution exposure are due to cardiovascular disease. Increases in air pollution have also been linked to decreases in quality of life.

There are certain subpopulations that are more sensitive to the effects of air pollution than the general population. One of these subpopulations is children because they are generally more active than adults, have higher ventilation rates, and spend more time outdoors. In addition, children's lungs are growing and developing thereby increasing vulnerability to insults from environmental contaminants. The elderly comprise another sensitive subpopulation due in part to the prevalence of comorbidities, which may modify the relationship and possibly heighten the deleterious effects of air pollution. Also, advanced age reduces the ability to repair damage caused by air pollutants.

A third and fourth sensitive subpopulation are low SES communities and racial/ethnic minority groups, many of them immigrants. These groups may be more vulnerable to air pollution due to socially patterned physical conditions such as exposure to multiple environmental contaminants from their residential environment or occupation, inadequate access to health care or poor nutrition. The presence of air pollution may act as a modifying factor increasing the susceptibility for or severity of illnesses with other causes. Or an existing illness may increase the adverse impact of air pollution on the body.

Regulations/Guidelines

Many nations have created laws to control the amount of air pollution emitted in their countries. In the USA, air pollution standards are set by the United States Environmental Protection Agency (USEPA) as well as state and city agencies. The USEPA was established after the enactment of the Clean Air Act (CAA) in 1963 and enforces the National Ambient Air Quality Standards (NAAQS) for criteria air pollutants. The CAA has been amended several times, most recently in 1990. Regulations are focused on controlling emission sources, usually point sources, such as power plants in order to meet NAAQS. The United Kingdom and Canada have also established Clean Air Acts in 1956 and 1970, respectively. The World Health Organization (WHO) has established Air Quality Guidelines (AQG) to help guide countries in reduction of adverse health outcomes of air pollution. The 2005 update of the AQG is designed to assist developing nations with high levels of air pollution by including a tiered set of target concentrations for contaminants, or indicators that are relatively easy to measure and linked to health outcomes.

Alcohol Abuse

► Alcohol use disorders

Alcohol Use Disorders

Christina M. Delos Reyes
Department of Psychiatry, University Hospitals Case Medical Center, Cleveland, OH, USA

An estimated 13% of the US adult population was born outside the United States. As they adapt to life in the United States, they may be differentially exposed to substance use norms and social challenges (i.e., language barriers, unfamiliar customs, and discrimination). One of the consequences of adapting to new circumstances may be an increased rate of substance use. Even among those from the same general regions of the world, there is a significant heterogeneity of immigrant populations which highlights the need to study the factors that may contribute to differential substance use rates. A more comprehensive understanding of the variability among racial/ethnic groups will contribute to the identification of at-risk populations that can be targeted for prevention/early intervention programs.

Conceptual Models for Alcohol Use Problems Among Immigrants and Refugees

Several different models have been developed to explain the use of alcohol and other substances by immigrants and refugees. The *acculturative stress model* states that alcohol and other drug use are resultant reactions to the immigration experience itself because of the stress from cultural conflict, and the lack of social and economic resources for coping.

The *assimilation model* states that, as newcomers adopt the customs of the host country, their patterns of alcohol and other drug use begin to reflect those of their new location. However, it is also possible that immigrants *continue the country-of-origin alcohol use patterns*. A fourth model, known as the *intracultural diversity model*, emphasizes the diversity of alcohol and other drug use patterns that exist within different immigrant and refugee groups. This model recognizes that differences in alcohol consumption exist among individuals within a specific group. It is incorrect to think of a specific drinking pattern as typifying all members of a particular group, and necessary to recognize heterogeneity.

The National Surveys on Drug Use and Health (NSDUH) have been conducted in the United States every year since 1971. Data from the 1999, 2000, and 2001 surveys represent the first nationally representative estimates of substance use among adult immigrants to the United States. Immigrants are defined in this report as US residents born outside the United States.

The rates of alcohol use were lower among immigrants than among US-born adults. This includes past year use (54.3% vs. 67.8%), past month use (39.5% vs. 52.4%), past month binge use (16.9% vs. 22.3%), past month heavy use (3.0% vs. 6.5%), and the average number of drinks per week among current drinkers (6.3 vs. 8.3). Among all foreign-born persons, men had higher rates of use across all alcohol measures than women, and younger age groups (18–49) had higher rates of use than older individuals (50 or older).

Among adult immigrants who were current drinkers, current weekly alcohol consumption was associated with per capita alcohol consumption in the individual's country of birth. Additionally, rates of substance use were associated with the length of time immigrants had been in the United States. Immigrants who had been in the United States for 5 or more years were more likely than immigrants who had been in the United States for fewer than 5 years to use alcohol in the past year or past month and to binge drink.

Estimates of substance use among immigrants from 16 selected countries revealed wide variation across these immigrant subgroups. These differences point out that comparisons based on broad regional groupings of immigrants, such as Latin Americans or Asians, can mask important within-region differences.

It has been hypothesized that among immigrants who were current drinkers, a portion of the variability in alcohol consumption was due to drinking patterns in one's home country. A linear regression model used the following variables as predictors: country-of-origin consumption, gender, age, total family income, marital status, education, and length of time in the United States. Results indicated that drinking in the country of origin was a significant predictor of past month weekly alcohol consumption, as were marital status (unmarried), education (completed less than high school), and sex (male). This model predicts a rise of approximately 4% in the current consumption rate for every liter increase in the country of origin per capita drinking rate.

Per capita alcohol consumption was organized into countries that had rates similar to, higher than, or lower than US rates. Immigrants from countries with per capita rates that were similar to or lower than US rates had significantly lower past month weekly alcohol consumption than US-born persons, 5.7 and 5.9 drinks per week, respectively, when compared with the US-born population (8.4 drinks per week). Past month weekly alcohol consumption was higher for individuals from countries with a higher per capita consumption rate than the US rate, but consumption was still lower than among individuals born in the United States (7.0 vs. 8.4 drinks per week).

Alcohol use patterns were examined among selected Latin American countries with the largest immigrant samples. Immigrants from Mexico, Puerto

Rico, Cuba, El Salvador, Jamaica, and Colombia were examined. A larger percentage of Cuban immigrants reported past month alcohol use (42.4%) than did immigrants from Mexico (34.9%). However, Cuban (9.9%) and Colombian (14.9%) immigrants had lower rates of past month binge drinking when compared with Mexican (22.3%) immigrants. The 9.9% prevalence rate for binge drinking among Cuban immigrants was lower than among Puerto Rican (23.7%) and El Salvadoran (19.7%) immigrants. Cuban immigrants also had lower past month heavy drinking rates (1.3%) than immigrants from Mexico (3.5%). Immigrants from Puerto Rico had prevalence rates similar to Mexican immigrants with respect to binge drinking (23.7% vs. 22.3 %) and heavy drinking rates (3.3% vs. 3.5%).

Mexican, Puerto Rican, and El Salvadoran immigrants had a higher average number of drinks consumed per week (8.1, 6.8, and 7.4 drinks, respectively) than Jamaican immigrants (2.8 drinks) or than immigrants from Cuba (3.3 drinks). In summary, across most drinking measures, immigrants from Mexico, Puerto Rico, and El Salvador had higher prevalence rates than Cuban or Jamaican immigrants. Although a larger percentage of immigrants from Cuba reported drinking in the past month, they had a lower prevalence of both binge and heavy drinking, and they drank fewer drinks per week than most of the other selected Latin American immigrant groups. These differences in alcohol use rates may be partially explained by the older age of immigrants from Cuba, who were on average 53.2 years old compared with immigrants from Mexico (37.3 years), Puerto Rico (46.4 years), and El Salvador (38.6 years).

Immigrants from Mexico, Puerto Rico, and El Salvador had binge drinking prevalence rates (22.3%, 23.7%, and 19.7%, respectively) and past month weekly consumption amounts (8.1, 6.8, and 7.4 drinks, respectively) that were equal to those for US-born adults (22.3% and 8.3 drinks). Immigrants from Cuba, Jamaica, and Colombia had past month weekly consumption rates and binge drinking prevalence rates that were lower than the rates for US-born persons. These differential findings may be due to the age distributions of immigrants from the Latin American region. A higher percentage of immigrants from Mexico and El Salvador were among the younger age groups (18–25, 26–34) compared with immigrants from Cuba, Jamaica, and Colombia.

Alcohol use rates and past month weekly consumption of alcohol were examined for the following individual Asian countries among respondents aged 18 or older: Japan, Korea, the Philippines, China, Vietnam, and India.

Immigrants from Japan (62.1%) and Korea (53.2%) had a higher prevalence of past month alcohol use than immigrants from the Philippines (24.1%), China (28.4%), Vietnam (26.4%), and India (26.6%). Korean and Japanese immigrants also reported a higher prevalence of past month binge drinking (27.9% and 18.6%, respectively) than immigrants from the Philippines (8.9%), China (7.5%), and India (7.8%). Immigrants from Korea had a higher prevalence of past month heavy drinking (3.5%) than immigrants from the Philippines (0.6%), China (0.7%), or Vietnam (0.6%).

A somewhat different pattern was observed for past month weekly alcohol consumption. Although Korean immigrants had the highest level of consumption, consuming on average 7.5 drinks per week, immigrants from Vietnam had the second highest past month weekly consumption rate of 5.1 drinks per week, followed closely by Filipino and Japanese immigrants at 4.6 and 3.5 drinks per week on average, respectively. Past month weekly alcohol consumption was significantly lower for immigrants from China (1.5 drinks) when compared with Korean, Japanese, Vietnamese, and Filipino immigrants. For most Asian immigrant groups, past month weekly alcohol consumption was higher with longer time spent in the United States. China and India had the largest percentages of immigrants who had been in the United States for fewer than 5 years (32.7 and 40.5%, respectively), which may contribute to their lower alcohol use rates.

When comparing rates for persons from individual Asian countries with rates for US-born individuals, Korean and Japanese immigrants had prevalence rates for past month alcohol use that were similar to those for individuals born in the United States. Across all alcohol use measures, rates for immigrants from China, Vietnam, India, and the Philippines were lower than the rates for the US-born population.

Alcohol use rates and past month weekly consumption among current drinkers were examined for three groups of European immigrants aged 18 or older. Immigrants from Germany, the United Kingdom (England, Scotland, Wales, and Ireland), and Poland were compared.

Immigrants from the United Kingdom had higher rates of past month alcohol use (67.5%), past month binge drinking (31.3%), and past month heavy drinking (12.2%) when compared with German immigrants, whose past month alcohol use was significantly lower (49.3%), as were their rates for binge drinking (17.3%) and heavy drinking (5.3%). The past month heavy drinking rate for United Kingdom immigrants exceeded that for Polish immigrants (4.4%). Past month alcohol use (55.9%) and past month binge drinking (23.8%) for immigrants from Poland were similar to those for immigrants from the United Kingdom.

Past month weekly alcohol consumption amounts among current drinkers also were higher among immigrants from the United Kingdom (10.2 drinks) when compared with immigrants from Germany (5.3 drinks) and Poland (4.1 drinks). Immigrants from Germany who had been in the United States for 5 years or more had higher past month weekly consumption rates (5.4 drinks) than those who had been in the United States for fewer than 5 years (3.6 drinks). Immigrants from the United Kingdom who had been in the United States for 5 years or longer had similar past month weekly consumption rates than those who had been in the United States for less time (10.0 vs. 11.5 drinks). Immigrants from Poland showed no differences in past month weekly alcohol consumption amounts whether they had been in the United States for 5 or more or fewer than 5 years (4.0 vs. 4.6 drinks).

Immigrants from the United Kingdom also had alcohol use rates that were higher than those for US-born individuals. Their past month alcohol use (67.5% vs. 52.4%), past month binge drinking (31.3% vs. 22.3%), and past month heavy drinking (12.2% vs. 6.5%) rates all showed a pattern of higher use when compared with US-born persons. Past month weekly consumption amounts were similar for immigrants from the United Kingdom (10.2 drinks) and US-born individuals (8.3 drinks).

Alcohol use rates and past month weekly consumption of alcohol among current drinkers were examined for Canadian immigrants. Immigrants from Canada reported higher rates of past month (64.5%) and past year alcohol use (78.3%) than US-born persons, whose rates were 52.4% and 67.8%. The average past month weekly consumption rate for immigrants from Canada (5.2 drinks) was lower than that for US-born individuals (8.3 drinks). Immigrants from Canada showed a similar pattern of past month binge drinking and past month heavy drinking (19.4% and 5.3%, respectively) as US-born persons (22.3% and 6.5%). Canadian-born persons living in the United States showed no differences in past month weekly alcohol consumption after being in the United States for 5 or more years.

There are several predictors of alcohol use among immigrants aged 18 or older. Younger ages are associated with an increased risk of alcohol use across all measures (i.e., past month use, binge drinking, heavy use, and past year use). Male sex and longer duration of residence in the United States were found to be associated with alcohol use. Being married was associated with lower odds of alcohol use compared with other martial statuses.

Research is limited on the alcohol consumption patterns of immigrant and refugee groups in the United States. Most research has focused on ethnic groups with long histories in the United States, such as Mexican Americans, Japanese-Americans, Chinese-Americans, and Korean Americans. However, much of this research fails to examine the differences that exist within these groups. Brief examples of the research conducted on alcohol use among newer Latino and Southeast Asian immigrant and refugee groups are as follows. These two groups are highlighted because limited empirical research exists on the alcohol use patterns of other more recent immigrant and refugee groups.

Intranational Differences: Mexican Immigrants

Mexican immigrants are an excellent example of the intracultural diversity model. This model recognizes differences in alcohol consumption among individuals within a specific group. Although individuals of Mexican descent have a long history of living in the United States, the immigration of Mexican Indians is a relatively new phenomenon. Mixtecos, Zapotecos, Mixes, Tarahumaras, and other Mexican Indians constitute 10% of the estimated one million persons in California's farm labor force. Alderete, Vega, Kolody, and Aguilar-Gaxiola noted in their 2000 paper that immigrant Mexican Indians are often included with other Mexicans, despite the fact that these very different groups have minimal social contact with each other, either in Mexico or in the United States. In a study of 3,012 Mexican-origin, Spanish- or English-speaking individuals in Fresno County (California), Mexican Indians were found to have higher rates of lifetime alcohol abuse and dependence than non-Indian Mexicans – 5.1% versus 3.3% for alcohol abuse and 17.4% versus 10.7% for alcohol dependence. However, there was no significant difference in lifetime rates for abuse or dependence between these groups after adjusting for sociodemographic factors.

Differences Between National Groups: Central America

In a study conducted by Marin and Posner of 531 immigrants from Central America (primarily El Salvador and Nicaragua), and 391 from Mexico, 64.4% of the Central Americans reported not drinking alcohol in the previous 30 days compared to 56.8% of the Mexicans. The number of days the Central Americans reported drinking in the previous 30 days (mean = 4.5 days) was lower than that reported by the Mexicans (mean = 7.4 days). The Central Americans consumed fewer drinks in the previous 30 days (mean = 5.9 drinks) than the Mexicans (mean = 9.2 drinks).

In a study comparing Dominican and Guatemalan immigrants in New Jersey, differences in the locations chosen for obtaining alcohol treatment were found between the two groups. Dominicans were most likely to seek help for their drinking problem from charismatic groups affiliated with the Catholic Church. In contrast, Guatemalans were more likely to seek help from Spanish-language Alcoholics Anonymous (AA) groups. Neither the Guatemalan nor the Dominican immigrants tended to go to clinics for alcohol problems.

Among Asian groups in California, Vietnamese and Chinese-Vietnamese have been found to report higher alcohol consumption levels in comparison to Japanese, Chinese, Koreans, and Filipinos.

Differences Between Immigrant and US-Born Groups

In a study of 264 young adult immigrants, primarily from Mexico, El Salvador, Nicaragua, and Honduras (mean age 23 years) compared to 188 US-born Mexican Americans, the US-born men and women were found to be heavier drinkers than the immigrants. Approximately 18.3% of the US-born men and 4.2% of US-born women were found to be in the highest drinking category (drinking at least once a week and drinking six or more drinks per usual occasion), in comparison to 9.4% of the immigrant men and 1.0% of the immigrant women. Additionally, US-born women were significantly more likely than their immigrant counterparts to describe alcohol as having social disinhibiting effects, being a mood elevator and tension reducer, and enhancing sociability. No differences were found between the immigrant and US-born males on their beliefs concerning alcohol.

In a study of Vietnamese men living in California, the percentage of drinkers was found to be the same as among men in the general US population. However, binge drinking was twice as common among the Vietnamese men.

Acculturation Differences

One factor that accounts for some differences in alcohol use patterns within specific groups is acculturation. In Alderete et al.'s study of Mexican Indians and non-Indians, both Indian and non-Indian Mexicans who chose to do the interview in English had a statistically significant increased risk for alcohol abuse or dependence compared to those who did the interview in Spanish. This was interpreted as suggesting that acculturation was a risk factor for both populations of Mexican immigrants.

In Marin and Posner's 1995 study of immigrants from Central America and Mexico, greater acculturation was significantly associated with less abstention in the previous 30 days (37.5% for Central Americans, 40.7% for Mexicans) in contrast to individuals who measured lower in acculturation (57.1% for the Central Americans and 68.7% among the Mexicans). The less acculturated Central Americans tended to drink significantly less often in the previous 30 days (mean = 3.9 days) than did their more acculturated counterparts (mean = 5.9 days).

Gender Differences

In a study of young adult immigrants from Mexico, El Salvador, Nicaragua, and Honduras, women had higher rates of abstention than males (59.4% vs. 28.1%). In the same study, US-born Mexican American women also had higher rates of abstention than males (31.6% vs. 21.1%). Both immigrant and US-born women were significantly less likely to be heavy drinkers than men. The immigrant women were also significantly less likely to endorse the belief that alcohol consumption enhances social acceptance, after-work relaxation, freedom from inhibition, global mood elevation, sexual pleasure, tension reduction, social pleasure, and social assertiveness. No association was found between depression and drinking level for either group of women. However, depression was positively associated with alcohol drinking level for both immigrant and US-born men.

Marin and Posner's 1995 study of Central American and Mexican residents found similar gender differences. A lower proportion of men from Central America, compared to women, reported being abstainers in the previous 30 days (51.9% vs. 73.0%, respectively). This finding was replicated among the Mexican men and women (37.7% vs. 72.6%, respectively). Men drank more often during the previous 30 days (mean = 5.3 days among Central Americans, mean = 8.4 days among Mexicans) compared to women (mean = 3.6 days among the Central Americans and mean = 5.8 days among the Mexicans). Men also reported drinking more during the previous 30 days (mean = 10.4 drinks among Central Americans, mean = 15.6 drinks among Mexicans) as compared to the women (mean = 2.8 drinks, among the Central Americans and mean = 4.0 among the Mexicans).

Gender differences in alcohol consumption have also been found among Southeast Asian groups. In a study among Vietnamese immigrants living in the United States for less than 6 months, men were significantly more likely than women to report any alcohol use. Another study in Santa Clara County in California found that 51% of Vietnamese women abstained from alcohol in contrast to only 6% of the men. Additionally 39% of the men were moderate to heavy drinkers in contrast to only 6% of the women.

Reasons for Drinking

In a study of 120 Cambodian refugee women conducted in Long Beach, California and Lowell, Massachusetts, more of the East Coast sample reported using alcohol to cope with nervousness, stress, insomnia, or pain. Cambodian women also described men's drinking as social in contrast to women's drinking which was used to deal with emotional or physical pain. The increasing use of alcohol for the self-treatment of insomnia, pain, and emotional stress has also been reported among the Hmong.

Caetano, Clark, and Tam observed that, among a study of Southeast Asian refugees, 45% reported having problems with alcohol use, and a large proportion found it acceptable to use alcohol to cope with stressful situations. Similarly, in a study of young people of different ethnicities, the recent immigrant Southeast Asian youth reported drinking primarily to forget their pasts, in contrast to the youth of other ethnic groups who reported drinking mostly for social reasons.

Substance use rates also may vary by length of time in the United States. Research findings on substance use patterns among immigrant populations are mixed, with some studies indicating that substance use increased with increased time in the United States. Other studies showed decreased substance use and mental health problems over time and with increased levels of acculturation. One explanation for these discrepant findings is the heterogeneity of immigrant populations. Even within subgroups of immigrants, there is wide variability in substance use patterns.

Makimoto demonstrated differences in drinking patterns among Asian Americans when comparing Chinese-, Japanese-, Korean-, and Filipino-American samples. Among adults, Japanese-Americans had the highest and Chinese-Americans had the lowest lifetime prevalence of drinking and heavy drinking. Alcohol abuse and dependence appear to be significant problems among Southeast Asians resettled in the United States, as a result of contributing factors, such as experiences of trauma during the refugee process and traditional beliefs about alcohol as a health-promoting substance. Other researchers have found that Asian Americans have shown a general increase in substance use patterns with length of time in the United States, and they have attributed the increase to the results of acculturation toward US drinking norms.

The reasons for this variability in drinking patterns are not well understood. Alaniz reported in a 1998 study that alcohol availability and advertising were disproportionately concentrated in low-income racial/ethnic minority communities, with five times more alcohol advertisements in Latino neighborhoods than in predominantly White neighborhoods. Variability in use patterns may arise from differential access to alcohol and other drugs, cultural mores limiting or supporting use, varying degrees of psychological stress, or differences in the use of alcohol in the country of origin. The variability in alcohol use rates could be due to a differential amount of time that immigrant groups have been in the United States or to the younger average age of some of the individuals within the regional groupings.

Clearly, the heterogeneity of the immigrant population of the United States provides a challenge to the substance abuse prevention and treatment community and to early intervention programming. The mixed findings from research with immigrant and minority populations may point to the need for considering cultural values and acculturation in designing interventions. For example, if substance use increases with increased acculturation in some groups of immigrants, it may point to the need to intervene with new immigrants.

Immigrants are faced with multiple socioeconomic, environmental, and cultural factors that increase vulnerability for substance abuse and related problems. Factors that increase the experience of stress include economic insecurity, high levels of poverty that force families to live in deprived neighborhoods, discrimination, experiences of inequality, levels of acculturation, and a pervasive sense of powerlessness. Substance use and abuse can result when attempting to cope with these specific stressors in addition to other daily challenges confronted by immigrants.

The utilization of prevention and treatment programs by immigrants is impacted by many of the same challenges that native-born Americans face. Nevertheless, immigrants also face unique challenges, such as language barriers and cultural barriers, which further hinder their ability to access health care services. Studies have found that immigrants are less likely to utilize medical care than their US-born counterparts regardless of what type of provider – e.g., primary, emergency, or specialized care providers – delivers the services. In order to obtain access to mental health and substance abuse programs, immigrants have to overcome many personal, structural, and financial barriers.

Personal Barriers

Personal cultural beliefs have the greatest impact on the perception of substance use and mental and substance abuse disorders. Culture shapes our beliefs with respect to health and illness, and the causes and remedies of illness. It determines how people understand and deal with substance use and abuse. For example, traditional Asian Indians may avoid substance abuse services due to the fear of stigmatization. For them, substance abuse is a moral problem and a source of family shame. In other cultures, such as in Latin America countries, concepts of *machismo* may promote the use of some substances like alcohol among men. In these cases, heavy drinking is not seen as a problem but as an expected behavior. Even when immigrants are willing to approach substance abuse services, there may be a clash between their health beliefs and the health care providers' beliefs. Western medicine's scientifically based vision of disease tends to compete with some cultures' concepts of illness that include a holistic view where medicine, religion, and cultural practices are intertwined. This disconnect between cultures can contribute to immigrants' mistrust of Western medicine and reluctance to seek help.

Negative past experiences within the health care system can also affect immigrants' willingness to seek services. Experiences of discrimination, alienation, health care providers' biases, as well as communication problems can prevent immigrants from utilizing health services. A survey from the Commonwealth Fund found that 18% of Hispanics felt discriminated against by their physician due to their race/ethnicity, inability to speak English, or to pay for the visit.

Language is one of the strongest barriers to accessing health services. The shortage of trained bilingual service providers in the mental health/substance abuse arena further complicates the problem. This shortage makes it almost impossible for limited-English-proficient immigrants to obtain appropriate services. Only 48% of Spanish-speaking immigrants who required interpreter services during their health care visits said they usually had one. Furthermore, among those receiving interpreter services, only 70% fully understood what the doctor was saying. Language barriers impede access to health at all levels, from primary care to preventive care, as well as specialty services such as substance abuse services.

Immigration status may also constitute a barrier to accessing prevention and treatment services. Undocumented immigrants avoid enrolling in public insurance programs and utilizing health services, due to the fear that data regarding their legal status may be shared with immigration authorities.

Financial Barriers

Lack of insurance is the most significant financial barrier that limits access to substance abuse prevention and treatment services among immigrants. Immigrants are much less likely to be insured than are US-born individuals. The 1997 Current Population Survey found that 34% of immigrants are uninsured compared to only 14% of US-born individuals. Although immigrants are as likely as the US-born to be employed, immigrants are more likely to have low-wage jobs that do not offer health coverage limiting their ability to afford private insurance. In general, uninsured individuals are less likely to have a regular doctor who can refer them to specialty services, are less likely to obtain preventive services, and usually delay obtaining medical care even when they are very sick.

Structural Barriers

In order to access the health care system, it is essential that patients understand how it works. As with many Americans, the majority of immigrants feel overwhelmed by the complicated maze of payments, appointments, multiple levels of service, paperwork, and insurance options that characterize the US medical system. Immigrants may not enroll in preventive and treatment services due to lack of awareness about service availability and/or their eligibility and access to services. When they are able to obtain care, immigrants face longer wait times, limited access to specialists, limited referrals to other services, such as substance abuse services, and less continuity of care.

Conclusion

In general, immigrants to the United States use less alcohol than US natives. At least four different models explain the patterns of alcohol use in immigrant and refugee groups. Among immigrants, alcohol use is highest in young men. There is a wide variation and much heterogeneity among alcohol use patterns seen in different immigrant and refugee groups. Language, financial, and structural barriers complicate the prevention and treatment of alcohol use disorders in immigrant populations.

Allergies

Kristin A. Cassidy
Department of Psychiatry, Case Western Reserve
University School of Medicine, Cleveland, OH, USA

Allergic reactions are caused by the body's immune system overreacting to a substance that is not harmful. Common causes of allergic reactions are certain types of food (e.g., peanuts, soy, dairy, wheat, eggs, and shellfish), seasonal or environmental substances (e.g., dust, mold, pollen, and ragweed), animals (e.g., cat hair, dog dander, insect bites, and cockroaches), and medications (e.g., penicillin, ibuprofen). The substances that cause allergic reactions are called allergens.

An allergic reaction begins when the person with the allergy is exposed to an allergen, usually by swallowing it, inhaling it, or touching it. The person's immune system reacts by creating a type of antibody, called immunoglobulin E (IgE). Antibodies are the weapons the body's defense (immune) system uses to attack substances that may cause harm, such as bacteria and viruses. In the case of an allergy, the IgE attaches to mast cells, which are a type of blood cell that can usually be found in the airways and intestines, as well as other parts of the body. The allergens then bind to the IgE. This binding causes the attached mast cell to release histamine along with some other chemicals into the blood stream.

The symptoms of an allergic reaction are mostly caused by histamine. Symptoms can vary by person and by event. Common symptoms of an allergic reaction are hives, itching, rashes, watery eyes, gastrointestinal disturbances (cramps, vomiting, and diarrhea), sinus and chest congestion, swelling, and anaphylaxis. Anaphylaxis is a severe reaction that affects the whole body and can include any of the above symptoms, as well as difficulty breathing, wheezing, tingling in the extremities, swelling of the tongue or mouth, tightness in the throat, and loss of consciousness. Since anaphylaxis can be life threatening and can progress rapidly, it must be treated quickly by seeking emergency medical treatment at the first signs of the reaction. Individuals who are known to be susceptible to a severe allergic reaction often keep an injectable dose of epinephrine (sometimes called an Epipen or Twinject) on hand to use in the event that they have an anaphylactic reaction.

If an individual suspects that he or she may have an allergy, testing by a medical professional can be done to confirm it and to predict the severity of the allergy. One type of test is a blood test (sometimes referred to as a "RAST" test) to measure the levels of IgE in the blood. Higher levels of IgE indicate more likelihood of an allergy. Other factors (such as medications) may interfere with the results of these blood tests and some individuals may have high IgE levels in their system and yet never experience the symptoms of an allergic reaction. Therefore, if a person has an allergy, the blood test is likely to be positive, but there is also a chance that the test results may be positive even if the individual does not have an allergy. These tests are most helpful when combined with other information such as the details of a reaction to an allergen exposure.

Another type of test is the allergy skin test. In these tests, the individual is exposed to a particular allergen either by pricking the skin after applying a solution containing the allergen, or by injecting the allergen just under the surface of the skin, or by wearing an adhesive patch containing the allergen. The reaction of the skin is evaluated to determine the degree of sensitivity to the allergen. Although the skin test is generally more accurate than the blood test, it is still not always reliable. Just as with the blood test, there is a chance that the skin test may indicate an allergy even if the individual does not actually have one.

In the case of food allergies, if the presence of an allergy is still questionable after combining the results of the blood or skin tests with the individual's history of exposure to the allergen, then a food challenge can be done. A food challenge is a test in which the person is closely observed during a controlled exposure to the allergen and is the most accurate test to determine whether a person has an allergy. During a food challenge, the individual eats increasingly larger amounts of the allergen every 15 min while being observed for an allergic reaction. A food challenge can only be done under the close supervision of a qualified medical professional as there is a risk of experiencing a severe reaction which could require immediate medical intervention.

The scientific literature is inconclusive regarding the risk of immigrants developing allergies in their new country. It is possible that country of origin, age at time of migration, length of stay in the new country, living conditions, and genetic factors may be better predictors of allergies rather than immigration status alone. Health literacy and access to health care are factors that should be evaluated when comparing the prevalence of allergies in immigrants and their native counterparts.

Ambiguous Loss

Jaina Amin
Department of Psychiatry, University Hospitals Case Medical Center, Cleveland, OH, USA

In a world where immigration and migration are prominent, cultural diversity becomes essential. The United States is known as a cultural "melting pot." Thus, in looking at the cultural diversity each ethnic group brings, there also is an element of cultural ambiguity for the displaced ethnic group. Cultural ambiguity is defined as an unclear culture, or of mixed uncertain cultures. As of 2010, the US Census had 310,233,000 total people living in the US, made up of American Indians, Alaskan Natives, Asians, Blacks, Hispanics, Native Hawaiians, other Pacific Islanders, and Whites. And amongst each of these limited groups are numerous subgroups of individuals that struggle to maintain their ethnic heritage.

Ethnic groups struggle with loss of their native languages, traditions, and traditional roles. For example, Scourby discussed the plight of first, second, and third generation Greeks. Questionnaires were sent out with questions measuring the rate of assimilation. One of the questions asked was if English should replace Greek in Church. Predictably, the individuals in the second and third generations said yes. Interestingly, these individuals were not as liberal-minded in having the liturgy (the devotional part of worship) in English and responded that as this was the sacred, transcendental aspect of the religious experience, it did not need to be verbally understood. This indicates that in younger generations, there are more leniencies to small changes than from the first generation. Another question considered ethnic identity – asking how they identify themselves. The younger generations (3rd) were more apt to identify themselves as Greek-American or American. Ethnic identity is influenced by the judgments and responses from the ethnic group and from the outside of the group. Whether the passing of cultural norms from one generation to the younger generation was a positive or negative experience will also affect the identity of the recipient.

Ambiguity is seen when the ethnic culture and dominant culture have differing expectations. For example, in many Asian communities parents raise male children with the expectation that they will remain at home after marriage and help care for them. This is not a value of the dominant "American" culture. Thus, individuals who are living in these two worlds simultaneously may feel lost and forge their own paths, thus changing the traditional norm. Each small change will eventually lead to a global change resulting in the loss of that ethnic group's traditional identity, moving it closer toward acclimation with the dominant culture.

Ambulatory Care

Brandy L. Johnson
Rynearson, Suess, Schnurbusch & Champion, L.L.C.,
St. Louis, MO, USA

Ambulatory care describes health care services that are provided to patients who are not inpatient nor bedridden. In fact, the very definition of the word "ambulatory" describes someone who is capable of walking and not bedridden. Medical care can include obtaining a diagnosis, observation, treatment, and rehabilitation if care is provided on an outpatient basis and does not involve a hospital stay. Thus, ambulatory care encompasses *any* care that does not involve inpatient treatment in a hospital or medical facility.

Types of Ambulatory Care

Ambulatory care can be divided into two major categories. The first category includes care provided by physicians. The second category involves care that is organized and provided in medical institution.

The care provided by physicians can be provided by a solo practitioner, individual physicians who have organized themselves into a partnership, or physicians who participate in a group practice. There are many different types of physicians that participate in ambulatory care. The care can be provided by primary care physicians and/or specialists. Therefore, physicians that provide ambulatory care include, but are not limited to, general practitioners, family doctors, pediatricians, internists, obstetricians, gynecologists, dentists, cardiologists, ophthalmologists, dermatologists, gastroenterologists, psychiatrists, podiatrists, allergists, neurologists, chiropractors, and orthopedists. Ambulatory care provided by physicians typically occurs at the doctor's office and requires an appointment. It should be noted, however, that when one of these physicians provide treatment to a patient, while they are admitted in a hospital, the care being provided is not deemed "ambulatory care." Additionally, the fee paid to the physician for the inpatient visit is often more expensive than what the same doctor charges for ambulatory care.

Although ambulatory care is provided by physicians, it can also be provided, in an outpatient setting, by other health care professionals. Patients often receive the treatment from physician assistants or nurse practitioners in the outpatient setting. If the patient is only appearing for a service that can be handled by a nurse, such as receiving an injection or bandage changes, the treatment may be provided by a registered nurse or licensed practical nurse.

The second category of ambulatory care involves treatment provided in medical institution–based settings. Such institutions include hospital-based outpatient clinics, walk-in centers, urgent care centers, hospital-sponsored group practices, surgery centers, health department clinics, community health centers, outpatient mental health centers, schools, workplace health services, diagnostic centers laboratories, outpatient rehabilitative and physical therapy centers, pharmacies, imaging centers, correctional health facilities, dialysis centers, laser surgery centers, fertility clinics, military clinics, women's health centers, and sleep centers. Many patients, however, are not admitted and discharged for follow-up care at home or with a health care provider.

Emergency rooms can also provide ambulatory care. However, if the patient is admitted to the hospital, the care is not considered ambulatory. Insurance companies may not include an emergency room visit under ambulatory care, as visits to the emergency often occur without notice and could result in hospitalization.

Growth of Ambulatory Care

In the last three decades, ambulatory care has seen tremendous growth. There are several reasons for this growth. The first reason is advances in technology. As medical science has advanced, the need for inpatient hospitalization and hospital-based services has decreased. For example, surgeries that used to require inpatient observation and care postoperatively can now be performed on an outpatient basis. The surgeries can be performed safely at a freestanding surgery center or a clinic. The development of diagnostic equipment, such as magnetic resonance imaging (MRI) machines, have also led to the development of centers that specialize in providing quality testing in an efficient manner.

The growing cost of health care has spurred the growth of ambulatory care. Often the cost of services at a hospital is greater than at an ambulatory care facility. For example, an imaging center will often charge less for an MRI than a hospital. Additionally, if a patient can undergo surgery and return home the same day, the fact that inpatient care is not needed, alone, serves to reduce the cost related to the surgical treatment.

Finally, patient convenience has contributed to the growth of ambulatory care. The manner in which ambulatory care has grown allows patients to access to health care that is closer to home. A patient who needs to have lab work performed can now find the closest laboratory rather than traveling to the hospital and utilizing its laboratory services. The patient also has more choices in where to obtain care and by whom. By moving certain types of care and testing outside of a hospital setting, hospitals also have the ability to direct more of its resources to patients who do need inpatient testing, observation, or procedures.

With easier access to ambulatory care, the utilization of ambulatory care providers and institutions has steadily grown. By way of illustration, there were 841,204 visits to doctors, emergency rooms, and outpatient departments in the United States in 1994. By 2006, this number had increased to 1,123,354. When examining the different types of ambulatory care used during these years, visits to physicians appear to constitute the largest percentage of the care utilized. In 2006, doctor's visits made up four-fifths of the ambulatory care sought by Americans. It was estimated that 902 million visits were made to physicians in their offices, with 58.3% being made to primary care physicians, 22.0% to medical specialists, and 19.7% to surgical specialists. Thus, on average, there were approximately 306.6 visits for every 100 persons. Similar increases in the use of ambulatory care have been noted in other countries.

Utilization of Ambulatory Care

Studies have shown that ambulatory care services are utilized by more women than men. The higher rate of ambulatory care by women may be explained by the fact that women tend to be more likely to use preventive care, attend regular checkups, be proactive in their care, and comply with all the treatment. Further, ambulatory care is used more by the elderly than the young. As the elderly tend to have more health issues and conditions that require monitoring, an increased use by this population is logical and to be expected.

The amount of access citizens have to health care, including ambulatory care, varies from country to country. In the United States, uninsured citizens have been found to have the lowest rate of utilization of ambulatory services such as physician office visits. Consequentially, illegal immigrants, immigrant groups, and others who cannot afford insurance and do not qualify for governmental assistance appear to have limited access to a majority of the ambulatory care services offered in their area. In countries that offer some form of universal health care, citizens do not face the same barrier and, therefore, may have greater access to ambulatory care.

Choosing Quality Ambulatory Care

As with all health care services, a patient must keep in mind that not all ambulatory care providers are equal. Providers vary in the amount of training received, availability, qualifications, experience, their bedside manner, the amount of staff on hand, accreditation, certification, equipment utilized, and the time they are willing to spend with each patient. As choosing a quality health care provider is an extremely important decision, an individual should research the ambulatory care providers and institutions available before enrolling in care. However, it is worth noting that an individual's choice of ambulatory care provider may be limited by factors such as insurance, provider's acceptance of the individual's insurance, and, in the network insurance programs, which providers are in network and available to the patient.

In circumstances where the patient is searching for a specialist or is considering the use of a medical institution, such as a diagnostic center or surgical center, the patient may be able to start his or her research with their primary care physician. While speaking to family, friends, or other community members may also be helpful, advice from lay sources should be placed in perspective and complemented by other information about the service.

Once the individual has a list of prospective providers, it is recommended that a visit to the facilities, a call, or a meeting with the manager or other staff members about the organization's services, policies, history, and staff credentials be conducted. However, depending on the provider, the amount of time and information the individual may receive could be minimal. Staff members may be unwilling or unable to discuss subjects concerning issues such as their employer's incident rates, infection rates, outdated equipment, or doctors' success rates.

Some physicians and facilities publish information about their qualifications, services, and success stories in brochures or Web pages. Consumer groups, Internet postings, and blogs are other research tools that are available. While publications, consumer groups, and the Internet are additional investigational tools, any such information may be limited and may not include such information as medical malpractice suits filed against them. Dissatisfied patients may also misrepresent information. Likewise, satisfied patients may offer helpful suggestions.

Questions an individual should consider when trying to choose an ambulatory care provider include:

- Will your rights and responsibilities as a patient be properly explained?
- Will you and your family be provided adequate and sufficient information to make appropriate decisions regarding your care?
- Can family members come into the recovery room?
- Does the provider have a license, board certification, hospital privileges, or accreditation?
- Do you have access to information about the provider's experience with the procedures, qualifications, and training?
- Are emergency services, such as cardiopulmonary resuscitation, available by trained personnel? Will you be transferred to a hospital if there is an emergency?
- Do you have access to information regarding how often the provider performs the procedure or treatment at issue and how successful he or she has been with the procedure or treatment?
- If there are complications, is the provider available 24 h a day, 7 days a week?

Conclusion

The majority of today's health care services are ambulatory care. More and more treatment and testing are moving from a hospital-based setting to doctor's offices and medical institution–based settings. By doing so, patients can usually receive quality care that is less costly, more convenient, and they have the opportunity to choose from a larger pool of providers. Despite this, ambulatory care tends to still be less accessible to certain segments of the population.

Underutilization of ambulatory care by immigrants could place them in a position where their health may be compromised. Immigrants often do not receive regular preventive care or treat diseases until the condition has become serious. By making care easier to receive and less expensive, however, immigrants, who may have refrained from obtaining care due to cost or an inability to fully understand the health care/insurance system, should be better able to receive care. Additionally, access to a larger pool of providers allows immigrants the opportunity to search for, and use, doctors and facilities that are aware of, and perhaps even cater to, their particular cultural needs and concerns. Additionally, education concerning ambulatory care, its availability, and its importance should be made widely available for both immigrants and the public at large.

Ambulatory Care Utilization

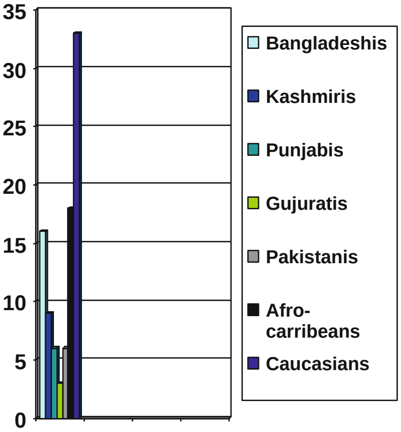
Mark Agius
Department of Psychiatry, University of Cambridge;
South Essex Partnership University Foundation Trust,
Weller Wing Bedford Hospital, Bedford,
Bedfordshire, UK

Most health services are accessed through primary care services. These are generally General Medical Practitioners or Family Doctors located in surgeries or other clinics distributed in the local community. Surgeries and clinics that often provide maternal and child health and family planning clinics are usually run by local health authorities, and in some countries may be called Health Centers or polyclinics. If patients are too ill to be served by primary care clinics, but not ill enough to need admission to hospital, or if they need more complex examination, then they will be referred to hospital outpatient departments. All of these services, including primary care and outpatient services, are referred to as ambulatory services, from the Italian "ambulare" – to walk, because these patients walk to the clinics to be seen by doctors and other clinicians, and do not have to be admitted to "lie in a hospital bed."

It will be clear from the above that most care from specialists in developed countries is given in outpatient "ambulatory" clinics, rather than within hospitals; the maintenance of hospital buildings makes care for hospital inpatients extremely expensive. Therefore, patients are only admitted to hospital for short periods of time for specific procedures. However, it is also true that different ethnic groups may have different perceptions of the need to attend outpatients; the figure (Fig. 1) below shows different rates of non-attendance at outpatient appointments for different ethnic groups in an ambulatory service for patients with an episode of Psychosis in Luton, Bedfordshire, and this clearly demonstrates different choices in terms of attending outpatient appointments.

Immigrants who do not access and utilize appropriate health services may realize consequences for themselves and their communities. Immigrants with serious illnesses such as infectious diseases may receive inadequate treatment if they do not seek care at clinics

- Bangladeshis have more missed outpatient appointments than the other Asian subgroups.
- The second largest number of missed appointments is found in the Kashmiri Population.
- In general however, Afro-Caribbeans and Caucasians have more missed appointments than any of the Asian subgroups.
- Only 1 Bangladeshi patient kept all his appointments.One Pakistani and 1 Punjabi patient kept all their appointments. All the other Asian patients did miss appointments.
- By contrast, 1 Afro-Caribbean and 15 Caucasian Patients attended all their appointments.
- There are 40 missed appointments in all Asian groups together.
- Missed appointments appear to be an important problem in the Asian Community and may lead to disengagement from services.



Ambulatory Care Utilization. Fig. 1 Missed appointments in different ethnic groups

where they are entitled to receive care and where the appropriate care is available. An immigrant entering a new country suffering from tuberculosis, for example, will continue to deteriorate and pose a risk to others if he does not attend an appropriate clinic to be treated. Untreated, the patient's disease will progress and this potentially fatal condition may prevent him from being fully productive at work, lead to his untimely death, and place his family at risk in a strange country. Ambulatory health services could provide substantial treatments for this patient and his family.

Ambulatory services make a major contribution in improving the health of mothers and children and preventing negative health outcomes., In Luton, Bedfordshire, England, for example, comparatively (as compared with the rest of the UK) high child and maternal morbidity is linked with the presence of numerous immigrants from Pakistan, Bangladesh, and India as well as from many African countries. These immigrants may not seek preventative maternal child services and thus suffer disproportionately high mortality rates.

Once immigrants have been accepted into a community in the UK, they are entitled to all the same health services as the rest of the population. In other countries, health services may be linked to insurance or public programs. Health Authorities in towns in the UK have set up special teams of nurses and health visitors to make contact with immigrants and to enable immigrants to use ambulatory health services and ensure the health of the population.

The first study about the utilization of ambulatory mental health services by South Asians (Indians, Pakistanis, and Bangladeshis) was carried out at the Institute of Psychiatry, London in 1970. The results suggested that these groups of immigrants appeared to utilize ambulatory services differently from the general population. The immigrants presented when their symptoms were so advanced that their behavior was clearly changed. They were discharged from hospital more quickly, missed outpatient appointments more frequently, and were discharged as outpatients more frequently than the indigenous population.

Recently, a study of the utilization of an ambulatory service for first episode psychosis in the town of Luton showed similar results. The patients were second-generation immigrants (that is, the children of immigrants). They, too, tended to present when their symptoms were so advanced that their behavior was clearly changed, tended to miss outpatient appointments more frequently, and also to be discharged from outpatients more frequently than the indigenous population. The examples highlight the importance of understanding how immigrants utilize ambulatory services to maintain their health.

It has been well reported that the utilization of ambulatory health services, including mental health services, may be different among certain groups of immigrants as compared to the general population. A number of reasons may be suggested.

First, immigrants may not be aware of the services to which they are entitled in their new country of residence or they may expect to pay for certain services, when these services are available to them for free.

Second, the "explanatory model" about the cause of various illnesses may differ from that which exists among the indigenous population of the country of residence. For example, many patients and families from India and Pakistan may believe a psychotic illness occurs because the patient is possessed by a "gene" or spirit, rather than that he is suffering from a disease of the brain. Consequently, these persons may seek a holy man to have the spirit appeased or persuaded to leave rather than attending outpatient appointments. This difference in belief of the cause of disease or illness is referred to as the "explanatory model." Lastly, the aims and motivations of the immigrant, in attending outpatient appointments, may be quite different from those of the host population. Thus, an immigrant's perception of when treatment begins and ends may very well be different from that of the native population. An immigrant is often poor and cannot "afford" to take much time off being ill. Prolonged absence from work may lead to losing his job, and even his livelihood. Hence, he may stop returning to outpatient appointments when he feels better. Such an expectation of a rapid return to work may not be as common in patients from the indigenous population, who may have greater knowledge of their rights to employment or sickness benefit and a greater sense of entitlement.

Differences in the use of ambulatory health services may persist in "second-generation immigrants," that is, the children of immigrants into a host country, who have been born in that host country, but may often continue to experience the original culture of their parents within the family home.

Cultural differences in the perceived utility of the ambulatory services may be an important cause of the reduced use of ambulatory services by some immigrant groups.

Health authorities and public health practitioners must engage immigrant groups and educate them regarding the importance of health services and what services they are entitled to access. Encouraging appropriate outpatient services early will avoid costly emergency treatment later. This will contribute to general population health of the host community as well as the general health of the immigrant populations.

Amnesty

Johanna Hanefeld
Health Policy Unit, London School of Hygiene and Tropical Medicine, London, UK

The term amnesty has two defined meanings in the English language: "the official act of forgiving people who have committed offences against the state and allowing them to go free" and "a period of time during which people can admit to doing something wrong without fear or punishment." In the context of immigration, amnesty has been of great relevance in recent years in two ways.

First, immigrants who are undocumented often lack access to adequate health care. This may be the case where the State wishes to withhold certain benefits such as free health care to undocumented immigrants. Legislation and entitlement for undocumented immigrants varies across and often even within countries; undocumented immigrants may fear that efforts to obtain health services will draw attention to their immigration status. Additionally, many immigrants, including those with documentation, face non-statutory barriers to health care, such as culture and language.

It is difficult to quantify the extent to which undocumented immigrants attempt to obtain health services as past research has not often collected data relating to immigration status. However, reviews from North America have consistently shown that immigrants overall have a lower health status. Researchers found that in the USA, immigrants' spending on emergency medicine was three times higher than that of US citizens, while health spending on other aspects of services was lower. This demonstrates that immigrants tend to seek health care services in the case of emergency but do not do so for preventive services. These findings echo the experiences of physicians providing health care to immigrants who have observed that their immigrant patients often seek medical help only after an illness has become worse. In the USA, undocumented immigrants have limited access to health insurance, which poses an additional barrier to diagnosis and treatment. A review of studies conducted in North America found that use of health care services is closely associated with insurance coverage, and that undocumented immigrants consistently seek fewer health care services than those with legal status.

Amnesty for undocumented immigrants has often faced opposition because of concerns related to the costs associated with providing health care to immigrants. Research findings documenting the relationship between undocumented status, lack of access to health insurance, and lack of access to health care present a strong humanitarian rationale for amnesty for undocumented immigrants.

Amnesty International

Cristina Cazacu Chinole
Center for Ethics and Public Policies, Bucharest and Iasi, Romania

Founded in 1961 by a British lawyer, Peter Benenson, Amnesty International is a well-known international human rights organization with more than 2.2 millions of supporters and subscribers from more than 150 countries. The declared mission of the organization is to work around the globe in order to stop the abuse of human rights; its purpose is to protect people wherever justice, freedom, truth, and dignity are denied.

According to its statute, Amnesty International is autonomous organization that does not support or oppose any government or political system. Moreover, the organization does not necessarily support or oppose the views of the victims/survivors or human rights defenders whose rights it seeks to protect. As it is fully funded through individual contributions and donations, Amnesty International is able to be free from any influence, since it does not depend on any government, political ideology, economic interest, or religion.

The basic premise of Amnesty International's activity is that each and every person has the right to enjoy all of the human rights enshrined in the Universal Declaration of Human Rights. When States or institutions fail to protect these rights, Amnesty International seeks to mobilize large numbers of individuals to react and offer public displays of support for those who need such protection. By undertaking meticulous research focused on preventing and ending grave abuses of the rights to physical and mental integrity, freedom of conscience and expression, and freedom from discrimination, Amnesty International documents abuses and violations; based on these findings it publicly demands governments, international institutions, and corporations to respect the rule of law. A large database of more than 50,000 reports about human rights issues, press releases, and appeals for action written by AI researchers is available online for any interested party at http://www.amnesty.org/en/library.

The philosophy of the organization is to campaign globally and locally in order to make a difference. Supporters and activists of the organizations work to improve human rights by, especially, organizing impressive mass demonstrations, vigils and direct lobbying, and attractive online and offline campaigning in order to mobilize large support for its causes. This is how Amnesty International is a powerful voice that can, to a certain extent, exert pressure on governments, political bodies, companies, and intergovernmental groups to put an end to human rights violations.

Starting with early years of activity, the organization has gathered an impressive record in gathering massive support for different campaigns such as to stop violence against women, stop political killings, abolish the death penalty, oppose torture and combat terror with justice, free prisoners of conscience, protect the rights of refugees and migrants, regulate the global arms trade, end poverty, and so on.

There are many significant milestones in the history of the organization: in January 1969, UNESCO granted Amnesty International consultative status as the organization reached another milestone and 2,000 prisoners of conscience were released as a direct result of the organization's campaigns. In 1971, the first worldwide campaign for the abolition of torture was launched and 2 years later the United Nations unanimously approved the Amnesty International-inspired resolution formally denouncing torture. In 1977, Amnesty International was awarded the Nobel Peace Prize for "having contributed to securing the ground for freedom, for justice, and thereby also for peace in the world." The following year, the organization won the United Nations Human Rights prize for "outstanding contributions in the field of human rights."

In 1985, the International Council Meeting in Helsinki, Finland, made a decision to broaden the statute of the organization to include work for refugees. At that moment, membership in the organization counted more than half a million members, supporters, and subscribers.

In 1996, Amnesty International launched the campaign for a permanent International Criminal Court, and a year later the human rights of the refugees worldwide became one of the crucial themes for campaigning for the organization. In 1998, the Rome Statute of the International Criminal Court was adopted.

In 2007, after a mobilizing campaign organized by Amnesty International and its partners in the World

Coalition Against the Death Penalty, the UN General Assembly (UNGA) Third Committee's 62nd session adopted resolution L29 calling for a global moratorium on executions.

Amok

Kristi Ninnemann
Department of Anthropology, Case Western Reserve University, Cleveland, OH, USA

Amok, often referred to as a Malaysian culture-bound or culture-related syndrome, is characterized by an unrestrained, sudden episode of extreme, often homicidal, violence. Although prodromal symptoms of *amok*, such as intense brooding, increased anxiety and agitation, or upset over a perceived criticism or insult have been reported, the majority of *amok* acts are largely indiscriminate, neither premeditated nor provoked. The extreme violence perpetrated during an episode of *amok* is further thought to be unconscious to the individual "going *amok*," as the perpetrator, or *pengamok*, is said to be in a dissociative state or amnesia. Due to the excessive frenzied nature of the *pengamok*, outside force is generally required to end an *amok* episode. Such confrontation and force may result in the death or suicide of the *pengamok*. If the *pengamok* survives, the destructive and murderous outburst is characteristically followed by total amnesia and intense fatigue.

Amok is classified as a culture-bound syndrome in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM IV-TR)* and the World Health Organization's *ICD-10 Classification of Mental and Behavioral Disorders*. The *DSM-IV-TR* reports *amok* as occurring solely in males. Further, the *DSM* posits a possible coterminous relationship between certain episodes of amok and acute or chronic psychotic processes. Both DSM and ICD classifications recognize the occurrence of *amok*-like behavioral patterns in other areas of the world. Examples of similar culture-related syndromes of unrestrained violence include, but are not limited to, *beserkergang* in Scandinavia and *ahade idzi be* in Papua New Guinea.

The term *amok* is also used in a modified form in common language. Co-opted as an adverb, amok is often used as a descriptor suggesting undisciplined, unruly, or uncontrolled behavior.

Anger

James Cavney
Regional Forensic Services, Waitemata District Health Board, Auckland, New Zealand

Anger is an intense emotion typically experienced in relation to feelings of displeasure or antagonism. It can be induced by a real or supposed injury or insult to one's self or others, or by the intent to do such injury. It is a common human emotion. It has been experienced by almost every person throughout human history. It is recognizable in infants and emerges at a predictable stage of their early development irrespective of culture or ethnicity. It is described in our oldest oral and written histories and has continued to be referenced in modern media and research.

The ubiquitous and enduring nature of anger as part of the human emotional experience makes it probable that it has served an adaptive function during the course of human evolution. However, anger has more often been viewed as a problematic and negative emotion due to its complex association with extremes of aggressive and violent behavior.

While there has been some disagreement over the intrinsic value of anger by scholars over the centuries, the view that anger is a natural and mature emotion is a reasonably modern one. It is also an important consideration when discussing anger in relation to immigration and health. Migrant populations are particularly vulnerable to a range of health problems that can potentially be affected by the regulation and expression of anger.

However migrant groups are also ethnically diverse and vary in their individual and collective capacities to sublimate anger and use it in adaptive ways. Understanding the origins and functions of human anger can thus help clarify how it differentially affects health outcomes of immigrant groups in a process of acculturation to the destination culture.

The Origin and Function of Aggression

Anger has primarily been considered to be a human emotion although our early understanding of its function was led by the study of comparative animal biology and behavior. Species-specific neurological pathways have now been identified that are presumed to have evolved to process emotionally significant information. These pathways run from the sensory organs to the amygdala, through the limbic system and to the forebrain. Complex neurochemical and hormonal cascades further activate the hypothalamic-pituitary-adrenocortical and pituitary-gonadal systems to release epinephrine, norepinephrine, and testosterone which help activate the body to respond.

For many decades anger was researched only in relation to aggressive and violent behavior and became subsumed within the behavioral and biological research traditions of the early and mid-twentieth century. Definitions were at times blurred and the terms anger, rage, and aggression were often used interchangeably. Anger came to be seen as a part of the general autonomic arousal system of the fight flight behavioral response. It was not until late in the twentieth century that any meaningful analyses of the cognitive processes underpinning anger were conducted.

Using cognitive-behavioral and social learning paradigms, researchers have since discovered that anger can be feigned or exaggerated as a strategy to achieve one's goals by manipulating or influencing others. People who look angry are perceived as more powerful than those who seem sad. Showing anger during a negotiation can be perceived as being dominant and powerful and people may be inclined to easily give up negotiations with an angry compared to a happy opponent.

It has been suggested that people analyze their opponent's emotions in order to decide about their own emotional expression and behavioral responses. Anger may therefore be considered as an evolved bargaining tactic that involves choosing to use certain behaviors to resolve conflicts in favor of one's own interests. It is a reaction that motivates a response connected to the impulse for self-preservation.

Anger is thus an emotional response to the provocation of an overt threat or perceived or anticipated transgression. It occurs through an interplay between cognitive (appraisals), somatic-affective (tension and agitations), and behavioral (withdrawal and antagonism) components. Anger reactivity and regulation are related to behavioral self controls that emerge out of our interpretation of learned social norms derived from our early environmental experience. These social norms in turn uphold accepted standards of conduct within any given social group.

Pathological Expressions of Anger

Different people at different times may express their anger adaptively or pathologically depending on social circumstances (states) and personality predispositions (traits). Extreme expressions of anger can impair one's ability to process information to exert cognitive control over their behavior. An angry person may therefore lose objectivity, empathy, or rationality and cause harm to others. If self-directed, anger can result in acts of impulsive deliberate self-harm or suicide.

The proposition of inherited predispositions, or traits, affecting the phenotypic expression of anger has led to promising advances in molecular genetics. The monoamine oxidase A gene, for example, appears to play an important role in differentially mediating neurotransmitters and hormones in the pathological anger responses between individuals. However, there remains a complex interplay between individual genetic and environmental factors that is yet to be fully elaborated.

The social and personal cost associated with the aggressive and violent extremes of anger has meant these areas have received a lot of research attention to prevent such behavior. However, modern psychologists have become increasingly interested in the possible harmful effects of suppression of anger. The passive anger response can relate to repression and denial of anger when it would be an appropriate response to the situation. This can also lead to persistent violent thoughts or uncontrolled violent displacement behavior.

Anger can also lead to mental health problems or aggravate pre-existing conditions. Research shows that people who suffer from excessive anger often harbor and act on dysfunctional attributions, assumptions and evaluations of people and situations. Distorted cognitive schemas are common across a range of mental health problems including depression, anxiety, adjustment disorders, posttraumatic stress disorder, and substance abuse problems. Anger can also fuel paranoia or prejudice in everyday situations and often presents as a symptom of underlying mental health problems.

Anger, Immigration, and Health

Understanding individual differences in regulating pathological and non-pathological expressions of anger is an important field of research. However, when considering anger in relation to immigration and health one needs to consider its expression in heterogeneous groups of individuals. The literature is full of comparative studies of poor mental health outcomes in migrant populations. Typically it compares the mental health of migrants to that of natives in the destination country as a result of acculturation, and overlooks preexisting differences between these groups.

To truly understand the effect of migration on mental health one must also consider what the mental health of migrants was like before they left their place of origin. The migration experience can be extremely traumatic and arduous for some and their different experiences en route can differentially affect mental health status prior to arrival at the destination. People generally migrate to improve their economic or social well-being, although for some the decision may be related to situations of extreme poverty, war, violence, or persecution.

The numerous losses experienced during the migration process coupled with the potential high level of distress prior to migration are undeniable sources of stress which can negatively impact on mental health prior to arrival in the new host culture. Individual variables primarily influence mental health status before arrival in the host country and include education level, socioeconomic status, sex, ethnicity, and identification to the group of origin.

In the post-migration context, there can be a crucial interrelationship between individual mental health with factors such as detention, bureaucratic processes, homelessness, poverty, unemployment, loss of language and culture, loss of family and friends, and social isolation. Acculturation refers to the cultural and psychological changes that occur as a result of intercultural interactions after arrival at the destination country. Factors contributing to the acculturation stress include those at both an individual and group level.

Group Identity, Self-Esteem, and Mental Health

Retaining a sense of one's ethnic identity greatly enhances psychological adaptation. Social groups are an important source of self-definition and have implications for the psychological well-being of individuals in the groups. Affective and evaluative components of cultural identity are integral to self-esteem and positive adaption to the host country and can enable a clear sense of personal and cultural identity, good mental health, and good self-esteem.

Integration within one's original and host culture provides more favorable psychological outcomes. Marginalization from host and original culture is the least favorable acculturation strategy. Negative outcomes can be associated with feelings of anger, anomie, depression, anxiety, psychosomatic symptoms, and identity confusion.

The variable rate of the expression of anger in migrant groups is far from clear. However, migrants are overly represented in mental health statistics although findings vary across ethnic groups. Given that anger can be a common symptom of a range of mental health problems, it is reasonable to suggest that migrant mental health problems may be a proxy measure for migrant anger problems. The ultimate expression of anger will however depend on social norms in their prevailing cultures.

Recent reports on the mental health care of migrants in Europe have drawn attention to several key issues in relation to the quality and quantity of available services. There are problems in the accessibility of mental health care and an absence of participation of migrants in the development and delivery of services. There is also poor quality and quantity of data on migrant's mental health problems and their use of services to guide good practice.

Anger, Discrimination, and Prejudice

When asked directly, migrants will most often identify discrimination as the thing that makes them most angry. Because social groups are characterized as cognitive representations of those belonging to the group, similar motivational and cognitive mechanisms apply to the social processes of both intergroup and interpersonal hostility. When individuals identify with one group over another they tend to over rate their intrinsic worth and evaluate themselves more favorably in reference to the out group on dimensions relevant to in-group definitions.

Structural social realities are subjectively perceived by the individual and come to affect a person's thoughts, feelings, and behaviors about themselves and their group. An individual's personal experience of negative stereotypes, prejudice and discrimination, low group status and social deprivation was once thought sufficient to explain both group hostility and individual anger.

However, the capacity of the individual to understand when collective deprivation is experienced by the group in relation to other groups also contributes to the expression of individual and group anger. Individuals can thus find solidarity with the group and defer to the decision of the group as to how to confront the discrimination. The anger of the group can in turn be expressed adaptively such as negotiating within the wider political systems of the host group or maladapatively through retaliatory violence.

Conclusions

Anger is a psychobiological state that varies in the intensity of expression between individuals and groups of individuals. It is functional in many ways and can motivate people to affect great change for personal or social benefit. However, anger also has the capacity to result in extreme aggressive and violent behavior and cause great harm to oneself and others. Anger can thus be considered as either adaptive or pathological.

Pathological expressions of anger are often associated with mental health problems. Migrant populations tend to be overly represented in poor health outcomes when compared to members of the dominant culture. However, these problems can emerge before, during, or after they migrate from their country of origin. To the extent that anger is related to mental health problems in different mental health statistics can serve as proxy measures of anger problems. Migrants should therefore be entitled to a full range of mental health services in response to their needs.

However, if services are to be effective they must seek to identify the interplay of factors and function to ameliorate the problems at different levels. Policies and procedures should be developed to ensure that the appropriate ranges of services are available for migrants to reflect their needs in relation to their individual migration journey.

Mental health services should be seen as vital part of immigration services and work in partnership with migrants to breakdown prejudice and stereotypes that can result in anger. Encouraging the active participation of migrants in defining needs is important to develop a knowledge base of good clinical practice for the future.

Anti-Asian Violence

Andrew Leong

College of Public and Community Service, University of Massachusetts/Boston, Boston, MA, USA

The history of Asians in the USA is replete with incidents of anti-Asian violence. This violence ran the gamut of physical assaults from individual perpetrators to mob violence. The violence also was perpetrated by the government on a local, state, or federal basis through officially sanctioned actions, or through inaction by the state, thereby denying Asians of any protection from the law. From the first wave of Chinese arriving in San Francisco in the 1850s to the most recent Indian immigrant coming off any plane in the twenty-first century, Asians, irrespective of their nationality, class status, age, and gender, could be potential victims of anti-Asian violence or bias.

When the Chinese arrived in California following the Gold Rush of 1848, many local city, state, and federal laws were enacted and implemented against them since they were seen as economic competitors. However, these laws were preceded by anti-Chinese hysteria and direct physical violence. The infamous 1854 case of *People v. Hall* demonstrated that even when there were witnesses to convict a White defendant who murdered a Chinese victim, the California Supreme Court still nullified the conviction because it was based upon the testimony of Chinese witnesses. Thereafter in California, the Chinese were disqualified from testifying for or against any Whites in any court proceeding. This was the beginning of the creation of a system of institutional racism and oppression against Asians in the USA.

Anti-Chinese political platforms (“The Chinese Must Go”) were established throughout the Western states from the 1850s to the 1870s. Political parties and unions held meetings and rallies to organize against the “yellow peril.” At one point in time, the USA was open to having many smaller remote Chinatowns and Chinese settlements scattered throughout the Western states, but anti-Chinese mob violence forced the Chinese to abandon these locations for the protection that bigger Chinatowns offered. There were countless episodes of destruction and violence by White lynch mobs throughout the Western USA. For example, in 1871, around 21 Chinese were murdered in Los Angeles and the Chinatown looted and burnt down; in 1885, over 40 Chinese were killed in the “Rock Springs Massacre” in Wyoming; in 1887, around 31 Chinese were murdered and mutilated in the “Snake River Massacre” in Oregon. Over the course of this anti-Chinese period in the nineteenth century, many Chinese were rounded up in smaller towns, some murdered, while the lucky survivors were forcibly put on ships or other transport and herded back to San Francisco Chinatown.

When various exclusion acts prevented the Chinese from immigrating in larger numbers, the cycle for the need of cheap labor continued for other Asians in the late nineteenth century and early twentieth century. Following the Chinese were the Japanese, then the Filipinos, Koreans, and Asian Indians. Each succeeding group experienced their own history of intimidation, violence, and eventual exclusion similar to the earlier experiences of the Chinese.

In the twentieth century, around 120,000 Japanese and Japanese Americans were forcibly removed from their homes during World War II and incarcerated in American concentration camps. The US government operated out of the assumption that there were some inherently disloyal Japanese residing in the USA. Since it was difficult to discern who in the general population were loyal or disloyal to the USA, it was easier to incarcerate everyone, from the babies up to the elderly. Similar camps existed for Japanese Canadians as well. Ethnic Japanese residing in South American countries were rounded up as prisoners of war and sent to US camps. This whole-scale incarceration did not occur for ethnic Germans or Italians in the USA.

By 1965, racially restrictive immigration quotas were removed and the Asian population began to increase in the USA. The end of the Vietnam War also meant refugee resettlement programs for Vietnamese, Cambodians, and other Southeast Asian groups throughout the 1970s. With the increase of Asians in the general population came a correlating increase of acts of violence against Asian Americans. The 1982 murder of Chinese American Vincent Chin by two unemployed White autoworkers illustrates some of the motivation in the hatred against Asian Americans. Mr. Chin was seen by his murderers as Japanese and thus responsible for the recession and decline of the auto industry in Detroit, Michigan. Similar to the result in the 1854 *Hall* case, the two killers of Mr. Chin never received 1 day of jail sentence as they were paroled and fined $3,000 for the killing. The Chin case led Asian Americans to begin organizing around the issue of anti-Asian violence. Organizations began collecting hate crime data and demonstrated a steady statistical increase against Asian victims. Civil rights advocates have indicated that for each hate crime reported, 5–15 other incidents are not documented due to cultural and language barriers on the part of the victim, or police or prosecutorial neglect. The range of impact to the victim is often physical; yet, the underlying emotional and mental trauma are often overlooked nor dealt with.

In anti-Asian violence cases, Asian victims are often blamed for economic woes in their newly adopted land since they are seen as foreign economic competitors. The stereotyping of Asians as the "model minority" leads to resentment by non-Asian groups when Asians are perceived to be able to achieve enormous success despite major obstacles. Victims are often erroneously labeled by their perpetrators to be of a different ethnicity or nationality, and repeatedly considered to be foreign (the "perpetual foreigner syndrome") even when the victims are natural born citizens. The numerous wars and conflicts that the USA has engaged in during the twentieth century against Japan, and in Korea and Vietnam, along with the Cold War with China, contribute to the hatred. Whether they are victims to overt physical violence or constant racial taunts, Asians in the USA and other adopted countries continue to experience a disparate number of such biased experiences or hate crimes.

Antiterrorism and Effective Death Penalty Act of 1996 (U.S.)

Robert W. Stephens
Rynearson, Suess, Schnurbusch & Champion, L.L.C.,
St. Louis, MO, USA

The Antiterrorism and Effective Death Penalty Act of 1996 (AEDPA) is an Act of the United States Congress signed into law on April 24, 1996. The bill was introduced as part of Speaker of the House Newt Gingrich's Contract with America, passed with broad bipartisan support by Congress following the Oklahoma City bombing, and signed into law by the United States President Bill Clinton.

AEDPA created a new procedure for the removal of alien terrorists. (The law uses the term "alien" to refer to any individual, including those who are permanent residents, who is not a citizen of the United States.) Special removal proceedings apply to any noncitizen who has engaged, is engaged, or at any time after admission into the United States engages in any terrorist activity as defined in the Immigration and Naturalization Act (INA). For noncitizens who meet the terrorist definition, a removal court was appointed, consisting of five federal district court judges. Proceedings before the special removal court will only occur if the noncitizen's removal through the normal removal procedures would pose a risk to the national security of the United States.

The regular rules of evidence applicable to trials are not applied in these special terrorist removal proceedings. A judge reviewing the application for removal may consider information that is not contained in the application for removal. This includes classified material. The noncitizen is provided some "standard" protections, which include the rights to: (1) be given a reasonable notice of the nature of the charges against him or her and reasonable notice of the time and place of the hearing, (2) counsel, (3) introduce evidence on his or her behalf, and (4) examine the evidence and cross-examine witnesses.

The government must show that the individual is an "alien terrorist" as defined in the INA. If the government is able to prove the individual is an "alien terrorist," then the court will order that the individual be removed from the United States. Either party may appeal the final decision of the special removal court. If, after appeals are final, the individual is still found to be removable, he or she will be removed to another country. If no other country will accept the individual who was found by the court to be an alien terrorist, the United States may detain the individual in custody while making periodic attempts to find a country that will accept him or her.

AEDPA states that membership in, or representation of, a terrorist organization is a ground to deny a noncitizen admission to the United States. It also adds provisions to the INA that limit the Attorney General's discretion to suspend deportation, adjust status, or allow voluntary departure, among other things, for those deemed to be alien terrorists. Additionally, the AEDPA states that asylum cannot be granted to any alien terrorist unless the Attorney General determines there is no basis to consider that individual a threat to the United States' national security.

AEDPA provisions affect the treatment of criminal noncitizens. The AEDPA added several immigration offenses to be considered offenses for Racketeer Influenced and Corrupt Organization (RICO) convictions. Other provisions include long-distance relocation plans for any individual found to be a criminal alien who has already attempted illegal entry into the United States at least three times. AEDPA also provides for deportation of noncitizen criminals before their entire prison sentence is served. If such an individual were to later illegally enter the United States, that noncitizen individual would have to serve the remainder of the prison sentence at that time.

AEDPA also added crimes to the list of aggravated felonies for which a criminal noncitizen would be subject to expedited removal. These offenses include forgery of a passport or other documentation for entry into the United States and running a gambling business. It also modified the expedited procedures, including limits on any challenge to the removal order and limitations on discretionary review of a removal order.

AEDPA provisions affect the access to health care for immigrants who have been deemed alien terrorists.

If an immigrant is suspected of being an alien terrorist, he or she will be held in custody according to the rules of the AEDPA. While in custody, the individual does not have access to private or public health care. These individuals are subject to the health care provided by the penal system. While in custody, the immigrant is allowed to communicate with and receive visits from members of their family, and to contact, retain, and communicate with an attorney. The immigrant is also allowed to contact an appropriate diplomatic or consular official of the alien's country of citizenship or nationality or of any country providing representation services.

Under the AEDPA, there are special rules for individuals who hold permanent residence in the United States. An alien lawfully admitted for permanent residence is entitled to a release hearing before the judge assigned to hear the removal hearing. The individual will be detained pending the removal hearing, unless the individual demonstrates to the court that he or she is a person lawfully admitted for permanent residence in the United States; if released upon such terms and conditions as the court may prescribe (including the posting of any monetary amount), he or she is not likely to flee; and he or she will not endanger national security, or the safety of any person or the community, if released.

Critics of the 1996 Antiterrorism and Effective Death Penalty Act point out that definitions of what constitutes crimes of “moral turpitude” or “aggravated felony” are intentionally vague and frequently changed to increase the number of deportable individuals. As a result, noncitizens are subject to laws that apply no matter how long ago their crime was committed, regardless of the amount of time they may have already served, without recourse to judicial review or appeal and without the chance to challenge their deportation based on ties to family or length of time in the United States, even if they arrived as infants.

Anxiety

Mark Agius
Department of Psychiatry, University of Cambridge,
South Essex Partnership University Foundation Trust,
Weller Wing Bedford Hospital, Bedford,
Bedfordshire, UK

Anxiety is both a psychological and a physiological state and includes cognitive, somatic, emotional, and behavioral components. These components, put together, produce an unpleasant feeling, which is usually associated with unease, apprehension, fear, or worry. Whereas fear leads to behaviors such as escape and avoidance, anxiety occurs as a consequence of threats that are perceived to be uncontrollable or unavoidable.

Anxiety is a normal reaction to stress. It acts to help a person deal with a difficult situation by prompting and enabling the person to cope with it. While anxiety can be adaptive, when it becomes excessive, it may manifest as an anxiety disorder, and such disorders may become important medical problems.

Anxiety acts to alert the person to the possible risks within the environment so that the person can manage them appropriately. Anxiety can cause a number of physical effects, which include heart palpitations, muscle weakness and tension, fatigue, nausea, chest pain, shortness of breath, stomach aches, or headaches. Physiologically, the body prepares to deal with a threat: blood pressure and heart rate are increased, sweating is increased, bloodflow to the major muscle groups is increased, and immune and digestive system functions are inhibited. This has been described as the *fight or flight* response. External signs of anxiety include pale skin, sweating, trembling, and pupillary dilation. A person with anxiety might also experience a sense of dread or panic. A person who experiences a panic attack, a particularly pernicious manifestation of anxiety may feel as if he or she is about to die or pass out.

Common sources of anxiety include seeking a better way of life and achieving a better financial status. For immigrants, living and working in an environment where they face competition from both the indigenous population as well as other immigrants can be a particularly potent source of anxiety. Some immigrants may find it unexpectedly difficult to find a job and may face resentment from the indigenous population, which can lead to discrimination.

Immigration is often associated with anxiety since it often exposes immigrants to entirely new environments, individuals with different cultural norms and customs, and different expectations about achieving success. The process of immigration can be anxiety provoking for many individuals. Immigrants, especially those entering the host country illegally, may have to travel long distances in inappropriate and risky forms of transport, with guides who in some cases put their lives at risk. Even when immigrants have legal status in a host country, uncertainty about the future and potential language barriers may induce anxiety. Research suggests that for some immigrants, obligations to support family at home or to repay debts that were made to underwrite their journey may be associated with anxiety. In some cases, immigrants may not have realized the demands that their host country places on themselves and their children to adapt to local norms, which in turn may pose a challenge to their own identity. Also, learning new methods of carrying out business in the host country may be challenging and may result in anxiety.

Issues about immigration status are another source of anxiety to immigrants. Those who have entered the host country may be particularly prone to anxiety; however, in many host countries, immigration is itself a source of political concern to the indigenous population, so that it is frequently discussed in the media by politicians in a way which can induce worry. Legal immigrants may face increased anxiety when visas need to be renewed; they may be required to leave the host country in order for visas to be processed.

Immigrants with anxiety may also experience feelings of apprehension or dread, difficulty in concentrating, feeling tense or jumpy, constantly anticipating the worst, feeling irritable, being restless, and being excessively vigilant for signs of danger. Cognitive effects of anxiety also include thoughts about suspected dangers, including fear of dying. Hence, chest pains (a physical symptom of anxiety) may come to be interpreted as being a "heart attack."

Because of the multiple stressors associated with immigration, anxiety is commonly experienced by immigrants. Clinicians who work with immigrants should consider routinely assessing and addressing anxiety.

Appetite Suppressants

Rami Abbass
University Hospitals Case Medical Center, Cleveland, OH, USA

Obesity has been a growing global health epidemic in recent years. The prevalence of obesity is 16% among immigrants in the United States (US) and 22% among US-born individuals. A 2004 study on obesity in US immigrants showed that living in the US for 15 years or more resulted in a body mass index (BMI) increase of 1.39 kg/m^2. Furthermore, immigrants were found to be less likely than US-born individuals to discuss diet and exercise with clinicians. Immigrants may be vulnerable to increased obesity – particularly when entering the US at an early age. Sons of immigrants have higher levels of childhood obesity than American boys. Some experts contend that a key factor in the development of this pattern of obesity is more readily available drinks and snacks in the US as compared to the immigrant's home country.

Medications and supplements used for weight loss have become more widely available in the past 2 decades. There has been a growing appeal among various ethnic groups to use these therapies. The use of medication for weight loss has been questioned due to concerns about safety and efficacy, with the subsequent withdrawal of several medications (Ephedrine and Fenfluramine) from the market by the US Food and Drug Administration (FDA). Immigrants may have different notions regarding these therapies. Studies have shown that negative perceptions of being overweight varied across ethnicities and races, such as among African-Americans, Whites, and Latinos. Therefore, the social stigma of obesity may vary with immigrants, resulting in a greater or lesser desire for weight loss medications and supplements.

Antiobesity medications can be used as an adjunct to diet and exercise for those with a body mass index (BMI) greater than 30 kg/m^2. After weight loss has not been achieved with at least six months of nonpharmacological treatment, antiobesity medications may be indicated, when used in conjunction with diet and exercise. It is suggested that drug therapy should be attempted by those considering gastrointestinal bypass surgery and by obese patients with sleep apnea. The goal of therapy with these medications is not to return to normal body weight; rather, therapy is considered successful when a more than 2 kg weight loss is achieved in the first month, and a weight loss of 5% below baseline by 3–6 months is achieved and maintained at that level.

Several medications have been approved by the US FDA for weight loss, including sibutramine, phentermine, diethylpropion, and orlistat. The first three are appetite-suppressing sympathomimetic drugs that influence the level of norepinephrine, serotonin, and/or dopamine by altering their reuptake into nerve terminals. These changes in neurochemicals result in early satiety or a feeling of fullness. Due to the potential for increased blood pressure, in those with high blood pressure, these drugs must be avoided altogether or used with extreme caution. Use of these medications results in more success when combined with appropriate lifestyle modifications, such as a calorie-restricted diet and exercise program.

These appetite suppressants are indicated for short-term use. Phentermine may be used for up to 12 weeks, while sibutramine has been used in trials for up to 2 years. Persons taking these medications should be aware that when therapeutic effect is achieved, weight loss stops, and when people discontinue therapy, weight is regained. Therefore, this is not a cure for obesity, as the medications do not have a significant long-term benefit on weight reduction. Common adverse effects with sibutramine and phentermine are dry mouth, headache, constipation, and insomnia; also patients may experience palpitations and tachycardia.

The atypical antidepressant bupropion has been shown to potentiate early satiety by modulating the action of norepinephrine and serotonin. Weight loss has been noted in depressed patients treated with bupropion for 6–12 months. Due to the small number of subjects studied, this drug is not currently FDA approved for the treatment of obesity.

There are multiple dietary supplements that are available over-the-counter that are marketed for weight loss. These include supplements purported to (1) increase energy expenditure, (2) modulate carbohydrate metabolism, (3) increase satiety, and (4) reduce production of fat. Due to uncertain product safety and/or uncertain efficacy, none of these supplements can be recommended at this time and should be discouraged or used with extreme caution. Glucomannan, psyllium, and guar gum have been marketed as appetite suppressants. It is theorized that, as soluble fibers, they may absorb water within the gut, thereby causing an increased sensation of fullness. While they are felt to be safe to use, in large randomized controlled trials, guar gum and psyllium have not been shown to have a weight loss benefit. Glucomannan has not been studied in large trials.

Pharmacological therapy for obesity has been found to be unsafe when multiple agents were compounded into one pill. Therefore, in 2006, the FDA banned the sale of compounded diet pills in the US. However, compounded diet pills appear to appeal to certain immigrant groups. For instance, in a Massachusetts clinic, of the women born in Brazil and now living in the US who were surveyed, 15% reported using compounded diet pills imported from Brazil. Of those who reported using the FDA-banned pills, 66% reported adverse effects, including palpitations, anxiety, and vomiting. In that particular study, factors identified increasing the odds of appetite suppressant use included being unmarried, college educated, and dissatisfied with one's weight. The pills frequently included three to six prescription medications, including amphetamines, benzodiazepines, antidepressants, diuretics, and laxatives.

Immigrants' perceptions may vary widely regarding obesity and their need to achieve weight loss with medications or supplements. Prescription appetite suppressants should be used with caution and only after counseling with a physician, especially for patients with hypertension. They are indicated for short-term use only, and after lifestyle modifications with exercise and diet adjustments have failed to achieve weight loss. Over-the-counter appetite suppressants have not been shown to have a weight loss benefit in trials.

Arab-Americans

Sherif Soliman[1], Natalie Wallace[2]
[1]Department of Psychiatry, Case Western Reserve University School of Medicine, Cleveland, OH, USA
[2]Department of Psychiatry, Wayne State University, University Psychiatric Center, Detroit, MI, USA

Arab-Americans are immigrants to the USA from Arabic-speaking countries. Arabic-speaking countries are primarily located in North Africa and West Asia. The following countries comprise the Arab world: Africa – Algeria, Djibouti, Egypt, Eritrea, Libya, Mauritania, Morocco, Somalia, Sudan, and Tunisia; Asia – Bahrain, Iraq, Jordan, Kuwait, Lebanon, Oman, Qatar, Saudi Arabia, Syria, United Arab Emirates, Yemen, and the Palestinian territories.

The majority of Arab-Americans nationwide live on the West Coast, in the Midwest, and on the East Coast, respectively. The 2000 US Census reveals that 48% of Arabs live in the following states: California, Michigan, New York, Florida, and New Jersey. California has the largest number of Arabs with an estimated 750,000 inhabitants. Southeastern Michigan has the highest ethnic density of Arabs in the country, numbering greater than 490,000. There are significant demographic differences between Arab-Americans living in different parts of the country. For example, Arab-Americans living in California tend to have higher educational levels than Arab-Americans in other parts of the country. Arab-Americans in the Midwest generally have lower socioeconomic status than those in other regions of the US. Arab-Americans in the Midwest and on the East Coast have poorer access to health care than Arab-Americans nationwide.

Arab-Americans predominantly practice Christianity or Islam. Thirty-nine percent of Arab-Americans are Roman Catholic, 34% are Muslim, and 18% are Eastern Orthodox Christian. Religion is highly relevant for Arab-Americans and is a potential risk factor for traumatic exposure. For example, Christians in the Middle East have faced increasing religious discrimination. Churches have been targets of religiously based violence such as bombings and shootings. In addition, Muslims have faced increased discrimination following the September 11, 2001, terrorist attacks, and some have felt marginalized in subsequent years.

A Brief History of Arab Immigration to the USA

Arab immigration to the USA can roughly be divided into three waves: 1870s to World War I, 1948 through the mid-1960s, and 1967 through the present. The first wave was from the 1870s until World War I (1914–1918). This first group of immigrants primarily came from Syria, Lebanon, Jordan, and part of Palestine. They were predominantly Christian (70–90%) and came to the USA for better economic opportunities. They were highly assimilated into American culture and settled primarily in the Northeast. Following World War I, the Immigration Act of 1924 significantly curtailed the flow of immigrants, including Arabs, into the USA. Immigration was capped at an annual quota of 2% of the population. Further, 1920s immigration laws and regulations favored immigrants from Britain, Ireland, and Northern Europe over those from Eastern Europe, Southern Europe, and other parts of the world.

The second wave of Arab immigrants to the USA was from 1948 until the mid-1960s. These immigrants mostly came from Israel and the Palestinian territories. This group was comprised of relatively more Muslims who came seeking refuge from conflicts in the Middle East. The Immigration Act of 1965 substantially changed US immigration law by abolishing quotas based upon national origin, establishing rules that favored family reunification, and reducing barriers faced by non-European immigrants.

Against the backdrop of a more open US immigration policy and increasing upheaval in the Middle East, the third wave of Arab immigrants began in 1967, following the 1967 Arab–Israeli War, and has continued to the present. This group comes from various countries, is predominantly Muslim, and has primarily come to escape economic, social, and political turmoil in their countries of origin. The second and third waves of immigrants have been assimilated less completely than the first wave.

Arab-American Acculturation

Acculturation is defined by Merriam-Webster in relevant part as “cultural modification of an individual, group, or people by adapting to or borrowing traits from another culture" or "a merging of cultures as a result of prolonged contact." The process of acculturation can be categorized into three types: assimilation, integration, and marginalization. Assimilation occurs when the immigrant becomes subsumed by the new culture to the exclusion of the native culture. Integration occurs when the immigrant accepts the new culture while retaining her native culture. Marginalization occurs when the immigrant feels as though he does not belong to either culture. Acculturation problems are potentially linked to poorer mental health and are sometimes the focus of treatment. In fact, the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (*DSM IV-TR*) recognizes "Acculturation Problem" as a potential focus of treatment.

Acculturation heavily depends on how integrated an individual is into his or her host country. Factors associated with successful acculturation in Arab immigrants include earlier age at immigration, a lack of recent travel to homeland, Christian religion, being US-born, fluency in English, and overall length of time spent in the USA (greater than 10 years).

Jack Shaheen's book, *Reel Bad Arabs: How Hollywood Vilifies a People*, focused on the portrayal of Arabs in films. Shaheen suggests that the nation has been inundated with images of Arabs as being perpetrators of terror and other negative connotations, while positive imagery of Arabs is lacking. In addition, the September 11, 2001, terrorist attacks and subsequent terrorism has led to increased negative stigma of Arab-Americans, many of whom came to the USA to escape terrorism or other forms of violence in their countries of origin. Experiencing discrimination has been linked to poor health outcomes and poor birth outcomes. Further studies are needed to examine more thoroughly the relationship between acculturation and health outcomes for both physical and mental illnesses in Arab-Americans.

Arab-American Health Status

In 2000 and 2001, the National Health Interview Surveys (NHIS), conducted by the US Census Bureau, was administered to Americans of European origin and Arab-Americans. Most of the previous studies suggested that immigrants of Arab descent were of poorer health than European Americans. However, these studies were limited by the fact that they were primarily conducted in southeast Michigan, where there is a preponderance of recent immigrants of lower socioeconomic status. The NHIS survey included 85,707 native-born non-Hispanic Whites, and 481 foreign-born Arab-Americans. Prior to the accumulation of the NHIS data, Arab immigrants were believed to have a higher incidence of hypertension, diabetes mellitus, and obesity than US-born non-Hispanic Whites. The study concluded that nationwide, Arab-Americans did not have poorer health outcomes than US-born non-Hispanic Whites. The following factors were associated with similar or improved health status in Arab-Americans compared with native-born non-Hispanic White Americans: noncitizenry, higher education, employment, annual income greater than $20,000, and the presence of health insurance. Conversely, US citizenship, lack of higher education (educational level less than high school), lack of employment, annual income less than $20,000, and lack of access to health care were associated with worse outcomes than the native-born non-Hispanic White cohort. The use of self-report without any objective corroborating evidence is a significant limitation of the NHIS survey. In a review article of 34 peer-reviewed studies of Arab-Americans' physical and mental health, El-Sayed and Galea highlight the presence of conflicting data, especially regarding the prevalence of diabetes and hypertension.

Mental Health

The mental health status of Arab-Americans is difficult to study because there are many barriers that prevent Arab-Americans from seeking mental health treatment. First, Arab-Americans, as a group, tend to hold negative views of mental illness. It is sometimes viewed as a moral flaw or divine punishment. For example, one of the authors (SS) treated an Arab-American patient who only came to treatment for severe depression after several months of prayer with his local religious leader. In fact, when he did not improve, the patient actually considered religious conversion before he considered mental health treatment. There are also culturally based beliefs about mental illness in the Arab-American community that transcend religious differences. One such belief is that mental illness is the result of the "evil eye." One variant of this belief is that the victim of mental illness was in effect cursed by a jealous person. Individuals who flaunt their success or wealth are often warned by family and friends about incurring the “evil eye,” which is believed to always lead to misfortune, such as a loss of health or property. Second, psychiatrists and other mental health providers often encourage patients to discuss their family background and ask about traumatic childhood experiences, usually during the initial diagnostic interview. Arab-American patients are often reluctant to discuss family information with outsiders, seeing the family, rather than the individual, as the most critical unit. Third, Arab-Americans may have a general unfamiliarity with Western approaches to psychiatry, which place an emphasis on the individual, rather than the family unit, as is the norm in Arab culture. Fourth, Arab-Americans often express emotional symptoms in physical terms. This may be due in part to the deeply ingrained negative attitudes about mental illness.

As with other patients, Arab-Americans who have been exposed to traumatic experiences in their countries of origin are at greater risk for posttraumatic stress disorder (PTSD). Intuitively, the prevalence is expected to vary significantly among Arab-Americans depending on the time and circumstances of immigration. There is a wide range of traumatic experiences that Arab-Americans may have been exposed to in their countries of origin, including war, atrocities committed by local governments, religious and sectarian violence, and terrorism. Some traumatic experiences may carry a greater risk of PTSD than others. For example, a study of 91 Palestinian children who had been exposed to home bombardment and demolition compared with a group who had been exposed to other traumas found higher levels of posttraumatic stress disorder among the children who had been exposed to home bombardment.

In a sample of 187 Arab-American mental health patients, Jamil and colleagues reported that the most common primary psychiatric diagnosis was depressive disorders, occurring in about half of the patients (49.9%). Anxiety disorders (other than PTSD) occurred in 12.5% of the patients, and schizophrenia was the primary diagnosis in 12.3%. PTSD was the primary diagnosis in 8.8% of the patients, but the rate among Iraqi refugees was nearly double that (16.7%). Of note, this study was conducted in 2002 and therefore measured rates of PTSD among Iraqi refuges following the 1991 rather than the 2003 Iraq war.

The data suggest that Arab-Americans, especially recent immigrants, may be at greater risk for PTSD due to the current social and political turmoil in the Middle East. Further, the prevalence of other mental illnesses may be underreported because of the many cultural barriers to seeking mental health treatment among Arab-Americans. More studies are needed to further define the prevalence of mental illness among Arab-Americans and the unique ways in which mental illness manifests itself.

Addiction

Substance abuse and dependence studies in Arab-Americans are currently in their infancy. A study examining a group of Muslim immigrant males in the Midwest who had been referred through the court for mandated substance abuse treatment is the first to describe an association between an increased level of acculturation and polysubstance abuse. Factors associated with polysubstance abuse compared with abuse of a single substance included fluency in English and greater time in the USA. Alcohol was the primary substance of abuse in 91% of the 156 men studied. Those who used more than one substance were likely to use alcohol as the main substance of abuse at 76.3%, then marijuana at 20.5%, followed by cocaine at 15.4%. Arab-Americans have a significantly higher prevalence of nicotine use, with one survey reporting 39% of Arab immigrants using tobacco while non-Hispanic Whites had a prevalence of 29%.

A Culturally Competent Approach to Arab-Americans

Translating descriptive data about Arab-Americans into practical suggestions for working with them is challenging due to the lack of controlled trials of different assessment and treatment strategies. However, clinical experience and the limited available evidence offer some guidance.

The assessment of Arab-American patients should take into account age, education level, time of immigration (if not born in the USA), country of origin, and reason for immigration. In addition, exposure to traumatic events in the country of origin or in the USA should be taken into account. Feelings of rejection by the host culture and by the culture of origin should be explored in detail as they have been correlated with increased risk for mental illness. Family and community support should also be assessed.

The treatment of Arab-American patients should also take into account cultural and religious factors. The importance of the family unit over the individual is a feature of Arab-American culture that transcends religious differences. Thus, it is not uncommon for Arab-Americans to wish to involve family members and even extended family members in the treatment. Individuation from the family should not, in general, be used to gauge psychological maturity as it sometimes is in western cultures. Arab families tend to remain close well into adulthood. It is not unusual for extended family members to live in the same home or nearby such as in the same apartment building and to be closely involved in daily life activities. The frequency and duration of treatment should be explicitly stated. Al-Krenawi and Graham have postulated that more directive treatment approaches are more effective in Arab-Americans. While all of the above factors are important to consider, the assessment and treatment must be tailored to the individual needs of the patient.

Conclusion

Arab-Americans are a diverse group of immigrants. They face a significant risk of having been exposed to traumatic experiences in their countries of origin and of discrimination in their host country. They face unique physical and mental health challenges and require culturally competent approaches to assessment and treatment.

Argentina

Amy N. Sharpton
Department of Veterans Affairs, Louis Stokes DVA
Medical Center Cleveland, Brecksville, OH, USA

Introduction

In the sixteenth century, Spanish explorers visited the region that is now Argentina; in 1580, they established a permanent colony in what is now Buenos Aires. In 1776, Spain created the Vice-Royalty of Río de la Plata, and Argentina became a flourishing port and an integral part of the Empire. In 1816, the United Provinces of the Rio Plata declared their independence from Spain. Bolivia, Paraguay, and Uruguay vacated the region, and the area that remained became Argentina. Argentina's population and culture were influenced greatly by European immigrants, particularly those from Italy and Spain. Combined, from 1860 to 1930, they provided the largest percentage of immigrants to the young country.

Geography

Argentina is the second largest country in Latin America, its 2,780,400 sq. km occupies most of the southern part of the South American continent. It is bounded by the Atlantic Ocean in the east and south; its neighbors are Brazil and Uruguay to the northeast and east, Bolivia and Paraguay to the north, and Chile to the west. The terrain is made up mostly of flatlands, although it features some mountain ranges and tablelands situated at a high altitude, the most famous being the Andes with its highest peak Aconcagua. By total area, Argentina is the eighth largest country in the world; it is slightly less than three-tenths the size of the United States.

Climate

Although Argentina's climate is temperate generally, there are great variations, including extreme heat in the northern Chaco region, a mild climate in the central pampas, to the subantarctic cold of the glacial regions of southern Patagonia. The wide variations of climate are owing to the country's range in altitude and to its large expanse of land. Recorded in the extreme north, the highest temperature on record in Argentina is 49°C (120°F). Conversely, recorded in the southern tip of Argentina, the lowest temperature on record is −16°C (3°F). Rainfall diminishes from east to west; at Buenos Aires it averages 94 cm (37 in.) annually, and the average annual temperature is 16°C (61°F). January is the warmest month and June and July are the coldest. North of the Río Negro, the winter months (May–August) are the driest period of the year.

Politics

On July 9, 1816, under the leadership of José de San Martin, Argentina formally declared its independence from Spain. A protracted period followed of conflict between federalist and centralist forces, and the Constitution of the Argentine Republic was not written until 1853. Conservative forces dominated until 1916, when – in Argentina's first free popular election – Hipolito Yrigoyen, the candidate of the Radical Civic Union, was elected president. In 1930, Yrigoyen was overthrown by a military coup, a catalyst for the subsequent pattern in Argentine political history of alternating civilian and military governments. After a failed bid to seize the Falkland (Malvinas) Islands by force, democracy returned in 1983 and has persisted despite numerous challenges.

Education

All children in Argentina who are between the ages of 6 and 14 are required by law to attend school. High school education is affordable and available generally, although attendance falls by roughly 50% among those older than 14. There are state and private schools, and primary and secondary schools; those in the city areas are better equipped usually than those in the country. School curriculum is similar to that in Australia and includes science, mathematics, languages, art, history, sports, and geography. Among Latin American countries Argentina has the highest levels of education and literacy. The country's public university system is free of charge also. The university system is comprised of nearly 70 institutions, divided equally between national institutions, public institutions, and private institutions.

Health

National health policy in Argentina is determined by the Department of Public Health, an agency of the Ministry of Social Welfare. In 1998, Argentina had an estimated 108,800 physicians, 28,900 dentists, 15,300 pharmacists, 29,000 nurses, and 11,100 medical technicians. There were an estimated 2.7 doctors per 1,000 people as of 1999. In 2000, 79% of the population had access to safe drinking water and 85% had adequate sanitation. Health and medical services for workers are provided by clinics of unions, and employers are usually required to provide free medical and pharmaceutical care for injured workers. The private sector plays a role in providing health services, ensuring social security through organizations called Obras Sociales. Funding for health services comes from employee payroll taxes and contributions.

According to the World Health Organization, there are currently 39, 134,000 people in Argentina. The life expectancy at birth today is 72 for males and 78 for females. Per 1,000 live births, the probability of dying under age 5 is 17, while the probability of dying between 15 and 60 years is 162 for males and 86 for females. The total expenditure on health as a percentage of GDP is 10.1.

Of the major infectious diseases, smallpox, malaria, and diphtheria have been nearly eliminated, and poliomyelitis has been reduced significantly. The incidence of tuberculosis in 1999 was 55 per 100,000 people, down 47% from 20 years earlier. The HIV rate was 0.69 per 100 adults in 1999, when a total of 130,000 people were infected. Argentina reported the second-highest incidence of AIDS cases (41 per million) in South America during the mid-1990s.

Immigration

For much of its history, Argentina was a country of immigration, welcoming millions of immigrants, many from Spain and Italy. Recent economic, political, and social instability, however, have seen Argentina in a state of immigration, emigration, and transit. Since the 1990s, dismal employment prospects combined with intense foreign-labor demand has given rise to increased emigration to countries such as the United States, Spain, Italy, and Israel. In a 5-year period during the early 2000s, an estimated 300,000 persons emigrated from Argentina. Despite those recent trends, however, Argentina's strong demand for predominantly unskilled, low-wage labor ensures its role as a regional immigration hub.

Arthritis

Elizabeth M. Valencia
Radiology Department, St. Joseph's Hospital & Medical Center, Phoenix, AZ, USA

According to the Centers for Disease Control & Prevention, an estimated 50 million people (1 in 5) in the USA have been diagnosed with arthritis by a physician. By 2020 the prevalence will increase to 60 million. In the USA, arthritis is the most common cause of disability and limits the activity of approximately 21 million people. Increased public awareness about arthritis may help improve early diagnosis and management.

Arthritis is joint inflammation associated with pain and stiffness in one or more joints. Mild forms of arthritis may be self-limited and require only reassurance and symptomatic treatment. Progressive forms of arthritis need further evaluation to obtain appropriate diagnosis, long-term management, and symptomatic treatment to reduce disability and morbidity. Aggressive forms such as infectious arthritis (septic arthritis) require urgent attention to avoid permanent joint destruction and disability. Arthritis is classified based on the number of joints, such as monoarticular, if one joint is involved and polyarticular if more than two joints are involved. Further classification is based on the pathologic process, such as inflammatory, non-inflammatory, crystal-induced, and infectious. A few examples of these classification types will be discussed: osteoarthritis, rheumatoid arthritis, gout, and septic arthritis.

Osteoarthritis is non-inflammatory and the most common arthritis. Key features of osteoarthritis include joint stiffness lasting less than 15 min that improves with rest and worsens with activity or weight bearing, minimal joint effusion, and lack of systemic manifestations. Risk factors for osteoarthritis include age greater than 40, repetitive joint use, joint trauma, and obesity. There are two forms of osteoarthritis: primary and secondary. The primary form is idiopathic and more common than the secondary form, which is due to an underlying cause. In primary osteoarthritis weight bearing joints are affected, such as knees, hips, and spine and other joints include hands and shoulders. Some causes of secondary osteoarthritis are joint overuse, neurologic disorders, metabolic disease, and trauma.

Excessive joint loading or abnormal cartilage/bones results in the cartilage loss and bone remodeling seen in osteoarthritis. In addition, osteophytes (bone spurs) and bone overgrowth around the joint can restrict joint movement. Management of osteoarthritis can include medication, physical activity, joint protection, physical or occupational therapy, rest, and weight loss. Medications can include acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), glucosamine and chondroitin sulfate. Surgical joint replacement is reserved for severe cases.

Rheumatoid arthritis (RA) is a chronic inflammatory arthritis which results in proliferation of the synovium, thickening of the joint capsule, and subsequent bone and cartilage destruction. Small joints frequently affected are the hands, elbows, knees, and ankles. In some cases involvement of the atlantoaxial joint (spinal bone at the base of the skull) leads to subluxation (dislocation) with spinal cord compression. Typical symptoms include joint swelling, tenderness, and limited range of motion. Generalized weakness, fatigue, and anorexia are common systemic symptoms in early rheumatoid arthritis. Other organ involvement can occur due to the systemic nature of rheumatoid arthritis.

The American College of Rheumatology established guidelines, which require at least four out of seven criteria for the diagnosis of rheumatoid arthritis. The seven criteria include: (1) morning joint stiffness which lasts at least for 1 h, (2) at least three or more joint areas affected by arthritis, (3) arthritis in the hand joints, (4) involvement of joints in a symmetric distribution, (5) firm nontender subcutaneous nodules (rheumatoid nodules), (6) positive serum rheumatoid factor, and (7) bony erosions in hands and wrists on x-rays.

First line medications aim to control pain and minimize inflammation with NSAIDs. Glucocorticoids are second line medications which aim to suppress inflammation and disease progression. Third line medications are disease modifying anti-rheumatic drugs (DMARDs), fourth line medications are cytokine-neutralizing agents, fifth line medications are immunosuppressive/cytotoxic agents, which are used to mitigate disease progression.

Gout is a crystal-induced arthritis (metabolic disease) which results in abnormal amounts of urate in the serum and affects mostly middle-aged men (over age 30), elderly men, and postmenopausal women. Acute gouty arthritis is typically monoarticular; however, in long-standing disease it presents as asymmetric polyarticular arthritis. Classically, acute gout presents with sudden pain at night localized in the great toe (podagra). Other involved joints and tophi (urate crystal soft tissue deposits) locations include the hands, elbow, knees, and ankles. The two forms of gout are primary and secondary. Primary gout is rare, caused by a genetic defect and secondary gout is the result of an underlying cause such as high ethanol intake. Rapid changes in urate serum levels, ethanol, high purine diet, or serious medical illness are common triggers for acute gout attacks.

Identification of urate crystals in synovial joint fluid or tophi is diagnostic for gout. Infection and gout can co-exist, thus, the synovial fluid should be analyzed accordingly. Medical treatment for acute attacks includes anti-inflammatory agents such as colchicine or NSAIDs; traditionally indomethacin is effective in 90% of patients. Oral glucocorticoids can be used if NSAIDs are contraindicated and as an alternative if NSAIDs are ineffective. Prophylactic management includes a low-purine diet, limited ethanol, and weight loss. If these measures fail to lower urate levels, then hypouricemic medications are used. Urate overproducers are treated with allopurinol and underexcreters are treated with probenecid.

Infectious arthritis (septic arthritis) is an aggressive acute arthritis which warrants urgent evaluation to prevent joint destruction, instability, deformity, and degenerative arthritis. The port of entry for infection is generally hematogenous (via the blood stream), direct extension from an adjacent infection, or inoculation from a penetrating procedure or injury. Within 48 h cartilaginous destruction can develop. Etiologies of infectious arthritis include mycobacteria, fungi, viruses, and bacteria such as *Staphylococcus aureus* and *Neisseria gonorrhoeae*. Generally, 90% of acute cases are monoarticular. Mycobacteria or fungi are associated with subacute or chronic monoarticular infections. Syphilis, reactive arthritis, and Lyme disease are associated with periodic inflammation, while *Pasteurella multocida* is associated with an animal bite or scratch. Key features of acute bacterial arthritis are sudden onset of monoarticular joint pain in a large weight bearing joint, elbow or wrist, accompanied with a joint effusion, severe pain, redness, limited range of motion, and fever. Definitive diagnosis is based on identification of a pathogen on the smear and/or culture. In order to prevent joint destruction, immediate synovial fluid studies, joint drainage, and systemic antibiotics are critical.

In summary, osteoarthritis, rheumatoid arthritis, gout, and septic arthritis are only a few of the many types of arthritis. There are limited data on arthritis particular to immigrant groups. However, the challenges that immigrant groups face with respect to health care access and the greater likelihood of undiagnosed infections in these populations both suggest that arthritis may well be a concern in these groups. Public awareness regarding arthritis may help reduce disability, and in the context of immigrants, physician sensitivity to the potential for arthritis is warranted. Several public health initiatives on education, prevention, and management are outlined in the 1999 *National Arthritis Action Plan: A Public Health Strategy*. Many federal and state agencies, organizations, and communities have partnered to continue to implement these national arthritis-related objectives.

Asia

AMY N. SHARPTON
Department of Veterans Affairs, Louis Stokes DVA Medical Center Cleveland, Brecksville, OH, USA

History

Usage of the term “Asia” became common in ancient Greece. In antiquity the continent was presumed not to extend past India. Asia’s coastal margin was home to some of the world’s earliest known civilizations, including those that developed in Mesopotamia, the Indus Valley, and the Huanghe. These civilizations may have exchanged discoveries such as mathematics and the wheel, while other creations appear to have been developed individually in each area. Cities, states, and empires developed in these lowlands.

Geography

Because the borders of the landmass are ambiguous, typically Asia is defined from the standpoint of both a cultural concept and a physical entity. Asia is a subregion of the super-continent Eurasia, which contains portions of Europe and Asia. The continent is comprised of eight regions: Central Asia, the Iranian Plateau, East Asia, the Far East, North Asia, South Asia, Southeast Asia, and West Asia.

It is characterized as the largest continent, containing approximately 30% of the world's landmass. It includes nearly 50 countries, assorted islands, and/or dependencies – although there is some disagreement over its boundaries. Mountains and plateaus comprise much of the continent, with the highest mountains located in Central Asia and north of the Indian subcontinent. Asia's significant features include the world's tallest mountain, Mt Everest, rising to 8,850 m, and the world's lowest point, found in the Dead Sea, at 392 m below sea level. The continent is bounded by three oceans: the Arctic, Pacific, and Indian. The western boundary is formed by a combination of Europe; the eastern Ural Mountains; the Caspian, Black, Aegean, Mediterranean, and Red Seas; and the Suez Canal. Asia is formed also by the islands of Sri Lanka, Taiwan, Indonesia's archipelagoes (excluding New Guinea), the Philippines, and Japan. The continent covers 44,614,000 sq. km and has a population estimated at 3,879,659,000.

Asia includes the most populated countries in the world, China and India. As of mid-2008, China had a population of over 1.3 billion people. As the country represents a full 20% of the world's population, approximately one out of every five persons on the planet is a resident of China. India, the world's second most populated country, has approximately 1.18 billion residents. Asia has approximately four billion people, hosting roughly 60% of the world's current population, and during the twentieth century the population nearly quadrupled.

Culture and Economy

While Asia is culturally diverse, there are five main cultural influences: Chinese, Indian, Islamic, European, and Central Asian. China has had the greatest influence in East Asia, from which originated Confucianism, artistic styles, and the Chinese writing system. Indian influence has manifested in Hinduism and Buddhism, impacting the Tibet Autonomous Region of China, Indonesia, Cambodia, and Central Asia.

Asia has five principle language groups including Sino-Tibetan, Indo-Aryan, Austronesian, Austro-Asiatic, and Semitic, while key singular languages include Japanese and Korean. East Asia contains three main ethnic groups: Chinese, Japanese, and Korean. The Indian subcontinent is extremely diverse; the majority of the people speak languages from the Indo-Aryan subgroup of the Indo-European family. Owing to the influence of China and the former Soviet Union, the Mandarin Chinese dialect and the Russian language are used widely.

The world's major religions have origins found in Asia. Hinduism originated in southern Asia; Buddhism and Jainism emerged in the fifth and sixth centuries BC. Judaism, Christianity, and Islam are traced to Southwest Asia. Daoism and Confucianism, originating also in the fifth or sixth century BC, have profoundly influenced Chinese culture and the cultures of surrounding peoples.

Asia is home to four major financial centers including Tokyo, Hong Kong, Singapore, and Shanghai. Due to the availability of a large pool of skilled English-speaking workers, call centers and business process outsourcings (BPOs) are becoming major employers in India and the Philippines. Due to extremely competitive information technology industry, India has become a major hub for outsourcing.

As in most regions of the world, there are great disparities in wealth. This is true especially of Asia due to its tremendous size and range of cultures, environments, historical ties, and political systems. The largest economies in Asia, in terms of gross domestic product, are China, Japan, India, South Korea, Indonesia, and Iran. If examining wealth as measured by gross domestic product per capita, it is mostly concentrated in East Asian territories such as Hong Kong, Japan, South Korea, Singapore, and Taiwan, and in the oil-rich Middle Eastern countries of Iran, Saudi Arabia, Qatar, and United Arab Emirates. China and India are the two most rapidly growing economies in the world, and much of Asia is currently experiencing rapid growth and industrialization. For economic growth, East Asian and Southeast Asian countries rely generally on manufacturing and trade, while countries in the Middle East depend more on the production of commodities, chiefly oil. With rapid economic growth and a large trade surplus with the rest of the world, Asia has accumulated more than half the world's total of foreign exchange reserves.

Politics

Asia's political landscape is continually evolving and diverse, including multi-party democracies and some of the world's most repressive regimes. Asia has three important recognized political divisions: The Middle East, Southeast Asia, and North Asia. While historical mistrust has the potential to explode rivalries into conflict, the creation of cooperative endeavors offers new opportunities for peace.

Health

Health measures for Asia vary dramatically. The World Health Organization uses the Human Development Index (HDI) as a composite statistic to rank countries by level of human development. The statistic is composed from data on life expectancy, access to knowledge (mean years of school and expected years of schooling), and standard of living (per-capita Gross National Income). East Asia has the strongest overall HDI performance of any region in the world; it has nearly doubled in average HDI attainment over the past 40 years. China is the second highest achiever in the world in terms of HDI improvement since 1970; its per capita income increased a stunning 21-fold over the last 4 decades. However, China was not among the top performance in improving school enrollment and life expectancy.

Mainly due to health and education achievements, Nepal, a South Asian country, is one of the world's fastest movers since 1970. The present life expectancy is 25 years longer than the 1970s, and more than four of every five school-age children now attend primary school – compared to just one in five 40 years ago. Out of the 169 countries assessed, Japan and South Korea currently rank highest, number 11 and 12 in the world, followed by Hong Kong, China, and Singapore. Afghanistan ranked lowest among Asian countries

Asian Americans

Henry H. Kim
Department of Sociology, Wheaton College, Wheaton, IL, USA

The conceptualization of the term "Asian American" is a fairly recent development due in part to the 1965 Immigration Reform Act. As a social construct, this term attempts to categorize people from East and Southeast Asia. Accordingly, six groups (Indian, Chinese, Filipino, Japanese, Korean, and Vietnamese) in the USA make up about 90% of all Asian Americans. The attempt to create a collectivity based on assumed commonalities often masks the actual differences in languages, cultures, histories, etc., and thus the immigrants' modes of incorporation and associated outcomes. For example, although about one out of three Asian Americans was native-born, Japanese Americans have the highest proportions of native-born persons

(58%) while Koreans have the lowest (24%) among the Asian subgroups. A general trend among the Asian American literature is the paucity of data that look at individual Asian American groups and what each group looks like over time.

The top three leading causes of death for Asian Americans in 2006 were cancer (malignant neoplasms), heart diseases, and brain complications (cerebrovascular diseases). Asian Americans tend to be disproportionately affected by cancers of the liver, breast, cervix, and stomach with respect to other racial groups (Whites, Blacks, and Latinos). Liver and stomach cancer rates among Asian Americans were the highest among all races for both men and women and cancer was the leading cause of death among Asian American women in the USA. In general, there was a positive association for Asian males and females regarding age and deaths per 100,000. Further, the frequency of deaths per 100,000 due to HIV were rather small for males (1–2) and females (the rates were so small that some accounts were deemed "unreliable"). In contrast, for Black Americans, the rates fluctuated from 12.2 to 61.4 depending upon the age group and sex. Though it may appear useful to speak of Asian American health outcomes, it is important to couch this discussion within their modes of incorporation in America.

Assimilation and Health

The traditional model of assimilation has been used with respect to European (White) immigrants. Due to the National Origins Quota Act (1921 and revised in 1924), non-White immigration was essentially stalled until 1965. Thus, White modes of incorporation are depicted by terms such as "assimilation," "straight-line assimilation," "pressure-cooking assimilation," "melting pot," and "triple-melting pot." For the greater part of the twentieth century, it was assumed that as White immigrants broke away from their country of origin and amalgamated into "White Americans" that they would progressively (inter- and intragenerationally) achieve higher levels of socioeconomic status (SES). In fact, classical assimilation models posited that as individual differences replaced group differences, one's life chances (thus health) would improve.

However, non-White modes of incorporation do not fit the traditional European models. Color precludes structural assimilation. Thus, terms such as "selective acculturation," "segmented assimilation," "ethnic enclaves," and "negative acculturation" are used to depict the Asian American modes of incorporation. Acculturation is a conceptualization of how acclimated one becomes in "American" culture. In some contexts, ethnicity and culture serve as a form of capital that is beneficial to health outcomes and post-immigration adjustments. At other times, retaining ethnicity and culture can become a hindrance to positive health outcomes. Further, the "push" and "pull" factors on post-1965 Asian immigrants can be very (self-) selective. Thus, different Asian American waves have unique contexts of departure and entry which in turn impact their health.

One measure of acculturation for Asian Americans is English proficiency. Japanese Americans are the most likely to have the highest median age and to speak only English at home. Indians and Vietnamese have the highest proportions of children under the age of 18 who speak another language than English at home. Over three out of five Asian Americans who are 5 years old or older, use only English at home or speak English very well. Although 77% of Asian Americans use another language than English at home, the range spanned from 47% (Japanese Americans) to 88% (Vietnamese). Around 35% of Asian Americans are deemed to have "limited English proficiency" (LEP). Some studies found that LEP is associated with psychiatric disorders for men but not for women. Language and cultural compatibility between the patient and caregiver have also been attributed to low rates of health utilization among Asian Americans. This may lead to the seeking of health services when the health condition becomes very severe. Asian Americans also tend to receive less medical counseling from their physicians and report lower favorable interactions than their White counterparts.

Health Patterns Among Native- and Foreign-Born Asian Americans

About 70% of Asian Americans are US citizens (via birth or naturalization). Around half of foreign-born Asian Americans arrived since 1990 and one out of three arrived in the 1990s. Foreign-born Asian Americans tend to evince better health patterns than their native-born counterparts. These disparities are especially pronounced prior to emigration but the differences shrink after immigration via acculturation processes. Some studies have found that intergenerational conflicts are associated with greater rates of depression for the second generation. Foreign-born Asian (and Hispanic) Americans appear to have better psychological dispositions and less behavioral disorders than native-born Asian Americans. For example, native-born Asian (and Hispanic) adolescents are more than twice as likely to be obese than their foreign-born counterparts. In general, pre-immigrants tend to have lower levels of obesity than those who have been acculturated in America. Yet, these weight differentials tend to disappear after 15 years as increased time in the USA is associated with poorer health and greater odds of obesity. Some studies claim that about 40% of the Asian women who came to the USA at age 18 or later would eventually gain over 20 pounds. In a study from 1976 to 1980, 15% of Asian American adults were considered obese. This proportion increased to 35% in 2005–2006. Further, under the same time frames, children aged 6–11 and adolescents aged 12–19 also experienced substantial increased obesity rates, from 7% to 15% and 5% to 18%, respectively.

In general, there is a positive association among first- and second-generation Asian Americans regarding duration in the USA and poorer health (mental and physical). Ten years appears to be a benchmark regarding duration in the USA and the positive correlation between linguistic discrimination and mental health and depression; for those who have lived in the USA for 10 years or longer, the greater the propensity of poorer health. It is possible that those who have been in the USA for less than 10 years did not recognize when discriminatory acts were leveled against them. Although Asian American adults and youths tend to use mental health services at a lower rate than other racial groups, the native-born are more likely than the foreign-born to seek psychological help. Further research is required to determine whether this difference is due to cultural differences (a stigma factor) or actual mental health differences. Another level of complexity concerning acculturation and health outcomes is that acculturation does not work in the same direction for the first and second (and third) generations.

Various studies posit that Asian American elders are among the fastest growing elderly population. Three common barriers in accessing adequate health care among the elderly were the absence of health insurance, mobility, and language. This group also tends to have higher rates of depression than their non-Asian elder counterparts. Among the elderly (65 and over), Asian women had the highest rates of suicide in their age category among all racial groups. Whereas some studies showed that Asian American females between the ages of 14 and 24 also had the highest rates of suicide in their age category among all racial groups, other studies placed native Americans as the leading group, followed by Asian Americans. In contrast, Asian males (and Black females) had the lowest rates among all races in 2006 with their respective sex. Since these Asians have a bifurcated distribution regarding SES, further disaggregated data is needed to make more definitive conclusions.

For example, first-generation Korean Americans, when controlling for SES, have a negative correlation with acculturation and depressive symptoms. Thus, higher levels of acculturation are associated with lower levels of depressive symptoms. Smoking is another example that shows the generational complexity of acculturation and health outcomes. Asian American mothers were the least likely among all racial categories to have smoked (2.4% versus 12.2% of all mothers). Studies have found that cigarette smoking is linked with low (less than 2,500 g) and very low (less than 1,500 g) birthweight. Interestingly, when using 12 years of education as a baseline (less than, equal to, and greater than) for all racial groups except Asians, the greater the level of education the lower the rates for low birthweight. However, for Asians, greater levels of education increased the odds for low birthweight.

Lower acculturation among first-generation Asian Americans has also been found to be associated with higher levels of smoking. However, for the second generation (males and females), higher acculturation was associated with higher levels of smoking. Among Asian subgroups, it has been estimated that over 70% of the Laotian and Cambodian men are current smokers. Studies have also found that the greater the duration an Asian female has resided in the USA, the greater the number of cigarettes she would smoke per day. Nonetheless, in a study conducted from 2005 to 2007, Asian men (17.2%) and Asian women (4.8%) were found to have the lowest proportions of those who were current smokers among all racial groups, with their respective sexes. In 2007, Asian Americans were also the least likely to report having used tobacco products, alcohol, and any illegal drug among all racial groups.

Thus, although Asian immigrants tend to have better health prior to their entrance into the USA, their health behaviors and outcomes appear to mirror the general population of Americans over time. Asian immigrants tend to gain weight as their health habits drift toward the consumption of foods with higher fat and sugar while physical activity diminishes. Filipinos have the greatest proportions of overweight and obese persons among all Asians. In 2007, about 40% of Asian Americans self-reported that they were physically inactive and 30% claimed that they were engaged in semiregular or regular physical activities. Interestingly, although studies show poorer health from the first to the second generation, the third generation does not appear to have significant differences in health with respect to their American counterparts. These findings are consistent with regard to educational attainment as well. Whereas second-generation Asians evince bifurcation ("model minority" and "culture of poverty"), there are relatively fewer differences between the third generation and their White counterparts. This is important because education and health have been found to have a positive correlation.

However, it is not just the duration of time (post-immigration) that affects immigrant health. The particular life stage at the time of entry may also affect health outcomes. Some studies have found that Asian Americans who arrived in the USA between the ages of 18 and 40 were less likely than those who arrived before the age of 18 and those who arrived after the age of 40 to experience substance abuse and mental disorders, even when controlling for sex and length of residence. Regarding Asian males and the risk of adolescent substance abuse, the native-born evinced the highest odds, followed by the 1.25 (individuals who arrived between the ages of 13 and 17) and then the 1.5 (individuals who arrived between the ages of 6 and 12) generations.

Socioeconomic Status and Health

Further, using SES (particularly education) to measure health outcomes for Asian Americans can be problematic for two reasons. First, Asian Americans are mistakenly identified as a "model minority" that conflates structural factors with (positive) cultural values. Second, Asian Americans are bifurcated regarding life chances in general and in education in particular. Among those who were 25 or older, about one out of five Asian Americans had a graduate or professional degree, compared to 10% of the general population. It would appear that Asians are highly educated but this is one end of the spectrum. Using a bachelor's degree as an educational measure, Indian Americans represented the high end (68% had at least a bachelor's degree) and Vietnamese Americans represented the other end (26% had at least a bachelor's degree). Similar to evincing a "high" level of educational attainment, Asian Americans had the highest median household (not individual) income among all racial groups ($61,094 in 2005). Again, by disaggregating Asian Americans via subgroups, Indians showed one end ($73,575) while Vietnamese showed the other end ($50,925). Based on 2004 data, Indians (alone) had the highest and Koreans (alone) had the lowest.

In 2004, about 12% of all Asians lived below the poverty level. However, those under the age of 18 had a rate of 13.2% (below the poverty level) and those who were 65 and older had a rate of 12.8%. Further, there is significant variation among the subgroups who fall below the poverty level: all ages (Filipino 5.2% and Korean 14.9%), under 18 (Japanese 5.7% and Vietnamese 17.1%), and 65 and older (Japanese 5.9% and Korean 19.2%). In 2007, 12.5% of the US population fell below the poverty line. Further, regarding all Asians, under 18, 18–64, and 65 and over, the respective poverty rates were 10.2%, 12.5%, 9.2%, and 11.3%. Regarding all races, for the respective age groups, the poverty levels were 12.5%, 18%, 10.9%, and 9.7%. Thus, for all of the groups except for the last category (65 and over), Asians had lower proportions of poverty compared to all races. Again, one may falsely conclude that most Asians are doing better than average. Yet, some studies have shown that the Hmong have a 30% poverty rate. Disaggregated data, or looking at individual Asian groups as opposed to "Asian Americans," is important because it shows that Asians are not in fact a "model minority" but evince bifurcated patterns of income, poverty, and education, and thus health outcomes. Further, disaggregating Asian Americans is important because some researchers claim, when holding race constant, it is actually class that affects life chances and thus health outcomes. The perennial argument between race and class is, of course, not delimited to Asians in particular.

Health Insurance Coverage

Southeast (SE) Asians (represented by the Vietnamese, Laotians, Cambodians, Hmong, and Indochinese) differ in their contexts of departure from other Asian Americans who were directly impacted by the 1965 Immigration Reform Act in two ways. SE Asians arrived more recently and are more likely to be comprised of refugees and family-reunification persons. Non-SE Asians have a longer immigration history and their first waves were generally comprised of labor-recruits who became naturalized and then enacted family-reunification provisions. Thus, it is problematic to incorporate indiscriminately SE Asians within the "Asian American" rubric. Although the first waves of both groups tend to have higher SES than the latter waves, which parallel non-Asian immigration inflows, SE and non-SE Asians have different contexts of departure and arrival. Further, SE Asians tend to have lower SES which is then associated with poorer health. Some of the poorer health traits associated with SE Asians can be attributed to their contexts of departure (physical and mental traumas) as well as their low SES in the USA. Later waves of SE refugees tend to have significantly lower SES and English-language proficiency when compared to other Asian Americans. Some studies have found that SE Asian refugees experience a delayed effect with respect to mental health, usually 6–24 months after their arrival into the USA. Among the SE Asian refugees, Cambodians and Hmong evince the highest proportions of mental health problems.

In 2006, the rates of uninsured for Asians, non-Hispanic Whites, Blacks, and Hispanics were, respectively, 15.5%, 10.8%, 20.5%, and 34%. Uninsured rates varied among Asian subgroups as the Japanese had the lowest (9%) and Koreans had the highest (35.5%). Among children (under the age of 18 and ages 6–17), Asian Americans accounted for the greatest proportions of uninsured among all racial categories. That is, these children were the most likely to be uninsured based on race. Asian adults had the highest rates of lack of health coverage (24.8%) in 1993–1994, yet in 2006–2007 the uninsured rates dropped whereby they had the lowest percentage (17.3%) of uninsured adults among all racial groups.

Regarding visits to a health care provider in the past year, Asians had the highest or tied for the highest of no visits in the past year for children under 18 (14.5%), under 6 (6.9%), and ages 6–17 (18.8%) among all racial groups. However, when asked about avoiding medical care, Asians reported the lowest proportions regarding costs. That is, it does not appear that cost precluded medical attention for these youths. Concerning health care coverage via employment in 2007, Asians under the age of 65 had a rate of 64.4% which was above all races combined (61.6%) and for all other racial groups except non-Hispanic Whites (70.2%). Conversely, 15.4% of all Asian Americans reported that they had no health insurance, which although lower than all races combined (16.6%) was greater than non-Hispanic Whites (12.6%).

In conclusion, there are pros and cons in using the term "Asian American" in general, and with respect to health in particular. The term is one of nominal convenience (particularly for non-Asians) based on appearance. It is also a term used by data collectors, researchers, academics, and policy makers. Unfortunately, Asian Americans are often mistaken to be a "model minority." Not only does this belie historical and structural factors, it also reifies a culture of poverty thesis for other minorities to fall short. A further unintended consequence of this ideology is that it hides Asian subgroups who have poor health status. The reality is that because the first waves tended to be overrepresented via high SES and better health, Asian American health patterns evince bifurcation. Health trends are evinced via different Asian subgroups and also among differing waves of departure and entrance to the USA. As many researchers have noted, future disaggregated (by subgroup, longitudinal, and generational) data are needed with respect to modes of incorporation to the USA and health outcomes. Of particular interest would be the use of religion in acculturation contexts, pushing the discussion of Asian American modes of incorporation beyond the intersection of race, class, and gender, and how this impacts health outcomes.

Demographics

Asian Indians or Indian Americans are individuals of Indian ancestry. India is the seventh-largest country by geographical area, the second-most populous country with 1.18 billion people, and the most populous democracy in the world. The US Census Bureau popularized the term "Asian Indian" to avoid confusion with "American Indian." They are represented under the broader classification of Asian Americans (AA) or Asian American and Pacific Islanders (AAPI). Sometimes they are also referred to as South Asians that denotes people belonging to various countries from the Indian subcontinent (India, Pakistan, Sri Lanka, Bangladesh, and Nepal). Asian Indians are a subgroup of the Asian American population. Asian Americans are a heterogeneous group and comprise 5% (13.9 million) of the US population. According to the Census Bureau population estimate, Asian Americans are the fastest growing racial/ethnic group and expected to reach 22 million by 2050 (212% increase). However, Asian Americans are frequently aggregated as a homogenized group. This is problematic as it masks the vast diversity among the over 50 Asian American subgroups (example, Chinese, Filipinos, Asian Indians, Pakistanis, Vietnamese, Koreans, Laotians, Japanese, Cambodians, Hmong, Thais, etc.). Asian Americans, whether they are immigrants or US born, represent a diversified and rich mixture of cultures, languages, beliefs, and practices.

Asian Indians are the third largest Asian American subgroup in the United States, after Chinese Americans and Filipino Americans. They are also one of the fastest growing Asian subgroups. For example, between 1980 and 1990, the Asian Indian population in the United States grew by 126% as compared to the 108% growth of all Asian Americans combined. The growth rate of Asian Indians between 1990 and 2000 was 106% and, according to the American Community Survey of the

US Census Bureau, the Asian Indian population increased from 1,679,000 in 2000 to 2,570,000 in 2007 with a growth rate of 53%, the highest for any Asian American community and among the fastest growing Asian subgroup in the United States. According to the US Census Bureau, currently Asian Indians are 16.4% of Asian Americans living in the USA.

Most Asian Indian immigrants entered the United States in the last 30 years, following the passage of the Immigration Act of 1965 which allowed increasing numbers of Asian Indians to enter the United States. The majority (71%) are 18–64 years old, and 77% are immigrants. Despite their increasing numbers, current research on Asian American health does not adequately address the health needs of Asian Indians. The literature on health behaviors and chronic disease indicates an increase in behavioral risk factors (e.g., consumption of high fat diet and more animal products, sedentary lifestyle) as well as biological risk factors (e.g., obesity, hypertension) for chronic diseases when individuals migrate to more prosperous countries. This is true among Japanese and Hispanic immigrants to the USA. A review of current health literature shows that while there has been a fair amount of research focused on some groups of immigrants such as the Japanese, Chinese, and Filipinos, others, particularly Asian Indians, have been less studied. Current national surveys are incapable of assessing preventive health behaviors and disease prevalence in specific Asian subpopulations because multiple ethnic groups are aggregated into the general category of "Asian and Pacific Islander," and because sample sizes of individual Asian subgroups are small.

Diversity

Unlike other Asian immigrants in the USA, Asian Indians are a more diverse and distinct subgroup than other Asian immigrants originating from a single nation due to their primary languages, provincialism, religious affiliations, and caste system. There are 14 official languages and Indians come from 28 different provinces or states. Additionally, there are at least four distinct racial types and five major religions representing this group. This diversity prevents Asian Indians to form clusters like the Chinese, Japanese, and Filipinos and contributes toward their lack of visibility socially, politically, and geographically in this country. Furthermore, Asian Indians, unlike many other Asian and South American immigrant groups, do not depend upon localized ethnic networks for financial and/or occupational support due to their high educational status and professional jobs. Although localized networks for different Asian Indian communities do exist, many immigrant Asian Indians do not use them very often. Consequently they are dispersed geographically. This geographic dispersion combined with the extreme internal diversities does not encourage them to form ethnic clusters in defined geographic areas as seen among Chinese immigrants.

First generation Asian Indians tend to retain the distinct languages, culture, and religious practices of their subgroups, which inhibits the development of ethnic solidarity as seen among Chinese, Japanese, or Filipino immigrants.

Religions

While the majority of Asian Indians emigrating to the USA are Hindus, there are significant numbers of Indian Sikhs, Muslims, Christians, and Jains that enter the country. As of 2000, the American Hindu population was around a million. The religious diversity is evident from numerous (diverse) Asian Indian cultural and religious associations and various communities of Hindus, Sikhs, Jains, Buddhists, Muslims, Christians, Parsis, and Jews from India that have established their religious organizations in the United States.

The first religious center of an Indian religion to be established in the USA was a Sikh Gurudwara in Stockton, California, in 1912. However, Asian Indians who follow the Hindu religion believe themselves to be quite different from Sikhs from the state of Punjab. Today there are many Sikh Gurudwaras and Hindu, Buddhist, and Jain Temples in all the 50 states. In addition, many sects such as ISKCON, Swaminarayan Sampraday, BAPS Swaminarayan Sanstha, Chinmaya Mission, and Swadhyay Pariwar are also well established in the USA. Yoga is also promoted and practiced by the religious leaders. More than 18 million Americans are now practicing some form of Yoga.

Indian Muslim Americans generally congregate with other South Asian and American Muslims, including those from Pakistan and Bangladesh. Immigrant Asian Indian Muslim organizations (such as the

Indian Muslim Council) exist in the USA. Christians, who comprise approximately 6% of the Indian population in India, are concentrated in states such as Kerala and Maharashtra (Goa). Immigrant Asian Indian Christians have several Indian Christian churches across the USA such as the Syro-Malabar Catholic Church, Syro-Malankara Catholic Church, Indian Orthodox Church, and Church of South India to name a few. There are also a number of Asian Indian Christians who use the mainstream American churches. The Indian Christian Americans have formed the *Federation of Indian American Christian Organizations of North America (FIACONA)* to represent a network of Indian Christian Organizations in the United States and Canada. The Parsi community and Indian Jews are perhaps the smallest Asian Indian minority communities in the USA.

Language

There are 14 official languages and Asian Indians from different states speak different languages. Hindi is the official national language in India. However, English is one of the official languages of India, and according to the census of India there are approximately 19 million Indian English speakers (as second or third language) due to the colonial rule of Britain in India. With the exception of some families who communicate primarily in English, as well as members of the relatively small Anglo-Indian community numbering less than half a million, speakers of Indian English use it as a second or third language, after their indigenous Indian language(s), such as Assamese, Oriya, Urdu, Gujarati, Punjabi, Hindi, Sindhi, Bengali, Kannada, Telugu, Marathi, Tamil, and Malayalam.

Socioeconomic Status

Education

Asian Indians also differ in their average educational level from other immigrant Asian groups. Asian Indians have the highest percentage of higher education when compared to other racial groups. According to the American Association of Physicians of Indian Origin, there are close to 35,000 Indian American doctors. AAPI is the largest ethnic minority physician in the United States. According to the 2000 census, about 64% of Indian Americans have attained a Bachelor's degree or more (compared to 28% nationally, and 44% average for all Asian American groups). As indicated by the Indian American Centre for Political Awareness, almost 40% of all Indians have a master's, doctorate, or other professional degree, which is five times the national average. Among Indian Americans, 72.3% participate in the US work force, of which 57.7% are employed in managerial and professional specialties.

Income

Asian Indians tend to be highly educated professionals, prosperous, and English speaking in the United States. Their mean income level is 25% above the national average, and the median income is $60,093, compared to $41,110 for non-Hispanic Whites. Hence, the economic power of Asian Indians in the USA is indisputable. Furthermore, 67% of foreign-born Asian Indians have a college education as compared to 21% of non-Hispanic Whites. Hence, Asian Indians are perceived as having good access to health care. However, there are marked variations in educational attainment, income, and wealth among Asian Indians. Recent immigrant cohorts comprise both highly educated professionals as well as individuals who lack education and job skills. The latter are mostly family members of earlier immigrants.

According to the 2000 US Census, Asian Indian men had "the highest year-round, full-time median earnings ($51,094)," while Asian Indian women had a medium income of $35,173. This phenomenon has been linked to the "brain drain" of the Indian intelligence from India. Recently, however, there has been a drop in immigration of Indians from India to the United States. This is generally attributed to the improving economy of India. With the immigrants from India since 1965, the percent of Asian Indians who are second or third generation is growing.

Although the majority of Asian Indians are professionals (doctors, computer scientists, academics, etc.), a significant number are business owners or involved with the hotel/motel industry. Indian Americans own 50% of all economy lodges and 35% of all hotels in the United States. In 2002, there were over 223,000 Asian Indian-owned firms in the USA, employing more than 610,000 workers, and generating more than $88 billion in revenue.

Culture

Food

Asian Indians have popularized the Indian cuisine in the United States, and there are hundreds of Indian restaurants and eateries nationwide. There are many Indian markets and ethnic grocery stores in the United States, especially in the cities with a large Asian Indian population. Some of the biggest Indian markets are in Silicon Valley, Chicago, New York City, the Philadelphia metropolitan area, and Edison, New Jersey. Areas with a significant Indian market presence also include Devon Avenue neighborhood/market in Chicago, Pioneer Blvd. in the Los Angeles region, and University Ave in Berkeley, California. Other predominantly Indian neighborhoods are Journal Square in Jersey City, New Jersey; Jackson Heights in Queens, New York; Hillcroft Avenue in Houston, Texas; and Richardson near Dallas, Texas.

Entertainment

Hindi (the national language of India) radio and television stations are available in areas with high Indian populations. Several cable and satellite providers offer Asian Indian channels such as the Sony TV, Zee TV, and Star Plus. Furthermore, many metropolitan areas with high Asian Indian populations now have movie theaters specialized for showing Indian movies produced at Bollywood (named after Hollywood). Bollywood is the informal term popularly used for the Hindi-language film industry based in Mumbai, Maharashtra, India. Bollywood cinemas and musicals are believed to influence musical films in the Western world and the USA since 2000. Bollywood film industry individuals such as A. R. Rahman, an Indian film composer, is popular since the music he wrote for Danny Boyle's *Slumdog Millionaire* (2008) has won four Golden Globes and eight Academy Awards. The influence of Bollywood music can also be seen in popular music elsewhere in the world.

Geographical Concentration

The US states with the largest Asian Indian populations, in order, are California, New York, New Jersey, Texas, and Illinois. There are also large Asian Indian populations in Pennsylvania, Florida, Michigan, Maryland, Virginia, Georgia, and Ohio. The New York metropolitan area, consisting of New York City and adjacent areas within the state of New York as well as nearby areas within the states of New Jersey, Connecticut, and Pennsylvania, is home to approximately 600,000 Asian Indians as of 2009, comprising by far the largest Asian Indian population of any metropolitan area in the United States. At least 17 Asian Indian enclaves characterized as a Little India have emerged in the New York metropolitan area.

Other metropolitan areas with large Asian Indian populations include San Francisco/San Jose/Oakland, Chicago, Los Angeles, Washington/Baltimore, Philadelphia, Boston, Detroit, Houston, Dallas/Ft. Worth, Charlotte, North Carolina, and Atlanta. The town of Edison, New Jersey (total population 100,499), is 17.5% Asian Indian – the highest percentage of any municipality in the United States. But the mostly agrarian Imperial Valley, California, near the Mexican border has a long history of Asian Indians (an estimated 21,000 live in Imperial County, California alone) since the first arrivals to the California desert in the early 1900s. The first American Sikh temples were in the Sacramento (Marysville and Yuba City) and San Joaquin Valleys (Lodi and Stockton) to serve the early wave of Sikh Indian workers arrived there. In contrast with East Asian Americans, who tend to be concentrated in California and other areas near the Pacific coast, Asian Indians are more evenly distributed throughout the United States.

High Risk for Chronic Diseases

The burden of diabetes and cardiovascular disease among Asian Indians living in the USA is well documented. For example, Foucan et al. found that Asian Indians with type-2 diabetes mellitus had a fivefold higher risk of cardiovascular disease than the general US population. Cardiovascular disease and diabetes among Asian Indians is among the highest in the world for both men and women. The relative risk of coronary artery disease (CAD) mortality is about 1.4 for American Asian Indians compared with the general US population. Enas and his colleagues reported Asian Indians have the highest rate of heart attacks of any ethnic group in the world. Similarly, the prevalence of diabetes is strikingly high in Asian Indian immigrants to the USA and is estimated to be two- to threefold higher than in the general US population. Diabetes may be a contributing factor in up to 20% of cardiovascular deaths in Asian Indians.

It is unclear why the CAD rate is so much higher in this population given that risk factors such as hypertension, smoking, and obesity are actually less prevalent than in the non-Hispanic White population. However, many Asian Indians have abdominal/visceral adiposity without BMI obesity. The prevalence of a high triglyceride (TG)/low High Density Lipoprotein (HDL) pattern in this population is high in India and in Britain, and this pattern is associated with excess cardiovascular risk. Lipoprotein (a) has been shown to be an independent risk factor for CAD, and this has also been reported to be especially prevalent in Asian Indians. Inactivity, commonly found in Asian Indians in the USA, and dietary patterns that are high in carbohydrates and low in fat exacerbate the high TG/low HDL pattern even further. Paradoxically, vegetarians appear to be an especially high-risk group because of the high carbohydrate dietary pattern, and some preliminary reports suggest an even higher CAD risk in vegetarians. Healthy diet and regular physical activity could help control these abnormalities. These factors warrant further research into disease prevalence and health behavior patterns of this high-risk ethnic Asian subgroup.

Conclusion

Asian Indians have distinctly different classes, social habits, cultural practices, diets, and lifestyles that characterize the Asian Indian diversity. They are generally well educated with the highest annual income among all Asian American immigrants. Hence, Asian Indians are perceived as having good access to health care. However, there are marked variations in educational attainment, income, and wealth among Asian Indians. Further, they have a genetic predisposition to chronic diseases such as diabetes and cardiovascular disease. Hence, primary and secondary prevention programs can help improve their health outcomes and quality of life. Although Asian Indians retain a high ethnic identity, they are known to assimilate into American culture while at the same time keeping the culture of their ancestors. They more easily assimilate than many other Asian immigrant groups due to the lack of language barrier (English is widely spoken in India), high educational level, and professional jobs. As a result of their assimilation, mixed European/White and Indian backgrounds are becoming more prevalent in the United States.

Asians

Bridgid M. Conn, Amy Kerivan Marks
Department of Psychology, Suffolk University,
Boston, MA, USA

In 2002, the U.S. Census Bureau documented that 25% of foreign-born people were from Asia. Of these foreign-born, 1.5 million were born in China, which is the leading country of birth for this nation's immigrants. Of note, also in the top ten countries of origin were India, the Philippines, Vietnam, and Korea. In fact, it is projected that by the year 2050, the population of people who identify as Asian will increase by 213%, making up 8% of the total population in America. Given the impact that this burgeoning immigrant group will have on this nation, including education and health services, it is imperative to understand how immigration and adjustment to living in a new society will affect their health and well-being.

In order to further our understanding of this immigrant group, it must be first considered that the labeling of all immigrants from the Asian continent as "Asians" is a socially constructed category that can have a unique bearing on how these unique immigrant groups see themselves. Many individuals that Americans might describe as "Asian" may in fact not identify themselves as such. There is great importance, therefore, in considering individuals' countries and subcultures of origin, regions within these countries, languages and dialects, and intraindividual identity differences when working with individuals from Asian countries. For example, within the USA, some "Asians" may actually consider themselves Black due to darker skin color and whether others treat them as Black rather than Asian. With this racial stereotyping, certain groups of Asian immigrants may experience discrimination and prejudice similar to other minority groups, such as Latinos and Blacks, while other groups of Asians may have the reverse experience being treated as "superior" to other minority racial groups but still inferior to Whites. For these Asians, they are subject to being treated as the "model minority," such that they experience expectations from the majority to outperform their other ethnic minority peers academically and occupationally (being smarter, more hard working, and more trustworthy) while still being treated like foreigners and a "threat" to native-born counterparts from whom they might take college scholarships and jobs. Further, due to political and economic turmoil in certain areas of Asia, immigrants from a country may not have necessarily originated from there, but rather emigrated from their place of birth to another country en route to America. While the rest of this chapter attempts to inform the reader about development of these diverse Asian individuals within this nation, as well as provide an understanding of their risk and protective factors and issues surrounding physical and mental health, it is imperative to take into account the diverse and unique pathways of individuals from various areas of the Asian continent.

Historical Context

The first documented immigrants from the "Far East" to the USA arrived in the mid-1700s and were Filipino sailors who escaped from Spanish galleons traveling to colonies in Mexico. However, major migration from East Asia to the USA did not occur until 1848, precipitated by the discovery of gold in California. The Gold Rush is considered one of the dominant factors in many Chinese leaving their home country to seek fortune in America and return home to their families wealthy. Simultaneous with this economic pull, there were other political factors that drove Chinese away from their country, namely, British dominance over China following their defeat in the Opium War (1839–1842). In addition, some Chinese were contracted as laborers in the sugar plantations of Hawaii and to work on the railroads in California. As a consequence, there was a tremendous influx of immigrants from China which the American people and policy makers did not know how to handle.

Initially, Chinese miners were welcomed in California as cheaper laborers, but soon White miners began to resent these migrant workers who were discovering gold that White miners thought they deserved. In 1852, California legislature passed the Foreign Miners Tax which levied egregious taxes aimed at the Chinese, forcing many to give up their land or to find other jobs. This was but one of the many growing political pushes to segregate and force Chinese immigrants into lower social class. In addition, they were forbidden from owning their own land, attending school, having certain occupations, living in certain parts of cities, and even marrying a White person. Because of these laws, Chinese and other Asian immigrants became more isolated, forming small communities and working in jobs that would support each others' lives (i.e., grocers, gardeners, etc.). This heated issue of immigration from the East culminated in the Chinese Exclusion Act of 1923, which sought to forever bar Chinese immigrants from coming to the USA, and those who were already in the USA were made permanent alien residents. Leaving the country provided little chance that one could return, preventing many Asian men from reuniting with their families back home. However, these policies that were meant to drive these immigrant groups home did not take into account the perseverance, determination, and astuteness of these individuals as they strove to make new communities in the USA and to bring their families over.

Finally, the Chinese Exclusion Act was repealed in 1943, though immigration was still severely restricted compared to before. However, Asians in the USA could not find "peace" from discrimination for long as World War II had devastating effects on the treatment of Asians, particularly Japanese. Prison internment camps forever changed the structure of the traditional Japanese family as they were forced to live communally, without privacy, and without the formal patriarchal structure. Moreover, though in some cases reparations have been made, the trauma and shame endured by these immigrants during this recent time period has invariably influenced their acculturation. For example, the experience of Japanese Americans in internment camps has irreparably impacted the cultural values and beliefs of successive generations of Japanese immigrant families.

Finally, in more recent history, global political turmoil has influenced the departure of many other Asian groups from their home lands to seek refuge in the USA (i.e., Vietnamese in the 1970s and Cambodians following Khmer Rouge). Given changes in US policy regarding immigration, the focus of these newcomers is on family reunification; however, the effects of these emigrations should not be forgotten and as the context of the experience of each of these immigrant groups is unique, much consideration should be given to understanding their unique acculturative experiences and how these experiences may impact both their mental and physical health and development.

Acculturation: What Does It Mean to Be Asian American?

For most immigrants coming to the USA, this nation shines as a beacon of hope and fortune. Many come to better the lives of their families and to raise their children in a land of opportunity and resources, which is in contrast to the sometimes dismal and stressful situations of their home country. In the past, the process of acculturation has been viewed as "stripping" one's self from the culture and identity of origins and embracing a new identity in the host country. However, this perspective was considered antiquated and did not embrace the dynamic and unique experiences of immigrants in adjusting to a new cultural context. Therefore, in the past few decades, there has been a shift from the "unidimensional model of acculturation," which posits this one-way shift to a new identity, to a dynamic "bidimensional model" that presents acculturation as a function of the degree to which immigrants strive to maintain their cultural heritage and identity and the degree to which they become immersed and involved in their new cultural environment. During this process, there is great variation in how individuals engage in acculturation strategies, generally related to their behaviors and their attitudes. Changes in these two areas are seen as a function of how the individual and society interact and how the individual tries to cope with the stress of acculturation. In examining psychological adaptation, immigrants tend to engage in one of four different strategies in acculturation: (1) integration, where individuals seek to maintain their cultural values while still engaging with society; (2) assimilation, where individuals choose not to retain their ethnic identity and fully embrace the culture of their host country; (3) separation, where individuals value holding onto their culture and do not engage with society; (4) marginalization, when there is no interest in maintaining one's culture (because of segregation or cultural loss) or engaging in the new culture (related to feelings discrimination or exclusion). Immigrants who utilize the strategy of integration or assimilation often have the best psychological outcomes, demonstrating higher self-esteem related to identity and less conflict and stress. However, for some immigrant groups, there is no choice for strategy, as in the case of marginalization, where society has enforced segregation or discrimination that does not encourage these immigrants to engage with the host culture nor is there means of remaining connected to their home country.

Regardless of nationality, emigration and immigration is a time of great stress (i.e., identity crises, economic/career changes, and family systems disruption) but also a time for growth and opportunity as individuals seek a new identity and opportunities within the host country. The process of assimilation varies from individual to individual and across the unique experiences and interactions with the mainstream culture. Furthermore, the process of acculturation for Asians has been further described as “segmented,” such that immigrants received into society may be propelled in different trajectories given differences in social mobility. Specifically, immigrant groups may either be confined to certain social status, such as lower class, without much mobility (i.e., impoverished refugees from South East Asia), or they could experience rapid economic and social upward or downward mobility (i.e., those who come with education or job experience either do or do not carry over to the American system), in which change, especially for those in the lower class, becomes much more difficult.

It is important to keep in mind the demographics of incoming immigrants and how these affect their outcomes within the USA. For example, Asian immigrants from less developed areas who immigrate to urban, industrialized areas may experience more difficulty in adjusting due to differences in cultural values, economic status, and support structures, while Asians from cities similar to the metropolitan areas in the USA (often the most common port of entries and areas of immigrant settlement) may experience less stress and conflict because there is less dissonance between their city of origin and destination city in terms of job status and environment. In addition, having an established community of their ethnic peers could provide irreplaceable social and structural support for newcomers, such that they feel a sense of belongings and are able to remain connected to their culture. Therefore, the characteristics of their areas of origin may affect the type and degree of acculturative stress they experience in the USA, while having similarities between destination and origin may actually buffer some negative effects for some outcomes.

Acculturation does not stop at any period after an immigrant moves to the USA. Rather it is an extensive and dynamic process for each individual. For those who move to the USA before adulthood, the experience of acculturation is vastly different. According to the 2000 US census, one out of every five children is the child of immigrants; either the child is an immigrant or has at least one parent who is an immigrant. These children and adolescents are experiencing a shift in their cultural values, beliefs, and identity during a period of development that is crucial to later physical, mental, and emotional health. As they are engaging in self-conceptualization, forming their identities through family and peer relationships, and participating in society, the experience of immigration can have a colossal impact on these processes, which result in varying pathways of development. For some children who arrive in early childhood, the process of acculturation may have less immediate consequences, though growing up in an immigrant family invariably affects their development; however, research with this population during this developmental period is limited leaving much supposition about current knowledge of early childhood among the Asian immigrant population. Undoubtedly, children who immigrate in middle childhood and adolescence experience greater amounts of stress and upheaval as they engage in normative processes of development within a novel cultural context. What this means for these children is that they will negotiate their identities as multicultural individuals, having to assimilate American and Asian cultural beliefs, ideals, and behaviors, often times without the assistance of their parents or family members who may not understand the experiences they are going through.

In addition, for some of these youth, there is an established ideal of the “model minority,” such that they must perform well scholastically, without outdoing their White peers, while also not engaging in negative behaviors, such as smoking, drinking, and participating in other delinquent behaviors that might be more typical of other minority groups. While delinquent behavior has been noted among recent, or first-generation, immigrants from Asian countries, it also appears that as these groups become more acculturated to the dominant culture, there is a significant increase in the prevalence of these negative behaviors. Specifically, in the second, third, and fourth generation of immigrant families, these youth are demonstrating an increase in risky behaviors, such as underage smoking and drinking and unsafe sexual activity. In addition, they experience an increase in depression, anxiety, and other negative mental health conditions related to intergenerational conflict with their families, struggles with identity, and discrimination from society. In order to combat marginalization, some groups of Asians have even formed gangs, modeled similarly to gangs of other ethnic minority groups, for protection and support. Though they appear to engage in these negative behaviors similar to other minority groups, for these youth, the factors related to initiation in gang membership, having unprotected sex, and performing delinquent behaviors may be much different, and stem from difficulties in identity development, cultural and societal pressure, and issues of generational conflict within the family. Finally, as there is greater acceptance of biracial relationships, this country will witness an increase of biracial Asian children for whom the process of development, including self-identity, peer relationships, and even racial status, is less understood. It is imperative that professionals who engage with these diverse individuals are aware of their very unique and challenging experiences and seek to gain more understanding rather than make assumptions based on statements of their general ethnic backgrounds as "Asian."

Despite evidence of acculturation and changes in cultural values and behaviors through generations, there is continued stigma in immigrant communities regarding health support and resources. Many still rely on traditional, Eastern methods of healing, often resorting to hospitals only when they are in dire condition and need immediate medical treatment. Further, the concept of mental health may be foreign and inconsistent with the cultural values of some Asians. The destigmatization of mental health is currently at the forefront as these groups are often the least likely to receive services or to seek mental health services support. In addition, health professionals must be educated in these barriers to service utilization as they will impact whether individuals seek treatment and whether they adhere with the treatment provided. Cultural adaptations of therapy and ways of speaking about health services are just some of the methods that current practitioners must educate themselves on in order to effectively engage with and treat this hard-to-reach group of immigrants. More information on the health of Asian immigrants will be covered later in this chapter.

Finally, immigrants may not have a full understanding of the laws and policies as they differ from their country of origin. While embassies and other resources exist, there may be fear and hesitation in the community regarding contacting these organizations for information about immigration services or naturalization processes. Because of their position in society, they may not have the means to hire an attorney nor locate a representative who speaks their language. Furthermore, interpreters are in short supply with a large demand, often lacking adequate training or support to effectively work with their clients. For policy makers and education professionals, it is imperative to support efforts to increase the skills of bilingual individuals, such that they may work as assets in bridging services with a hard-to-reach community. Providing training and education for bilinguals as interpreters will not only provide them with invaluable marketable skills for the work force, but also increase access of resources for the underserved. However, it is extremely important to recognize that immediate or extended family members should not be utilized in this role as they have been historically. For these individuals, the role conflict of interpreting between service professionals and their family members can be deleterious, such that they experience stress from having to convey often negative information to family members, as well as perform a role that may be in direct conflict with their position in the family. This tension may exacerbate family relationships and create tension with the service professionals.

Asian Immigrant Physical Health

A recent Surgeon General's Report found that Asian immigrants have less incidence of coronary disease and stroke than non-Hispanic Whites and are generally more healthy with few exceptions (high rate of cervical cancer among Vietnamese women which may be related to less prevalence of screenings and decreased utilization of Western medicine). However, evidence exists for underreporting and underdiagnosis of mental health issues which may lead to increase in physical health problems through somatization, effects of depression and anxiety, etc. For all immigrant groups, there are noticeable differences between the health of recent immigrants and the native citizens of the USA. The National Health Survey from 1992–1995 indicated that the general health of Asian and Pacific Islander immigrants was better than their native counterparts. Moreover, there was a consistent pattern of deterioration in health as length of residence in the USA increased. It was also noted that use by Asian and Pacific Islander immigrants of formal medical care increased with duration of immigration, perhaps due to decreased cultural barriers to using these services. The variation in the health of Asian groups, especially those for whom there is a large, established community in the USA, can be fully understood only by taking into account additional factors, such as immigration history and diversity among cultural norms and values.

Among Asians, there was noticeably better physical health compared to their native-born peers, which differed among immigrants' areas of origin. For example, the mental and physical health of refugees from countries experiencing internal conflict and war may be markedly less compared to Asian immigrants from less unstable nations but with better preexisting health services. However, this does not blind us to the findings that regardless of moving from Third World countries or areas with less health care, these immigrants still show better health than native-born Americans. Regardless, this seeming advantage over earlier immigrant or American-born individuals appears to dissipate the longer they live in the USA, and this is assumed to be a by-product of acculturation. There are hypotheses as to the cause of this deterioration in health condition, such as limited access to health care in the USA, exposure to health risks (i.e., environmental toxins, cigarettes, high-fat foods, etc.) which may invariably result in increases in health issues. While there do not appear to be any biological bases for health differences, there do appear to be cultural differences in health practices, such as eating and exercise habits, as well as health service utilization, which could influence these observed group differences. This perspective appears most cogent when examining evidence of generational deterioration of health benefits and increased health risks. For these immigrant groups, it is imperative to promote interventions aimed at targeting stigma surrounding health professionals and Western models of medicine, and the adaptation of these interventions and services to incorporate cultural values and perspectives. For most professionals, one of the most important variables in treatment is gaining an alliance with the client, such that there is trust and credibility in the relationship. Thus, given the variety of viewpoints among professionals, there should be flexibility in service delivery in order to be able to reach these individuals. Specifically, if we are to ask them to engage in a behavior that is novel and foreign, there should be some flexibility on the part of the professionals to establish credibility by utilizing knowledge of the individual's culture and make the service valuable to them within that context.

Asian Immigrant Mental Health

In contrast to their natural "protective" barriers for physical health, Asian immigrants tend to experience disparities in mental health, such that they report greater prevalence of certain mental health issues. For example, the National Health Interview Survey (1992–1995) found that Vietnamese immigrants demonstrate a significant increase in depression as their length of residence in the U.S. increases. Among other Asian immigrant groups, there are also noticeable increases in depression, anxiety, and substance abuse, such that there is a significant increase in these issues with length of residence and generational status where second- and third-generation immigrants are significantly more at risk than their first-generation peers.

Findings from ADD Health, a national survey of adolescents' health, indicated that Filipino adolescents experienced more depressive symptoms and engaged in more delinquent behaviors than other Asian groups and compared with European American adolescents. For Chinese American adolescents, they reported increased somatic symptoms associated with third-generation status, compared to both first and second generations for Chinese Americans. Generational influences on delinquency and substance use were noted with both Chinese and Filipino American youth. Being second generation was associated with more delinquency compared to first-generation status among Filipino youth only. Generation effects for delinquency were not significant for Chinese youth. However, generational influences were present among both Chinese and Filipino adolescents with respect to substance use. For the Chinese Americans, being third generation, compared to second, was associated with increased substance use. For Filipino youth, being second and third generations, compared to first, was associated with increased substance use. These findings highlight the differences among Asian groups, such that differences in skin color, cultural values and behaviors, and environment may influence engagement in negative health behaviors. For example, Chinese Americans have historically been considered one of the "model minorities" and there is an expectation of higher academic achievement and less involvement in delinquency, while for other Asian immigrants, specifically from South East Asia, they may experience more stereotyping as being less educated and more likely to engage in delinquent behaviors. Finally, these findings demonstrate differences influenced by generation or length of residence in the USA. Most of our knowledge about mental health issues comes from research with Asian youth in middle childhood, adolescence, and young adults, given the convenience of collecting information with these groups. There is still a paucity of information in early childhood when many children are immigrating to the USA. Therefore, research with this area has increased recently and continues to be an area for interest in understanding mental health issues in development among young Asian immigrants.

Descriptive studies among various Asian immigrant groups have noticed a significantly higher level of internalizing symptomatology compared to native-born peers, which may be related to the cultural value of maintaining group harmony while suppressing one's own feelings. Additionally, these groups also exhibit high anxiety, specific to social situations in which their language proficiency or other factors may make them feel uncomfortable. However, compared to native-born peers or Americans, recent immigrants exhibit much less externalizing symptoms, such as aggression. As stated previously, the prevalence of these issues appears to change dynamically in line with acculturation. In addition, perceived discrimination among Asian immigrants severely impacts mental health. A great deal of evidence has demonstrated the impact of racial discrimination on the health of Asians, such that the stress of experiencing overt or micro-aggressions from others can impact self-esteem and well-being. For these groups, feeling marginalized and experiencing discrimination is related to increases in depression. However, perceiving social support from friends and family can decrease the impact of discrimination, acting as a buffer against these negative experiences. Furthermore, Asians who are members of other marginalized groups, such as the lesbian-gay-bisexual-transgender-questioning community, may experience more negative mental health effects due to increased experiences of marginalization related to their culturally disparate behaviors, family conflict, and legal barriers to marriage and child-rearing, including adoption and acceptance in schools. These groups are subject to greater family conflict given their sexual orientation which is not acceptable within their traditional cultures. For these individuals, there is a struggle between family honor and piety and living a more individualized, "free" life in the USA. America may serve as "safe" place to explore their sexuality while pressure from their families may make it difficult to do so and cause interpersonal conflict and distress. Though these groups are not noticeable in mainstream culture, they exist and more knowledge is needed to be able to provide appropriate support and counseling surrounding safe sex, parenting, couples therapy, etc.

There are cultural barriers and misconceptions about the health care system that decrease the likelihood of Asians seeking help for any mental health problems, especially child behavior problems. In general, Asian immigrants tend to be extremely wary of mental health services as they are even more incongruent with some of their cultural beliefs than physical health services. However, in terms of seeking services, it appears that, especially in the case of child behavior issues, the perceived severity of the problems influences parents' intentions for seeking help. Value orientation indirectly influences help-seeking intentions of individuals through its effects on their feelings about the issue. These findings coincide with evidence that the severity of the mental health issue is often the catalytic factor in seeking services. For some Asians, like the Chinese, depression can be seen as a sign of character and part of life, and therefore, it is not necessary to seek intervention. Furthermore, among these groups, because of collectivistic ideals that value the privacy of family issues, mental health services carry a heavy stigma, because seeking therapy can be viewed as betraying the trust and secrets of the family. Therapy can be seen as "complaining" about your family situation and lead to experiences of "losing face" or diminishing the respect and honor of one's family in front of a stranger. For example, more traditional Chinese American parents tend to respond to hypothetical child behavior problems with higher levels of shame and stigma-related negative affect related to communicating about one's family issues. Historically, Asians tend to seek support from their friends and family before seeking services outside, and like physical health issues, they often enter therapy when they have exhausted all other resources and are in crisis.

Moreover, recent immigrant adolescents who are experiencing high parent–child conflict (possibly related to differential rates of acculturation between parent and child) are significantly more likely to engage in suicidal behaviors than their more acculturated counterparts. While there are many factors that influence psychopathology and self-injurious behavior, among them perceived discrimination/marginalization, peer and family support, and ethnic identity, it is important to note the paucity of knowledge in measurement and training on identification of these factors to recognize immigrants at risk. While frequent experiences of perceived discrimination, a lack of social support, and a history of comorbid psychopathology are excellent indicators of Asian immigrants at risk for suicidality, more information is still needed to understand the role of culture and mental health in identifying those who are more or less likely to complete suicidal behaviors. For example, for some Asians groups (i.e., Japanese), committing suicide following experiencing extreme shame (i.e., losing a job) may be culturally normative and expected within the context. Therefore, working with such an individual would entail understanding those cultural beliefs but also abiding by American ethics, such that therapy would work toward decreasing suicidality and preventing suicidal actions but also acknowledge the cultural bases of the client's values and behaviors.

Further, discussing the limits of confidentiality and the role of their service provider can be particularly difficult when working with individuals who carry stigma about mental health and who may not see the services as necessary or beneficial. For these clients, feeling like they have "lost face" or that their personal information has been shared with someone with whom they have not established trust or credibility could result in an abruptly terminated relationship, and that client may never seek services again. Therefore, knowledge in the areas of cultural competence pertinent to the populations you will be working with is essential for forming positive working relationships. Even with this knowledge, individual differences among Asian immigrants also need to be taken into account so that the nuances of each person's experience are not ignored. By taking an integrative approach, one can utilize a culturally sensitive perspective supported by empirical research in understanding and working with Asian immigrants.

Assimilation

Mark Agius
Department of Psychiatry, University of Cambridge,

Weller Wing Bedford Hospital, Bedford,
Bedfordshire, UK

It is almost inevitable that when an immigrant moves from his or her home culture to a different culture, there will be some tension between the cultures of the home and host countries, which will influence the immigrant's behavior.

Culture may be viewed as a set of shared attitudes, values, goals, and practices that characterizes an organization, institution, or group. Cultures have evolved over centuries and continue to do so. Furthermore, culture may provide a strong sense of identity to members and may inform how members view themselves and others. Some immigrants find it challenging to navigate potentially discrepant home and host cultural beliefs and practices.

Acculturation is a dynamic process. It reflects the degree to which the original culture is retained while adapting to the new culture. There are four different patterns of acculturation: integration, assimilation, separation, and marginalization. Assimilation may be described as "unicultural acculturation." Assimilation may involve changes in choice of language spoken and the adoption of the host culture's attitudes and values. In extreme cases, the immigrant who assimilates adopts all the values of the host culture and eschews those of the home culture. In practice, this is a process that may take many generations. For example, the Rhodans who moved to Malta with the Knights of Saint John in the sixteenth century kept their own churches and parishes for many years. Over the course of centuries, they intermarried with the Maltese; all their churches were closed except one, which has maintained its Greek Rite till today.

Acculturation is usually viewed, particularly by the host nation, in terms of the extent to which immigrants adopt the habits or language patterns of the host culture. However, acculturation may be reciprocal, with the members of the host culture adopting patterns typical of the immigrant group. For example, in Britain, Chicken Tikka Masala, a South Asian dish, may be viewed as a national dish alongside British "fish and chips." In countries with a diversity of immigrant groups, such as the United Kingdom, it is now frequently argued that a multicultural society in which all cultures are valued has now evolved.

Asthma

Michele Palella
Floating Hospital for Children, Tufts Medical Center, Boston, MA, USA

Once thought to be an acute, sporadic illness, asthma is now understood to be a chronic, inflammatory lung process which is becoming increasingly common across the globe. Generally the diagnosis is made when the patient, usually a child, presents to the health care provider with wheeze, cough, and/or breathlessness which is not accompanied by an acute illness. The diagnosis is not made, however, on the first presentation, but at the second or third, with the patient having normal respiration at other points in time, and the chronic nature of the ailment can be established.

The chronic inflammation causes the interior wall of the airways to become swollen, reddened, with increased mucus production. This causes the lumen of the airway to narrow, and the wall itself becomes more irritable and responds easily to irritants. This response takes the form of bronchoconstriction (tightening of the muscles which circle the smallest airway bronchioles). While the bronchoconstriction is reversible when the appropriate medication is administered, different medications are needed to decrease the airway inflammation. It is because of these two different components that the presentation of asthma varies greatly between those persons in which the bronchospasm takes precedence, causing wheezing and chest tightness; as opposed to those individuals who develop chronic cough due to inflammation, who may never wheeze. In older children and adults, objective measurement of airflow obstruction and airway inflammation is easily made, but objective data is difficult to obtain in children under the age of 5. Yet, asthma is increasingly one of the most chronic illnesses with the greatest morbidity in childhood.

The goal of asthma treatment is to diminish the chronic inflammation; thus decreasing the bronchospastic component as well. This is done through the use of "maintenance" or "controller" medical therapy, medication taken daily rather than episodically. Those medications required at the time of an exacerbation are termed "rescue" medications. Most medications are inhaled, thus placing the treatment directly on the area of concern. The medication is provided in metered dose inhalers in which the medication is suspended in dispersal medium; fine powder inhalers and nebulized therapy in which the medication, in salt water, is suspended into small droplets through a nebulizer device connected to an air compressor. Control is achieved when patients are able to go for prolonged periods of time asymptomatic, thus requiring little or no rescue medication.

A number of natural history studies of asthma have identified biologic, genetic, and environmental risk factors for persistent asthma. Among the biologic risks are atopic dermatitis, allergic rhinitis, elevated total serum IgE in the first year of life, peripheral blood eosinophilia >4% (2–3 years of age), and food or inhalant allergen sensitization. Parental asthma or other atopic conditions may indicate genetic risk. Early lower respiratory tract infections and environmental tobacco smoke exposure are among the exogenous causes. The Tucson Children's Respiratory Study in Tucson, Arizona, established a predictive index with two major and three minor criteria: the former are parental asthma and eczema; the latter, allergic rhinitis, wheezing apart from viral respiratory infections and an eosinophil count greater than 4%. These criteria were amended by Guilbert and colleagues during their PEAK (Prevention of Early Asthma in Kids) to add "Allergic sensitization to one or more aeroallergen" to the major criteria group, and "allergic sensitization to milk, egg, or peanuts" to the minor criteria group.

The eight-center Childhood Asthma Management Program (CAMP) study of over 1000 asthmatic children ages 5–12 years found that allergy-associated asthma appears to be the most common form of asthma in elementary school-aged children in the USA, and that 88% of the study group were sensitized to at least one inhalant allergen at study enrollment.

In the ISAAC studies (The International Study of Asthma and Allergies in Childhood, established in 1991 to investigate asthma, rhinitis and eczema in children worldwide) and the European Community Respiratory Health Survey, asthma has been found to be more common in those English-speaking countries that are predominantly countries with high dust mite exposure. However, The ISAAC findings to date have shown that while these diseases are increasing in developing countries, they have little to do with allergy, especially in the developing world. Further population studies are urgently needed to discover more about the underlying mechanisms of non-allergic causes of asthma, rhinoconjunctivitis, and eczema and the burden of these conditions. ISAAC is the largest worldwide collaborative research project ever undertaken, (involving more than 100 countries and two million children); its aim is to develop environmental measures and disease monitoring in order to form the basis for future interventions to reduce the burden of allergic and non-allergic diseases, especially for children in developing countries.

There are many current theories as to the mechanism non-allergic asthma, rhinoconjunctivitis, and eczema. For one author, in rural Greece, the explanation is simple, arguing that villages have not changed for hundreds of years and that what is new are motorized vehicles and equipment. This author notes that in many low-income countries, people rely on solid fuel and that secondhand smoke has become more common as well.

However, with immigration, other factors emerge. There are a number of conflicting studies, wherein immigrants to new environments have statistically more or less susceptibility to asthma than natives. Most immigrants move from developing countries to more developed ones seeking better opportunity; in doing so they may either improve or worsen their exposure to pollens, pollution, and sanitation. In the circumstance where immigrants are less likely than the local natives to develop asthma and "allergic" type diseases, the "hygiene" hypothesis holds great appeal. It postulates that children born in less developed countries with poor sanitation are more likely to acquire protective infections (most likely parasitic, helminthes, etc.), early in life.

Alternative theories involve sunlight exposure and Vitamin D effects. Dietary changes may also affect the immune response; clearly diets rich in fish oil and the protective effects of omega-3 fatty acid are immunogenic. Diets rich in fruits and vegetables (filled with antioxidants) are preferable to those diets rich in meat and carbohydrates which are consumed post-migration to the United States. The prevalence of obesity (itself an inflammatory illness) has significant comorbidity with asthma and again is tied to poor dietary habits of those in lower socioeconomic strata of the industrial world.

Depending upon the countries of origin and destination, immigration may confer some immunity or offer some added risk to the acquisition of asthma. However, asthma, although chronic, is very treatable, making access to healthcare the critical element in asthma severity for the individual immigrant.

Asylum

Domnița Oana Bădărău
Department of Bioethics, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Globalization is one of the most significant factors that favors the phenomena of migration, along with the deepening disparities between countries. Migration is most commonly caused by poor economic and social conditions that pressure people to look for employment or a better education outside their native country. Following family or reuniting with family members also serve as the impetus for people to leave their home country. However, the most decisive factors that force people to migrate are the need to escape from a conflict zone, to avoid war, and to flee from persecution. A civil war, rebellion, or any kind of violence that continues over a long period of time or is directed towards specific targets, such as minorities or political opponents, presents such a high degree of risk that people from that country or habitual residents decide to go outside that territory. These persons may be persecuted because of their religion, political opinion or affiliation, sex, race, ethnicity, or national origin, becoming refugees within the definition of the relevant international conventions.

International Regulation

Internationally, one of the most comprehensive legal guides to refugees' status and rights was promulgated in 1951 by the United Nations and entered into force in 1954. A unified international codification of the rights of refugees, the United Nations Convention on the Status of Refugees ("Refugee Convention") reinforces previous international instruments concerning refugees and provides additional clarity with respect to international practices. At the same time, the

Convention broadens the concept of refugees and defines the circumstances in which a person becomes a refugee: a person who, due to a certain degree of fear of being persecuted, finds himself or herself outside of his or her national territory and is unable or unwilling to return under the protection of that state. A stateless person may be a refugee if he or she cannot return or due to fear is unwilling to return to his or her country of last residence. Individuals having more than one nationality become refugees only when they cannot benefit from the protection of either of the countries of which they are nationals.

The Convention specifies the basis of persecution that would entitle a person to seek refuge in another country as being political, racial, nationality, membership in a particular social group or political opinion. The Refugee Convention and the subsequent 1967 Protocol Relating to the Status of Refugees, which removed the geographic and date limitations imposed by the Convention, guide the national legislation of the signatory States in terms of defining refugees and their rights. These documents also enable the United Nations to monitor the application of the Convention's and Protocol's provisions. The signatory States provide the U.N. with the information and statistics required to complete reports for the relevant bodies of the U.N. This information must be submitted in a specific form and contain data relating to the refugee's condition, the stage of the application of the Protocol, and any legislative act that has or may have an impact on the status of refugees.

The United Nations High Commissioner for Refugees (UNHCR) recognizes the importance of border control in fighting international crimes, but at the same time it reinforces the U.N.'s mission to ensure protection for those who left their countries in search of freedom. As an example, the UNHCR evaluates the measures used to combat crimes to determine whether they are applied so excessively that refugees are denied access to a safe place.

The Convention states the conditions to be met in order for a person to be recognized as a refugee; however, this status should not be confused with the political asylum seekers. While refugees represent a compact group of persons in search of a safe territory, the right of asylum refers to individuals and so each case is analyzed differently. The Institute of International Law defines *asylum* as a State's commitment to offer protection within its territory to a person who is in search of such a protection. A State can offer asylum to an individual also in another territory that is subjected to one of that State's organs.

Non-Refoulement Rule

A State can grant asylum either implicitly or explicitly or simply refuse to grant asylum. If asylum is denied, the person who requested it is subject to expulsion from that country. The Convention of Geneva established the non-refoulement rule to prevent repercussions to asylum applicants who are denied that status and would otherwise be returned to their countries. Article 33 of the Convention prohibits the expulsion or return of any refugee or asylum seeker to the territories where they are most likely to lose their freedom or to face life threatening situations. This danger could be related to race, religion, nationality, or association with a social group or political organization. At the same time, the Convention recognizes the fact that asylum may not be granted to a person who represents a serious danger to the community of the country where he seeks asylum.

The non-refoulement principle is a critical component of international refugee law and has been developed within the human rights international law. Being a customary international law, the principle applies not only to refugees that have been recognized as facing persecution in their country, but also to persons seeking asylum status, as their request may lie on solid grounds.

When asylum is granted to a person, he or she becomes an *asylee* and is protected by international as well as national law. The international law does not solely include the Convention and Protocol Relating to the Status of Refugees. Asylee rights are stated and protected under the Universal Declaration of Human Rights (1948), the International Covenant on Civil and Political Rights of 1966 and additional human rights treaties.

The International Covenant on Civil and Political Rights (ICCPR) reinforces the basic civil rights: freedom from torture, equality before the law and the chance for an unbiased trial, equality, and freedom of opinion. It also recognizes the right of individuals to enjoy civil and political freedom, which must be protected by each State.

Political freedom is closely linked to concepts like civil liberties and individual rights, which are protected by international laws and, in democratic states, are also protected by national laws. The ICCPR states that every person is entitled to hold opinions and to express them freely, as long as they do not break any necessary law. Exercising this right means liberty to seek, share, and obtain information on any matter, even across borders. Peaceful assemblies can be organized by any person and should be allowed. Article 22 provides for the right to form an association freely or to join trade unions or other kind of organizations. Citizens of any country have the right to be part of the public affairs, to be elected as public representatives, to vote, and to have access to the country's public services. Any restrictions relating to these rights are allowed only when necessary to protect others. Limiting these rights beyond the mentioned restrictions is a step towards constraint. The context and the specific measures applied in order to limit or prohibit the exercise of these rights are relevant to a determination of persecution. If persecution is found to exist, those individuals whose rights have been overridden may have a valid claim for asylum. If the rights that are ignored refer to one's opinions, liberty of expression, peaceful assemblies of a political organization, forming such an organization, the persecution is political. As a result, the person who suffers from that type of persecution is entitled to seek political asylum.

During recent years, threats of terrorism have led to various conventions that have a direct impact on the asylum-granting process. As the right to grant asylum is an exercise of a State's national sovereignty, the State has the freedom to offer and grant asylum between its frontiers to any individual as it pleases. At an international level, in doing so, a State could face a negative reaction from other States, not only the one from where the asylee comes.

Ataque de Nervios

Daniel S. Schechter
Division of Child and Adolescent Psychiatry,
Department of Psychiatry, University of Geneva,
Geneva, Switzerland

The Spanish term *ataques de nervios*, translated as "attacks of nerves" and as described in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM) of 1994 glossary of culture-bound syndromes, refers to an "idiom of distress" found among many Latin American and Latin Mediterranean groups. The term "idiom of distress" describes the expression of a range of symptoms, which despite their variable presentation (see below), communicate a message whose meaning is shared within a given culture. Thus, an "ataque de nervios," which can appear as a quiet panic attack, a crying spell or as a violent pseudoseizure, above all, is labeled as such by the affected individual and clearly recognized by other members of that individual's culture as expressing acute discomfort, anguish, and/or actual or perceived impairment in individual or interpersonal functioning necessitating assistance to that individual.

Ataque de nervios first appeared in the North American psychiatric literature as the "Puerto Rican Syndrome" by Fernández-Marina in 1961. Ataques de nervios encompass a range of paroxysmal experiences and behaviors that are often reactive to emotionally laden events (i.e., the announcement of an accident or natural catastrophe, the experiencing of violence, bereavement) or to reminders of those events. Hyperarousal becomes linked to affects of anger, worry, intense fear, despair, or shame.

Affected individuals may seek mental health and/or medical evaluation with self-labeled "ataques de nervios" as a complaint in a number of different settings including the emergency room. Ataques de nervios, importantly again, may not be labeled as such without the subject's naming his or her experience clearly as "ataques de nervios." The scientific literature supports ataques de nervios as having a range of possible clinical presentations ranging from a discretely experienced panic attack to a fit of violent agitation requiring physical restraint, and at times involving self-mutilative, suicidal, and/or other-directed violent behavior.

Typically, the subject experiences an acute sense of distress and hyperarousal preceding and during the episode which is most often, as described above, triggered by a real interaction or event. Shortness of breath, hyperventilation, palpitations, perspiration, trembling, feeling faint even to the point of fainting (syncope), chills, piloerection (i.e., goose pimples), or alternatively a sensation of a "hot flash" are only a few of the commonly described somatic phenomena that accompany ataques de nervios. Frequently, these somatic sensations are associated with subjective fears of "losing control" of one's body and/or behavior. Patients may fear becoming insane, or dying of cardiac or respiratory arrest.

Dissociative phenomena are also quite commonly associated with the episode including depersonalization, derealization, and partial or total amnesia for the occurrence of the ataque, as well as occasionally the feeling that the subject is "possessed" or behaving like a different person. Some ataques resemble pseudoseizures (i.e., a conversion or other somatoform disorder according to the *DSM-IV*) and involve falling to the ground dramatically, writhing, and self-directed aggression, which is followed by a confusional state or by amnesia. These manifestations of ataque may be mistaken for epileptic activity or as evidence of intoxication or withdrawal from alcohol or drugs.

Ataques are relatively common phenomena with an estimated prevalence of 13.8% in Puerto Rico, which is more predominant among females (60%) than males (40%). More than 75% of subjects who reported having experienced one or more ataques sought health care and/or reported significant functional impairment.

Interestingly, at least one study has empirically shown a positive association between "reporting of ataques de nervios as a problem" and years of acculturation to US society. Whereas the ataque may have functioned as a culturally sanctioned rally for support by a social network in the culture of origin, it can be viewed as a "problem" or "form of pathology" only once the immigrant arrives in a new cultural setting. Similarly, the ataque's individual meaning for an individual (i.e., its link to a traumatization) can be misunderstood by, for example, North American medical culture in a hospital emergency room, leading to further traumatization, isolation, and pharmacological intervention that can place the individual at risk.

This suggests that "ataques" might best be considered as a "problem" or form of "pathology" when subjects leave their home countries and there the phenomena are viewed within a new cultural context in which the original function and meaning of the ataques are no longer shared from the same point of view. That being said, individuals reporting chronic ataques de nervios are found to be as much as five to six times as likely to have a depressive and/or anxiety disorder and nearly three times more likely to have a substance abuse disorder. It may therefore be more useful to consider the chronic occurrence of ataques de nervios as a marker of vulnerability for a psychiatric disorder such as, most commonly, posttraumatic stress disorder (PTSD), and comorbid dissociative and depressive symptoms following from traumatic experience(s).

While Fernández-Marina in 1961 made mention of the resemblance of ataques to symptom expression among returning veterans suffering from "war neurosis," an empirical link to childhood trauma, posttraumatic stress disorder (PTSD) as it is presently conceptualized, and dissociative disturbances was not published until more than 40 years later (see Suggested Readings below). As such, one can understand how the ataque might represent a trauma-related disturbance in emotion regulation that has implications for an adult subject who becomes the parent of an infant or cares for a young child during the development of emotion regulation.

In any given clinical situation in which ataques de nervios are encountered, the clinician should try with the patient to understand the patient's individual experience, the precipitants, effects, and meaning that the patient and her/his family attributes to the ataque, along with carrying out a full psychiatric evaluation to look for comorbid conditions – both according to industrialized Western "medical" classification, as well as other cultural-bound syndromes (see, e.g., the entry on Nervios in this encyclopedia).

Phenomena such as "fits" in African-American or African-Caribbean culture are similar in phenomenology to "ataques" as are "hysterical attacks" described in the European psychiatric literature of the late nineteenth century by Charcot in France and others. Despite the similarity of ataques de nervios to these other phenomena, given the absence of empirical comparison to these other phenomena, ataques de nervios should be considered both in terms of its meaning within its respective cultural context and in terms of its meaning to the individual patient. Some inner-city patients, whether Hispanic or of mixed ethnicity, may use "ataques de nervios," "fits," or "falling out" interchangeably.

So, for such a patient, the labeling of their experience of paroxysmal distress has both an individual meaning and may also likely reflect the different cultural influences with which they identify. Similarly, popular culture impacts the individual's use and avoidance of self-labeling distress as an "ataque de nervios." Due to the popularity of the 1988 film by Spanish director Pedro Almadóvar entitled "Mujeres al borde de un ataque de nervios" and its English translation as "Women on the Verge of a Nervous Breakdown," a popular translation of the term has been "nervous breakdown" with all of the latter's attached implications and stigma.

Immigration to Australia

Experts estimate that approximately 50,000 years ago, ancestors of the Australian Aborigines arrived on the continent by means of Malay Archipelago and New Guinea. Europeans followed, arriving in the seventeenth and eighteenth centuries. Britain, needing a new penal colony to alleviate the burden on its overcrowded prisons, set sail for Australia in 1787, 11 ships with approximately 1,350 convicts. On January 26, 1788, the ships landed at Sydney Cove. This date is now celebrated by some as Australia Day, while some Aboriginal people and supporters regard it as "Invasion Day." The new colony was proclaimed as the Colony of New South Wales on February 7, 1788.

The Colony of New South Wales began to grow rapidly in 1815; as settlers arrived from Britain and Ireland, lands were opened for farming. The voyage by sea was long and perilous, but settlers were drawn by the prospect of a new life on virtually free land. Many settlers, known as squatters, occupied land without authority and became the basis of a powerful landowning class. As a result of agitation by the free settlers, transportation of convicts to Sydney ended in 1840, although it continued to smaller colonies for some years longer. The small settlement of Perth, founded in 1829 in Western Australia, failed to prosper. Instead, the settlement asked for convicts. In contrast, South Australia, founded in 1836, has no convict settlement history.

The discovery of gold in 1851 in New South Wales and then in Victoria transformed Australia economically, politically, and demographically. The gold rushes quickly followed a worldwide economic depression. As a result, about 2% of the population of the British Isles emigrated to New South Wales and Victoria during the 1850s. There were also a significant number of continental Europeans, North Americans, and Chinese who immigrated during the gold rush era. From 1851 to 1861, the population of Victoria increased sevenfold – largely due to the gold rush.

During the latter half of the nineteenth century, several colonies funded the immigration of skilled immigrants from Europe. The government found that if it wanted immigrants, it had to subsidize migration. The distance from Europe to Australia made it a more expensive and less attractive destination than Canada and the United States. The number of immigrants needed during different stages of the economic cycle could be controlled by varying the subsidy. Before Federation in 1901, migrants received passage assistance from colonial government funds; the British government paid for the passage of convicts, paupers, the military, and civil servants. Few immigrants received colonial government assistance before 1831.

The need for a common immigration policy was a key impetus for creating a federated Australia. There was significant resistance to Chinese immigration and to importing indentured workers from New Caledonia. The White Australia Policy, the policy of excluding all non-European people from immigrating into Australia, was the official policy of all governments and all mainstream political parties in Australia from the 1890s to the 1950s. Aspects of the policy survived until the 1970s. Notably, although the expression "White Australia Policy" was never in official use, it was common in political and public debate throughout the period.

Over the last 15 years, immigration numbers have grown significantly. For example, net overseas migration increased from 30,042 in 1992–1993 to 177,600 in 2006–2007, the highest number on record. Immigration to Australia is comprised in large part from the skills migration and family reunion programs. Incidentally, the recent decision to mandate the detention of unauthorized arrivals by boat has generated much controversy both for and against.

Immigration Programs

The Australian government seeks in its immigration policy to balance social, economic, humanitarian, and environmental concerns. Australia's permanent immigration program has two components: (a) *migration* – for skilled, family, and special eligibility stream migrants, and (b) *humanitarian* – for refugees and others needing humanitarian aid. The planning level for the 2010–2011 Migration Program is set at 168,700 places, while the Humanitarian Program is set at 13,750 places.

Migration Program

The 2010–2011 Migration Program has allocated 168,700 places. This figure is divided into 54,550 places for family migrants who are sponsored by family members already in Australia; 113,850 places for skilled migrants who gain entry due to their needed skill set; and 300 places for special eligibility migrants and people who apply under the Resolution of Status category and have lived in Australia for 10 or more years. The planned ratio of skilled migrants to family migrants is 6.7:3.2.

Resolution of Status

The Australian Government's Department of Immigration and Citizenship works to engage clients who have overstayed their visas and clients on bridging visas to resolve their immigration status in a fair and timely manner. Resolution of a client's immigration status is reached through either the granting of an appropriate visa or through the client's departure from Australia. The department's status resolution initiatives work with clients to encourage voluntary compliance and to ensure that all decisions to detain individuals are justified.

Unlawful noncitizens may be granted bridging visas which allow one to depart voluntarily or to remain in the community while one or more of the following are being considered: a visa application, the merits of a case, or judicial review proceedings. If it is determined that a client has no lawful entitlement to remain in the country, the client is informed that if a voluntary departure does not follow, the client may be detained and removed.

Humanitarian Program

The Humanitarian Program for 2010–2011 is set at 13,750 places. This total is comprised of 6,000 places allocated for *refugees* and those arriving from overseas and 7,750 places allocated for *other humanitarian*, including the offshore Special Humanitarian Program and onshore needs. The onshore component of the Humanitarian Program provides options for persons who are in Australia and who wish to apply for asylum; each year, several thousand apply. Applicants are granted permanent Protection visas if they are owed protection under Australian migration law – meaning they have been found to be refugees and have satisfied health, character, and security requirements. The United Nations' Refugees Convention qualifies a refugee as one who is outside his or her country and is unable or unwilling to go back due to a well-founded fear of being persecuted because of one's race, religion, nationality, political opinion, or membership in a particular social group.

Offshore Resettlement

The offshore resettlement component of the humanitarian program is comprised of two categories of permanent visas: (a) *Refugee* and (b) *Special Humanitarian Program*. Permanent visas for refugees are for those who are subject to persecution in their home country, usually who are outside of their home country, and who are in need of resettlement. The majority of those considered under this category are identified and referred to Australia for resettlement by the United Nations High Commissioner for Refugees (UNHCR). The Refugee category includes the following visa subclasses: Refugee, In-country Special Humanitarian, Emergency Rescue, and Woman-at-Risk. The Special Humanitarian Program is for persons outside their home country who are subject to substantial discrimination amounting to gross violation of human rights in their home country. A proposer, who is an Australian citizen, permanent resident, or eligible New Zealand citizen, or an organization that is based in Australia must support applications for entry under the SHP.

Offshore Resettlement: Size and Composition

The size and composition of the offshore resettlement program are shaped by a variety of factors, for example, the UNHCR assessment of the resettlement needs of refugees overseas. During regular community consultations, the Minister for Immigration and Citizenship seeks input from individuals and organizations in Australia on the size and composition of offshore resettlement. Australia's capacity to assist perhaps is the most significant factor shaping offshore resettlement.

Australian Politics

The Commonwealth of Australia was created in 1901 when the former British colonies agreed to federate, forming what is now Australia's six states. While Australia is an independent parliamentary democracy, Queen Elizabeth II of the United Kingdom (UK) is formally the Queen of Australia. All citizens over the age of 18 must vote in federal and state government elections, and failure to do so may result in a fine or prosecution. Australia's government is founded in the liberal democratic tradition that is based on the values of: religious tolerance, freedom of speech and association, and the rule of law. Australia's institutions and government reflect British and North American models; yet, they remain uniquely Australian.

Responsible Government

Australia's government is one of the oldest continuous democracies in the world. Such democratic principles that shaped the pre-federation colonial parliaments, such as "one man, one vote" and women's suffrage, were adopted by Australia's first federal government. The Australian colonies had inherited an electoral tradition from Britain; however, abuses such as bribery and intimidation of voters prompted electoral change. Australia pioneered reforms that underpin the electoral practices of modern democracies.

The secret ballot was introduced in Victoria in 1855, quickly becoming known worldwide as "the Australian ballot." In 1856, South Australia eliminated professional and property qualifications in order for men to vote, and in 1892 gave adult women the vote – nearly 30 years before passage in the United States. In the 1890s, the colonies adopted the principle of one vote per person, stopping the practice of plural voting.

Australia's government is based on a popularly elected parliament with two chambers: the House of Representatives and the Senate. Ministers appointed from these chambers conduct executive government, and policy decisions are made in Cabinet meetings – which are not disclosed – apart from the announcement of decisions. Ministers are bound by the principle of Cabinet solidarity, which closely mirrors the British model of Cabinet government responsible to parliament. While Australia is an independent nation, Queen Elizabeth II of Great Britain is formally Queen of Australia also. On the advice of the elected Australian Government, The Queen appoints a Governor-General to represent her. Although the Governor-General has wide powers, on virtually all matters, he or she acts only on the advice of ministers.

Parliament and the Constitution

The Australian Constitution defines the responsibilities of the federal government, including: foreign relations, trade, defense, and immigration. All matters not assigned to the Commonwealth are the responsibility of the states and territories, and they, too, adhere to same principles of government. In the states, the Queen is represented by a Governor for each state. Similar to the Supreme Court in the United States, the High Court of Australia arbitrates on disputes between the Commonwealth and the states. Many of the court's decisions have expanded the constitutional powers and responsibilities of the federal government.

Frequent Elections

A general election must be held within 3 years of the first meeting of a new federal parliament, on average approximately 2.5 years. General elections are held when the Governor-General agrees to a request from the Prime Minister, who then selects the date of the election. On average, the governing party has changed about every 5 years since 1901. The Liberal Party had the longest hold on government – 23 years – from 1949 to 1972, while prior to World War II, several government were in power less than 1 year. However, since 1945, there have been only seven changes of government.

Parties

Although Australia's political parties and their internal operations are somewhat unregulated in comparison to other developed countries, their internal party discipline is extremely tight. Through the Australian Electoral Commission and its state and territory equivalents, there is an official system of party registration and reporting of party activities.

Australia has four main political parties: the Australian Labor Party (ALP), a social democratic party founded by the Australian labor movement; the Liberal Party, a party of the center right; the National Party of Australia, a conservative party representing rural interests; and the Australian Greens, a left-wing and environmentalist party.

Australian Politics: Shaping Immigration

Over the last decade, leaders of the major Federal political parties have demonstrated support for high level immigration. Over the period of the Howard Government, from 1996 to 2007, there was an upward trend in the number of immigrants to Australia; the final immigration intake of the Howard era was the largest in Australia's history. The Rudd Labor Government, that has followed the Howard Government, has increased the quota again. In 2010, both major parties continued to support high immigration.

At times, immigration policy has been controversial, especially during the economic downturn of the early 1990s. It was then that the policy of mandatory detention of unauthorized immigration arrivals was established by the Australian Labor Party. The policy was designed to prevent the circumvention of the immigration process. However, the policy became increasingly controversial, particularly after a system of processing claims for asylum offshore was established. While the policy was popular with the electorate initially, it came under criticism from a range of religious, community, and political groups until, in 2005, the Liberal Government ended the practice of detention of children.

With projections of a population of 35 million by 2050, there is considerable debate as to how to organize infrastructure to accommodate accordingly. The current Federal Finance Minister Lindsay Tanner rejects arguments that Australia should lower immigration on environmental grounds. Still others remain vocal critics of high immigration, touting that population growth is unsustainable on a dry continent. The Australian Greens also favor keeping Australia's population low on environmental grounds.

Emigration

Emigration, persons leaving Australia, has increased steadily in recent years.

A total of 86,277 persons indicated that they left Australia permanently in 2009–2010. Statistics are based on information given by persons as they depart Australia. It is important to note that the figures provide a glimpse of the current emigration trends; however, they do not represent totally the emigration picture. For example, the numbers do not account for those who record they are leaving temporarily but who do not return, nor do they include those who indicate they are leaving permanently but who then return.

Reasons for Emigration

Usually the decision to leave Australia is based on a variety of complex reasons that are influenced frequently by personal, social, or familial concerns. Foreign-born emigrants may return to their country of birth because of feeling homesick or insecure; this is true especially of those who exit within a year or two of arrival. Older emigrants sometimes are spurred to depart after they retire, while widowhood or divorce will motivate others. Also, younger immigrants may return to their country of birth when needed by family in their former country.

For native-born persons, usually the decision to leave permanently is based on economic reasons, particularly employment. Some children born in Australia to former settlers return eventually with their parents to their country of origin. With the exception of New Zealanders, there is no significant relationship between unemployment rates and emigration; high unemployment rates do not necessarily lead to increased emigration.

Emigration by Native-Born

In terms of Australia's foreign-born during the postwar period, emigration levels have been associated with high or low numbers of permanent arrivals 2 years prior, as only a small number migrating to Australia chose to leave within 2 years. In recent years, however, more Australian-born residents have been emigrating, a trend likely to continue as a result of the internationalization of labor markets.

Emigration by Foreign-Born

Of the 86,277 persons who departed permanently in 2009–2010, 50.7% were born overseas, a slight increase on the 2008–2009 figure of 49.1%. The largest group of overseas-born emigrants in 2009–2010 was the New Zealand-born, with 8,744 people, comprising 10.1% of all emigrants. Permanent movements between Australia and New Zealand reflect differences between incomes and employment opportunities in the two countries. The United Kingdom–born were the second largest emigrant group, with 7,127 people (8.3%) leaving permanently. The majority of these groups returned to their country of birth, for example, New Zealand (81.3%), United States (66.9%), Singapore (63.5%), and Vietnam (59%).

Emigration by Australian-Born

In 2009–2010, 42,570 Australia-born persons departed permanently; this includes the Australia-born children of former settlers. The majority of Australia-born who are leaving are emigrating to the United Kingdom, the United States, or to New Zealand. In 2009–2010, 46.3% of Australian-born emigrants went to one of these three countries. The next most popular destinations were Singapore (9.1%), the United Arab Emirates (6.3%), and Hong Kong SAR (5.2%).

Effects of Emigration

The effects of emigration are varied, but in general they include: implications for private and public services planning; represent a potential loss of skills and experience due to *brain drain*; and represent a loss of social investment in education, training, and health services. By facilitating access to overseas markets, emigrants help establish links between Australia and its trading partners. Emigrants may send back substantial remittances and invest foreign currency in Australia, and those who return to Australia may bring back new skills and knowledge.

Health Care

Health care in Australia is provided by private and government institutions. Primary health care is the responsibility of the federal government, elements of which are overseen by individual states. The current system, known as Medicare, was instituted in 1984. Medicare coexists with a private health system and is funded partly by a 1.5% income tax levy, but mostly out of general revenue. An additional levy of 1% is imposed on high-income earners who do not hold private health insurance. As well as Medicare, there is a separate Pharmaceutical Benefits Scheme that subsidizes prescription medications. In 2007–2008, Australia spent 9.1% of its Gross Domestic Product on health care.

Health Statistics

The life expectancy of Australians in 1999–2001 was 79.7 years, 77.0 years for males and 82.4 year for females. In 2000, the infant mortality rate was 5.2 per 1,000, and the death rate was 6.7 deaths per year per 1,000 persons. Also in the year 2000, the neonatal infant mortality rate in Australia was 3.5 per 1,000 births, and the postneonatal infant mortality rate was 1.7 per 1,000.

Indigenous Health

Health and well-being statistics indicate Indigenous Australians are much less healthy than the rest of the Australian community. One leading indicator, infant mortality rates, including stillbirths and deaths in the first month of life, show Indigenous child mortality is two times as high as non-Indigenous child mortality. Another indicator is the 17-year disparity in average life expectancy between indigenous and other Australians.

Preventable Diseases

Tobacco use is the largest preventable cause of death and disease in Australia. Australia has one of the highest proportions of overweight citizens of all developed nations. Australian health statistics reflect that chronic disease such as heart disease, particularly strokes – reflective of a more affluent lifestyle – is a common cause of death. Australians are prone to skin cancer, affecting Queensland the most. Other health issues include compensation for victims of asbestos exposure–related disease, provision of adequate mental health services, and quality care for the elderly.

Autonomy

H. Russell Searight[1], Scott F. Perkins[2]
[1]Department of Psychology, Lake Superior State University, Sault Sainte Marie, MI, USA
[2]Department of Psychology, Western Kentucky University, Bowling Green, KY, USA

This entry focuses on autonomy in health care. A patient's right to make decisions about their health and medical care is a fundamental value in the United States. Patient autonomy has a long history in US case law and more recently, in medical ethics. Legal decisions have consistently upheld the doctrine that competent adults have the right to determine if they will receive medical care as well as to choose the type of care they will receive. Similarly, autonomy is a priority in principlism, the prevailing framework for bioethical decisions in the United States. Among the four core ethical principles, respect for autonomy (self-rule or self-governance) is often given priority ahead of beneficence (acting in the patient's best interests), nonmaleficence (doing no harm), and justice (treating people fairly). Veatch emphasizes that autonomy is a foundational principle from which other ethical values stem. Autonomous acts have three components: (1) intentionality, (2) understanding, and (3) freedom from external control.

Background of Autonomy

In making autonomous health care decisions, patient understanding is reflected in the requirement for patients to provide informed consent for medical procedures. To meet this standard, patients should receive the following: complete information about their medical condition, therapeutic options including the choice of no treatment, risks and benefits of treatment options, and the condition's prognosis with and without treatment. Historically, the ethical emphasis on patient autonomy is, in part, a reaction to a recognized power imbalance between health care professionals and patients. This chronological shift away from physician paternalism is illustrated by changes in practice about informing patients of a cancer diagnosis. In 1960, only about 10% of US oncologists reported regularly disclosing a cancer diagnosis to patients. By 1990, the pattern was reversed, with 90% of physicians reporting disclosure. This move away from paternalism was accelerated by legislative reaction to several publicized legal cases involving end-of-life care. In both the Quinlan and Cruzan cases, young women in persistent vegetative states were being maintained on life support or feeding tubes for years, to a large extent, because their wishes regarding treatment options had never been articulated. In the absence of a clearly communicated autonomous choice by the patient, legal authorities were unwilling to withdraw life-sustaining therapy.

Soon after the death of Karen Quinlan, the US Congress passed the Patient Self-Determination Act (PSDA), which included mechanisms to extend individual autonomy to situations in which patients could no longer convey choices. The PSDA required health care institutions receiving federal support to implement policies for educating patients about advance directives (AD). These methods, which would become active when patients could no longer articulate choices, included the living will (documents listing specific desired life-sustaining measures) and the durable power of attorney (a document naming someone, typically a family member, to make decisions on the patient's behalf). Both forms of ADs, in effect, extended patient autonomy to possible future situations where decision-making and/or communication were not possible.

Culture and Autonomy

Challenges to the priority of patient autonomy became apparent early in the PSDA's implementation with minority communities. Particularly among immigrants who were less acculturated to the United States, the requirements for informed consent to medical procedures and patient-centered decision-making were often disturbing. Blackhall and colleagues conducted several studies that provided empirical evidence of cultural differences regarding patient autonomy in making medical decisions. In their now landmark study, 200 adults from each of four ethnic groups were asked whether patients should be directly informed of a diagnosis of metastatic cancer. Among the ethnic groups, there were distinct differences: Korean-Americans were least likely (47%) along with Mexican Americans (65%) to state that patients should be directly informed of their diagnosis compared with European Americans (87%) and African-Americans (63%). When asked who should make decisions regarding life support, 28% of Korean- and 41% of Mexican-Americans indicated that the patients themselves should make these decisions while 60% of European Americans and 65% of African-Americans preferred patient-centered decision-making. Both Korean- and Mexican-Americans reported a preference for family members to make these choices. The results of this study and others suggest that autonomous choice for patients is not a universal value. In particular, cultures which are more collectivist, emphasizing one's relationships and pattern of obligation to others, are less likely to value individualism in making significant health care decisions.

Alternative Conceptions of Autonomy: Rationale

From the perspective of principlism, the de-emphasis on autonomy is associated with greater value for nonmaleficence and beneficence. Nondisclosure, a practice in many countries, is often guided by a desire to avoid emotional harm to the patient as well as to maintain their hope and optimism. In her study of contemporary Japanese health care, Long observed that disclosure of a diagnosis to patients was often at the physician's discretion. In the United States, there are multiple accounts of families of Asian background requesting that the physician not disclose a cancer diagnosis to a parent or grandparent.

Maintaining a positive outlook is also important both for the patient and their family. The patient's knowledge of a serious illness would have a detrimental effect on any hope for recovery and diminish emotional strength for fighting their illness. This theme has emerged in studies involving diverse populations ranging from Caresse and Rhodes' observations of the US Navajo to Searight and Gafford's interviews with Bosnian immigrants.

The norm of non-disclosure may create particular dilemmas when foreign language interpreters are necessary. Case reports indicate that some interpreters either do not interpret physicians' communication of diagnoses of conditions such as cancer. Instead, similar to physicians in many countries, interpreters may use euphemisms such as “tumor” or “mass.” This failure to disclose nearly always stems from concern for the patient’s psychological well-being.

Alternatives to Individual Decision-Making

Cross-culturally, this concern about patients’ emotional welfare is associated with alternative approaches to decision making. With a relative emphasis on beneficence and non-maleficence, family members receive information about the patient’s diagnosis and prognosis from the physician and make treatment choices, often without the patient’s direct input. Several studies have found a preference among Korean-American, Mexican-American, Japanese, and Bosnian patients for physicians to inform the family about a patient’s condition rather than the patient, themselves. With greater acculturation, Mexican-Americans were more likely to agree that patients should be directly informed of their conditions. However, even more acculturated Mexican-Americans continued to view decision-making as a family-centered process.

Among Asian cultures, illness is often considered a family event rather than an individual occurrence. Similarly, treatment decisions are made with a collective orientation which often results in extraordinary measures to maintain a parent’s life in the face of futility. However, interests in Asian families are often bidirectional – there is an equivalent concern about the impact of the elderly person’s death on the family. Among immigrant families attempting to navigate the financial, legal, and social demands of US culture, this mutual responsibility may be diluted with greater emphasis on the individual burden of caring for aging parents.

While multiple forces, such as consumerism and managed care, are contributing to reduced authority among American physicians, many cultures attribute a high degree of authority, respect, and trust to physicians. In these cultures, the physician’s judgment about end-of-life care supersedes that of both the patient and their family. Eastern European medicine has had a long tradition of physician-centered, paternalistic decision-making. In Russian medicine, the physician rather than the patient or patient’s family, often unilaterally determines a patient’s level of life support. Recent Bosnian immigrants to the United States viewed the physician as an expert who would independently make the best decisions on their behalf.

While many investigators and ethicists have concluded that personal autonomy is less significant in collectivist versus individualist cultures, this position is likely to be an oversimplification. Instead, Western concepts of autonomy are challenged by new definitions reflecting broader psychosocial boundaries of the individual. In cultures influenced by collectivism, personhood is defined very differently than in the West. Ethnographic studies of cultures from Italy to many African countries have concluded that individuals are inextricably defined by their participation in social groups. Personhood does not exist outside of these relationships.

While White Europeans’ well-differentiated individual selves are highlighted in cross-cultural studies, a closer examination qualifies this picture. An often cited reason for White Europeans’ desire for complete medical information, treatment options, and prognosis is to address practical issues. Planning is necessary to insure that moral responsibilities to spouses and children are met after one’s death.

Conclusions

Autonomy is an evolving concept in health care. In many countries, it is still a common practice for physicians to withhold diagnostic information from patients. Even in societies such as Japan where patient participants in clinical cancer trials are not informed of their condition or the reasons that they are receiving an experimental treatment, Western views of patient autonomy are beginning to be appreciated. Younger Japanese physicians, particularly those with training in the United States, are informing patients of their diagnosis and their right to decide their own treatment.

The distinction between the individual and the collective in autonomous decision-making may be overstated. From the perspective of principlism, Beauchamp and Childress suggest that patients relying on family-based decision-making are making an independent choice to have others decide for them. Similarly, while informed consent is generally seen as necessary for truly autonomous decisions, patients may intentionally waive their right in the interest of their emotional well-being and to sustain the energy to live as long as possible.

In the United States, health care providers have become increasingly aware of differing definitions of autonomy. Many physicians and nurses have begun asking patients if they would like to be informed of and make decisions about their condition. If patients prefer being uninformed, they should be asked if they have designated someone, such as a family member, to communicate with the health care provider on their behalf.

Autopsy

Diana Bulgaru Iliescu
Institute of Legal Medicine Iasi, Iasi, Romania

Autopsy (also known as necropsy or post mortem examination) is a surgical procedure that consists of the examination of tissues and organs of a corpse to determine the cause and the manner of death. Having in view the medical and judiciary purpose and relevance of this procedure, a distinction between pathology autopsy and forensic autopsy must be made. Pathology autopsy is directly conditioned by the deceased's consent expressed during her/his life or by her/his family's consent. Consent is not required for autopsy in some countries, but families may object to non-forensic autopsies. Survivors may also sue for damages based on their mental anguish for autopsies that were performed without legal approval or that were more extensive than authorized.

Forensic autopsy is carried out when legal authorities explicitly ask for it in the limited situations indicated by the criminal law (violent death, death of unknown causes, suspicious/sudden death). Forensic autopsy is undoubtedly a social necessity in helping to resolve juridical/police investigations. In this case, the wish of the deceased person to not be submitted to an autopsy (a wish that was expressed while the person was still alive) and the family's similar wish cannot prevail in the face of legal provisions that protect the general community's interests (medical or judiciary).

Autopsy has to be clearly differentiated from the anatomic dissection of a human corpse. The invasion of the corpse during autopsy is partial and temporary; at the conclusion of this procedure, the corpse is returned to the family in order to undergo traditional religious and funeral services. The purpose of the autopsy is to determine the cause and manner of death. The anatomic dissection consists of the in-depth exploration of the tissues and organs for teaching or research purposes. The corpse that is submitted to an anatomic dissection does not usually undergo traditional funeral services.

During the autopsy the corpse is obviously subjected to invasive procedures. The necessity to perform the autopsy may conflict with both the right to physical integrity of the deceased person and the respect owed to the human corpse. Nevertheless, performing an autopsy on a human corpse under strictly controlled conditions may be accepted and even obligatory from a moral, ethical, and legal point of view in certain circumstances (such as those indicated by the criminal law).

Traditions, beliefs, and practices surrounding death may conflict with anatomic dissection and postmortem examination. Persons from more Westernized or diverse environments who have less cohesive connections with traditions, religion, and beliefs may show a greater acceptance of autopsy and dissection. However, non-Westernized, less diverse cultural groups may have more unified traditions, beliefs, and practices surrounding death, and they more frequently have religious objections related to autopsy and dissection.

Although cultural or religious beliefs are often cited as reasons for opposition to autopsy, most religions and cultures accept autopsy as a medical procedure either based on the individuals' beliefs or special circumstances. Certain religions prohibit autopsy outright (e.g., Islam and Judaism) in that bodily intrusion violates beliefs about the sanctity of keeping the human body whole; however, religious doctrine does not in itself strictly forbid autopsy. Instead, it is a matter of interpretation of the doctrines which have changed over time.

For example, Jewish law, in general, prohibits cutting or dissecting the body and considers the autopsy an act of desecration, except under exceptional circumstances. It also requires that the body be buried in consecrated ground and that burial take place as soon as possible after death. Islamic tradition requires burial before sunset on the day of death. It is obvious that this requirement cannot be respected when autopsy is performed.

Catholics recognize the value of the autopsy and generally agree with its use for determination of the cause of death and medical education. In the Catholic view the autopsy may even be considered an act of charity.

Worldwide changes in legal systems, particularly in the European countries, often permit the free movement of persons; as a consequence, international migration increased. Apart from legal immigrants, there are also a large number of illegal immigrants who do not hold any identity documents.

Deceased illegal immigrants may become the subject of forensic autopsy, mainly because they cannot be identified (because they do not hold identity documents). Many immigrants do not have access to medical services and that is why it is impossible to have any medical evidence of their health status; therefore when such a person dies, the cause of death is often unknown, and a forensic autopsy is required in order to clarify this aspect.

When an individual dies in a foreign country, the autopsy may be requested or required upon the body's return to her/his home country (even if it has already been autopsied) to clarify insurance claims or to investigate criminal activity.

Back Pain

Sebastian Straube
Department of Occupational and Social Medicine,
University Medical Center Göttingen, Göttingen,
Germany

Back pain is one of the most frequent medical problems; 80–90% of adults experience back pain at some time in their lives. The low back is most commonly affected. Back pain is also one of the most common reasons why people consult their doctor or are absent from work. Therefore the economic impact of lost productivity due to back pain is substantial, as is the cost of rehabilitation and pensions for back pain.

A number of underlying diseases can give rise to back pain including problems with muscles, bones, intervertebral discs, and nerves, but often no specific cause for the pain can be identified. One differentiates acute back pain (usually lasting for a few days to a few weeks) from chronic back pain (lasting for 3 months or more) by the duration of the problem. Of back pain with an acute onset, about 90% is reversible within a few days to a couple of months. The remainder becomes chronic. The following have been described as risk factors for progression to a chronic condition: problems with integration into society, dissatisfaction with work, unemployment, low educational attainment, depression, and physical strain.

While back pain as a symptom is very common in native and immigrant populations, it may be more common among certain immigrants compared with nonmigrants of the same ethnicity. For example, it has been reported that low back pain is more common among Pakistanis living in England compared with Pakistanis in Pakistan. Furthermore, certain groups of immigrants may differ from native populations of their adopted country with regard to the susceptibility to specific diseases that can cause back pain because of a different ethnic background. For example, elderly women of Asian ethnicity (like non-Hispanic Whites) are at high risk of developing osteoporosis, a disease that can lead to back pain after vertebral fracture; African American and Hispanic women are at lower risk. Psychosocial causes of back pain can also differ according to socioeconomic status or ethnicity and therefore differently affect immigrants and native populations. For example, a recent study found that perceived discrimination was a strong predictor of back pain in African Americans but was minimally related or unrelated to back pain in Whites.

Jobs that involve heavy lifting, bending, or twisting are associated with occupational back injury. Such manual occupations are common among immigrants, especially those who are unskilled or whose qualifications are not recognized in their adopted country.

Approaches to back pain management may also differ between native populations and immigrants, for example, with regard to the use of Western medicine versus alternative and traditional remedies. Access to medical care and social services is vital for those with chronic back pain but can be difficult for illegal immigrants or those with language difficulties.

Bangladesh

Sharmeela Saha
Department of Internal Medicine, University Hospitals Case Medical Center, Cleveland, OH, USA

Country Characteristics

Bangladesh spans approximately 140,000 km^2 and is home to approximately 150 million people. The country is bordered by India on the west, north, and east; by the Bay of Bengal on the south; and by Myanmar to the southeast. It was part of India until 1947, when it was designated "East Pakistan," finally gaining independence in 1971.

Bangladesh is an Islamic nation and has one of the largest Muslim populations in the world. Approximately 80% of its inhabitants are Muslim, while Hindus account for about 15% of the country's residents. Hindus are concentrated in certain areas, such as Khulna and Barisal. In Bangladesh, the work week is Sunday through Thursday. Friday is considered the holy day in Islam, during which there are large morning prayers at mosques.

Hurricanes, or cyclones, are common in Bangladesh, and they lead frequently to flooding. From May to September, there is heavy rainfall, while during the winter, the country endures a dry season. With its low elevation, Bangladesh is vulnerable to flooding. Due to heavy rainfall and the prevalence of mosquitoes, malaria and dengue are widespread. Three large rivers run through Bangladesh – Ganga, Jamuna, and Meghna. The Sundarbans in the southwest of the country is the world's largest mangrove forest. Cox's Bazaar in southeastern Bangladesh, spanning 75 miles, is the world's longest beach.

The capital, Dhaka, is the country's largest city, followed by Chittagong, located in the southeast. Three-fourths of Bangladeshis live in a rural setting. In urban settings like Dhaka, wealthier people live in tall apartment buildings, while in the villages people live in simple homes mostly made from dried mud with roofs of thatch or metal sheets. Kitchens and toilets in the villages are in separate structures built away from the primary house.

The soil in Bangladesh is quite fertile; however, due to flooding and a high population density, there is comparatively little land for farming and grazing. Rice is the main crop and the main staple of the diet in Bangladesh. Other significant crops are tea, tobacco, and jute. Jute is a fiber that can be used to make ropes or mats; its export is central to the economy. Two-thirds of the country's workforce is involved in agriculture. About one million of the population are fishermen, and many more people fish occasionally to supplement their diet. Chittagong is the main seaport. Also, with a large portion of exports going to the USA, manufacturing garments is a significant part of Bangladesh's industry.

The national currency is the taka, and about 70 taka is equivalent to 1 US dollar. The approximate average yearly income in Bangladesh is about 430 US dollars. Roughly 45% of Bangladeshis are below the poverty line, while 20% of the workforce is comprised of children.

The structure of Bangladesh's government is a parliamentary democracy consisting of 300 members. The National Parliament, called Jatiya Sangsad, is elected by citizens of districts. Forty-five additional seats are reserved for women, and these positions can be obtained by traditional election or by appointment from other Parliament members. The president, elected by Jatiya Sangsad, serves a 5 year term, must be at least 35 years old, and cannot be a Member of Parliament. The president appoints the prime minister from majority party members of Parliament to serve a term up to 5 years. Any other cabinet members are appointed by the prime minister, and the prime minister is responsible primarily for creating and executing public policy.

The country is composed of six administrative areas called divisions, including: Rajshah, Dhaka, Kulna, Sylhet, Barisal, and Chittagong, which are further divided into districts. Bangladeshis can vote at age 18. Awami League, Bangladesh National Party, Jamaat-i-Islam, Jatiya Party, Isla Oikya Jote, and The Bangladesh Communist Party are some of the political parties.

The official language is Bengali, also known as Bangla, derived from the Indo-Aryan linguistic family. Bangla script is composed of 12 vowels and 52 consonants. The food and clothing is similar to neighboring India.

Men in the urban areas wear shirts and pants, while in the rural regions they may wear the traditional lungi, which is a type of sarong. Generally, women wear saris, a long piece of fabric that can be draped in a variety of ways.

The water lily is the national flower. The national flag is a red circle, symbolizing bloodshed during the Liberation War, as well as the "rising sun of a new country" against a green background – referring to Islam and the country's rich plant life. Nobel laureate Rabindranath Tagore, from West Bengal, India, wrote the country's national anthem. The endangered species, the Bengal Tiger, lives in the Sundarbans; however, they are not seen frequently. Popular sports include cricket, hockey, and soccer.

Only about 20% of the population finishes high school. Elementary school is free and compulsory, although not strictly enforced. To encourage women to continue education and not enter into child marriage, secondary school is free for women from rural villages. About 40% of the total population is literate, with about 50% of men and 30% of women able to read and write. The largest university in Bangladesh is the University of Dhaka.

Less than 40% of Bangladeshis have access to a radio, and only 10% have televisions. Music and dance include classical and folk styles; both have roots in Indian culture. The classical dances include bharatnatyam and kathak, while the Bangladeshi folk dances include manipuri and dhali. Terra-cotta pottery is a popular folk-art form. Eid-Ul-Fitr is the largest religious festival in Bangladesh. Secular holidays include Pawhela Boishakh, or Bengali New Year, in mid April and International Mother Language Day on February 21st. Secular holidays often are celebrated with music and dance.

Typically, Bangladeshis eat three meals a day. They may eat flatbread in the morning, but will eat rice for lunch and dinner if financially feasible. Typically they eat with their hands, using the right hand specifically. It is important to understand cultural practices to facilitate patient care, as many immigrants maintain traditions similar to their home countries.

Immigrant Health

A major health problem in Bangladesh is diabetes. For many reasons, including patients not seeking primary care, often diabetes is underdiagnosed. It has been documented that 20% of South Asian immigrants to England suffer from diabetes. Furthermore, South Asian patients have a three- to fourfold higher mortality from cardiovascular disease than other diabetics. It is not known why Bangladeshis suffer more than other populations from high insulin levels and impaired glucose tolerance, but it is postulated that this may have been an evolutionary process to cope with famine and survive in periods of low food consumption.

Bangladeshi immigrants have a high incidence of cardiovascular disease, in addition to insulin resistance; a major risk factor is diabetes. Other risk factors seen in the South Asian population include low high-density lipoprotein cholesterol and high triglycerides. Central obesity has been associated with high levels of insulin and coronary artery disease. A high waist to hip ratio, an indicator of central obesity, has been cited as a strong independent predictor of coronary artery disease. Some nontraditional risk factors in Bangladeshis include arsenic contamination, low physical activity, and ghee (clarified butter) consumption. A high proportion of Bangladeshi immigrants are smokers, and smoking is a known risk factor for coronary artery disease. Smoking cessation is key to cardiovascular health.

Malnutrition is a common finding in Bangladeshi children. The immigrant population in the London borough of Tower Hamlets has been studied, and prevalent maladies include rickets, iron deficiency anemia, difficulty weaning from a milk predominant diet, and gastroenteritis. Immigrants' diets tend to be high in carbohydrates, and generally children consume adequate Vitamin C, calcium, and protein. Many children continue a milk diet even into their second and third years of life. Most of the children with rickets had prolonged breastfeeding without vitamin supplementation. It is essential for children to have adequate vitamins and fortified foods to supplement their diets.

Vaccinations are crucial for improving children's morbidity and mortality. Historically, poliomyelitis has been a problem in Bangladesh – the last reported case was in August 2000. Polio has been controlled successfully with extensive public health programs supported by the World Health Organization. Often other routine vaccinations are missed in Bangladesh and in the immigrant population. Barriers are numerous, but it is essential to emphasize adherence to vaccination schedules. It has been observed that adherence to immunization schedules is higher among children of mothers who have higher incomes and education.

Barriers to healthcare include difficulties with language, transportation, poverty, and stereotypes. Some families may be conservative and not allow women to leave the home alone, and situations have been described in which patients cannot access care because they have no chaperone to accompany them to an appointment. Attending primary care visits can be challenging. Immigrant families may be large, and there can be many different obligations including health care visits for older family members or religious activities that may prevent routine care. Other well-studied barriers common worldwide include poverty and ignorance.

Barriers to Care

Mihaela-Catalina Vicol
Department of Bioethics, University of Medicine and Pharmacy “Gr. T. Popa”, Iasi, Romania

In seeking health care, immigrants face different kinds of barriers that could affect their willingness to seek care from a doctor or a hospital. Immigrants, often frightened or skeptical of health care and often with no health benefits, may only seek care in emergencies when treatment options may be limited or complications more severe. Understanding barriers to care may reveal strategies to encourage preventive and routine care in this vulnerable group. These barriers are summarized into several categories:

1. Economic and financial barriers
2. Political barriers
3. Legal status barriers
4. Language barriers
5. Cultural and/or religious barriers
6. Social perception barriers
7. Health status

The context of accessing the healthcare system by the immigrants will be illuminated as, each type of these barriers are identified and discussed.

Economic and Financial Barriers

Immigrants, important members of society, contribute to the cultural diversity and the economy of every country. Despite these contributions they receive fewer health services than native-born citizens. The first plausible explanation is the one related to the insurance status. Romania, a country that has a public health insurance system, requires mandatory health insurance contributions paid by legally employed people. In addition, a part of it is paid by the employer, in order that the employee is insured. Therefore, immigrants that work legally and whose employer pays part of the contribution have health-insured status. Direct payments by citizens in Romania will also provide health insurance. Thus, only immigrants that are legally employed or pay themselves are insured in this public healthcare system. If one of the family members is legally employed and health insured, the children are also considered insured. Another member of the family has to pay only a small amount of money (coinsured) to be insured. This public system offers health insurance that benefits the whole family, getting free access to the healthcare system. In other countries, like the USA, the immigrants have to pay for health insurance. Often they cannot afford health insurance or work for an employer who does not offer health insurance. This is why only legally employed immigrants might be considered as health insured.

Lack of health insurance is a major barrier that limits the access to health care of the immigrants. According to the 2006 Report from the New York City, Department of Health and Mental Hygiene, foreign-born adults (under 65 years) are more than twice as likely to be uninsured (22%) than the US-born citizens (9%). The lowest rate of uninsured immigrants in New York City has been attributed to immigrants coming from Israel (2%).

The financial situation of the immigrants, most of them having a very low income, poses a further barrier to health care. The study called "Immigrant in Romania: Perspectives and Risks" (2008) done by the Soros Foundation draws attention to the fact that foreign immigrants in Romania are an easy target for some employers willing to make a good profit with a cheap workforce. Immigrants may have cultural and language differences, lack union representation, and lack information regarding immigrants' rights, making them vulnerable to unscrupulous employers. Usually, immigrants are paid less for the same job than are native-born citizens, though the income is higher than in their native country. Thus, immigrants often have poor work environments and poor wages, and experience financial constraints in accessing services.

Disparities confronting immigrants appear similar to those faced by low-income populations. Yet, still there are differences between immigrants and low-income groups. For example, a study in the USA shows that in 2001 low-income noncitizens were twice as likely to be uninsured than low-income US citizens, more precisely, from 11 million low-income noncitizens, 60% were uninsured, compared to 28% low-income citizens. These facts point out that besides the economic situation and the insurance status, there are other barriers to be considered when analyzing immigrant's access to health care.

Political Barriers

In the USA, the 1996 welfare-reform legislation has restricted immigrants' access to the public-funded health programs, Medicaid, for example. Since 1996, Medicaid has been restricted only to legal immigrants that must wait for 5 years after obtaining a "green card" for permanent residency, in order to apply for this program. Further, it shifted most of the healthcare responsibility to state and local governments that often have fiscal constraints. In addition, another legal provision in 2005 stipulated that every citizen applying for or renewing Medicaid insurance had to provide proof of identity and of US citizenship. These eligibility and documentation requirements pose a barrier for many immigrants in getting needed health care.

In Romania, the policy for access to the healthcare system is directly related to the insured/noninsured status. Only the legal immigrant also employed legally and his/her children may have free to the healthcare system. This policy, the same as the one for Romania's native-born citizens, discourages work on the black market, and attempts to protect immigrants' rights as well as native-born individuals. Most of the countries have policies regarding accessing the healthcare system in emergency cases. In Romania, as well as in the USA, in these situations the access is free, no matter the insured/noninsured status. Although free, immigrants may overutilize emergency care rather than preventive care.

Legal Status Barriers

Laws and regulations affecting immigrants pose substantial barriers to accessing health care. Researchers underscore that immigrants coming from countries where medical practitioners report patients with diseases related to possible illegal activities such as infections resulting from illegal abortions, drug abuse, sexually transmitted diseases acquired through prostitution or extramarital sexual activity to law authorities may be particularly fearful of seeking health care. Illegal immigrants may also be fearful that visiting a hospital could draw the attention of immigration officers and result in deportation. The number of undocumented immigrants is significant and continues to grow emphasizing the importance of the issue. For example, in the USA, in 1970, less than 5% of the immigrants were undocumented, but in 2002, almost 50% among immigrants for less than 5 years, were undocumented. This legal barrier in addition to uninsured status and low-income status may explain why immigrants access the healthcare system mostly in emergency situations.

Language Barriers

Language barriers have two important parts. First, most immigrants face language difficulties. In addition, the level of education of the immigrants is sometimes lower than high-school level. Language barriers impact communication when the patient is not able to understand the medical information and/or the translator may not be available or qualified. Using a translator or interpreter seems logical, and convenient, yet may not be the best solution. For example, some terms or phrases might not be so easily translatable in other languages or are just not translatable (do not have a good equivalent), leading to misinterpretations and confusion. On the other hand, hospitals and clinics are not able to provide translators for every language and the role of a translator might be played by a family member, a friend, a colleague. In this situation, these persons may translate the information with their own opinions and understandings that could contribute to inaccuracies or confusion.

The second aspect of the language barriers is that healthcare providers do not know or comprehend every patient's speaking language, so cannot communicate with the patient or in this manner or check the accuracy of translation.

Language barriers impair the patient–physician relationship that must be based on effective communication and understanding. Good communication influences the patient's autonomy and future willingness to access the healthcare system. For example, a group of Mexican Americans born outside of the USA accessed the mental health services at a rate that was two-fifths of the Mexican Americans born in the USA. Language barriers were suggested as the explanation since none of the mental healthcare providers spoke Spanish.

Cultural and/or Religious Barriers

Cultural and/or religious barriers may conflict with the recommendations of traditional medicine. Beliefs regarding pregnancy such as age at marriage and conception, prescription of herbs or foods encountered in different cultures and religions, illustrate how cultural values may present different perspectives about how to access care and engage in treatment approaches. For example, Southeast Asian immigrants in the USA have been found to have the lowest rate of cervical cancer screening (Papanicolau test) among all racial or ethnic groups. The unacceptability of blood transfusion among Jehovah's Witnesses, not even in emergency cases when it is a matter of life and death, is another example of the influence of cultural and religious values on health care. Circumcision of the newborn after birth, a ritual that may bring the significance of the "social birth," is another example that may conflict with medical practice. In some cultures and traditions, menstruation is seen as a sign of impurity and menstruating women are segregated from their family, partner, or from their religious community.

Also, in some cultures, the autonomy of the patient is not valued in the same way as in Western cultures. For example, in some Indian groups, only the family must be informed about patient's health and they have to decide what is best for their relative; the patient is not informed.

These examples underscore the fact that cultural and/or religious values are strong determinants of "health." In case of the immigrants, these values might come into conflict with medical values, influencing the desire to seek health care and comply with medical guidance.

Social Perception Barriers

Anti-immigrant sentiment is well documented. Immigrants who obtain specific benefits may be perceived as getting these at the expense of natives and thus provoke feelings of unfairness. In addition, the fact that the immigrants work more cheaply than the native-born citizens and cause competition for jobs, may lead to even a stronger anti-immigrant attitude.

Health Status

Studies suggest the US foreign-born population appears to be healthier than the population born outside the USA, when comparing obesity, tobacco use, hypertension, and some forms of cancer. Immigrants are also younger than US-born citizens. Age and health status of immigrants are two reasons that may explain why immigrants defer and avoid going to a doctor and only seek treatment when injured or are acutely ill. They may not feel like they need care if they are perceived as young and healthy.

These barriers play an important role in explaining why immigrants avoid seeking medical care, fear healthcare providers, or are anxious at learning and communicating in an unfamiliar culture. Healthcare seeking, when it occurs, is largely in emergency circumstances. Immigrants generally do not seek preventive primary care services that could maintain their health status. Most of the money spent for immigrants' health care, therefore, is focused on care of acute diseases or emergencies rather than a system of care that addresses the barriers to health care for this population.

Battered Spouse

Diana Bulgaru Iliescu
Institute of Legal Medicine Iasi, Iasi, Romania

The term "battered spouse" has most frequently been used to refer to the beating of a wife by her husband. Later, the use of the term was expanded to include nonmarital heterosexual partners. There has been increasing recognition that battering also occurs between same-sex partners who are cohabiting or dating. More recently, the promulgation of laws in various jurisdictions, including Spain, Canada, Mexico City, various states in the United States, and others, to permit marriage between same-sex partners has called into question current understandings of the dynamic underlying spousal violence.

Understandings of "Battered Spouse" in Heterosexual Marriages

The problem of violence against women by their husbands began to receive increased attention during the mid-twentieth century, as it became increasingly clear that wives were receiving less protection than strangers might for the same injuries, and that husbands were being treated more leniently by legal systems than strangers committing the same degree of violence. There has also been increased recognition of the negative consequences that can result from such violence, at both the individual and family levels.

The historical premises for the patriarchal organization of family and society date back centuries, to times when women were deemed to be the exclusive "property" of men. The passage from polygamy to monogamy has greatly contributed to women's subordination to men, since polygamous relationships often permit privileges to men whereas women are often required to maintain absolute fidelity. The subordination of women within their own marriages was often reinforced through institutional sexism.

It has been estimated that battering occurs in approximately one-quarter of all marriages, although it is much lower or much higher within specific cultures and groups. Why individuals batter their spouses and why the battered spouses remain in the relationship are questions that have been the focus of extensive study. Each case of marital violence occurs under particular conditions and has its specific causes, but there is a series of common factors that define the existence and the tendencies of this phenomenon. In the context of heterosexual marriages, these factors include the social attitudes and stereotypes that support and reinforce the "dominating" role of men and the "subordinate" role of women, gender inequality, the patriarchal organization of family and society, and women's economic dependence on their marital partner. External pressures, such as rapid social changes and an increased societal emphasis on sexuality may also contribute to pressures felt within the family. It is important to note, however, that there is not a linear correlation between the status of women in societies and the rates of wife abuse in those societies.

In many cases, violence against spouses is not just an isolated incident, it is repetitive and it occurs periodically in a specific three-step way: tension, aggression, and detente. During the tension stage the abuser humiliates the victim, using different techniques of intimidation. The victim tries to calm the aggressor because she feels helpless. In the next stage the situation becomes explosive, and therefore violent acts occur. Finally, the aggressor is remorseful and makes overtures to repair the relationship . . . until the cycle begins anew.

In order to continue their existence, abused women may use various strategies, such as trying to conceal or minimize the problem in an attempt to increase safety for themselves and their children. Some of them stand firm, others run away or try to keep peace and quiet in the family, being obedient to their husbands and their requests. Very often, what is seen from the outside as being passive can be just a survival strategy that women have adopted in order to protect their children from the violence.

Many battered spouses prefer not to divulge their history of abuse. In some cases, the attitude of society to violence can produce an acute feeling of embarrassment and even of guilt on the part of the victim for having been aggressed. The general tolerant attitude of society toward violence, manifested in various forms, can lead women to adopt an attitude of resignation and accept pain and humiliation as a "norm of life."

Most cases of immigrant women who are abused are not reported (occult family violence). Many women are abused in the course of a longer period of time and at the same time they are trapped in hopeless situations that they cannot immediately escape. These cases may include either relationships in which the victims are financially dependent, or in which they fear that they could have their children taken away from them or that they could discredit their families or could be ostracized by the other members of their family. Women's desire to become economically independent and to escape the violence that they suffer in their homes may prompt their migration.

In many cases, women do not trust the judicial system because of the prevailing societal attitudes toward women and the trauma associated with police and judicial procedures. This distrust may be heightened among immigrant women, who may fear deportation or whose husbands have threatened them with deportation if they should complain about their abuse.

There are several markers that may indicate to a health care provider that a woman is being abused by her partner, such as: chronic pains that indicate a poor state of health; frequent visits to doctors; sleep disorders (insomnia; violent nightmares); severe agitation, anxiety, permanent state of irritation; mental confusion, incapacity to decide, lack of concentration; use of tranquilizers and/or alcohol consumption; suicidal ideation or suicide attempts; low level of self-respect; emotional dependence on the partner; assuming responsibility for the partner's behavior; and inflexible opinions regarding the role of men and women.

Detection of abuse of immigrant women may be more difficult to identify due to their geographic and/or linguistic isolation. Isolation from family members and their usual social network also inhibits the discovery of and intervention against the violence.

Men may be the victims of partner abuse within heterosexual relationships. They may be even less likely to report the abuse than women, out of a belief that they should "take it like a man" or shame and embarrassment that they are being beaten by a woman. As with battering in same-sex relationships, the battering of men by their female partners challenges the theory that battering is necessarily associated with a patriarchal societal structure and the subordination of women.

Same-Sex Battered Spouse

Significantly less research has been conducted to examine the underlying causes and dynamics of battering within same-sex partner relationships. Current research suggests that the prevalence of battering between male partners may be even greater than that among heterosexual couples. Younger age and HIV seropositivity seem to place men at greater risk of being battered by their male partners.

A major issue for men is their lack of awareness of their situations; men may not see themselves as victims or as suffering from trauma specifically because they are men. They may be less likely than women to report their abuse due to multiple factors, including the perception that they are supposed to be strong, the lack of structural supports such as shelters for battered men, and condemnation of homosexuality by segments of the society in which they live. Some men may have internalized homophobia and feel that they deserve to be battered because they are gay.

Both men and women involved in same-sex partner relationships may also not perceive a distinction between self-defense and battering. They may see themselves as the perpetrator even if the violence that they committed was in response to an attack by their partner. This perception may also reduce the likelihood that they will seek help.

Like immigrant women involved in heterosexual relationships, immigrant men and women involved in same-sex relationships may be reluctant to report their abuse and to seek help. There may be cultural and linguistic barriers that prevent them from doing so. Additionally, in countries that do not permit same-sex marriage, individuals who are undocumented may fear deportation to an even greater degree than their heterosexual counterparts because there is no possibility of regularizing their immigration status through marriage even if they were to become involved in a healthy relationship.

Behavioral Health

Hiren C. Bhakta
Department of Psychiatry, Case Western Reserve
University School of Medicine, Cleveland, OH, USA

Scenario 1

An immigrant family was seen by a family doctor to establish themselves as new patients in his practice. The man was from Hong Kong and had been in the USA for 20 years working as a chef. The woman had emigrated from El Salvador 9 years previously, leaving behind her mother. She was hard-pressed to communicate the details of her prenatal care and experience with an obstetrician with the male doctor. She was uncomfortable having a male doctor perform the pelvic exam; she also seemed apprehensive about having a genital examination in the absence of any symptoms. The doctor explained that there are some diseases that begin without symptoms but they can be detected at an early stage with certain tests. She agreed to see a female doctor, but did not indicate whether she would agree to a PAP smear.

Both the husband and the wife spoke minimal English. Nevertheless, the doctor learned that they had been using the Emergency Department for their healthcare needs. They brought documentation showing that both had been treated for tuberculosis. It seemed that their child prompted them to get a family physician. Although they had been in the USA for an extended period of time, the couple had not seen any reason to go to a family doctor. They had dealt with any illness at home and had sought care at a hospital when they felt other care was necessary. Reliance on a family physician instead of the emergency department permitted them to obtain medical attention while avoiding the extreme costs and burden of the emergency room.

This family was amenable to seeking care through the established medical system. Some immigrants are less willing to do so. A failure to do so may, in some circumstances, compromise their health.

Scenario 2

In 2007, a tragedy struck the campus of Virginia Tech University. Seung-Hui Cho, a 23-year-old Korean immigrant, killed 32 people, wounded many others, and committed suicide. The story is a horrific illustration of the importance of behavioral health in immigrants. Seung-Hui was diagnosed with selective mutism and severe anxiety disorder at age 8 when his family moved to the USA. He underwent therapy and medication during his middle school years. However, his support system was removed when he began college. After the shooting, reports came out that his family had been reaching out to local churches near his college to address concerns with what was referred to as his "demonic power," as one pastor put it. Such reliance on the church and spiritual leaders is common among many immigrant groups. Some immigrants may be reluctant to seek help at all and may attribute mental illness to religious or spiritual roots.

These cases illustrate the importance of behavioral health concepts for health professionals who provide care to immigrants. This entry provides a basic discussion of behavioral health and an introduction to immigrant behavioral health.

Concepts in Immigrant Behavioral Health

Immigrant behavioral health includes many concepts and principles from psychology. They are listed here as a reference for terms used later in the entry.

Acclimatization or *acclimation* is the process of adapting to a new environment. For behavioral psychologists, this term describes a set of behavioral changes that an individual makes to survive in an environment in which living conditions have shifted. This term originated in physiology, but now has application in mental health as well.

Acculturation is a type of acclimation that describes the psychological experience during adaptation to a new culture. Acculturation is paired with another term, enculturation; the idea is multidimensional in that there is the retention of the native culture and also the adoption of the foreign culture or the culture of the new environment. A key point about acculturation/enculturation is that there are degrees of shift away from the culture of origin and degrees of adaptation to the new culture. Thus, an individual may retain features from the culture of origin and combine them with or add to them features of their new culture. Furthermore, this process occurs in multiple domains, such that the culture, practices and norms of business, religion and social relations each may have their own processes of acculturation/enculturation.

Acculturation has been studied extensively and has become a highly relevant topic in the past decade. As an example, the ARSMA – II (Acculturation Rating Scale for Mexican Americans – II) is a psychometric test that was designed to measure the degree of acculturation in an individual. The results of this test have been correlated with measurable behaviors and outcomes such as stress level, pregnancy anxiety, and birth weight.

Many psychologists and psychiatrists in developed nations have examined the barriers that may prevent immigrants from seeking mental health treatment.

Language is a common barrier for any immigrant in any part of the world. Even when the provider and the patient have knowledge of a common language, such as English or Spanish, there are colloquial terms and idioms as well as variant dialects that can make communication challenging.

It is important to recognize the delicate balance a care provider must achieve to adequately diagnose and treat without stigmatizing and alienating an already vulnerable population. Poverty and lack of health insurance are also challenges that are known to impede the receipt of medical services. These factors are often compounded by the inflexibility of a patient's work hours, and the lack of evening office hours in a private practice or clinic, thereby hindering the patient's ability to obtain care.

There may also be vast differences in attitudes toward mental health between an individual's country of origin and his or her country of immigration. Generally, developed countries emphasize mental health more than undeveloped countries; in the USA, for example, this is evident in the media advertisements for antidepressants. This increases the population's awareness of mental illness and, consequently, individuals may be more likely to attribute symptoms to a mental illness. For many immigrants, acknowledgement of a mental illness is not an option due to stigmatization, embarrassment, or shame. Many immigrants are reluctant to share feelings, especially when vocalizing complaints is considered a sign of weakness in their native culture. Some immigrants who are ultimately diagnosed with a psychiatric illness may have initially presented with physical symptoms, such as back pain or digestive abnormalities. These are called somatic symptoms of mental diseases.

Individuals may also be concerned about confidentiality. Immigrants may be apprehensive about sharing personal information with a practitioner because they are not certain how that information will be used. It is important that medical professionals caring for immigrant patients assure the patients that their personal and medical information is kept private.

There is a marked difference between those immigrants who choose to immigrate to new countries and those who are forced out of their countries. Often the circumstances that force people to flee their countries, such as violence and persecution, can lead to severe trauma. Therefore it is important to determine if the immigrant patient has had such experiences. Many individuals who have undergone such experiences will have entered their new country as refugees. Their experiences may have led to the development of severe phobias or posttraumatic stress disorder. These conditions require the attention of mental health professional.

There are additional factors to consider when managing the mental health issues of child and adolescent immigrants. As illustrated by the case of Cho, a support structure is critical for mental stability in early life. Furthermore, a culturally sensitive and responsive education system, focused activities, or targeted guidance can provide a boost to help a child or adolescent better adjust to his or her new environment. Common ailments of immigrant children include anxiety issues and stress management problems. Because the school setting is a key intervention point, efforts are being made in countries such as the USA to include programs in the education system that are directed toward promoting community and acceptance in diversely populated schools.

Culture-Specific Conditions

The American Psychiatric Association publishes the *Diagnostic and Statistical Manual of Mental Disorders IV Text Revision* (*DSM-IV-TR*) to guide mental health providers in making accurate diagnoses of mental illnesses. Appendix I of the *DSM-IV-TR* provides some guidelines to help clinicians to become culturally sensitive, and may be useful for professionals caring for a patient that has recently immigrated. The first section describes the five basic steps for approaching the client: to identify the culture of the individual, to become aware of cultural explanations of the individual's illness, to identify cultural factors that are relevant to the individual's psychosocial environment and levels of functioning, to understand cultural factors relating to the clinician–patient relationship, and to fuse culture with the diagnosis and treatment. The second portion of the appendix is a glossary that provides information about 26 culture-specific syndromes. This is an important resource in trying to understand an immigrant's perspective on a mental illness.

Bereavement

Susan Hatters Friedman
Departments of Psychiatry and Pediatrics,
Case Western Reserve University School of Medicine,
Cleveland, OH, USA

Bereavement is generally defined as the feelings of sorrow over the death or loss of a loved one. Bereavement is a normal adaptive process, which is expected and occurs cross-culturally. One works to assimilate and move forward in life, rather than to "get over" the loss. Hand-in-hand with the sorrowful feelings, people may experience symptoms such as decreased appetite, weight loss, and insomnia. Various cultures have their own rituals which are part of the process of healing and moving forward. It behooves a clinician to be aware of these important cultural customs, as many may look to their providers in times of bereavement.

Normal grief and bereavement needs to be considered separately from pathological bereavement. Certainly those who are bereaved feel intensely sad, may experience other strong emotions such as guilt about the person they lost, and may feel like withdrawing from others. Periods of sadness are part of the human condition. However, it is important that normal bereavement and grief be considered separately from depression.

Bereavement and grief may lead to a major depressive episode; however, they more often resolve over time as the person comes to term with the loss and their feelings. Those who are bereaved and who are not clinically depressed are capable of happy feelings, while those with major depression may be depressed for the vast majority of the time. Also those with depression have a marked functional impairment, or are preoccupied with their own suicidal thoughts, or feelings of worthlessness.

A recent study compared depressive episodes related to bereavement with depressive episodes caused by other stressors. The results suggested that the many similarities outweighed the differences and suggested that perhaps the DSM should not exclude those with bereavement and significant associated depressive symptoms from a diagnosis of major depression.

Depending on the loss and the person's history and age, different reactions are expected and considered within the range of normal in bereavement. For example, children may express bereavement differently than their parents. Children may not understand the permanent nature of death, and may experience regressive behaviors. As another example, when one loses a spouse, social isolation may come to the forefront as an issue, differently than if one lost a parent.

While grieving and bereavement are personal experiences, there are commonalities across cultural groups and across time. Ritual is often used as a final expression of caring. Remembrance includes many small rituals over time.

For example, in Caribbean cultures, the traditional religious mourning practices have been fairly constant over time. However, as other cultures assimilate during the immigration process, they may keep some portion of the mourning practices from their homeland and adopt some of their new home culture's practices.

Health care providers and hospices may seek involvement in rituals as appropriate in the ethnic and religious community. Particularly with certain unexpected losses, such as the loss of a child, families may look to the health care community for direction. Some programs specifically have assistance with bereavement, such as helping with the creation of memory/memorial books.

However, there are different rituals cross-culturally, and different accepted behaviors within those rituals. Certain communities have very specific cultural processes of expressing grief and bereavement (e.g., sitting shivah for 7 days in Judaism). Increased grieving and bereavement may occur among immigrants because they may hear distantly of relatives who are decreased and may not have the opportunity to participate with others in their homeland community as they grieve. Beliefs about continuing ties and relationships with the deceased will vary.

Treating health care providers should be aware that persons from different cultures express bereavement differently. Understanding what is normal and what is abnormal bereavement may require liaison with families or other cultural or religious representatives. When the provider and patient are from dissimilar cultures, there is a risk of cultural insensitivity to bereavement, which one must strive to work against. Keep in mind that rituals of funeral and burial provide some support and structure immediately after the loss, there are longer term emotional needs and re-assimilation needs. Attentive active listening can help individuals and families express and work through their feelings of loss. Support groups, as well as phone calls from health care providers at an interval after the loss, may be beneficial to those in mourning. The health care provider should see the eventual goal of bereavement to include the reconstruction of meaning after the loss.

Berlin Wall

Brandy L. Johnson
Rynearson, Suess, Schnurbusch & Champion, L.L.C,
St. Louis, MO, USA

The Berlin Wall was a 96 mile wall that was erected on August 13, 1961, and stood as a concrete barrier until November 10, 1989. The wall was built by the German Democratic Republic and was meant to separate West Berlin from Eastern Germany.

After World War II, Germany was divided into four sectors. The United States, Great Britain, France, and the Former Soviet Union each controlled a sector. The sectors controlled by the United States, Great Britain, and France joined to form The Federal Republic of Germany, or West Germany. The sector controlled by the Former Soviet Union became The General Democratic Republic of East Germany and was a communist state. The division of the two sectors was coined the "Iron Curtain" by Winston Churchill.

The capital of Germany, Berlin, was similarly subdivided into four sectors. The United States, Great Britain, and France joined their sectors to form West Berlin. The sector held by the Former Soviet Union, East Berlin, became the capital of East Germany. Like East Germany, East Berlin was under Communist rule. Due to restrictions imposed by the communist regime, many East Germans immigrated to West Germany where they were afforded more freedom, better economic choices, and a better standard of living.

From 1949 to 1961, large numbers of East Germans immigrated by merely crossing from East Berlin into West Berlin. Once in West Berlin, the immigrants were permitted to move in West Germany or other Western European counties. Many of these individuals were professionals or skilled workers. To stop this egress, the German Democratic Republic built the Berlin Wall ("the Wall").

The Wall went through several versions. The first version of the Wall, consisting of 96 miles of barbed wire and guards, was essentially raised overnight. A more effective barrier was built in 1962. At that time, a second fence, which was built parallel to the first fence and was up to 100 yards further into East Germany, was constructed. The second fence was made up of barbed wire and concrete blocks. The buildings between the two fences were demolished to create an empty space that became known as the "death strip." This area was covered with raked gravel and provided guards a clear field of fire. In 1965, a third version was erected using a concrete wall and steel girders. The final version of the Wall began in 1975. It was officially named "Stützwandelement UL 12.11" (retaining wall element UL 12.11) and it was constructed of 45,000 concrete segments that were 12 ft. high and 4 ft. wide. The top was lined with smooth pipe that made it more difficult to scale the fence. The Wall was reinforced with methods that included mesh fencing, signal fencing, minefields, anti-vehicle trenches, barbed wire, dogs, over 300 watchtowers, and 20 bunkers.

The wall effectively separated families and friends. Those who lived in East Berlin no longer had contact with residents of West Berlin. Additionally, after the Wall was built, many people in West Berlin no longer had access to their jobs in East Berlin. There were only seven places along the Wall where one could access checkpoints and cross the border between East and West Berlin. The checkpoints were mainly utilized by officials and those who obtained a permit allowing passage. Checkpoint "Charlie," was located on the border between East and West Berlin at Friedrichstrasse and became infamous being used mainly by Allied personnel and Westerners.

Despite the obvious dangers, there were escape attempts. At first, escapes were attempted, and made, by climbing over the wall or jumping from apartments that were built along the wall. Further fortifications, coupled with the interdiction imposed by East Germany on its citizens near the Wall, made escape by these routes more difficult. Despite these restrictions, some of the East Berliners continued to try to scale the Wall, use underground tunnels, drive vehicles at the barrier, fly over the wall, and, on one occasion, fly in a hot air balloon.

It is estimated that over 5,000 people escaped over the wall into West Berlin. According to a collaborative project of the Berlin Wall Memorial and the Center for Contemporary History Potsdam entitled "The Dead at the Berlin Wall 1961–1989," at least 136 people were killed at the Berlin Wall between 1961 and 1989. Among the 136 people who died there were 98 refugees from the German Democratic Republic, 30 citizens from East Berlin and West Berlin who were not trying to flee, and 8 were border guards. Moreover, at least 251 passengers died either during, or after, checks at boarder crossings in Berlin.

The fall of the Wall began when Hungary raised its border restrictions in August of 1989. This allowed East Germans to escape to the West. As a result, the German Democratic Republic prohibited travel to Hungary to its citizens. A similar event occurred in Czechoslovakia. Additionally, protests broke out in East Germany. On November 9, 1989, Gunter Schabowski, a spokesperson for the East German government, declared, at a press conference, that visas would be freely granted to those wanting to travel outside or leave the country. This announcement resulted in thousand of East Berliners rushing to checkpoints of the Wall and ultimately crossing into West Berlin where they were met by residents of the West Berlin. The following weekend, the East German government announced the opening of ten new checkpoints. By December 23, 1989, East Germans and West German citizens could cross the border without any visa requirement. The "fall" of the Wall was met with a celebratory atmosphere on both of its sides. The Berlin Wall was officially dismantled on June 13, 1990, and Germany was reunified the same year. Short sections of the Berlin Wall have been permitted to stand as a memorial.

Betel Nut

Sajay P. Nair
Beachwood, OH, USA

The betel nut (more commonly known as the areca nut) is a seed of the areca catechu palm, a tree similar in shape to a coconut tree and found in the rainforests and moist lands of the Pacific Islands, Southeast Asia, and east Africa. The nut is commonly combined with a betel leaf and lime paste to form paan, a stimulant chew rooted in tradition and customs in Asia and Africa. Globally, it is the fourth most widely used drug after nicotine, ethanol, and caffeine. Studies have emerged about its carcinogenic effects and its associations with oral diseases.

The betel nut itself has a wood-like consistency, which can be chewed on its own or combined with a betel leaf. The main active ingredient is an alkaloid called arecoline and is responsible for its effects on the human body. The main effects are on the parasympathetic nervous system, mainly on nicotinic and muscarinic receptors. Because of its CNS stimulating effects, betel nut is used in a manner similar to the western use of tobacco or caffeine. Chewing the nut stimulates salivary flow, thereby aiding digestion. Betel nut also has been used as an appetite stimulant. It has been reported that betel nut chewing produces feelings of well-being, euphoria, heightened alertness, sweating, salivation, a hot sensation in the body, and increased capacity to work.

Studies have shown that the betel nut, even when chewed alone, has been associated with oral submucous fibrosis, a debilitating condition of the oral cavity that can lead to marked rigidity and inability to open the mouth and is considered to be precancerous. When betel nut is combined with the constituents of paan, there is a higher incidence of leukoplakia (a precancerous oral lesion) and squamous cell carcinoma of the mouth.

Bigamy

Loveth Adenuga
Family Medicine Research Division, Case Western Reserve University School of Medicine, Cleveland, OH, USA

The practice of being married to one person while lawfully remaining married to another individual at one point in time is referred to as bigamy. If divorce has taken place or the marriage has been nullified, bigamy is not committed. Bigamy and polygamy are often confused with one another. Bigamy is the practice of being married to two women at the same time, hence the prefix “bi-.” Polygamy is the practice of being married to many women at the same time, hence the prefix "poly-." Bigamy has been the bane of law enforcement officials' for centuries in many locales around the world. It is one of the hardest crimes to recognize and is usually practiced by discreet parties.

During the eighteenth and nineteenth centuries, bigamy became a con artist's way of acquiring a mass amount of assets and funds. Partners of bigamists involved in these schemes were often oblivious to the criminal activity taking place in their "counterfeit" marriages; some were eventually murdered by their partners. George Joseph Smith, notoriously known as the Brides in the Bath Murderer, was executed on August 13, 1915 for the murder of three of his wives, to whom he was bigamously married. Smith murdered his wives for money, killing them by strategically drowning them in the bathtub. Smith had many wives, and to this day the exact number is not known. One of his wives, Caroline Thornhill Smith testified against him at the trial, exposing their marriage as one where Smith prevailed upon Caroline to steal from her employer.

Another famously known bigamist is Sigmund Engel, the "Lover of 1001 Women." Although the previous number is exaggerated, Engel bigamously married over 200 times, by far the largest record of bigamous marriages to date. Engel carried on his criminal ways over a period of 50 years, amassing over $6 million from his victims' savings and assets. His bigamist lifestyle was exposed in 1949, when a woman by the name of Reseda Corrigan brought charges of bigamy and fraud against him. Engel would usually swindle his women by informing them that he was going out to buy luggage for their honeymoon after he had cleaned out their accounts, ultimately disappearing and abandoning the marriage. On November 9, 1949, Engel was sentenced to 2–10 years in prison, where he eventually died.

As recently as 2007 a man by the name of Darrell Leach was convicted in Ohio of being bigamously married to three different women. He was ordered to pay a $500 fine and was given a year of probation after the judge instructed him to straighten out his marriages.

Serial bigamists have a sense of invincibility, giving them the idea that as long as they are clever, they will not get caught. Bigamy is outlawed in many countries, yet it is still widely practiced today. For individuals that come from a nation where bigamy is accepted and live in a country where it is not accepted, life can be very difficult. Depending on the level of punishment, the individual may risk committing bigamy.

Bigamy has caused several concerns in the area of immigration. For instance, if an individual desires to immigrate to another country but is currently married, they may leave their spouse behind and immigrate to the new country, claiming they are single. Eventually, they may get married to a citizen of the new country in order to gain citizenship, making the new marriage a fraud. Problems like these have caused immigration bureaus to closely monitor visa and citizenship applications for what could potentially be illegal marriages for residency and citizenship purposes. Other difficulties arise for individuals who are migrating from a country that permits multiple wives to a country in which bigamy and polygamy are illegal. The destination country will generally not allow the individual to immigrate with him more than one wife, creating difficulties within the larger family.

Birth Control

Mihaela-Catalina Vicol
Department of Bioethics, University of Medicine and Pharmacy "Gr. T. Popa", Iasi, Romania

One of the greatest achievements of medical research is considered to be birth control methods. Concerns for controlling the reproductive behavior have been present in history since the use of *coitus interruptus* or other natural methods such as the calendar method, the basal body charting or the temperature method, the cervical mucus, etc. Abortion itself had been described as a method of controlling child bearing. All of these methods had one major inconvenience: a low rate of success in preventing the pregnancy. This is why several other methods had been developed, with a better rate of success and higher safety, such as the condom, birth control pills, intrauterine devices, hormonal implants, surgical sterilization (vasectomy and tubal ligature), spermicides, diaphragms, etc.

Immigrants' birth control must be discussed in relation to several issues that may have an impact both on the choice to control their own childbearing, as well as on the acceptability of the methods, such as access to health care, socioeconomic status, cultural, religious and traditional factors, political and demographic factors.

Immigrants' access to health care may be limited by their illegal status, their low income, their uninsured status, and/or their cultural and religious beliefs. When discussing birth control, access to health care is crucial for several reasons. First, there are many types of birth control methods – from natural to intrauterine devices and to sterilization. Choosing the appropriate method is a decision in which method-specific counseling, i.e., providing appropriate information about the methods, instructions, conditions, safety, risks, possible complications and side effects, costs, etc., plays an important role. Beside the role of providing information, the counseling also provides follow-up case management that should encourage the patient to discuss: side effects, further advice, or modification of contraception method. Second, some of the birth control methods considered to carry a higher risk of serious complications (like intrauterine devices, oral contraceptives) should be used only on condition of health care access. Third, before choosing the birth control method, each patient should benefit from a medical examination. The medical condition of the patient, the patient's age, and the patient's sexual behavior should be closely examined in order to prescribe the appropriate method and to prevent method-specific risks.

In this context, immigrants' access to health care plays a very important role in the safety and effectiveness of the birth control process. Any limitations to health care access, regardless of the reason, may have serious consequences for immigrants' health.

Immigrants' low socioeconomic status may have a twofold impact: On one hand, immigrants' low income may limit access to medical care and to an adequate and appropriate birth control method, and on the other hand, the low income may be an important reason for reducing the number of children in a family by means of birth control. Though birth control methods were created for all women, there are major access disparities between social classes. Upper-class women are privileged because they have access to information, education and can buy any available method. Women of lower socioeconomic status, who may be, less educated and poor, do not have the same access to information or to affordable birth control methods. As an example, several studies of Friedlander et al. concluded that during the 1950s, immigrant women from North African and Asian countries in Israel experienced a fertility decline, due to their poor socioeconomic status. The low income had been considered the first determinant that contributed to this decline. The economic explanation points out the costs of having a child that leads to direct and indirect expenses which a low income could not cover. Other studies support the idea that low income does not produce the fertility decline alone, but acts in addition to other important factors, such as the cultural ones.

Culture, religion, and traditions of immigrants may influence the birth control basically at the level of the fertility behavior. The literature speaks about two main models that synthesize the influence of sociocultural factors on the fertility behavior.

The first one is the *adaptation model* according to which birth control behavior is the result of couple's adaptation to the society's changes. An example of the adaptation model is the decline of Mormon fertility in the USA in the nineteenth century, as the adaptation to the "decreasing ability of the Church of Jesus Christ of Latter-day Saints to maintain an economic, political, educational and religious separation from the national system." As a result, a large number of women practiced spacing behavior between pregnancies.

The second one is *the innovation-diffusion model.* According to this model, the diffusion of scientific innovation and people's attitudes toward these innovations may have an important impact on the reproductive behavior. This impact differs with the immigrants' country of origin, because it is filtered through different cultural factors.

Cultural and traditional influence upon fertility behavior is also reflected in the role of the decision-making person in the family. For example, though Asian and African immigrant women desired a smaller family than their husbands, the male gender power determined a higher rate of fertility or clandestine abortions. Religion may influence the birth control behavior based on the acceptability of some birth control methods and on the aspect of the bond between marital sexuality and procreation. Most of the religions consider that procreation is an act of love within the marital union. From this perspective, there are conservative societies such as the Israeli Jews; in 2000, only 2.8% of births had been attributed to never-married women.

Political and demographic strategies may influence the fertility behavior in the society. For example, in Romania, before 1989, abortion and birth control methods had been prohibited as part of the demographic strategy. Today, in China, the number of children allowed per family is limited by law at only one.

The promoter of the American birth control movement was Margaret Sanger, an Irish immigrant woman. She wanted to promote fertility control rights among all women. However, the manipulation of her ideas led to eugenics, which actually aimed to reduce the number of people who were considered to be socially undesirable: poor minorities, less educated, immigrants, etc.

Birth Defects

Doug Brugge
Department of Public Health and Community Medicine, Tufts University School of Medicine, Boston, MA, USA

According to the March of Dimes, there are about 120,000 babies born with birth defects each year in the USA. Worldwide the numbers are much larger, estimated to be 7.9 million per year with a higher prevalence in developing compared to developed countries. Many of these conditions are either preventable, can be ameliorated or treated.

Several studies of immigrants to the USA have found that children born to native- and foreign-born mothers have a different prevalence of birth defects. The study of differences in the prevalence of birth defects is complicated by the large number of type of birth defects. If comparisons are made regarding individual types of birth defects, cleft palate and neural tube defects, for example, the pattern might be, and often is, quite different for each. Thus, birth defects are a heterogeneous set of conditions that may be caused by different genetic or environmental factors.

Few studies have focused on narrow classes of birth defects (although these also have subclassifications within the broader classification). One study focused on two types of oral cleft defects in newborns in Texas. This study found that US- and foreign-born Hispanic mothers did not differ relative to non-Hispanic White mothers for one type of cleft, but that the Hispanic mothers, regardless of place of birth, were less likely to have babies with another type of cleft.

A case-control study compared Mexican immigrants and White non-Hispanics for neural tube defects in California. This study found that recent Mexican immigrant mothers had a seven times higher risk of giving birth to babies with these defects. Another study looked at three types of cardiovascular (heart and circulatory system) defects in children born in Texas. One of these types of defects was more common in counties along the border with Mexico, and the authors suggested that this might be due to environmental exposures.

More recent studies have looked at a larger range of birth defects in the Hispanic population and considered maternal place of birth. A study of Hispanic women giving birth in New York State considered a dozen major organ system defects and a similar number of specific defects, and broke the term "Hispanics" down by nationality: Puerto Rican, Mexican, and a mix of other countries of origin. Although the analysis was somewhat complex, the overall finding was that foreign-born mothers were at lower risk of delivering babies with birth defects, both overall and for some of the specific organ systems and types of defects.

The most recent study, a case-control design, considered 29 specific birth defects from the National Birth Defects Prevention Study, which collected data from ten states in the USA. This study sought to identify associations between mothers being US- or foreign-born and having children with birth defects. Different associations were found for different birth defects, with some more likely to be found in babies of foreign-born mothers and others more likely for US-born mothers. For most types of defects examined, there was no statistical difference based on the place of birth of the mother. However, there were differences between mothers from Central America/Mexico and other countries of origin. The authors suggest that their findings might be due to culture, behavior, or diagnosis of birth defects.

Overall, the picture for a relationship of immigration, measured usually by country of birth of the mother, and birth defects is not entirely clear and needs further research. The large number of types and subtypes of birth defects makes these analyses particularly difficult.

Birth Weight

► Birth weight paradox

Birth Weight Paradox

Erin R. Hamilton
Department of Sociology, University of California at Davis, Davis, CA, USA

The birth weight paradox is a subset of the more broadly defined epidemiologic paradox. The epidemiologic paradox describes a set of research findings showing that some groups of Hispanic immigrants, particularly of Mexican origin, have paradoxically good health and mortality outcomes in the USA, given their socioeconomic disadvantage relative to other major US racial and ethnic groups. This paradox has been most clearly documented in patterns of infant mortality and birth weight, a major risk factor for infant mortality as well as for health and developmental problems in childhood and beyond. Vital statistics data from 2006 show that the rate of low birth weight (<2,500 g) among Mexican American births was 6.6%, compared to 7.3% among non-Hispanic White births and 14% among non-Hispanic Black births. This pattern corresponds closely to rates of infant mortality documented in National Center for Health Statistics linked birth-death files, which, for 2005, show an infant mortality rate of 5.5 deaths/1,000 live births among Mexican-origin women, compared to a rate of 5.8 among non-Hispanic Whites and 13.6 among non-Hispanic Blacks.

The low rate of low birth weight among Mexican American infants is due to the fact that there are fewer small, preterm (<37 weeks gestation) births in this population, as there is a slightly higher rate of preterm deliveries to Mexican-origin women, compared to non-Hispanic White women. Preterm Mexican American infants are, on average, heavier than non-Hispanic White infants, but there is a crossover in mean weight at term, which is reflected in the fact that non-Hispanic White infants are, across all gestational ages, heavier than Mexican American infants. Errors in recorded gestational ages impede analytical focus on gestational age as a measure of infant health.

Social explanations for the birth weight paradox include data issues, cultural protection, and migrant health selectivity. Data issues include, most importantly, the selective return migration of sickly migrants to their countries of origin where their deaths go unrecorded in US vital statistics, which may downwardly bias postneonatal infant mortality and adult mortality rates. However, this bias is irrelevant to birth weight, which is recorded on birth certificates for all infants born in the USA. The cultural protection argument primarily involves health behaviors: immigrant mothers are less likely to use tobacco, alcohol, and drugs than other mothers. They may also be protected by familism, a cultural orientation emphasizing the group over the individual, which highly values mothers and children as well as kin and co-ethnic social support. Migrant health selectivity is the idea that, because of the costs, risks, and challenges associated with migration, migrants are a select group in terms of health and a number of unmeasured characteristics that may influence health, such as a strong sense of personal efficacy. Selectivity is supported by patterns of infant mortality, which are lower among immigrants in comparison to their native-born counterparts across all racial and ethnic groups, as well as by a study using pooled origin–destination data from Puerto Rico, which showed that migrants to the mainland have a lower risk of infant mortality than nonmigrants on the island.

Some research questions whether this good health at birth persists into childhood. Mexican American children are at a higher risk of some health and developmental problems than non-Hispanic White children. Scholars have suggested that the paradox may deteriorate over time due to a process of unhealthy acculturation, due to regression to the mean, or due to cumulative exposure to deleterious social conditions for Hispanic immigrants and their descendents in the US context.

Bisexual

Daniel J. O'Shea
HIV, STD and Hepatitis Branch, Public Health Services, County of San Diego, San Diego, CA, USA

A bisexual is an individual who has sexual interest, physical or romantic attraction to or desire for both members of the same sex (homosexual orientation) and members of the opposite sex (heterosexual orientation). Bisexual orientation is one of the three main categories of sexual orientation, along with heterosexual and homosexual. Research indicates that sexual orientation is influenced by a combination of biological (genetic), environmental (including fraternal birth order, specific prenatal hormone exposure, and prenatal stress on the mother), cognitive, and cultural variables in interaction, leading to different types of bisexuality. A bisexual may be more attracted to one sex, attracted equally to both, or find people's sex unimportant. A bisexual may have erotic, affectionate, or romantic feelings for, or fantasies of experiences with, both men and women without having ever acted on them. The strength of their attractions to men and women may vary over time.

Some clinical surveys suggest there are a significant number of bisexual persons in terms of desires and practice. Sigmund Freud maintained that bisexuality was a normal part of development and every person has the ability to become bisexual at some time in his or her life. Based upon research in the 1940s and 1950s, Alfred Kinsey posited that individuals exhibiting strict heterosexual and homosexual behaviors be considered as end points along a continuum ("0" and "6," respectively, on the Kinsey scale), with those falling in between considered bisexual to varying degrees. People at "3" on the scale were about equally attracted to men and women.

The term "bisexual" frequently conjures misconceptions and false ideologies. Bisexual identity is frequently linked in research, health, and social contexts with homosexual identity, minimizing bisexuality as a separate and genuine orientation. Bisexual women and men face stigma from both outside and inside gay and lesbian communities, creating a sense of disenfranchisement and invisibility, not "fitting into" either homosexual or heterosexual communities. Coming out has been identified as particularly unsettling for bisexuals, and health care providers are often confused or make false assumptions about bisexuals' sexual practices or histories. Some bisexual persons are committed to forming their own communities, culture, and political movements, while others may merge into either homosexual or heterosexual society.

Bisexuality has been observed in various human societies throughout recorded history, although the term did not originate until the nineteenth century. Tolerance of homosexual behavior increased in many societies in the late twentieth century, and the number of people identifying as bisexual correspondingly increased. Even so, both bisexuality and homosexuality continue to challenge ingrained cultural concepts of sexuality, gender identity, and traditional family relationships and structures. An openly bisexual or homosexual life style remains unacceptable in many parts of the world, vilified and shamed by family members, neighbors, or society. In the last decades of the twentieth century, several regional and global cities emerged as cultural centers for lesbian, gay, bisexual, and transgender (LGBT) communities, including London, New York, San Francisco, Sydney, Sao Paolo, Johannesburg, and other Western European, American, and Canadian cities. These serve as destinations for millions of LGBT visitors and migrants, some of whom choose to make their homes there to escape from constricting, wearisome, economically depressed, conflict-ridden, traumatic, oppressive, or discriminatory conditions in their country of origin. The goal for many is to fulfill a desire, and likely a psychological need, to explore their sexual identity or live an openly LGBT life style, which would not be possible at home, or to find sexual or romantic partnerships. Studies, including gay and bisexual male immigrants in London and Mexican immigrants to the USA, described the phenomenon of international relocation of people driven to move, in whole or part, by issues of sexuality, as "sexual migration." For many, the move is unfortunately sometimes opportunistic and poorly planned, resulting in cultural shock and, particularly for those with limited language skills, overwhelming economic uncertainty; restricted job options, such as temporary and menial work and sometimes prostitution; and/or dependence on benefits. The result may be a loss of individuals' control over basic aspects of their lives and future, sometimes leading to risk taking with their health. Engagement in HIV risk behaviors has frequently been reported by gay and bisexual men after migration to another country.

Unlike other immigrants, LGBT individuals face specific and varying challenges from immigration laws that unfairly discriminate against them, leaving their lives and status often precarious and endangered, and in fear of deportation. At present, LGBT immigration advocates are at the epicenter of the heated national policy debate in the USA surrounding immigration, pushing for inclusion of LGBT people, families, and partners, and creating a history of LGBT immigration case law and policy to ensure justice for LGBT immigrants. Since 1994, persecution based on sexual orientation has been grounds for asylum for LGBT immigrants in the USA. Rarely used until recently, more immigrants from the Middle East, Africa, Latin America, and the Caribbean are now seeking asylum on the basis of sexual orientation to escape rape, persecution, violence, and threats of death from places where homosexuality is either outlawed or shunned. Applicants for asylum are required to apply within the first year of arrival in the USA, but may be allowed to apply later if within a reasonable time frame and under extraordinary circumstances, or if conditions in his or her native country have changed such that the person may be harmed upon return based on those changes.

Blacks

Brittany Daugherty
Department of Psychology, John Carroll University,
Cleveland, OH, USA

The commonly used racial term "Black" has been used to describe people of African descent. Among other labels, African Americans have been given a slew of names to represent their supposedly diverse nature, such as Nigger, Colored, Negro, and African American. The term "Black," derived from the Latin word "niger," bestows the label of distinct membership to a racial group. It is not only a racial characteristic essential for identity but symbolically embodies degradation and negativity. Blacks have been subject not only to overt discriminatory action but to a structured institutional system that actively and passively exercises discrimination. Blacks have been subdued to a stereotypical legacy and are presently struggling with its negative backlash of effects. Blacks – and their social significance – are linked with race, racism, science, and politics.

The Emergence of Race and Biology

Within the field of natural philosophy emerged the concept of race. Racial classifications served as a way for prominent thinkers during the seventeenth and eighteenth centuries to describe the division of people. Immanuel Kant, a famous German philosopher of the eighteenth century was the first to establish a consistent concept describing the diversity between races with his theory of race. He defined race as deviations that were preserved over many generations, which were the result of migration and interbreeding. All people belonged to a single line of descent, one human species which comprised different races. According to Kant there were four distinct races, the White race, the Negro race, the Hun race, and the Hindu race. The Negro race was considered to possess a particular essence of laziness and indolence. Blacks were thought to have essences, or inborn qualities, which made them an uncivilized race subject to inferiority. Their characteristics such as facial and cranial measures were linked with mental capacity and morality. Kant used skin color and physical characteristics to determine inherited characteristics. He believed that intellect and skin color were inextricable and related to racial essences. Race was a predictor of intelligence and morality, a biological construct that entailed environmental underpinnings. The concept of race created a hierarchy of racial stratification in which science was used to validate European ideals. It was during this time the traditions and physical characteristics of Whites were proposed to be superior to those of non-Whites, especially Blacks.

Separating racial meaning from its scientific justifications means extracting the innate characteristics of race from its attributed structure of racial hierarchy. Many scientists have used phenotypic traits to try to prove unambiguous distinctions between the races. However, these traits, such as skin color and blood type, are highly varied within racial groups and provide no empirical evidence to support a biological racial theory. Common racial groups such as "Blacks," "Whites," or "Asians" are in fact large social groups, which do not constitute a race, and in fact, have no real biological foundation because they lack scientific referents. Therefore, the "Black" race is a social construction which possesses a strong social and political reality. Scientists and researchers have long tried to associate racial essence with disease, blood type, and body structure. For instance, the disease sickle cell anemia is known to affect a large majority of Blacks. This led the scientific community to believe that race was a determining factor for the disease. However, research has shown that sickle cell anemia is a genetic disease in which the abnormal shape of red blood cells that lack hemoglobin is a defense mechanism that protects the individual against malaria. In fact, sickle cell anemia is seen in areas where there is a high incidence of malaria; therefore the disease is not based on racial identity but geographical location.

A theory such as the legendary "one-drop-rule" supports the idea of racial essences. Due to the fear of racial mixing, Whites sought to make clear rigid distinctions between races and created a formal rule which socially classified anyone with any African ancestry as Black. A single drop of Black blood gave racially mixed persons subordinate racial status. This was adopted politically and also used to discourage racial mixing, or miscegenation. This historical idea of inherited racial essence supports racial labeling. Labeling is key to racial identification because it has two main parts, collective and individual. Collective labeling is how others assign labels to an individual, and individualistic labeling is how labels are adopted by the individual in order to self-identify. These racial labels not only represent ones' identification, but the history of its effects as well. Racial labels tend to accompany expectations, or those anticipated behaviors that are related to a particular racial identity. Therefore, socially constructed racial ascriptions sustain innate biological distinctions.

Usage and Changes of Racial Labeling

Upon arrival to the United States in the 1600s, the term "Africans" was frequently used as the racial label for newly acquired slaves from Africa; this word served as a sense of dignity and racial inclusivity among slaves. Soon after, a movement to change the racial term from "African" to "Colored" became apparent. The new label demonstrated the anticipation of slaves wanting to be associated with emancipated slaves and free White Americans. As the institution of slavery continued to grow during the 1800s, racial epithets began to surface as well. These racial terms served to keep the morale of the slave to a minimum, while maintaining dependency and servitude at a high level. Black slaves were portrayed as irrational, idle, promiscuous, and in need of governance. The depiction of Black men and women was in accordance with slavery's progression and outcome; these images changed as slavery grew stronger and as it weakened. Black slave women were portrayed in a combination of derogatory images, for instance, a Black woman who was seen to be a temptress and erotic was known to be a "Jezebel," a biblical term used to portray sexual prowess. The image of the "Mammy" portrayed a loyal slave who raised the slave master's children and possessed no sexuality. She was an obedient and stable southern icon, possessing no gentleness or beauty, a direct contrast to White women. These depictions of Black women were contradictory; however, both images possessed the common theme of Black female slaves being incapable of motherhood. The image of Black slave men was that of the "Sambo," a simple, irresponsible Black man, who surrounded himself with games, food, and laughter. The Sambo and Mammy caricatures served as slavery defenses, illustrating the decency of slavery and the benefits it served for slaves' well-being. During the Antebellum Era (1800–1860s), these caricatures followed the political current.

The Jim Crow Era (1875–1965) was a period during which racial slurs and laws against Blacks caused them to suffer disproportionately, and formalized economic, social, educational, and political segregation. It is believed that the term "Jim Crow" originated from an exaggerated slave dance in which White performers in blackface, Blackface Minstrels, portrayed the myth of happy slaves. The minstrels' vernacular and performance were assumed by the broader White society to be an accurate portrayal of Blacks. During the slave emancipation and the Reconstruction Era (1865–1877) political debate began to drastically change and shape new Black caricatures. The "Zip Coon" caricature emerged primarily out of the North, and symbolized a failed Black freedman who was unaccustomed and unable to adapt to a life absent of subjugation. The "Black menace" and the "Black brute" caricatures emerged as a symbol that portrayed newly released slaves as unmanageable, irate, animalistic, and prone to violence. These images posed a threat to White society and especially White women. In 1915, the film *Birth of a Nation* by D.W. Griffith was released. The film plays on the myth of deviant Black behavior, is set during the Civil War, and encourages Southern White supremacy. In the film, emancipation of slaves brought destruction to the south and showed Blacks rioting, committing violent acts and raping White women. Attempting to restore order, a group of vigilante White men known as the Klu Klux Klan (KKK) rose up to defend White societal order. This popular film created racial tension, especially in the South. It made Whites fear emancipation and its effects on Black pride, group solidarity, independence, and progression.

Following emancipation, Blacks were no longer legally subjected to servitude yet, racial oppression was rampant. Blacks were subjected by discriminatory laws and use of derogatory language. The term "Nigger" was derived from the Northern English word "Neger" which was derived from a Spanish word "Negro" meaning Black. The term "Nigger" became a racial slur because users knowingly mispronounced it as a sign of disrespect. By the early 1800s, the term "Nigger" had become a recognized racial epithet.

Even though slavery was abolished in 1865 through the Thirteenth Amendment, the legacy and impact of racial labels on Black people can still be seen. Racial labels such as Negro and Afro/African American share a historical and contemporary perspective which are both derogatory as well as a sign of strength and solidarity. There has been a generational change in Black racial identity to form and retain Black status and consciousness. Group status and advancement in society and politics provokes changes in racial terminology, therefore producing an evolution of racial labels. The adopted racial label "Colored" used during the nineteenth century was the dominant label accepted by both Blacks and Whites. It was an inclusive term, describing all types of Blacks including those of mixed race and those with full Black lineage. It in many ways lacked specific group membership, however, it possessed group dignity. Late in the nineteenth century, influential Black leaders such as Booker T. Washington and W.E.B. Dubois moved to replace the term "Colored" with "Negro." Booker T. Washington was a prominent public figure, educator, and political leader who advocated for Black civil rights and education. He gained the approval and financial support of many Whites while advocating race integration for the progression and betterment of Blacks. He believed that Blacks could gain social acceptance through hard work, gaining prosperity, and by seeking education. W.E.B. Dubois, author, historian, and civil rights activist, was a prominent figure during the early 1900s. His key concern was for the positive development of Black people. He believed that the small group of Black elites also known as the "talented tenth" would work to positively increase the social standing of Black people by leading them in the right direction. He also campaigned for the political representation of Blacks to achieve civil rights. Although Dubois opposed Booker T. Washington's integrationist ideas, they both focused heavily on the positive attributes of African American society, social progression, and political power. During the twentieth century "Negro" gained great acceptance and was proposed by many influential Black leaders. The term was highly favored due to its grammatical versatility and strength. Despite some opposition due to its derogatory use by Whites, it portrayed not only social strength but political growth as well. By the 1930s the expression "Negro" had become associated with racial progress, Black aspiration, militancy, defiance, and assertion of racial honor.

As the Civil Rights Movement began to materialize, so did a new racial label. During the late 1950s and early 1960s the term "Negro" was considered a vestige of slavery, servitude, and complacency. The new label "Black" was promoted to symbolize power, militancy, and racial separation. The term was preferred and promoted by many Black radical groups who encouraged progression of the Black race. Stokely Carmichael, a Black activist during this time was a strong proponent of the racial label "Black." His involvement in the Student Nonviolent Coordinating Committee (SNCC) and the Black Panther Party made him an influential organizer and civil rights advocate in the Black community. The racial label "Black" was considered to provide balance against the term "White" and emphasize racial separatism. It also was an identifier that was absent of pathology and inferiority. The label marked a time of self-improvement and activism. During this time the racial label "Black" produced great controversy, often seen as derogatory and conflicting with modern symbolism of the American lexicon which associated the word black with evil, destruction, and undesirable traits. But these negative connotations were confronted directly with strong Black political messages such as "Black is beautiful" and "Black and I'm proud," which turned it into a symbol of encouragement and positivity. With help from the Black Social Movement throughout the 1970s and early 1980s, "Black" became a highly favored racial label.

In the late 1980s, a new movement emerged and Ramona Edelin, President of the National Urban Coalition proposed to replace "Black" with "African American." Many were in favor of this, including civil rights activist Jesse Jackson. Since other ethnic groups such as Chinese Americans and Jewish Americans had a recognized source of lineage, it was felt that reference to a historical culture was necessary for Blacks as well. This cultural label replaced the race characteristic and debunked the myth of an inherent essence seen in previous racial labels. The main goals of the newly acquired race label were to identify with Black heritage and the native motherland of Africa, to positively improve public attitudes toward Black individuals and to promote dignity and self-esteem. The term "African American" was used to draw parallels with other cultural groups and rise to their level of social progress and ethnic tolerance. The term was to heighten the global presence and competitiveness of Blacks as well as connote equality with and inclusion into mainstream society. Just as there was enthusiasm for the label, there was also controversy. Many opposed this change because it was seen as a distraction to other issues that were disproportionally affecting African Americans such as poverty and limited access to education; others felt the term to be too inclusive and that the ties made to Africa were simply a delusion. Linguistically, the hyphenated term increased the use of negative "back to Africa" sentiments and other racial epithets. Despite opposition, the new racial term “African American” gained endorsement quickly. It is worth noting that many of these racial labels are still used today, in both mainstream and the Black communities. However, it is not of great importance as to which term is currently being used; it is the uniqueness and course of the term changes that are most relevant. The use of these racial identifiers has developed strength and guidance for social, psychological, and political liberation.

The Resurfacing of “Nigger”

While continuing to gain leverage in society, the resurfacing of the term “Nigger” specifically as used by Blacks has proven to be an even larger progressive step toward inclusion as well as a step back toward subordination. Full of political and linguistic complexity, the word “Nigger” contemporarily changed to “Nigga” has adopted multiple meanings; it has been used as a sign of endearment or affection, for identifying a person who is Black, for negatively associating someone with Black qualities, and for expressing deep disapproval. Its versatile usage has found its way into American popular culture through hip-hop, comedy, and even film. Supporters of the word find it to be liberating and a source of great pride and unity. Opponents find this contemporary usage insulting, disrespectful, and detrimental to the future of Blacks, as it makes the word acceptable for use by everyone and diminishes its historical importance. It has become an unwritten rule that the term “Nigga” is a collective expression only to be used within the Black community. Tension and disapproval still arises if the word is used by Whites and others who do not identify as Black. This strong racial distinction concerning the word “Nigga” serves as entitlement for Blacks, making them sole heirs of the term that was once used to derogatorily distinguish Blacks as an inferior and shameful race.

Impact of Racism and Racial Labeling

The psychological impact of derogatory or other common words for group classification can be detrimental. The words used to describe Blacks can injure one’s self-respect and self-esteem by provoking psychological responses such as humiliation, isolation, self-doubt, self-hatred, and ambivalence about self-worth and identity. Since many of these racial labels were used to negatively portray Blacks and discredit their status, merit, and dignity, the negativity that stems from these terms may become the “truth” in the minds of Black people. The image of blackness has always been a difficult reality to face. The subtle acceptance of defeat and inferiority has proven to be damaging to Black character. Echoes of a previously enslaved mind into the present can perpetuate itself across generations in the form of persistent rage, frustration, and the willingness to overcompensate. However, underlying these symptoms are feelings of hopelessness and despair, which is evidence of psychological damage and incapability. Even children recognize racial differences and cultural attitudes, and apply these differences to how they view themselves. Children carry these racial burdens with them into adulthood, establishing a mind frame of inadequacy and challenging the development of a positive self-image and racial inclusivity. The impacts of racial discrimination can leave traces of physical and psychological distress which perpetuate systemic oppression. Changing the racial labels through which one identifies as being Black may instill group pride and increase self-esteem within a racial group whose ancestral ties were stripped when they arrived as slaves. The change of racial labels has the possibility of breaking the vicious cycle of oppression.

Present Racial Disparities

The social and economic position of Blacks has improved immensely in the United States. However, there is still quite a disparity as it pertains to healthcare, employment, and education. While only constituting 13% of the population, Blacks account for about half of all HIV/AIDS cases and AIDS is the leading cause of death in HIV/AIDS as compared to other racial/ethnic groups. Blacks also have high rates of diabetes, a debilitating disease which affects the body’s use of blood sugar. Diabetes currently affects 13% of the Black population over the age of 20. Unemployment rates for Blacks have soared to about 15%; nearly twice the unemployment rate for Whites and far exceeding the national unemployment rate. The educational opportunities available to low income Black communities are limited, and only 42% of Black students complete college as compared to 60% of their White counterparts. Despite the improvements seen for the Black community, there is still a need to fight for stronger political stability and social acceptance to eradicate the racial disparities. Institutionalized racism, an invisible structure of discrimination that is heavily embedded into society's morals but is not supported by overt law and action, still impedes advancement of the Black population.

Immigrants

It is important for immigrants to acknowledge that there are many different races and behind each race there is a social legacy that is incorporated into each racial identity. Blacks and how they are perceived relates closely to their economic, legal, social and political positions. Blacks have often demonstrated strength and perseverance to withstand social pressures. Blacks, like many other immigrant groups who arrive in the United States have an identity and consciousness that is highly significant. Blacks and immigrants continue to experience assimilation difficulties. The Black experience has been heavily shaped by racism and White superiority. The strong public emphasis on race in the USA is in its own right unique. Unlike other countries such as Brazil, Colombia and many other Latin American countries, racial distinctions are less rigid, although discrimination may be equally prevalent. Due to the fact that Blackness varies depending on particular countries, those immigrants with dark skin do not qualify racially as Black. However, their dark skin is still associated with inferiority. Their skin tone still has a political element and can have a negative effect on economic status, employment, and educational opportunities. This discrimination based on skin tone is known as colorism.

American immigration history displays its close relationship with race and politics. The influx of immigrants during the late 1800s and early 1900s was historically relevant both to the United States and to the creation of whiteness. Immigrants during these times were seen as outsiders, not fully aligned with American ideals. The increase of European immigrants from Ireland and Italy provoked fear of a future decline in the White race; the mixture of races posed a threat to the existing "White" American life and predicted a future of weakness and demise. Many of these immigrants were perceived as having undesirable traits innately different from Whites. For instance, Irish and Italian Americans were considered savages, innately prone to criminality. They were seen as unfit to participate in American political life. These immigrants would need more than their White skin to fully assimilate – they would need to show how distinct they were from non-Whites. A close relationship to non-Whites was a violation of a social racial code which resulted in condemnation. Immigrants who were thought to be equivalent to non-Whites gave mainstream Whites valid reasons for discrediting and discriminating against them. They had to distance themselves from non-Whites in every way in order to solidify their racial distinctiveness. So in order to assimilate into a White-dominated culture, one must side with White Americans and equally degrade non-Whites, especially Blacks who were considered the lowest of the racial groups. The assimilation of immigrants soon prompted whiteness to be redefined as variegated. Whiteness is an exclusive and exclusionary racial category, in which non-Whites have no access to its privileges.

Immigration today is still influenced by racial views that involve the biological conception of race which is often supported by public policy. Immigrants may have a hard time assimilating into new cultures because they are viewed as inferior and lacking in rationality. The xenophobic fears of some sectors of American society have fueled the proposal of racist policies, which effect immigration and race relations.

Blood Cholesterol

Jawali Jaranilla[1], Thomas E. Kottke[2]
[1]Regions Hospital, HealthPartners Medical Group & Clinics, Saint Paul, MN, USA
[2]HealthPartners Research Foundation, Minneapolis, MN, USA

Of the estimated 214 million migrants in the world today, the USA has the largest number of international migrants. The dynamic concept of migration has evolved and gradually changed over time, leading to significant challenges to the existing political and healthcare systems of developed countries.

These challenges, which are often incongruous with the immigrant's vision and traditional values, range from poor access to quality preventive care to lack of understanding of the healthcare system. Despite the concept of the "healthy migrant effect," these barriers have predisposed immigrants to practice behaviors that lead to the early development of disease and disease risk factors like elevated cholesterol.

Cholesterol and triglycerides are substances in the bloodstream required for physiological functions such as metabolism, cell membrane permeability, and hormone synthesis. High cholesterol and triglycerides, broadly termed "hyperlipidemia," are important risk factors for cardiovascular events. Hyperlipidemia is defined biochemically as elevated bad cholesterol (LDL-cholesterol), low good cholesterol (HDL-cholesterol), and elevated triglycerides (TG). Hyperlipidemia can cause myocardial infarction ("heart attack"), stroke, and peripheral arterial disease. Hyperlipidemia shares a common disease risk factor and treatment strategy with a more epidemiologically concerning condition, cardiometabolic syndrome (CMS).

The age-adjusted prevalence of CMS among immigrants ranges from 26.9 to 38.2%, with rates increasing in women with age greater than in men. The rate of CMS among immigrants is higher than the rate for US-born adults, which ranges from 18 to 32%. Among Asian Indian immigrants in the USA, the prevalence of elevated LDL-cholesterol (LDL-C) is 41.4%, low HDL-cholesterol (HDL-C) is 26.4%, and hypertriglyceridemia is 42.3%.

The etiology of hyperlipidemia is subdivided into primary and secondary causes. Primary causes, which are more common among children, include genetic mutations that lead to underproduction, overproduction, or defective clearance of cholesterol and triglycerides. Secondary causes are related to lifestyle factors that include physical inactivity, poor dietary habits, smoking, alcohol abuse, and use of certain drugs. Chronic medical conditions like diabetes and chronic kidney disease also cause hyperlipidemia.

For most individuals, hyperlipidemia is a preventable metabolic risk factor. Drug treatment, considering both direct and indirect costs, may be challenging and not sustainable for immigrants if priorities are considered for thriving in a foreign land. The high and slow rate of decline of death rates from cardiac diseases among immigrants is a major public health issue. In order to address this issue effectively and produce change, a sensitive and culturally based treatment program tailored to the needs of the individual is necessary.

CMS is a cluster of physical conditions and metabolic abnormalities. They commonly occur together, which increases the risk for cardiovascular disease and diabetes. The American Heart Association criteria for CMS include elevated waist circumference (≥102 cm in men and ≥88 cm in women), elevated TG (≥150 mg/dL), reduced HDL-C (≤40 mg/dL in men and ≤50 mg/dL in women), elevated blood pressure (≥130 mmHg systolic or ≥85 mmHg diastolic), and elevated fasting glucose (≥100 mg/dL). Any three of the five constitute the diagnosis of CMS.

An important step in the pathogenesis of CMS, insulin resistance, is also characteristic of familial combined hyperlipidemia (FCH). Insulin resistance is associated with increased TG levels, low HDL-C, small dense low-density lipoprotein, and increased apolipoprotein B.

Immigrants are a growing group of people with high risk of cardiovascular disease and a tendency toward unhealthy behaviors. These risk factors and behaviors include poor dietary habits, obesity, smoking, and physical inactivity. These factors are not attributed to rapid Westernization, but to time since immigration, acculturation, and assimilation. This is concerning because immigrants may have a prevalence of risk factors that, over time, may surpass those of nonimmigrants.

Cardiometabolic risk factors vary among immigrant populations, especially in those of different ethnic backgrounds. For instance, the rate of obesity among immigrants to the USA approaches those of born in the USA if they have lived here for more than 15 years. This is in contrast with immigrants to Spain, where length of residence is not associated with obesity.

Physical activity plays a significant role in prevention of obesity and other chronic diseases. Physical inactivity contributes to higher cardiovascular risk and is prevalent in immigrant populations, especially those from South Asia. Lack of physical activity has been correlated with cultural beliefs, values, and low socioeconomic status. For example, some immigrants perceive people with bigger size and frame as being more healthy and prosperous than those who are thin, which is perceived as a reflection of impoverishment.

Immigrants are vulnerable to various degrees of food insecurity that occurs if there is no sustainable access to healthy food. In the USA, the root of food insecurity is poverty, which leads to poor health conditions and bad eating behavior. Food insecurity among low-income immigrants is associated with hyperlipidemia, obesity, and other cardiovascular risk factors.

Post-migration dietary changes can lead to both better and worse health outcomes. Based on a systematic review of dietary patterns of ethnic groups in Europe, age and generation were the two major factors responsible for dietary changes, with older generations maintaining consumption of staple foods rich in carbohydrates, while the younger generation is accultured to the Westernized diet and processed foods, which are often high in fats and low in carbohydrates. Other factors contributing to higher body mass index (BMI) are lack of exercise, genetic predisposition, and disadvantaged socio-economic status.

Smoking is an important risk factor for low HDL-C, though the prevalence is lower than in the nonimmigrant population, and it varies across subpopulations of immigrants. Cigarette smoking has a direct dose response. Smoking more than 11–20 cigarettes per day alters the lipid profile through nicotine-induced lipolysis and the development of hyperinsulinemia among smokers.

Lastly, psychosocial and socioeconomic factors have been implicated as important risk contributors in some studies. The role of these factors may have added impact in the escalating rate of chronic medical conditions among immigrants.

With continuing unhealthy behavior, hyperlipidemia establishes itself in the immigrant population and continues as an important cardiometabolic risk factor. Risk reduction strategies such as lifestyle modifications and prescribed medications are important to reduce morbidity and mortality associated with hyperlipidemia and CMS, regardless of migration status.

Prevention of hyperlipidemia requires a comprehensive approach that incorporates therapeutic lifestyle changes and risk-modifying strategies tailored to the values and beliefs of the immigrants using translated and culturally-relevant educational tools. In general, guidelines to manage hyperlipidemia and cardiometabolic risk factors share similar features (Table 1).

Blood Cholesterol. Table 1 Profile of immigrant and management of hyperlipidemia in CMS

Immigrant's profile	Recommendations
No lifestyle or metabolic risk factors	1. Optimal physical activity and diet to keep BMI <25 kg/m^2 2. Diet rich with complex carbohydrates, reduced saturated fats, and high intake of fruits and vegetables 3. Smoking cessation
Obesity with or without sedentary lifestyle	1. Physical activity with regular moderate intensity. At least 30 min of continuous or intermittent 5 day/week to reduce body weight by 10% until BMI is <25 kg/m^2 2. Dietary fat should be unsaturated with reduced trans fat and simple sugars. Total fat intake must be 25–35% of total calories 3. Smoking cessation
Low HDL-C and high TG	1. Physical activity with regular moderate intensity. At least 30 min of continuous or intermittent 5 day/week to reduce body weight by 10% until BMI is <25 kg/m^2 2. Dietary fat should be unsaturated with reduced trans fat and simple sugars. Total fat intake must be 25–35% of total calories 3. Adding fibric acid or niacin 4. Smoking cessation
Elevated LDL-C	1. Physical activity with regular moderate intensity. At least 30 min of continuous or intermittent 5 day/week to reduce body weight by 10% until BMI is <25 kg/m^2 2. Dietary fat should be unsaturated with reduced trans fat and simple sugars. Total fat intake must be 25–35% of total calories 3. Add LDL-C lowering drugs depending on number of CVD risk factors. If patient has high CVD risk factors, the LDL-C goal is <100 mg/dL. If moderate risk, LDL-C goal is <130 mg/dL. If low risk, the LDL-C is <160 mg/dL 4. Smoking cessation

BMI body mass index, *CVD* cardiovascular disease, *HDL-C* high-density lipoprotein cholesterol, *LDL-C* low-density lipoprotein cholesterol, *TG* triglycerides, *CMS* cardiometabolic syndrome
Source: Grundy et al. (2005)

Physical activity and weight reduction have a significant role in the management of hyperlipidemia and CMS by improving lipid profile and insulin sensitivity. Following the goals and recommendations of the American Heart Association on modifying lifestyle risk factors, physical activity that involves at least 30 min of moderate-intensity aerobic activity, like brisk walking, preferably daily, is recommended. For those at high risk for or with established cardiovascular disease, a medically supervised program is advised. Reduction of 7–10% of body weight from baseline within one year or until BMI of <25 kg/m^2 is desirable.

Barriers to implementing physical activity are particularly great for low-income immigrants. Physicians must promote physical activity and improve their knowledge through multiple channels with realistic goals in order to increase their participation and improve self-management behavior.

Similarly, diet management and smoking cessation are also important factors to address. Diet management through the assessment of dietary patterns, nutrition education, and personalized dietary regimens that consider food preferences are effective strategies that can alter unhealthy dietary acculturation. The recommended diets are focused on consumption of complex rather than simple carbohydrates using polyunsaturated and monounsaturated rather than saturated and trans fats and increasing consumption of fruits and vegetables. Immigrant-directed dietary regimens may have better compliance and an increased chance of improving dietary habits.

The most important class of drugs to treat hyperlipidemia are HMG-CoA reductase inhibitors ("statins"), niacin, and fibric acids. These may be used alone or in combination. These drugs, thought to have a significant lipid-lowering effect in Whites, have been found to produce ethnically based differential responses. This is an important issue when selecting appropriate drugs to treat hyperlipidemia. In addition, fibric acid is more effective than statins in the treatment of the lipid profile associated with cardiometabolic syndrome characterized by low HDL-C and high TG.

Risk stratification using a number of CVD risk factors, with LDL-C as the main target, guides clinical care providers when initiating an optimal treatment strategy, whether lifestyle therapies or lipid-lowering drugs are indicated. CVD risk factors are established atherosclerotic CVD, diabetes, metabolic syndrome, smoking, or 10-year risk for coronary heart disease of 10–20%. If the patient has one CVD risk factor, treatment is targeted for LDL-C <160 mg/dL. If more than two risk factors are present, targeted LDL-C must be <130 mg/dL. If there is coronary heart disease or a coronary heart disease risk equivalent, the targeted LDL-C is <100 mg/dL. Though there is no goal for low HDL-C, lifestyle therapies or adding fibric acid or niacin can increase it.

In cases in which elevation of cholesterol is related to family history or genetic disorder, like familial hypercholesterolemia, counseling and screening are an important part of management. If the underlying cause is due to a medical condition, such as diabetes or chronic kidney disease, control of glycemia through lifestyle modification and use of lipid-lowering drugs improves disease outcome.

Smoking cessation through the use of drugs like bupropion and community- or clinic-based counseling is a challenging task and requires an intensive and comprehensive approach. Recommended strategies that employ a combination of pharmacotherapy, counseling, and behavioral modification offer a higher chance of quitting.

Migrant population–based interventions must be implemented over an extended period with supervision to support the program. These interventions should be low cost, accessible, and implementable as large community-based programs.

Immigrants' health differs from that of nonimmigrants, whether their condition improves or deteriorates as a result of assimilation and acculturation to their new environment. Clinicians must increase their awareness of immigrants' higher health risks compared with nonimmigrants.

Hyperlipidemia is not an isolated disease risk factor but part of a spectrum of factors that synergistically work to cause disease. With immigrants' heterogeneity and differential exposure to behavioral and environmental factors at various stages of their lives, a comprehensive approach is mandatory. With a wide range of effective strategies available, future research must focus on longitudinal studies and the conduct of evidence-based, ethnic-specific community interventions on health promotion and disease prevention.

These tasks can be very challenging. Following the principles of theory of planned behavior and reasoned action, immigrants have various behavioral beliefs. Modifying the value attached to it through education and frequent follow-up will motivate them to comply until they fit in with the healthcare systems. This will improve their perception of the ease or difficulty of behavior performance, because immigrants have different healthcare needs and outcomes.

In addition, highlighting the importance of examining health risk behaviors by immigrant status is a mounting interest among policymakers, as their proportion in terms of overall population continues to increase along with the cost of care.

Blood Glucose

JOANNE K. UJCIC-VOORTMAN
Department of Epidemiology, Documentation and Health Promotion, Public Health Service Amsterdam, Amsterdam, The Netherlands

Levels of blood glucose in the human body are regulated by insulin, a hormone secreted by the beta cells of the pancreas. Insulin facilitates the transport of glucose across cell membranes. When the regulation by insulin fails and glucose transport across cell membranes is impaired, the result is hyperglycemia: high blood glucose levels. Hyperglycemia is a common effect of undiagnosed or uncontrolled diabetes, a chronic disease caused by a lack of insulin activity. This lack of insulin activity may have two causes: The pancreas does not produce enough insulin or the body is not able to effectively use the available insulin, also known as insulin resistance. There are two major types of diabetes: Type 1 diabetes is mainly caused by a decline in insulin secretion by the pancreas and type 2 diabetes mainly by insulin resistance.

High levels of blood glucose can over time lead to serious damage to the body's systems especially to the blood vessels and nerves. Patients with diabetes have a high risk of microvascular (small vessel), peripheral vascular (blood vessels in the extremities), or cardiovascular disease. Half of all patients with diabetes eventually die of cardiovascular disease, primarily coronary heart disease and stroke. Other common consequences of diabetes are damage to the eyes, eventually resulting in visual impairment or blindness, kidney failure, neuropathy (nerve damage), and gangrene foot.

Diabetes is a rapidly spreading global health problem. Currently, over 220 million persons worldwide are estimated to have diabetes and this number is expected to have doubled by the year 2030. People with a sedentary lifestyle resulting in excess body weight and low levels of physical activity are at higher risk of developing diabetes. Furthermore, a low socioeconomic position, high age, and ethnicity are important determinants of diabetes. Particularly, migrants to Western societies have an increased risk of diabetes. This has been clearly demonstrated for South Asian and African migrants to the USA or the UK, who have a far higher (two- to fourfold) risk of having diabetes than the indigenous White population. In the USA, studies have also shown relatively high prevalence rates for diabetes among American Indians and Hispanic ethnic minorities. In the Netherlands, relatively high risk levels for diabetes have also been shown among migrants from South Asian and African ethnic origin. Compared to the Dutch ethnic population, diabetes prevalence rates are two- to fourfold higher among South Asian Surinamese and African Surinamese migrants. Interestingly, two large Mediterranean groups in the Netherlands, namely Turkish and Moroccan migrants, also show relatively high diabetes prevalence rates.

In Europe, migrants from Turkey and Morocco are among the largest ethnic minority groups. Turkish migrants mainly live in Germany and the Netherlands.

Migrants from Morocco mainly reside in France, Belgium, and the Netherlands. The first wave of migrants from Turkey and Morocco came to the Netherlands in the late 1960s, mainly as labor migrants. Nowadays, in Amsterdam, the Netherlands, Turkish and Moroccan migrants account for around 5% and 9% of the total population, respectively. Because of the relatively high immigration figure and high birth rate in these groups, their numbers are expected to rise in the coming years.

A recent population-based survey performed by the Public Health Service of Amsterdam and the Dutch National Institute of Public Health and the Environment among the Amsterdam adult population (18 years and older) has shown two to almost three times higher diabetes prevalence rates among Turkish (5.6%) and Moroccan (8.0%) migrants as compared to the indigenous Dutch population (3.1%). Although differences in demographic factors, such as age, sex, and socioeconomic status, and lifestyle-related factors, such as physical activity, body mass index, and waist-to-hip ratio, are shown to be of influence, they can only explain part of these ethnic differences. Furthermore, as is seen among migrants from South Asian or African origin, the typical age of onset of diabetes is lower among Turkish and Moroccan migrant groups, respectively, one and two decades younger than in the Dutch indigenous population. When taking into account the fact that these migrants are relatively young, ethnic differences in diabetes risk are expected to in fact be even higher.

Lifestyle-related determinants such as excess body weight and a lack of physical activity are important risk factors in developing diabetes. Primary prevention targeting on these lifestyle factors is crucial in all ethnic groups. However, migrants often have a higher risk of being overweight, and therefore, a special focus should be on them. Taking into account the lower age of onset of diabetes in many migrant groups, screening for diabetes among these migrants should start at an earlier age, preferably before the age of 45 years.

Since the number of migrants in countries such as the Netherlands is increasing and their age is expected to rise, it is of crucial importance to develop interventions targeting ethnic minority groups aimed at the prevention and/or early detection of diabetes.

Blood Pressure

Enrico A. Marcelli[1], Louisa M. Holmes[2]
[1]Department of Sociology, San Diego State University, San Diego, CA, USA
[2]Department of Geography, University of Southern California, Los Angeles, CA, USA

Blood pressure is the pressure exerted on blood vessels by blood circulating in the body. It has two phases: systole and diastole – systole occurs when the cardiac muscles contract and pump blood through the body's arteries, and diastole occurs when the cardiac muscles relax between heartbeats. Blood pressure is therefore measured using both systolic and diastolic readings with millimeters of mercury (mmHg) as the unit of measurement. Normal blood pressure levels in adults are below 120 systolic and 80 diastolic mmHg. Adults with blood pressure measurements between 120 and 139 systolic or 80 and 89 diastolic mmHg are said to be prehypertensive, while those with blood pressure readings of at least 140 systolic or 90 diastolic mmHg suffer from hypertension (high blood pressure). Hypertension is an important risk factor for cardiovascular disease, kidney disease, and mortality, but is often manageable with the use of antihypertensive medications and lifestyle alterations, such as increased physical activity and a low-sodium diet. Approximately 90–95% of hypertension is referred to as *essential* hypertension, meaning the causes of the condition are unknown; the remaining proportion of high blood pressure cases are labeled *secondary* hypertension and are linked to a specific cause, such as stress, smoking or obesity.

The opposite of hypertension is “hypotension” or abnormally low blood pressure (defined as blood pressure below 90 systolic or 60 diastolic mmHg). However, hypotension is less prevalent (as we report in the next section) and less often studied than high blood pressure. When it does occur hypotension can lead to depression, increase the risk of falls as a result of increased dizziness, and in severe cases it may lead to organ failure and brain damage.

Hyper- and Hypotension Prevalence in the United States by Nativity

Analysis of the National Health and Nutrition Examination Survey (NHANES) data for 2005–2008 indicate that the prevalence rate of hypertension (according to blood pressure measurements, self-reports of hypertension diagnosis, and whether respondents were currently taking antihypertensive medication) in the adult U.S. population was approximately 28%. This rate was considerably higher among adults 70 years of age and older (55%). Separated by nativity, these data suggest that 29% of U.S.-born adults had hypertension and 22% of foreign-born adults did. This hypertension nativity difference reverses, however, as the populations age – while both U.S.- and foreign-born adults were at increased risk of hypertension the older they were, 54% of U.S.-born adults over the age of 70 were hypertensive compared with 64% of foreign-born adults in this age group. Although we were unable to identify any studies that have investigated the prevalence or sources of hypotension by nativity in the United States, 2005–2008 NHANES data suggest that 17% of U.S.- and 21% of foreign-born adults were hypotensive.

Hypertension Awareness and Management

Not all U.S.-born adults who have hypertension are managing or even aware of the condition, partly because high blood pressure is not always accompanied by obvious symptoms. For example, 34% of U.S.-born and 20% of foreign-born adults who have hypertension report that a health professional has never informed them of this diagnosis. One implication, of course, is that U.S.-born individuals have a higher prevalence of hypertension than typically reported and are less aware and potentially less likely to be in control of their blood pressure. Furthermore, among adults who have been diagnosed with hypertension, it is estimated that approximately 75%, regardless of nativity, were taking antihypertensive medication. Unfortunately, little research exists on blood pressure management and medication compliance among foreign-born residents of the United States. Studies that have been conducted – mostly among international Mexican and Chinese migrants – convey three messages: (1) migrants are less likely to be screened for blood pressure than nonmigrants; (2) migrants, especially those who have been in the United States for less time, are less likely to maintain medication compliance when prescribed antihypertensive medications; and (3) more research is needed to understand the determinants of blood pressure awareness, management, and control among the foreign born.

Ethnoracial and Nativity Differences in Blood Pressure

Racial differences in blood pressure have been well documented in the United States, with non-Hispanic Black adults consistently demonstrating a higher prevalence of hypertension and lower rates of blood pressure screening and medication compliance than non-Hispanic Whites. However, the 2005–2008 NHANES data indicate that non-Hispanic U.S.-born

Black adults actually had a lower prevalence of hypertension (31%) than non-Hispanic U.S.-born Whites (38%). This ethnoracial minority advantage disappears around the age of 50 though, and as the population ages non-Hispanic U.S.-born Black hypertension rates begin to exceed those of non-Hispanic U.S.-born Whites. Consequently, it appears that differences in hypertension rates exist not only by nativity in the United States, but also within foreign-born populations by age and race. Such heterogeneity between and among ethnoracial-nativity groups intimates that researchers need to be careful when comparing various subpopulations residing in the United States, and at the very least age-standardize data before presenting statistics comparatively. The evidence to date regarding blood pressure (and in particular hypertension) among specific migrant groups, in the United States or elsewhere, is relatively scant. Initial studies have tended to focus either on Latinos as a whole or on Mexicans – who constituted the largest legal and unauthorized foreign-born populations in the United States as of 2008.

In general, foreign-born Mexican residents of the USA appear to have lower rates of hypertension than U.S.-born populations regardless of race or ethnicity. For example, according to the 2005–2008 NHANES data, the hypertension prevalence rate among foreign-born Mexicans is 15.8%. In line with the immigrant selectivity hypothesis, one study also found that foreign-born Mexican residents of the USA had the lowest rates of hypertension when compared with U.S.-born Mexicans and those living in Mexico. However, some evidence suggests that foreign-born Mexican residents of the United States are also less likely to obtain blood pressure screening than U.S.-born Mexican Americans and non-Hispanic U.S.-born Whites.

When looking specifically at other Latin American groups, the story seems less consistent; a few studies have found darker-skinned Latino populations, such as those from the Dominican Republic, to exhibit hypertension prevalence rates more similar to those found among non-Hispanic U.S.-born Blacks, and that Central American migrants fall somewhere in between Mexican and Dominican migrants. The NHANES data suggest that immigrants from Spanish-speaking countries other than Mexico have a hypertension prevalence rate of 27.3% – notably higher than foreign-born Mexicans but still slightly lower than U.S. adults viewed collectively. However, among Latino migrants with hypertension, Mexicans appear less likely to be in control of their blood pressure after having been diagnosed (66% taking medication) than other Spanish-speaking migrants (78% taking medication). In terms of race, migrants who characterize themselves as White are more likely to suffer from hypertension (28.7%) than those who self-identify as Black (27.1%) or Latino (20.2%).

Only a few studies have looked at other non-Hispanic migrant groups, and again foreign-born Asians (usually including Arabs and Persians) and foreign-born Africans tend to be considered as single subpopulations rather than separated by place of birth. Still, existing research indicates that foreign-born Asians have the lowest rates of hypertension. One study using 1993–1994 National Health Interview Survey (NHIS) data found only 8.9% of Asian immigrant adults to be hypertensive. In contrast, U.S.-born Asians in the same study had a prevalence of 19.9%, higher than the non-Hispanic White prevalence of 17.5%. Another study looking at adult immigrants in the United States from all over the world found that foreign-born Europeans had the highest hypertension prevalence rates, followed by Latinos, Africans, and finally Asian and Middle Eastern immigrants. A household study of Arab immigrants in Michigan, published in 2008, found a hypertension prevalence rate of 18% and another survey of foreign-born African physicians and nurses found that the African migrants had a lower rate of hypertension than the African-American comparison group.

Hypertension and the Acculturation Hypothesis

Although immigrant groups in the United States appear healthier than their U.S.-born counterparts with respect to hypertension, research on acculturation – often measured by English-language proficiency or duration in the United States – suggests that immigrant health declines across a variety of outcomes the longer they reside in the United States. The limited research on hypertension and acculturation is inconsistent on this point, with some studies finding time in the United States to be associated with greater hypertension prevalence and others reporting no association. Comparisons between the findings are often difficult, as data and acculturation measures employed vary from study to study.

For example, one study using the Multiethnic Study of Atherosclerosis (MESA) data included Latino immigrants aged 45–84 and measured acculturation with two variables: language spoken at home and proportion of life spent in the United States. A second study employed the 2005 New York City Community Health Survey data, including U.S.- and foreign-born Latinos, as well as non-Hispanic Blacks and Whites, and examined differences between immigrants who had been in the United States for more than 4 years and more recent immigrants. Another study utilizing NHIS data looked at all foreign-born residents and the relationship between hypertension and length of time in the United States measured according to three categories: less than 10 years, 10 to less than 15 years, and 15 years or more. The first study found that those respondents who spoke Spanish at home and had been in the United States for a smaller proportion of their lives had higher systolic blood pressure, while the second study found a positive relationship between length of residence in the United States and hypertension. The third study reported no association between hypertension and having lived in the United States for 15 or more years. Thus, the dynamics of the migration process and their influence on blood pressure remain unclear.

Individual and Sociogeographic Determinants of Hypertension

Beyond the migration experience itself, there are a variety of risk factors for high blood pressure. Most research has honed in on individual genetic, physiological, and lifestyle factors, but there is increasing evidence pointing to the importance of sociogeographic factors as well. Age is the foremost risk factor for developing high blood pressure – the prevalence of hypertension increases considerably beyond the age of 50. According to the NHANES data, the prevalence rate of hypertension in foreign-born adults ages 50 and over in the United States is 45.6% (48.9% for U.S.-born), and that for adults between ages 18 and 49 is only 9.9% (14.5% for U.S.-born). Having a family history of high blood pressure is also a serious risk factor for developing hypertension.

Many of the remaining risk factors for hypertension are more modifiable than age or family history. Lifestyle factors, or health behaviors in particular, are often implicated in cases of high blood pressure and adjusting these factors may be required in order to control hypertension. For example, smoking, a high-sodium or high-fat diet, lack of physical activity, and alcohol or drug abuse are risk factors for hypertension. While some non-U.S.- born groups are less likely to engage in such habits, others may be more likely to do so depending on the environment from which they migrated as well as their current environment.

In China, for example, more than 60% of the male population smokes compared to 23% of U.S.-born men, and this habit may increase the probability that Chinese migrants in the United States will smoke. Foreign-born Mexicans in the USA are often employed in manual labor jobs in which they engage in employment-related physical activity on a daily basis when they arrive, and this may buffer against hypertension. Studies of Brazilian and Dominican migrants in the United States have found both groups to be less likely to engage in harmful behaviors compared to the U.S. population as a whole, but Brazilian migrants are healthier than Dominicans across various metrics. Thus, not all migrants engage in behaviors likely to contribute to hypertension, but consistent with the acculturation hypothesis, evidence suggests that the longer migrants reside in the United States, the more likely they are to emulate relatively unhealthy habits of the U.S.-born population.

Finally, there are sociogeographic factors that may influence the probability of experiencing hypertension, many of which pertain especially to immigrants in the United States. Specifically, a large proportion of the foreign-born population in the United States is from Latin America, and Latino migrants tend to be of lower socioeconomic status and to live in more residentially segregated neighborhoods than their U.S.-born counterparts. Some migrants are unauthorized to reside in the USA, and each of these circumstances separately and together may induce stress and anxiety. Stress is a multifarious risk factor for high blood pressure, and if chronic, may predispose individuals not only to hypertension but to a host of concordant health problems, such as cardiovascular and metabolic diseases.

Legal and unauthorized migrant populations also have less access to health insurance and medical care than U.S.-born residents. A study using the NHIS data for 1998–2003 found that foreign-born residents of the United States were far less likely to have access to health insurance than U.S.-born individuals – 26 versus 11%. Among the foreign-born, Latino immigrants were least likely to have insurance, with 37% of the population lacking access to care. A second study suggests that approximately half of all legal and a full two-thirds of unauthorized Latino migrants in California lacked access to health insurance between 1993 and 2001. Without access to insurance, people are less likely to obtain preventive care, such as blood pressure screening, and less likely to successfully manage hypertension once diagnosed.

With the foreign-born population comprising a substantial and increasing proportion of the United States population, and generations of their U.S.-born children growing in number, it is important to gain a clearer understanding of the risks of hypertension (and hypotension) among these immigrants and the factors explaining these risks. While research that currently exists offers a useful starting point, further work is necessary to elucidate the differences in risk and prevalence among the many foreign-born population groups in the United States.

Body Image

Andrea M. Przybysz
Case Western Reserve University School of Law,
Cleveland, OH, USA

Practitioners should be aware of several body image-related issues when dealing with immigrants. One's body image can be defined as the way an individual perceives himself or herself and is often complicated by the process of immigration insofar as immigrants may perceive themselves according to the cultural standards of both their native and receiving countries. It appears that the longer immigrants remain in their nonnative land, and the more immigrants absorb the culture's attitudes toward body image, the more susceptible immigrants are to certain body ideals and pitfalls of the dominant culture. The major issues a practitioner should consider with respect to body image include unhealthy dieting, media images of thin and fit women, the impact of media on body image distortions and body dissatisfaction, eating unhealthy comfort foods, obesity, and, increasingly, eroticized White bodies.

In contrast with the numerous mental and physical health issues modern immigrants face as a result of poor body image, historically, this has not always been the case. In the wake of Europe's mass exodus after World War II, many individuals immigrated to the USA and other European safe havens in the hopes of achieving physical safety and health. While immigrant health and positive body image may be partially attributed to the new feminine ideal of the 1940s and 1950s (led by buxom actresses such as Marilyn Monroe, Lauren Bacall, and Marlene Dietrich), it can also be attributed to Holocaust survivors who promoted the new ideal. The new ideal hailed curves and large breasts, and Holocaust survivors who had been deprived of food and drink for numerous years latched onto such voluptuous images.

Because today's immigrants leave one set of stressors in their native land, only to arrive to an entirely new set of stressors and limited opportunities in receiving countries, poor eating and inadequate self-care dominate today's immigrant culture. In the USA, Latino individuals provide insight into this phenomenon, which essentially manifests itself in several ways, including unhealthy dieting, overeating comfort foods, and vacillating between the ideals of their native countries and Western ideals. Nonphysically active Latina women living in the USA concerned with health maintenance and body image have expressed grievances over the thin American ideal in contrast to the curvaceous Latin ideals. At issue for these immigrants is the desire to preserve their cultural pride in feminine curves versus the desire to assimilate into a receiving culture that tends toward an ideal of thin actresses and supermodels without curves.

As a consequence of mixed media and cultural messages, many Latinas are at risk of developing mixed feelings toward healthy eating and physical activity. Overeating affects many immigrants whose comfort food in their native lands was deep-fried. Many developed countries have incorporated significant amounts of ethnic food into their common cuisine, and while this multicultural phenomenon is progress in the sense that just about anyone can get a burrito or chop suey anytime, day or night, this phenomenon indeed puts immigrants at risk. Specifically, those immigrants who are overworked and stressed may find that the easiest and most comforting meal often consists of fast food that vaguely resembles food from home.

Mixed feelings regarding Western ideals of thinness extend beyond Latinos in America. As immigrant women in Australia and Canada acculturate, they may eventually experience a shifting of their weight-related values, and at the extreme can develop disordered eating. It appears that the longer immigrant individuals live in societies steeped in Western ideals, the higher the risk is that they will develop disordered eating. This trend rebuts previously accepted notions that factors for disordered eating are restricted to non-Hispanic White females in Western societies, and, instead, posits the notion that self-assessment increases as women take on less traditional female roles and become more competitive in the workplace. As such, it can be important for practitioners to speak with clients and instill in them the value of preserving one's cultural heritage and the ways in which their respective heritage values the female figure.

Many immigrants also struggle with feelings of inferiority due to skin color. A closely held belief emerging, almost transcontinentally, is the belief that lighter skinned individuals are better situated and fare better than darker skinned individuals, regardless of race/ethnicity. This tension is presently playing itself out in Asia and increasingly among Asian, Jamaican, and Indian immigrants who see skin bleaching as a means to upward mobility. The perceived need for skin bleaching stems from the idea that white skin is both noble and aristocratic, while dark skin is a result of manual labor and agrarian living. Because of the inherently racist undertones, US marketing corporations that promote skin-bleaching products are careful to designate products as "brightening, not whitening products." But, the so-called sensitivity seems insincere in light of numerous reports of mercury poisoning in China. Mercury is an active ingredient in many bleaching products and, the higher the mercury content, the better results a bleaching product has. The problem, of course, is that mercury is toxic and can cause psychosis, kidney failure, and injure the nervous system. While various countries have regulations to prevent harmful products from entering the market, immigrants whose receiving countries do not have such safeguards run the risk of bringing in or importing harmful products and jeopardizing their health in an effort to fit in and get ahead.

The lasting impact of body image distortion and body dissatisfaction on immigrants remains to be seen, but should the current trends continue to dominate, Western ideals of stick-thin models and pale skin will likely prevail at the expense of healthier ideals such as those prevalent in Latino and Mediterranean cultures.

Body Mass Index

Connie H. Carr
Center for Research, The Institute for Palliative
Medicine at San Diego Hospice, San Diego, CA, USA

Body Mass Index or BMI is a simple way to measure body fat based on a person's height and weight. It is often used to determine a person's health and fitness status. It is also used to screen for weight categories that serve as indicators for potential health risks. BMI was originally developed by the Belgian statistician, Adolphe Quetelet, between 1830 and 1850. The mathematical formula to calculate BMI is Weight (in kilograms) Height (in meters)^2. The standards are the same for men and women.

According to the National Institutes of Health, BMI classifies weight as follows:

- Below 18.5: Underweight
- 18.5–24.9: Normal weight
- 25–29.9: Overweight
- 30 and over: Obese

There are over 1 billion overweight adults in the world and at least 300 million of those are obese. Obesity has clearly become a global epidemic. Overweight and obesity are major risk factors for serious diseases such as type II diabetes, heart disease, hypertension, stroke, and cancer. Over the last 20 years, there has been a dramatic increase in the obesity rates in the United States. Rates are especially high for non-Whites. The CDC reported African-Americans had a 51% higher prevalence of obesity and Hispanics had 21% higher obesity prevalence compared with Whites between 2006 and 2008.

A large study conducted in Canada over a 12-year period revealed that non-White immigrants to the country had a lower BMI than native born Canadians. Although the immigrants did have a rise in their BMI over time, they remained lower than their native counterparts. Immigrants to the United States are also at risk for increased BMI and obesity. Studies show many immigrant groups have significant weight gain associated with their length of residence in the United

States. Among the different ethnic groups, higher BMI scores were strongest among Hispanics with longer time of residence in the United States. This often results as immigrants adopt an unhealthy sedentary lifestyle and an American diet of fast food and snacks. In another study of hotel workers in Hawaii, BMI of immigrants from the Pacific Islands and Philippines was actually greater than the BMI of White natives.

Body mass index is the generally accepted method of determining a person's body fat based on the individual's height and weight. The National Institutes of Health categorizes overall health and risk of developing health-related problems based upon the BMI. Some immigrants to the United States are at risk of increased BMI and obesity the longer they reside in the country. Although BMI varies among ethnic and immigrant groups, there has been an overall rise in BMI demonstrating the rise in obesity internationally.

Body Shape

Kathleen Franco
Department of Psychiatry and Psychology, Cleveland Clinic Foundation, Lerner College of Medicine, Cleveland, OH, USA

Body shape is a complex topic and greatly impacted by the world around us, as well as our own internal thoughts and perceptions. The ideal body shape or image is a construct an individual believes is what they should look like. This may or may not match their actual appearance. Perceived body shape may also be distorted or accurate. Thin anorexic patients perceive themselves as fat and try to avoid eating to gain weight, even when detrimental to their health. Conversely, some obese persons have grown up in families where being overweight is the norm and not believed to be problematic. The medicalization of obesity has also impacted how persons feel about themselves and their shape. This chapter will discuss a range of influences on immigrant shape.

A range of body shape consequences can occur after immigration. Young Asian immigrants are at risk for anorexia, bulimia, or disordered eating while older immigrants who lose their former eating habits and exercise patterns gain more weight over the years than the amount generally expected in peers living in their homeland. Immigrants to the USA find themselves adapting to many changes: less exercise, more processed foods, increased portion sizes, and an abundance of energy dense foods bringing weight gain and higher body mass index. Immigrants who reside in the United States for 15 or more years are much more likely to be obese than new immigrants who have lived in the USA less than a year. Although immigrants may come with healthier habits, these gradually diminish the longer they remain. Women in particular, who move to the USA by the age of 20 or younger, are more vulnerable than those who immigrate over the age of 20. When immigrants go to a physician for care they are less likely to discuss weight, exercise, or diet with their doctor and therefore, not as likely to receive advice about their body shape or weight management.

Several studies report daughters born in the USA of Asian and Hispanic immigrants reportedly have more dissatisfaction with their bodies and are more likely to exhibit disordered eating than White US females of the same age. Even if young women recognize overprotection as a reflection of caring, it remains a risk factor for the development of abnormal eating patterns. Over-protection and conflicts, particularly with mother, are associated with higher scores on eating disorder assessments aimed at detecting anorexia and bulimia. The same has been found in Great Britain when comparing second-generation female British Asian college women to White college women.

Income, education, gender, and birthplace in the USA, or birthplace in another country can impact body mass index (BMI) but in somewhat complex patterns. For example, higher education is more predictive that US-born females can maintain a healthy weight, but that is not necessarily valid for immigrants living in the USA. Although true for women, it is inconsistent for immigrant males. The country of origin also impacts (BMI) and shape. Adult immigrants may come to the USA with lower rates of obesity, but acculturate to diet changes and inactivity leading to larger body shape. Puerto Ricans and Cubans are susceptible to increased body mass the longer they live in the USA. In a study without controls, Mexican immigrant women believed that physical activity provides health benefits but are still unlikely to exercise. First generation Hispanic adolescents as a group are more likely to become obese after moving to the USA than are US-born Hispanic adolescents.

Foreign immigrant families are likely to have lower income, less maternal education, and live in isolated immigrant sections of cities where the primary language is not English. Higher socioeconomic level is more protective against obesity for White nonimmigrants than immigrants. Nonetheless, looking at large populations of all socioeconomic levels, obesity remains higher in White US-born individuals than immigrants.

Native Alaskan women are content with larger body shapes than White Alaskan women. However, as Native Alaskan women move, acculturate, and spend more time in urban areas, they are more likely to adapt the Western ideal.

Studies in Sweden demonstrate that multiple immigrant groups by nationality are susceptible to obesity. Socioeconomic level, education, occupation, and social network all impact rates of obesity in immigrants to Sweden. The stress of immigration and acculturation is believed to lead to increases in unhealthy behaviors that lead to obesity. However, risks of physical inactivity were less important in males from southern European or Finland currently living in Sweden.

Even without immigrating to another country and culture, younger women in third world regions may be influenced by thin actresses coming to make movies in their nations.

In summary, immigration and multiple other factors influence how individuals perceive their weight and body shape. Conflicting values, gender, ethnicity, religion, availability of fast food, and willingness to exercise can impact both body shape and commitment to choices.

Border

Jennifer Pope
School of Public Health, University of Texas,
Brownsville, TX, USA

A "border" typically refers to a clearly demarcated, geopolitically defined boundary. Borders are primarily established for the purpose of territorial control and characteristically have defensive security measures in place to contain or limit the entry or exit of various things into a region. Crossing a border usually requires complying with laws and standards set forth by its founding governing entity. For example, the presentation of a passport is required protocol for entry into most foreign countries. Worldwide, border disputes are commonplace and generally tied to power struggles over resources, regional jurisdiction, or cultural clashes. Past and present efforts to regulate borders include the construction of a number of controversial, heavily supervised physical barriers, such as the Berlin Wall, the Korean Demilitarized Zone (DMZ), the US–Mexico border wall, the Great Wall of China, and the Israeli West Bank barrier.

Globalization, the intensified interdependence and interconnection between nations, has had an integral role in shaping modern border policy and directive. For instance, border relations have been profoundly altered by increasingly liberalized international trade restrictions. The North American Free Trade Agreement (NAFTA), a trilateral trade agreement implemented in 1994 that encourages import and export between the USA, Canada, and Mexico, is an example of policy that has generated noticeable ripple effects in the political, economic, and social climate of the US–Mexico frontier. Although NAFTA is responsible for dramatic economic growth in these nations, critics assert there have also been negative ramifications. For example, the explosion of the export industry triggered by NAFTA led to a significant rise in *maquiladoras*, or foreign-owned factories found along the Mexican side of the border. Maquiladoras are frequently depicted as unsafe to work in, with laborers working long hours and receiving low wages and little to no benefits. These factories have also been blamed for exacerbating serious environmental problems and posing additional threats to the health of the workers exposed to them.

US–Mexico Border

The US–Mexico border, the most frequently crossed international border in the world, stretches 1,969 miles from the Pacific coast cities of San Diego, CA, and Tijuana, Baja California, to the Gulf of Mexico and the cities of Brownsville, TX, and Matamoros, Tamaulipas. In total, there are 48 US counties in four states and 39 municipalities in six Mexican states that line the border. Approximately 12 million individuals reside in this region, the predominant portion of whom live in 14 pairs of sister cities. The US state with the largest section of the border is Texas, which hosts four of the six highest traffic crossing areas. US government figures from 2006 declare 250 million individuals legally crossed into the USA from Mexico by land at various ports of entry. Current statistics indicate there are between 11 and 12 million illegal immigrants living in the USA, the largest portion of whom are Mexican born. However, recent data reveal a decline in subsequent years of both legal and illegal immigration from Mexico, a trend that some researchers suggest is primarily the result of the struggling US labor market and economy.

National security concerns over the permeability of the border, coupled with a volatile sociopolitical debate over the effects of illegal immigration in the USA have intensified the management of this nearly 2,000-mile border. The majority of more than 20,000 US Border Patrol agents are stationed along this border. A controversial fence, which runs intermittently along the border and is still being erected in some areas, was constructed to deter persons trying to gain illegal entry into the country as well as control the flow of drugs and other illegal goods. Although proponents of the fence believe that it has been effective in reducing the number of arrests relating to illegal entry, critics perceive the barrier as detrimental to the physical and social environment, and ultimately as an ineffective long-term deterrent to illegal crossing. Human rights groups are concerned with the number of immigrants, both confirmed and presumed, who have died in their attempts to cross the border. These deaths are mostly attributed to dehydration and heat stroke from crossing in areas with harsh natural conditions, such as the Sonoran Desert in Arizona.

Colonias

The passage of NAFTA also initiated a sizeable increase in the number of *colonias*, or poor, unincorporated settlements found along the US–Mexico border that developed in response to the need by low-wage workers for inexpensive housing. The largest US colonia population currently resides in Texas, where approximately 400,000 individuals live in over 2,000 colonias. Because housing in colonias is obtained informally, it is often constructed of substandard materials and lacking in adequate infrastructure such as plumbing and electricity. Colonias characteristically have unpaved roads and problems with animal control. One of the greatest health threats to colonia residents is accessibility to potable water. Consequently, exposure to and prevalence of infectious diseases such as hepatitis A, dysentery, cholera, and salmonella are considerably higher in these communities. Improper waste disposal by colonia residents has also engendered concerns about the creation of environmental hazards and contamination of the larger ecosystem. In addition to higher incidence of infectious disease, current research in the Lower Rio Grande Valley (LRGV) region of Texas reveals that colonia residents and surrounding border populations also have high rates of obesity and chronic disease such as diabetes.

In comparison to the rest of the state and the nation, colonias have higher rates of poverty and unemployment, lower levels of education and literacy, and an increased number of individuals who are uninsured or underinsured. Lower levels of acculturation (e.g., solely speaking Spanish), an inability to acquire transportation to clinical sites, educational inequities in health knowledge and lack of awareness about available programs, a general distrust of government entities and perhaps having an undocumented citizen status are just some of the barriers faced by colonia residents in accessing traditional US health care. Delayed treatment or going undiagnosed is also of great concern for the mental health of colonia residents and others in border populations.

Conclusion

As discussed, borders impact the lives of citizens in physical, economic, and social ways. The US–Mexico border is a frontier of special concern, as residents in close proximity to the border on both sides often experience critical health disparities. Attention to health literacy, and improvements in overall infrastructure will likely enhance the quality of life for citizens living in these regions.

Border Health

María Luisa Zúñiga
Division of Global Public Health, Department of Medicine, University of California San Diego, La Jolla, CA, USA

Border health is a broad term that is characterized by the health care markets, regulatory environments, health laws, environmental factors and health care consumer and individual behaviors (risk and protective) that shape the health of immigrant and other populations living in the region intersected by the geopolitical boundaries of two or more nations. In the 2009 book, *Condiciones de salud en la frontera norte de México* (Health conditions in the northern border of Mexico), Salgado de Snyder provides a comprehensive description of border health in the context of the Mexico–USA border, emphasizing the dynamic and interdisciplinary nature of border health as field for understanding the health priorities and challenges faced by nations with mutual interest in improving health outcomes of migrant and transnational populations.

This definition serves as a foundation to understand immigrant and border-dwelling communities in a global context as evidenced by the recent formalization of cross-border health policies among member nations of the European Union and bordering nations in Latin America. In a global context, historical, regional, and societal factors influence the health of populations living in a border region, particularly those populations that migrate to and from the cojoined countries. A socio-ecological approach provides a useful framework to describe *environmental factors* (e.g., defining a border region, laws, policies, health service infrastructure), *interpersonal factors* (e.g., population mobility and disease exposures), and *individual factors* (e.g., health knowledge, perceptions, and practices) that influence health outcomes and characterize border health. We draw on examples from the USA border with Mexico, bordering nations in South East Asia and South America, and discussions between EU member states about issues relevant to providing cross-border health care in Europe.

Environmental Factors

Defining a Border Region

Although desirable from a comparative standpoint, a strictly geographic definition of the boundaries that determine a border region generally, and border health more specifically, is elusive. Simple metrics of distance from the political boundary may not explain the influence on the health of populations near borders that can be exerted at state, municipal, or national and international levels. The extent to which the health of border inhabitants and immigrants who cross borders is influenced by their proximity to a border region will depend on: regional, occupational, or environmental health risks or protective factors; the availability of and access to desirable health resources on either side of the border; the connectivity between the nations (e.g., roads, bridges, pedestrian crossing points); the regulation of a political border; how porous the region is to unregulated crossing; the ability to cross and costs that may be associated with crossing (e.g., visas); the perceived benefit of crossing or desire to cross among border inhabitants; and the physical distance of residents from the geopolitical border that can moderate cross-border care-seeking activities (e.g., distance lived from the border may be prohibitive to crossing for routine health care). A more global conceptualization of border health may refer to population or environmental health in border counties or municipalities, border states, and even border countries. To this effect, EU member States and border countries in Latin America are formulating health policies that will better define and improve coordination of care for immigrant and binational populations (those who routinely work, visit, and purchase goods and services, including health care, on both sides of the border).

Policies and Laws

Decisions on regulation of who can enter the respective border country to consume health care, or regulation of goods (e.g., medications) that can be introduced into a country are dictated by national security and other interests or perceived threats of the potential for “undesirable” individuals or unregulated goods to enter. In regions where there are political arrangements for free flow of populations (e.g., EU member states), environmental factors that determine mobility may be different than between nations whose borders are more protected from population mobility. For neighboring countries in vastly different stages of economic development and relative per-capita wealth, a more developed neighboring nation may be concerned with the immigration from the lesser developed nation where it is perceived that these individuals would take advantage of a public good such as health care or fear that foreign individuals might work at jobs that would otherwise be held by that country's citizens. Policies governing the cross-border flow of individuals may be further dictated by the political climate and sentiments expressed by the general public toward the potential immigrant or foreign visitor, including racism and xenophobia.

Border health can be influenced by national laws, policies, and political decisions made thousands of miles from the border region, by government representatives who may be unfamiliar with the local reality or needs of border populations, or whose national interests supersede those of its border inhabitants. For example, the US Food and Drug Administration along with the US Customs and Border Protection set policies governing conditions under which medications can be crossed from Mexico to the USA, as well as the type and quantity of medications that can be brought into the USA. The policy is enforced by another federal agency, the US Customs and Border Patrol, whose agents may have discretionary power in the application of certain policies. Border health can also be influenced by health policies operating on each side of the border and the extent to which the health care delivery system from one nation can influence or interact with that of the other. In the State of California, USA, for example, the 1998 amendment to the Knox-Keene Health Care Service Planning Act of 1975 (Senate Bill 1658) was the first state legislation in the USA to allow Mexican health maintenance organizations (HMOs) to offer USA populations health insurance that covers receipt of health care in Mexico. A 2007 amendment to the law required the reporting of certain diseases and health conditions to the California health officer. This type of unilateral legislation can impact the health of residents on both sides of the border, where the worker covered by insurance in one country may have health care access for members of their family living in the neighboring country. Similar considerations, such as care for temporary visitors or workers and quality assurance of medical services are currently being discussed by EU member states. The global health care market is also experiencing growth in private insurance companies that make transnational arrangements with health care providers in regions such as the USA–Mexico border, South East Asia, and China for a network of cross-border care provision.

Health Service Infrastructure

Formal and informal sectors of the health economy in a border region provide care to border inhabitants. The formal health care infrastructure includes hospitals (both public and private); public or private clinics that provide immunizations and disease testing [e.g., testing for human immunodeficiency virus and other sexually transmitted infections, and tuberculosis (TB)]; and an array of public and private agencies that provide out-patient care and other health services. Healthcare delivery from the informal sector may include provision of medications and health advisement from pharmacists, herbalists, traditional healers, and providers of alternative treatments or therapies. Persons living in a border region may access formal and informal health care services on both sides of the border, complementing care that is unobtainable or unaffordable on one side with care available on the other side of the border. Examples include USA residents crossing to Mexico border to obtain medications, dental care, and surgeries at a reduced cost, or to access traditional medicine or traditional healers. When there are significant differences in cost and availability of health care services and medical therapies between bordering nations, health care consumers, who can cross the border and are comfortable doing so, will cross for care. In the absence of care coordination between clinicians or health care systems, the opportunity for fragmented patient care, duplication of services and disease surveillance data, and potential medication interactions increases. The benefits of cross-border coordination of patient care could include improved patient health outcomes, reduced redundant use of health care resources, and improved regional management of chronic and infectious diseases. An example of cross-border coordination includes a TB care program administered by the San Diego County Department of Health and Human Services, California that links USA patients with active TB and their contacts who travel between the USA and Mexico with a Mexican health care provider who can assist with continuity of TB care. The program contributes to improved regional and binational health by helping patients adhere to and complete their TB therapies and avoid development of multi-drug resistant strains.

Interpersonal Factors

Cross-Border Mobility

To the extent that the border between two nations serves as a conduit for migration or is crossed by persons who lead binational lives (e.g., work, live, or purchase goods and services on both sides of the border), cross-border immigration and population mobility is an important component of border health. Persons who are able to cross to and from a neighboring nation may do so to access health care services. As mentioned earlier, border-dwelling populations may exhibit a variety of cross-border health care utilization practices depending on their ability to cross and the availability of services that they may desire or have access to in the neighboring country. Reasons for crossing a border to access health care may be driven by considerations such as preference, availability, and lower relative cost of health care. Individuals who live on one side of a border and work on the other side may access care on one or both sides. This behavior has been reported in numerous studies with residents living in the US–Mexico border region, in the border shared by Thailand and Myanmar and among residents of European member nations. Cross-border mobility and immigration can also be driven by economic factors (e.g., persons who cross daily from one side to the other for work or shopping), political factors (e.g., visas and other government-granted permissions for some members of the population to cross at will), forced migration, repatriation (i.e., deportation) of persons who are in the country undocumented, or individual factors (e.g., crossing to visit family).

Individual Factors

Individual health behavior may change depending on the side of the border the behavior takes place. For example, persons who choose to cross a national border for sexual tourism and engage in behavior that may place them at risk for acquisition of HIV or other sexually transmitted infection (STI) or risk that they may transmit HIV or an STI to an uninfected person (e.g., sex without condoms with a partner with unknown HIV/STI status and sharing contaminated needles or injection drug paraphernalia among injection drug users). Unprotected sex and needle sharing among injection drug users who cross a border and participate in these behaviors on the other side may increase the potential for greater number of HIV cases in a border region. This risk activity adds to the public health burden of screening, diagnosing, and caring for individuals and immigrant populations living in the neighboring country or of both countries. In another example, availability of prescription medications in a neighboring country next to a country with more costly and highly regulated sale of prescriptions may also drive border crossing behavior. The purchase of prescription or other medications may contribute to promotion of health if affordability and accessibility to medications favor better health outcomes. To the contrary, the purchase of medications without proper clinical guidance can undermine public health if, for example, patients consume antibiotics without a prescription or supervision and generate resistant bacterial strains. When populations frequently engage in binational medication purchase and consumption, public health policies regulating access to medications, and the effective enforcement of these policies, are critical to public health efforts in border regions and beyond. For example, to mitigate the potential for patient antibiotic self-medication in the wake of the H1N1 viral epidemic in 2009, in June of 2010, the Mexican government–imposed restrictions on the pharmacy sale of antibiotics, requiring that all antibiotics be sold only with a provider prescription.

A discussion of border health would be incomplete without consideration of gender and how health outcomes and experiences surrounding health and illness may be different for men and women in a border context. For example, there are distinct gender differences in the populations affected by TB in San Diego, California. In 2010, an epidemiologic study conducted by Rodwell and colleagues in the San Diego, California region bordering Mexico found that the profile of persons most affected by TB included males of Latino ethnicity, aged 30–49 years, and who are injection drug users. Other research in border health includes improved understanding gender-related disparities in health for women in the USA–Mexico border region (e.g., cancer and diabetes). Attention to gender differences in the health of border residents can allow for improved targeting of public health resources on both sides to reduce gender disparities in health.

Border Health Research

Research with communities in border regions should strive to meaningfully consider influences that may come from either side of the border to impact the health issue under investigation. Using both quantitative and qualitative research methods to capture the breadth and depth of binational issues that impact health, researchers should take into account the day-to-day experiences of consumers as well as the perspectives of professionals delivering care. In a border context, this would necessitate inclusion of populations that cross back and forth as well as border-dwelling immigrant populations that have relocated to the other side of the border and do not cross. A comprehensive border health research agenda should also include understanding of border community assets and resources that may provide creative avenues for resolving health issues (e.g., community clinics with novel care delivery models that successfully serve underserved, binational populations). Given that individuals residing in border regions frequently cross borders to work, one avenue might include fostering public health and private sector partnerships to improve the health of workers.

Public Health Surveillance and Epidemiology

Current data from border regions clearly indicates that from an epidemiological perspective, border populations are different in many ways when compared with non-border populations. As indicated by Weinberg and colleagues in 2003, border populations should be viewed as one population, instead of two, because diseases are able to make seamless transitions from one nation to another. Recent border health studies indicate that health problems and disease profiles in border regions may differ substantially from non-border regions in the same country or may parallel one another, but vary in the type of population affected. Rodwell and colleagues illustrate an example of this phenomenon through the study of TB in the San Diego-Tijuana region, where TB prevalence is higher both in Tijuana and San Diego than in the interior of each respective country. In the USA, TB disproportionately affects residents of Mexican-origin, who also have worse TB health outcomes than other San Diego residents. The Southeast Asian border between Thailand and Myanmar experiences similar problems. Both nations are considered high-burden TB countries and both face substantial public health challenges in addressing TB and HIV in the border region. The burden of TB in one Thai province is carried by persons from Myanmar, including immigrants and refugees and Myanmar residents and refugees who cross to Thailand for health care or work.

Binational and transnational coordination of disease surveillance activities in many border regions is fraught with challenges due to differences in disease classifications, laboratory tests and metrics, passive and active disease surveillance infrastructure, and reporting requirements. Unilateral approaches to cross-border disease surveillance include the aforementioned Knox-Keen Act that allows for insurance health care coverage of US residents in Mexico. Amended in 2007, the Knox-Keen Act now requires Mexican doctors to provide information to the local US health officer on diseases that are reportable in the State of California (S.1658) and the standards for disease reporting in Mexico continue as per national policy. From a regional health perspective, however, it is unclear whether this type of unilateral legislation would promote duplicate reporting of new cases, such as a confirmed positive HIV test detected in the Mexican border city of Tijuana that is reported both to the centralized Mexican surveillance system and to California's HIV surveillance system. Another polemic involves surveillance of diseases among populations that seek health care on both sides of a border. In many border regions it is common for patients to seek health care services on both sides, including testing for HIV or other reportable diseases, underscoring the importance of a coordinated approach to epidemiological surveillance and public health cooperation between border nations.

The Future of Border Health

The future of border health includes two important elements that will favor the health of populations living in border regions: better systems for electronic transmission of health information and movement toward regional cooperative health agreements. Technological innovations and improved capacity to transmit and share health information electronically is a rapidly growing field. Although public health tends to fall behind in the adoption of new technologies, the "e-health" movement is already being explored among border nations in the USA, Mexico, Asia, and the Pacific. Use of e-health in cross-border health care services can include referrals for care, continuing education for clinicians and other health practitioners, cross-border communication between health care providers, surveillance, medical records, and international travel for the sole purpose of seeking health care (i.e., medical tourism).

Cooperative cross-border or pan-border surveillance and health coordination initiatives are emerging from many regions throughout the world and will also favor the health of border-dwelling populations. The role of binational health organizations or organizations that represent public health interests from two or more countries can serve as a platform to bring together clinicians, researchers, and other public health practitioners to move border health agendas forward. Border health dialogue should include the representation of non-government agencies as well as government-sponsored agencies. Examples of cross-border coordination agencies and initiatives include the US–Mexico Border Health Commission, the US Center for Disease Control and Prevention's Early Warning Infectious Disease Surveillance Program; the Euro-Mediterranean consortium "Impact of migration on HIV and TB epidemiology in the Mediterranean Area"; the 2010 border health plan implemented jointly by Bolivia, Chile and Peru, and European Commission collaboration among member nations to improve cross-border care. These activities will ultimately lead to improved regional surveillance data and to better management of infectious and chronic diseases in border regions throughout the world. The challenges of promoting coordinated border health are many, and include issues of national sovereignty, differing laws regarding the practice of medicine and licensure of practitioners, and clinician perceptions of the quality of care delivery provided in the neighboring country where their patients may seek care. Political and social will to address these issues is critical, as the benefits of coordinated care, improved patient health outcomes and improved epidemiologic surveillance data are measurable, desirable, and make better use of health resources on both sides of a border.

Bracero Program

Daniel J. O'Shea
HIV, STD and Hepatitis Branch, Public Health
Services, County of San Diego, San Diego, CA, USA

The Bracero ("Strong Arm") program was the impetus for large-scale legal and illegal migration between Mexico and the USA. For 22 years (1942–1964), 4.6 million legal contracts were signed with Mexican workers for temporary agricultural work in the USA, making it the largest US contract labor program in history.

Concerned by impending labor shortages for the fall harvest due to conscription for World War II, California farmers asked the US and Mexican governments in the spring of 1942 to allow Mexicans to work seasonally on US farms. Coupled with Mexico's burden of an excess number of unemployed laborers, serious labor negotiations ensued between the USA and Mexico. Even as US farm labor reformers protested that the only shortage was in reasonable wages and working conditions and not workers, the two governments moved forward and signed a bilateral agreement in 1942 for the importation of temporary contract laborers from Mexico to the USA. Desperate for cash work, Mexican workers were willing to take jobs at wages derided by most Americans. Only agricultural workers from Mexico, not urban residents, could participate and prospective candidates often were required to show calloused hands as proof of experience as farm laborers. As part of the processing, Braceros were fingerprinted and disinfected with DDT before being allowed to enter the USA.

The Bracero program was relatively small during the war years, peaking in 1944 at 62,000, less than 2% of the four million US hired agricultural workers. The initial agreement expired in 1947, but the program continued through a variety of laws and administrative agreements until 1964. As the first agreement ended in 1947, many Mexican workers began to migrate into the USA illegally, which was tolerated. If caught, they were legalized by being taken to the border, issued documentation, and returned to the farm from which they were taken; this process was pejoratively called "drying out the wetbacks." With no penalties for farmers who knowingly hired illegal workers, the number of illegal workers soon exceeded the number of legally admitted Braceros. Texas received no Braceros due to racial discrimination and relied upon illegal workers for manual labor, flagrantly violating a 1948 agreement when the Border Patrol welcomed migrant workers across the Rio Grande despite Mexican threats to close the border. US President Truman and the Mexican government supported a 1951 US government commission recommendation to impose fines on US employers who knowingly hired illegal workers, but Congress did not. The 1952 Immigration and Nationality Act that made harboring illegal aliens a felony specified that employing an illegal alien was not "harboring."

One argument for Braceros was that allowing Mexicans to enter legally would reduce illegal migration. This was proven wrong since 4.6 million Braceros were legally admitted to the USA between 1942 and 1964, while 4.9 million illegal Mexicans were apprehended in the USA during the same time frame; both numbers double-count individuals who entered the USA several times. Subsequent to a new Bracero agreement, the Immigration and Naturalization Service launched "Operation Wetback" in June 1954, removing 1.1 million Mexicans, including US-born and therefore US citizen children of Braceros. The US Department of Labor relaxed regulations on Bracero housing, wages, and food charges in the mid-1950s, leading more farmers to hire legal Braceros, whose admissions peaked at 445,200 in 1956.

The Braceros significantly affected the business and culture of farming in the USA, and set the stage for subsequent patterns of Mexico–US migration. The availability of low-cost Braceros permitted the expansion of a labor-intensive agriculture to meet the growing demand for fruits and vegetables. This resulted in a demand-pull for Mexican workers, creating and sustaining circular migration patterns of Mexicans into the USA, linking US farm jobs to rural Mexican villages that became dependent on money earned in the USA. Facing competition from Braceros, US farm workers left the agricultural industry for other labor markets with better wages and working conditions, leading to farm labor shortages that subsequently brought more Braceros whose share of the workforce in major California agricultural commodities soon exceeded 50%. Even legal Braceros confronted competition from illegal workers willing to take an even lower wage, and farm wages as a percentage of manufacturing wages fell in the 1950s.

In November 1960, CBS aired a television documentary, "Harvest of Shame," about the Bracero Program, convincing US President Kennedy that Braceros were "adversely affecting the wages, working conditions, and employment opportunities of our own agricultural workers." President Kennedy ordered enforcement of Bracero regulations. While farmers lobbied heavily to preserve the program, Congress ended the Bracero program on December 31, 1964.

The end of the Bracero program prompted several changes in US agriculture: (1) many farmers joined or formed associations ("super labor contractors") to recruit and supervise fewer US workers, increasing worker earnings; (2) successful unionization, prompted by a strike against grape growers in the fall of 1965 by the National Farm Workers Association led by Cesar Chavez, winning a 40% wage increase for grape pickers largely because no Braceros were available; and (3) new impetus to illegal migration, increasing steadily since 1965 using established patterns, fostered by socioeconomic conditions in Mexico, including unemployment, large disparities in income distribution, and discrimination toward the rural sector in allocating government funds.

Brain Death

Cristina Gavrilovici
Department of Legal Medicine, Medical Deontology and Bioethics, University of Medicine and Pharmacy "Gr. T. Popa", Iasi, Romania

Traditionally, and prior to 1970s, the only criterion to validate death was the irreversible cessation of cardiopulmonary function. It was believed that persons who suffered cardiopulmonary arrest immediately lost brain function and this event would predict permanent nonfunctioning of the organism as a whole, therefore serving adequately as a criterion for death.

In 1968, the Harvard Medical School Ad Hoc Committee decided that brain death should be accepted as the definition of death. The first country to adopt brain death as a legal definition (or indicator) of death was Finland in 1971. In the USA, Kansas enacted a similar law earlier, but the agreement has been later signed by virtually all the leading authorities on the subject in the USA in 1981 (31 states having adopted the Uniform Determination of Death Act that was first proposed in

1981). It became a consensus view of the American Academy of Neurology in 1995.

Brain death is defined as the irreversible cessation of all the functions of the entire brain, including the brainstem. If the brain can be viewed simplistically as consisting of two parts – the cerebral hemispheres (higher centers) and the brainstem (lower centers) – brain death is defined as the destruction of the entire brain, both the cerebral hemispheres and the brainstem. In contrast, in the permanent vegetative state, the cerebral hemispheres are damaged extensively and permanently, but the brainstem is relatively intact. Thus, anencephaly, in which there is no higher brain present, is generally not considered brain death, though it is certainly an irreversible condition in which it may be appropriate to withdraw life support.

The diagnosis of brain death needs to be rigorous, in order to be certain that the condition is irreversible. The patient has no response to command, verbal, visual, or otherwise. A brain-dead individual has no clinical evidence of brain function upon physical examination. This includes no response to pain, no cranial nerve reflexes (pupillary reflex – fixed pupils, oculocephalic reflex, corneal reflex, no response to the caloric reflex test) and no spontaneous respirations. A confirmatory examination (e.g., brainstem auditory evoked response, transcranial Doppler, sensory evoked potential, computed tomography angiogram, magnetic resonance angiogram) must document complete and irreversible loss of brain function including brainstem function.

The EEG exams must show complete absence of brain function (it is usually flat). It is important to distinguish between brain death and states that may mimic brain death (e.g., barbiturate intoxication, alcohol intoxication, sedative overdose, hypothermia, hypoglycemia, coma or chronic vegetative states). Medical conditions that could cause an error in the examinations listed above should be excluded.

As most of the social concepts are with moral implications, brain death has been both accepted and rejected.

For immigrants' health, matters regarding life and death are paramount. More than for anybody else, their own cultural values are at stake, shaping their own decision and the moral acceptability of the host-country medical decisions as well. Many immigrants may accept brain death because, like Lisa Cahill, their belief is that *"life fails to constitute a sufficient condition for the fulfillment of human value in either the presence of gross suffering or the absence of consciousness."*

On the contrary, others have strongly opposed the brain death, considering that Harvard criteria perceive the patient as she is "...already decapitated because the brain has already been destroyed. And even if the heart is able to beat all the time and the patient has no ability to breath independently she is considered dead."

From all the cultural values that have a strong impact on the acceptability of the brain death, religion is one of the dominant factors. According to Islamic tradition (that shapes the life of many Asian and Middle Eastern immigrants), life and death are controlled by God. There is no right to die, since only God can decide when someone will die. Moreover, death is considered to have occurred when the soul has left the body, but this exact moment cannot be known with certainty. The Muslim population in the USA is very diverse; the cultural background of different Muslim groups might influence the way in which they respond to illness or other life crises. For example, some Muslims may perceive a sudden death as a sign of punishment, or a test from God. Moreover, when an immigrant Muslim family moves to a larger non-Muslim society, they may adopt certain elements of their new cultural environment.

However, one aspect that is usually the same for all Muslims, regardless of country of origin, is in relation to the practices surrounding death and dying. Traditionally, many Muslims have agreed with the cardiopulmonary definition of death. Even if the concept of brain death was accepted by many Muslims, not all Muslim countries accept now brain death criteria.

According to the Iranian perspective, as long as the heart is beating, the skin is warm, and the patient is actually looking "alive" (even if he/she is artificially ventilated), it is hard to accept that being brain dead means being dead. It is a moral duty to seek medical help, if needed, and continuous life support (no matter if the patient shows irreversible signs of brain death) is viewed as an obligation, not an option. Generally, the concept of options and patient's autonomy is foreign to traditional Iranian culture. Given the necessity of informed consent in the USA, and taking also into account that informed consent is the essence of a liberal society, dealing with a dying Muslim immigrant patient in the USA signifies a complex exchange of cultural, social, and religious values. In Iranian culture, it is rude to go directly to the point and explain, for instance, that a loved one is “almost” dead and thus a potential donor for organs. There is a need of very sensitive dialogue about the terminal stage of a patient’s disease.

Some Eastern cultures are patriarchic and authoritarian, with great emphasis placed on deference to elders and suppression of personal interests for the good of the family. Immigrant Muslims may often hold these views because of societal norms. Thus, when talking about Muslims’ concept about brain death, one has to understand that we retrieve selected information that comes from their representatives (usually male heads of the families). Brain death is not human death, but the family definition of death.

Many Japanese, especially lay people at the bedside of a family member, may not accept brain death, thinking that brain death should not be considered human death, as long as the brain-dead patient’s body is still warm and moist. Brain death is an “invisible death” that conflicts with everyday intuition. The Japanese criteria for brain death could test only the cessation of the brain’s observable functions, not the actual death of all brain cells. If some brain cells remained alive after the determination of brain death (which is unknown, since an electroencephalogram cannot detect the activities of cells deep inside the brain), some inner consciousness might exist inside the patient’s brain.

For Japanese people, the core site or physical location of personhood is associated with the heart, not the brain. A patient is considered “alive” until the heart stops beating. It should be noted that a “clinical” brain death diagnosis is to be distinguished from a “legal” brain death diagnosis. The clinical diagnosis is a tentative one. The determination does not require an apnea test (the test to see whether breathing has stopped) since such a test might be detrimental to the patient’s body. Physicians are not allowed to reach a legal diagnosis of brain death (including an apnea test) on the patient unless the patient has a donor card, and has agreed to brain death and organ donation (and designated the names of transplantable organs on the donor card).

Other Asian immigrants, like Korean or Korean–American families, also maintain a strong degree of adherence to religious beliefs relating to life and death concepts (including brain death). For them, traditional values dictate that a patient die at home, meaning that basically they will never agree with the Harvard criteria.

One multicultural society, composed of a multitude of immigrants, is Israel, where, beside the native-born Jewish and Muslim citizens, live many people from former ex-Soviet Union, other Eastern European countries, Ethiopia, and South America. In Israel, according to Brain Death/Respiratory Law of 2008, the time of death of a person is determined to be when there is brain/respiratory death or cardiac/respiratory death. Among the reasons why the cadaveric donation rate is very low in Israel is the public’s difficulty in accepting brain death. There has been a decades-long controversy among primarily Orthodox Jewish legal authorities over whether to accept brain death. Many authorities in Israel argue that the traditional definition has always included cardiac death in addition to absence of respiration. This religious opposition is the reason for the clause in the law that allows families to request continuation of the treatment. Notwithstanding the law’s existence, Israel did not adopt one legal definition of death, but left it up to the individual as to how to define death.

In conclusion, brain death is a medical concept and a legal issue with a tremendous moral and social impact. Life and death decision making is a process during which many stakeholders share different views, options, feelings, and uncertainties. When such a sensitive issue arises in immigrants’ lives, more than for anybody else, their cultures, traditions, and values will interact with those held by the host country. Sometimes such an interaction will ease the family’s pathway toward acceptance of the fact that their loved ones’ life is coming to an end, but sometimes will transform the dying process into an unbearable journey. Being very hard to judge one side or another, we may say that respecting the cultural values and, most of all, the individual’s values is the only way in which brain death may equal the human death.

Brain Drain

Domnița Oana Bădărău
Department of Bioethics, Case Western Reserve
University School of Medicine, Cleveland, OH, USA

Human capital is a concept often used by economists to define all the attributes that persons come to possess by natural inheritance or by attending schools, building an education, and lifelong learning through trainings and courses. It is as much an aggregate of knowledge, skills, experience, and competencies as it is an amalgam of personal qualities and values that a person holds. Economically, investing in human capital means creating the premises for economic growth, for social development, and better living standards. Sustainable growth requires an analysis of the costs and benefits of investing in human resources. Access to medical care, education, training, and other resources provides the means for individuals to reach their potential, both physically and mentally. Such an individual will soon incorporate into the human capital by performing labor in order to produce value, especially economic value.

Individual efforts to enhance its potential on the labor market must be sustained within a State by policies aimed at promoting access to education and continuous efforts to improve the quality of it, but also ensure that the human capital will be absorbed by the labor market. Creating jobs must be a priority and the highly skilled should be compensated according to their training and education.

Globalization and the integration of economies have not only increased international trade, but stimulated people mobility. A healthy economy and sound governing ensure the attractiveness of the labor market. A State's inability to provide the opportunities that the highly skilled require in order to fully exercise their potential encourages them to seek other labor markets that are more likely and able to satisfy their need for a bigger income and better working conditions. If such a phenomenon happens at a large scale, it is called *human capital flight* or *brain drain.*

Brain Drain Causes

One of the first uses of the term brain drain was in the 1950s regarding the influx of scientists belonging to the Soviet bloc into the United States. Over the years, the concept came to define the general movement of higher educated individuals that left developing countries and settled in developed ones.

The brain drain phenomenon can be easily confused with the migration process, but the two are not identical, even though they share some common factors that influence the decision to leave a country. Migration is a general process that includes many types of individuals' movements from one country to another, whereas brain drain focuses on highly skilled individuals that decide to emigrate. In other words, brain drain is in fact a migration process, but the main characteristic that separates it from other types of migration is that the individuals leaving a country are educated and the impact on the destination country is mostly positive while the impact on the country of origin may be positive or negative.

Highly skilled persons will more likely find a work place easily and will provide the destination country with the human capital it needs, and at the same time they will probably send part of their income to the origin country. Brain drain supplies countries rich in capital with the labor force they need and also provides origin countries with part of the capital it lacks.

Whether highly trained people are employed in sciences or arts, their behavior is influenced by similar motivations. Commonly, human capital flight is determined by a conflict, lack of opportunities, socioeconomical struggles, or political instability. However, the prospect that the destination country will offer a real income increase over an expected period is the main reason of the highly skilled individuals' migration.

The Impact of Human Capital Flight on Countries' Socioeconomical Environment

The brain drain phenomenon seems to be directed from the developing countries toward the developed ones, richer in resources, and with more possibilities of absorbing the influx of human capital. It also can be argued that the degree of the brain drain, place of origin, and final destination can affect a country's development negatively. Developing countries will be disproportionately affected by the brain drain, as many university graduates leave those countries and important sectors like education and health remain to face a lack of personnel. These are crucial human resources for the country of origin and the individuals might end up employed in another area of the industry than that in which they trained. Migration flows are a key factor to a country's economic, social, and cultural environment. Human capital is, among the other productivity factors, essential to the growth and development of an economy.

It is arguable that the origin countries do not benefit in any way from the brain drain phenomenon. This type of migration increased in the last couple of decades, thus offering a prospect of return to higher education. Such a prospect encourages developing countries' population to seek attending colleges and faculties.

For most developing countries, the highly educated individuals represent a scarce economic resource. Usually, the education these individuals receive is financed by the State from the public finances. The State's effort of encouraging higher education and adjustment to the necessities of the labor market are sabotaged and the investment in people's skills does not produce positive results. Furthermore, the migration of the highly skilled people will affect the society, as the investment made in the individual will not be returned and the competencies, education, and skills will not be used to produce value in the country of origin.

A significant impact of brain drain on the receiving countries is the performance in the labor market. This is determined by the education the highly skilled migrants have obtained and in which country. Most of the migrants within a brain drain process are very well educated and possess great valuable skills. However, once they arrive in a new country, due to either cultural differences or economic conditions, some of these highly skilled individuals might find employment in other areas than the ones they have expertise in. Globalization increased the number and the frequency of the brain drain flows and, as a result, the persons seeking employment might be facing a saturated labor market.

The variation of highly skilled migrants' placement on the labor market can be explained by the cultural baggage an individual carries when leaving the country of origin. Social, personal, and taught values and experience guide a person to make decisions and increase or decrease their capacity of adapting to a new setting. However, the sociopolitical and economical situation in a country influences the decision of the highly skilled persons to emigrate. The most affected countries as a result of this event are the smaller countries with a weak or underdeveloped economy, that lose an educated and needed human capital.

Another aspect worth considering is the selection of the destination country. Aspects like distance, openness to immigrants, standard of life, language, and facilities for foreigners to adapt are usually considered.

Circulation of the Human Capital

Over the last decades, migration patterns changed and new models developed, which caused changes in public policy. The perception of the brain drain phenomenon improved and the movement of highly skilled individuals came to be seen as natural, a process which should not be subjected to restrictive public policies. Instead of being a brain drain, this type of mobility is more and more referred to as the brain circulation. This implies that public policy must suffer changes that would reflect that the migration of the highly skilled could be and, in fact, is a process that can benefit a state and should not be stopped.

The worldwide human capital transfer was in general considered to cause prejudice to the country of origin. Brain drain is a negative external phenomenon with consequences for the population left behind to continue living in the origin country. In addition, it leads to an increase in the disparities between developing and developed countries and to an unjust human resources allocation. In recent years, the perspective on brain drain is influenced by a shift in global economy models. A knowledge based economy concept has surfaced and it promotes the significance and contribution of human capital to the development of economy.

The impact of the brain drain effects was considered for many years to be negative for the origin country, which suffered a loss of essential economy resources. It was one-way migration of the highly skilled from the developing countries to the developed ones. On the other hand, if brain drain is caused by the impossibility of accessing the labor market in the country of origin, it can be argued that a positive effect occurs: avoidance of brain waste.

Significant changes in the context that fosters migration, such as the improvement of transportation, an increase in international commerce, cooperation, and the development of intercultural relations, determine characteristic transformation in the brain drain phenomenon. This process is not necessarily permanent and is multi-directional, affecting not only the origin, but the host country as well. Contact with the country of origin is less likely to be suppressed, as there are many means of communication accessible to almost anyone.

The brain circulation approach recognizes that there can be compensatory mechanisms to the loss of highly skilled human resources in the developing countries. Fostering international cooperation among scientists, the transfer of technology from developed countries to the developing ones are some of the measures that counterbalance the negative effects of the brain loss.

Brain Fag

Gary Edmunds
Center for Minority Public Health, Case Western Reserve University, Cleveland, OH, USA

The syndrome known as "brain fag" was first described in 1960 by Canadian cultural psychiatrist Raymond Prince, following his field experience in Nigeria, Africa. Yap later reviewed the literature on what were thought to be "peculiar" disorders from the perspective of comparative psychiatry and suggested the term "atypical, culture-bound, psychogenic psychosis." He later suggested using the term "culture-bound, reactive syndrome" in order to encompass various psychopathologies or atypical syndromes that were observed in specific cultures and that occurred as the result of psychological reactions. The following year, he revised the term to "culture-bound syndrome." Although often referred to as a culture-bound syndrome, brain fag has also been characterized as a somatic idiom of distress and as a folk illness.

Brain fag syndrome has been associated with intellectual impairment in the form of cerebral memory loss and poor concentration, visual disturbance in the form of blocked vision, and somatic complaints described as burning feelings in one's head. It is most frequently observed in equatorial regions of Africa and has been reported to occur in Nigeria, Uganda, Liberia, Côte d'Ivoire, and Malawi. The syndrome has been characterized as a very common, minor psychiatric disorder and is thought to occur most frequently among secondary and university students and other "brain workers," such as teachers and government clerks.

Patients often attribute their illness to fatigue of the brain due to excessive mental work. Others in their environment may report that the illness is a form of bewitchment, brought about by the ill person's individualistic educational achievement and abandonment of communal responsibility. In contrast, several scholars have suggested that the syndrome is a response to the stress and pressure that some students experience as the result of family pressures. Not uncommonly, one of the brighter children in a family is supported financially by family members in order to attend school. In turn, that individual is held responsible for the other family members when the need arises. This expectation places great stress on the student to succeed.

Prince, however, attributed the syndrome to childrearing practices such as late weaning, mothers' prolonged close contact with the child, late toilet training, and group life in polygamous and extended families. He theorized that the placement in a Western-type school environment of such a child may bring about the child's breakdown and regression to an earlier state of dependence on the mother. The syndrome has, accordingly, been interpreted as "an unconscious rejection of the superimposed Western educational system."

Depending upon the specific locale, it may be difficult for immigrant patients who believe that they are suffering from brain fag to locate a physician who is familiar with the illness. Brain fag, like other diagnoses that appear to be specific to specific cultures, is difficult to fit within a single diagnostic category, such as might be found in the *Diagnostic and Statistical Manual (DSM-IV-TR)* that is currently in use in the USA for the diagnosis of psychiatric disorders. If the ethnocultural group in a particular geographic area is large, the individual may be able to locate a provider with whom he or she shares a common language and culture. However, the shared language and culture do not guarantee that the patient will receive culturally appropriate care because of differences in socioeconomic status and subcultural groups.

Brazil

DeAnne K. Hilfinger Messias
College of Nursing and Women's and Gender Studies,
University of South Carolina, Columbia, SC, USA

For most of its history, Brazil was a nation of immigrants, not emigrants. Beginning with the early Portuguese settlements in the 1500s through the late twentieth century, multiple waves of immigrants have arrived in Brazil. There were early Dutch and French settlements in Brazilian territory, in addition to continuous Portuguese colonization throughout the sixteenth to eighteenth centuries. Due to the decimation of the sparse indigenous populations, the majority of which either succumbed to European diseases, warfare, and forced labor or fled to the vast hinterlands of Brazil, Portuguese landowners did not have access to a ready supply of labor. To meet the agrarian labor needs of the new colony, the Portuguese imported approximately four million African slaves into Brazil between 1550 and 1850. The abolition of slavery occurred gradually and was not consummated until 1888. By then Brazil had established itself as a major coffee producer, and São Paulo had already put in place provincial policies to encourage immigration to meet the increasing labor needs of coffee cultivation. As a result, there was a clear surge in European immigration to Brazil in the post-abolition period. During the nineteenth and twentieth centuries, Brazil absorbed large numbers of immigrants arriving to work in agricultural and commerce. Portuguese, Italians, and Spanish immigrants were the largest groups contributing to Brazil's cultural melting pot; in the early twentieth century, significant numbers of Japanese, Lebanese, Syrian, German, and Jewish immigrants arrived; Koreans, Chinese, and Bolivians are more recent newcomers. Over time, through widespread ethnic/racial intermarriage and cultural cross-fertilization, these diverse immigrant groups and cultures have contributed to modern Brazilian culture and identity. Throughout its history, Brazil has been characterized as a nation of tremendous social/economic disparities with strongly embedded stratifications of social and economic class. Although racial/ethnic dividing lines are often blurred, there are racial/ethnic undertones to class stratifications based on social, economic, educational, and occupational levels. Brazilians speak Portuguese, and their language and culture are distinct from other Latin American populations.

It was not until the late twentieth century that Brazil became a major sending country. During the initial years of the military dictatorship in the 1960s, some Brazilian political exiles fled to Europe; Previously there had been small numbers of emigrants to major cultural centers such as New York, London, and Paris, but no large-scale out-migration. This situation changed in the late 1980s, when failed Brazilian economic policies, rampant inflation, and labor instability devastated the economic and social stability of middle-class Brazilians, many of whom were highly educated but unable to find or maintain stable well-remunerated employment in their fields. It was this chaotic economic context that fueled large-scale Brazilian emigration beginning in the late 1980s, as Brazilians left to seek jobs in United States, Japan, Europe, and Australia. For many middle-class Brazilians, the economic impetus to emigrate was also infused with a desire to explore other social, cultural, or educational experiences (e.g., learn another language, gain broader cultural experiences, or explore new opportunities).

At least initially, these new Brazilian immigrants often framed their migration as a temporary sojourn rather than a planned permanent settlement. In the United States, many entered on valid tourist or student visas and eventually overstayed their visas or obtained residency status. Very few Brazilians from the poorest classes emigrated, although some poor women did leave the country as domestic employees of Brazilian officials, diplomats, or multinational business executives. Thus, for many Brazilians, the immigration experience was one of downward social mobility. In the United States, and also in Europe, Australia, and Japan, many (although certainly not all) middle-class Brazilian immigrants engaged in low-skilled, low-wage jobs (e.g., domestic work, restaurant work such as waiting tables or dishwashing, landscaping, babysitting) that are considered totally off-limits to persons of middle-class stature in Brazil. Similarly, Brazilian immigrants in Japan also experienced negative social mobility and social and cultural discrimination. Beginning in the 1990s, due to domestic labor shortages, Japan began encouraged immigration of Brazilian *nikkejin* (Japanese descendents). Yet, these Japanese Brazilian immigrants were not recognized as full-fledged members of Japanese society.

In the United States, the fact that Brazilian immigrants tend to be urban, middle-class, and well educated distinguishes them from many Hispanic immigrants, who have a tendency to be of lower classes, less educated, and are often from rural areas of Mexico or Central America. Despite the distinctions, many Brazilian and Hispanic immigrants often share other characteristics (e.g., undocumented status, limited-English-proficient, working in low-level unskilled jobs). For Brazilian immigrants living in areas with large Hispanic populations, negotiating one's personal and public identity as either distinct from or associated with a Latino/Hispanic identity is often necessary. For middle-class Brazilian women, the immigration transition from a *dona de casa* (lady of the house) accustomed to having paid domestic workers in her own home, to being an *empregada* (paid domestic worker) in the homes of others, in addition to taking on the responsibilities of cooking, cleaning, and laundry in her own home, can involve significant social and personal identity transformations. The convergence of migration and domestic work and employment experiences create opportunities for more fluid, transnational perspectives on gender, class, and culture, but may also contribute to stress and health risks. Separation from family and traditional social networks are commonly expressed through *saudades*, a Portuguese word and cultural construct referring to an intense longing and yearning for that which is not present. For some Brazilians, economic and social transitions related to migration may be a source of stress, family discord, or embarrassment; others may consider their migration experiences as contributing to and enhancing their personal growth and development. The price of economic migration is often higher than anticipated, as work is not necessarily easy to come by and is often arduous and socially isolating. Many endure the stress and social hardships in hopes of eventually accumulating funds to return to Brazil to pursue other dreams.

When immigration is a planned or semi-planned process, Brazilians tend to engage in some type of premigration health practices, either as part of formal migration procedures or to validate their positive health status or prevent untoward future expenses for medical and dental care abroad. Documented occupational health issues among Brazilian immigrant domestic workers include physical stress and exertion, muscular-skeletal problems, infectious diseases, and respiratory and dermatological problems from exposure to household cleaning agents. Among Brazilians with a temporary, sojourner mentality whose lives are focused on work, the practice of putting personal health care needs on hold is common. Delays in seeking care may also be related to lack of information and concerns about the costs of professional care, in terms of time and money. Brazilian immigrants report reliance on informal social networks to access information and health care resources; those who have experienced feelings of being discounted, blamed, not understood or acknowledged by US health care personnel may be less eager to seek further care or follow-up. There is widespread recognition of transnational medication practices among Brazilian immigrants. These include self-medication with prescription drugs obtained in Brazil (e.g., antibiotics, birth control pills, pain medications, and compounded diet pills) or herbal remedies. Immigrants obtain these medications by bringing a stock of drugs with them, sharing with other immigrants, and asking relatives and friends to bring or send medications from Brazil.

Recommendations for practitioners caring for Brazilian immigrants include:

- Do not assume that a Brazilian patient speaks Spanish. Most do not, although some may have acquired knowledge of Spanish through contact with US Hispanic populations. Some Brazilians take offense at being classified as Hispanics; although they are South Americans and Latinos, the general preference is to identify as Brazilian.
- A Brazilian's current occupation may not reflect previous educational, occupational, or socioeconomic status. Explore with Brazilian immigrants how their immigration and occupational transitions have influenced their health practices in order to uncover possible sources of stress and personal coping strategies and explore how perceptions of immigration and occupational transitions may have influenced personal health practices.
- Review correct use of oral contraceptives with Brazilian women, who may have obtained birth control pills in Brazil without a prescription.
- When conducting a health history or performing a tuberculin skin test (PPD), inquire about a Brazilian patient's history of BCG vaccination; carefully explain the implications of a positive tuberculin skin test following BCG vaccination. Because BCG vaccination is routine in Brazil, tuberculin skin tests are not used as a diagnostic or screening tool. Brazilians may perceive providers as insensitive or domineering in their approach to immigrants with positive tuberculin skin tests.
- Among Brazilian immigrants, screen for diseases that are endemic in Brazil but less common in the United States (e.g., malaria, Hansen's disease, Dengue fever, Chagas disease, intestinal parasites).

Breast Cancer

Valentina A. Andreeva
Department of Nutrition Epidemiology, University of Paris XIII, Bobigny Cedex, France

Breast cancer is a class of cancerous tumors originating in breast tissue. When such cancers remain within the ducts or lobules of the breast, they are called in situ. Upon diagnosis, almost all in situ breast cancers can be cured. When breast cancers spread to surrounding tissue, they are referred to as *invasive*. Upon diagnosis, the extent to which the cancerous cells have spread determines the stage and prognosis of the disease.

Breast cancer is the most common cancer in women worldwide; however, its incidence (i.e., number of new diagnoses per unit of the population, usually 100,000 people) varies greatly. The lowest incidence is observed in Africa, intermediate rates are observed in Eastern Europe and South America, and the highest (i.e., 4–6 times higher than the lowest) rates are observed in Western Europe and North America. Generally, emigrants from low-risk countries to high-risk countries experience an increase in their breast cancer risk. The estimated lifetime risk of developing breast cancer is currently one out of every eight U.S. women. Men can also develop breast cancer, but their risk is very low, i.e., less than 1% of all cases of breast cancer.

Classification

The presence of breast cancer can be detected via several techniques, such as mammography (X-ray), biopsy, estrogen and progesterone receptor test, and magnetic resonance imaging. Two main cancer classification systems are commonly used. One of them – developed by the American Joint Committee on Cancer – takes into account four factors: (1) size of the tumor; (2) spread within the breast and nearby tissue and organs; (3) spread to lymph nodes; and (4) spread to distant organs. Based on these fators, breast cancers can be classified in one of four stages, with "I" as an early stage and "IV" as the most advanced stage. This classification system is used primarily in the diagnostic context. Research with immigrant populations has indicated that the person's place of birth might be linked to the stage at diagnosis. For example, foreign-born Hispanic women in the U.S. might be less likely to be diagnosed with an early-stage breast cancer compared to Hispanic women born in the U.S.

The other cancer classification system was developed by the Surveillance, Epidemiology, and End Results (SEER) program. It assigns cancers to one of three stages: (1) local: when the tumors are confined to the breast; (2) regional: when the tumors have spread to surrounding tissue or nearby lymph nodes; and

(3) distant: when the tumors have spread to distant organs. This system is employed primarily in cancer registry reporting, public health research, and program planning.

There are cultural variations in women's approaches to breast cancer detection and follow-up, which are related to their level of acculturation (i.e., the process of adoption of the host country's language, behaviors, and norms), attitudes and beliefs about the causes of cancer, a sense of fatalism, body image concerns, and social norms.

Treatment and Worldwide Survival

Different types of treatment are available for patients with breast cancer, such as surgery, radiation therapy, chemotherapy, and hormone therapy. As with most other aspects of the disease, the type of treatment also varies by race and ethnicity owing to socioeconomic and cultural factors. Currently, for women with stage I or II breast cancer, standard primary care constitutes either breast-conserving surgery combined with radiotherapy or a total mastectomy (removal of the breast). However, there is evidence that immigrant and minority women might be less likely to receive adequate care than the native White women. Recent research reports show that breast-conserving surgery was performed about 15% less frequently among foreign-born compared to U.S.-born Hispanic women.

Similar to the incidence, breast cancer survival also displays important worldwide variation. Overall survival in North America, for example, is about 80% or higher, whereas survival in middle-income countries is about 60% and in low-income countries – about 40%. Scientists usually attribute the low survival rates in less developed countries to the lack of screening (i.e., programs aimed at the early detection of cancer) and the lack of adequate treatment facilities. Whereas the survival rate in the U.S. is among the highest in the world, all racial and ethnic groups are considered less likely than White women to survive for 5 years after breast cancer diagnosis. Generally, immigrant status appears to be associated with worse expected prognosis.

Risk Factors

Increased levels of ovarian hormones, especially estrogens, throughout one's lifetime have been associated with an increased breast cancer risk. Estrogen levels can be influenced by a number of genetic, biological, behavioral, and social factors, most of which are considered risk factors for breast cancer. Some of the most important risk factors are not easily modifiable, such as female sex, age >60 years, inherited genetic mutations, family history of breast cancer (e.g., in mother, sister), increased breast tissue density, older age (>30 years) at first full-term pregnancy, and late menopause (>55 years). Regarding age, research shows that Hispanic and Asian women typically develop breast cancer at younger ages (i.e., in their 50s) compared to native White women (i.e., in their 60s). International research studies have shown that there are also differences in breast tumor biology related to race and ethnicity. For example, breast tissue density, which is an important marker of breast cancer risk, varies by country. A study with Chinese immigrant women observed that a longer duration of residence in the U.S. could lead to higher breast tissue density.

There are additional, modifiable risk factors and they include use of combined estrogen-progestin menopausal hormones, alcohol consumption, avoidance of breastfeeding, and physical inactivity. Interestingly, obesity has been associated with a decreased risk of breast cancer in premenopausal women but an increased risk in postmenopausal women.

Socioeconomic Status as a Risk Factor

Socioeconomic status (SES) referes to one's position relative to other members of society based on education, occupation, and income. Generally, women of higher SES have higher breast cancer rates. In the U.S., the immigrant (foreign-born) population overall experiences decreased SES. Research shows that the SES gradient in breast cancer incidence is strong and increasing among Hispanic and Asian American women, but not among White or Black women, possibly as a result of health behavior changes following immigration.

Immigration as a Risk Factor

Between 1970 and 2005, the percentage of the foreign-born civilian non-institutionalized U.S. population more than doubled and currently constitutes over 12%. The foreign-born represent over two-thirds of the Asian population and over a third of the Hispanic population. Migrant studies frequently note that migration to a high-risk country, such as the U.S., might increase breast cancer risk. However, the immigrants' risk does not always lie between that in the native and the host countries, and there are both known and possibly yet unmeasured protective factors.

Generally, immigrants who have resided in the U.S. fewer than 10 years as well as those who have emigrated after the age of 20 have reduced breast cancer risk compared to longer-term immigrants or the native-born. A study with Hispanic immigrants in California showed that the third- or higher generation immigrants had at least four times higher risk of developing breast cancer compared to recent immigrants. Studies with Italian migrants, U.S. Hispanics, and internal migrants in California suggest that the timing of migration might be a stronger predictor of breast cancer risk than duration of residence.

Higher levels of acculturation (expressed in terms of duration of residence and language use in the host country) have been linked to fewer pregnancies, decreased duration of breastfeeding, and less healthy dietary patterns. In turn, more acculturated immigrants might be at increased risk for obesity but also might be more likely to utilize cancer screening owing to a reduction in structural barriers, and increased education and career opportunities.

A recent, comprehensive review of breast cancer incidence among immigrants worldwide confirmed the importance of potentially modifiable environmental and behavioral determinants of risk, acting both pre- and postmigration. Specifically, about a third of the available research studies highlighted the importance of early exposures (i.e., during the first two decades of life) such as diet and residential history. Among women originating from low-incidence areas and migrating as adults, the place of birth exerted a protective role, whereas breast cancer incidence was shown to increase among the younger migrants. Among women migrating from areas of high incidence to areas of low incidence, a negative effect of birthplace was also observed. About a fifth of the reviewed studies highlighted the importance of environmental and behavioral factors after migration, particularly the roles of diet modification, increasing SES, delay of childbirth, or avoidance of breastfeeding.

Prevention and Screening

Breast cancer prevention consists of minimizing one's risk of developing the disease. This can be achieved by decreasing the number of known risk factors, such as by avoiding postmenopausal weight gain, engaging in physical activity and in breast cancer screening. For women who are at average breast cancer risk, periodic breast self-exams are recommended after the age of 20; clinical breast exams every three years are recommended for those in their 20s and 30s; annual mammography is recommended after the age of 40. Recent national reports show that approximately 53% of non-Hispanic White women, 42% of Hispanic women, and 38% of Asian women report having a mammogram within the previous year.

A number of research studies dealing with diverse immigrant populations (e.g., Hispanic, Asian, Eastern European) have shown that the level of acculturation is associated with a greater number of clinical breast exams and mammograms. Recent national reports indicate that mammography use is about 25% higher among immigrants who have been in the U.S. more than 10 years, compared to those who have resided in the U.S. for a shorter period.

Researchers have identified many factors that prevent immigrant and minority women from engaging in breast cancer screening. Such factors include lack of health insurance, lack of transportation, impermissible work schedules, lack of understanding of the healthcare system, language difficulties, fear of cancer, fatalism, and culture-bound family dynamics. For example, in 2008 the proportion of the foreign-born population without health insurance was about two and one-half times that of the native-born population.

Future Directions

The ethnic and cultural diversity of the American society is more pronounced than ever before and global migration has diversified the populations of many other countries. Even though fitting a perfect breast cancer prevention model is not currently possible, by means of continued scientific research and informed public health efforts, all women could limit their exposure to the known risk factors and engage in proactive behaviors, thus promoting their overall health and decreasing their breast cancer susceptibility. The collection of comprehensive lifestyle information, such as dietary and physical activity practices, the development of measurement standards, and the inclusion of understudied populations are all on the migrant research agenda. In addition, due to heterogeneity in breast cancer risk among same-race women, the need for disaggregating racial data is critical.

Identifying and understanding differences in all aspects of breast cancer could help in developing culturally and linguistically appropriate interventions and improving outcomes. Theory- and evidence-based comprehensive prevention programs are needed for all immigrant populations in order to increase engagement in preventive behaviors as well as decrease the rates of late-stage diagnosis. Efforts at removing breast cancer screening barriers, for example, can be made at different levels. On the macro-level it is possible to conduct community needs assessments, employ trained community outreach workers, implement provider training for the provision of culturally sensitive care, and engage breast cancer survivors in educational and screening efforts. Possibilities on the micro-level include education initiatives regarding breast cancer signs and symptoms as well as navigation of the healthcare system, reduction of linguistic barriers, and empowerment strategies.

Immigrant Health: Screening for Breast Cancer

Previous research has documented cancer incidence in immigrant populations in the United States to reflect those of their native country in first-generation immigrants with evolution to patterns seen in the USA in subsequent generations. However, immigrant women are often unaware of their own risk and that of their children and may also differ in philosophy regarding approaches to preventive screening compared to what is deemed "standard of care" in US culture. The number of new breast cancers diagnosed in 2010 is estimated at 207,090 or 28% of new cancers in women. Mammography, a type of x-ray evaluation, is an effective screening test for breast cancer prevention. Efforts to engage immigrant women in education about breast cancer screening and treatment programs remain a priority.

Screening for breast cancer in immigrant women represents a challenge on multiple levels. Often, there is misunderstanding and fear around health in the USA and barriers to effective communication with clinicians. Remennick has identified types of barriers to breast cancer screening as *structural* including issues related to health insurance, transportation, work/childcare demands, *organizational* including language barriers or health system navigation, *psychological* such as fear or denial and "fatalism" philosophy, and *sociocultural* such as the position of women in the native culture. Similar structural and organizational factors have been cited as contributors to health care disparities in all minority populations in the USA.

Health care disparities are frequently found in immigrant populations and may be related to low socioeconomic status and other determinants of health. Specifically, Gomez et al. recently reported disparities in breast cancer survival among Asian women in California and noted poorer survival among foreign-born Asians compared to US-born Asians. The factors influencing this notable finding likely represent a complicated interplay of health preferences, access to and types of interaction with the health care system, and disease-specific characteristics.

The concept of fatalism in which the individual believes that their fate is predetermined, or determined by something/someone outside of themselves, is more common in nonmainstream US cultures and may significantly influence health preferences. The attitude of "you control your own destiny" is often projected by health care providers in the USA, while many cultures prefer deference to a higher power for health outcomes. Acceptance of breast cancer screening by immigrant women, desire to know of a diagnosis of cancer, as well as compliance with treatment interventions may be affected by this philosophy. Often, native culture may introduce traditional and not Western medicine prevention options. This may be an additional barrier in obtaining recommended evidence-based screening. Additionally, many immigrant populations experience miscommunication with health care systems and providers due to language barriers. While trained interpreters are helpful in this situation, they are often not readily available.

Another barrier to obtaining breast cancer screening with mammography is the access to care when immigrants are noncitizens. One study showed that even after adjusting for age, education, family income, and marital status, noncitizens remained significantly less likely to report having a mammogram than US-born women (14% point difference; $P < 0.01$). Initiatives to diminish disparities in screening should prioritize improving access through culturally sensitive interventions to care for noncitizens.

Addressing known barriers to breast cancer screening is critical to effective care for immigrant women. This includes educational interventions which are often supported by public health agencies and targeted toward immigrant at risk communities for low health literacy and health numeracy (one's ability to use numeric information in the context of health care). Use of community leaders as advocates to decrease mistrust and encourage proactive preventive breast cancer screening in immigrant women has been successful. Others have found that automated reminders and registries that do not rely on individual recall or visits to a physician promote mammography completion.

Breast cancer is important for all women as it is the most common non-skin cancer in women, and the second deadliest. As women age, breast cancer becomes more prevalent. Statistically, the 1-year incidence is 1 in 800 in a 40-year-old woman, 1 in 400 in a 50-year-old woman, and 1 in 200 in a 60-year-old woman. Given the substantial increase in risk as women age, screening recommendations differ by age, yet clinicians and patients must also consider family history and previous history of breast biopsies as these factors may also contribute to increased risk.

Breast cancer screening recommendations in the US have changed in the last several years due to new studies. In 2009, the US Preventive Services Task Force (USPSTF), a group of health experts that reviews published research and makes recommendations about preventive health care, issued revised mammogram guidelines. According to the USPSTF, women who have screening mammograms die of breast cancer less frequently than do women who do not get mammograms. Those guidelines included the following: screening mammograms every 2 years beginning at age 50 and up to at least age 75 for women at average risk of breast cancer. Very few patients over age 75 were included in studies making recommendations unknown. Screening mammograms before age 50 is controversial and recommendations from USPTF state that mammograms should not be done routinely and should be based on a woman's values regarding the risks and benefits of mammography. These guidelines differ from those of the American Cancer Society (ACS). The ACS mammogram guidelines call for yearly mammogram screening beginning at age 40 for women at average risk of breast cancer. Screening mammograms can detect breast abnormalities early in women in their 40 s. Findings from a large study in Sweden of more than one million women in their 40 s who received screening mammograms showed a decrease in breast cancer deaths by 29%. And it is important to remember that most women who get breast cancer have no family history or other known risk factors for the disease. However, it is important to note the false-positive results are much more frequent in younger patients. Patient discussion with health care professionals about their values and preferences is essential.

The American Cancer Society recommends that some women – because of their family history, a genetic tendency, or certain other factors – be screened with a more sophisticated medical imaging technique (magnetic resonance imaging, MRI) in addition to mammograms. (The number of women who fall into this category is small: less than 2% of all the women in the USA.)

It is currently not recommended that doctors teach women to do breast self-exams. There are a few studies that show reduced risk of dying from breast cancer with this method of screening alone or in combination with mammograms. Potential harms may include false-positive results that lead to unneeded breast biopsies and accompanying anxiety and distress. However, physician/clinician clinical breast exam is recommended for women starting at age 40 and depending on different guidelines, from annually to every 3 years.

Breast Self-Examination

Evaon Wong-Kim
Department of Social Work, California State University, East Bay, Hayward, CA, USA

Breast Self-Examination (BSE) is a screening method performed by individual women on a monthly basis in order to detect early breast cancer. To conduct BSE, a woman may touch and look at each breast for possible lumps, distortions, or swelling. BSE was once considered as the best approach for woman to take control of her own health by finding the breast lump that may be cancerous yet in early stage. After the detection of any lumps, and if women seek breast cancer treatment accordingly, they may be diagnosed with breast cancer at an earlier stage.

An estimated 2.4 million women are living with breast cancer in the USA. Another 192,370 female breast cancer cases are estimated to be newly diagnosed in the USA in 2009. Breast cancer is the most common cause of cancer-related deaths among women worldwide. Breast cancer deaths are at 40,170 according to the most recent record published by the American Cancer Society, 2009.

Despite evidence supporting early detection such as performing BSE as the best approach to reduce breast cancer mortality, it continues to be underutilized by minority women, especially new immigrants. Data showed striking disparities in breast cancer outcomes among different ethnic groups in the USA, especially among ethnic minority women. As compared to women who are born in the USA, immigrant women who have less access to health care and use health care less than often are more likely to be diagnosed with breast cancer at a later stage. Although there is no research focusing specially on undocumented immigrant women in the USA, these women are even less likely to utilize preventive services such as breast cancer–screening services and treatment as compared to other immigrant women.

Breast cancer is also the number one cause of cancer-related mortality for a large group of both American-born and immigrant women, the Asian American and Pacific Islander (AAPI) women. As compared with new immigrants, Asian American women who immigrated to the USA at least a decade ago have an 80% higher risk of being diagnosed with breast cancer. For Asian women born in the USA, the breast cancer risk is similar to that of non-Hispanic White women.

Besides practicing BSE at a lower rate, only 48.5% of Asian and Pacific Islander women 50 years and older in the USA have had a mammogram or clinical breast examination within the last 2 years. This is the lowest rate of screening among all racial/ethnic groups. Immigrant women may also experience more barriers to practicing BSE such as modesty, a perception due to cultural training that touching one's own breasts is inappropriate, or a lack of resources to practice BSE correctly. Therefore, promoting BSE among immigrant women may be beneficial. When performed competently and with appropriate frequency, BSE has the advantage of being a user-friendly screening technique that may enhance the likelihood of early detection of breast cancer.

Controversial Aspects of BSE

Although BSE was once promoted heavily as a means of finding cancer at a more curable stage, large randomized controlled studies found that BSE was not effective in preventing death, and actually, may cause harm through needless biopsies and surgery. Therefore, BSE is no longer promoted as the best preventive approach a woman can take to prevent breast cancer by early self-detection. However, breast cancer advocacy organizations have continued to encourage women to practice BSE and provide training materials with a caution regarding newer research findings.

The controversy and debate of the effectiveness of BSE started after a research analysis was published in The Cochrane Library indicating women who practice BSE have the similar likelihood of dying of breast cancer when compared to women who do not practice BSE. This analysis merged data from two studies, one from Shanghai, China, and the other one from Russia with a total of 388,535 women conducted in 2002. In both studies, factory workers were trained to do BSE. Both studies found that women who were trained to perform BSE were not less likely to die of breast cancer, as compared to the women who did not receive the training. However, it is not clear if these women from other countries, their practice of BSE, and their health care systems are comparable to the US women's experience and the US health care system. Given the studies of immigrant women in the USA, it may be presumptive to suggest BSE is not effective in detecting breast cancer if it is practiced correctly and on a regular basis.

The Advantage of Practicing BSE

In comparison to clinical breast examination, mammography, ultrasound, and magnetic resonance imaging, BSE can be performed independently by women of any age in the comfort of their home. Several studies and reports indicate, however, that cultural barriers may discourage immigrant women of Asian descent from practicing BSE. Common barriers – such as dependence on medical professionals and forgetting – predicted older Chinese women's nonpractice of BSE. AAPI women with lower income and without private insurance were less likely to practice BSE. Newly immigrated Vietnamese women, especially those with a lower level of education, are less acculturated and less likely to learn about preventive screening and medicine compared to those who have lived in the USA for a longer period of time. Among Korean American women, acculturation, proportion of life spent in the USA, and English-language proficiency were significant factors in seeking cancer-screening tests. Lack of interest in BSE may be influenced by inaccurate beliefs regarding cancer, such as some Chinese immigrants' beliefs that all cancers are contagious, so why would they go out of their way of finding cancer by not knowing cancer is most curable when it is found early.

BSE has been described as a highly accessible method supporting early detection of breast cancer. However, the appealing notion that BSE is consumer driven and is independent of overcoming access-related barriers may assume a normative culture that does not apply to immigrant women.

Given the recent controversy and debate on the importance and necessity of practicing BSE, all women should know their risk of having breast cancer. This risk may include but not limited to family history of breast cancer, personal risk factors including cigarette smoking and sedentary life style, diet, or amount of exercises. Women who have an average risk of breast cancer should have mammogram every year starting at age 40 and practice BSE. Knowing how one's breasts look and feel is also an important aspect of BSE. If a woman thinks there is imbalance or feel something may be wrong, a physician's opinion should be obtained. For immigrant women, research shows that cultural and structural barriers may prevent them from obtaining other screening tests such as mammography and clinical breast exam. By promoting BSE immigrant women may gain the power to have some knowledge about their own body and seek care if they find anything unusual.

Breastfeeding

Jill F. Kilanowski
Frances Payne Bolton School of Nursing, Case Western Reserve University, Cleveland, OH, USA

The American Academy of Pediatrics and the National Association of Pediatric Nurse Practitioners in their policy statements support the tenet that breastfeeding is the physiologic norm for both mothers and children, and offers overwhelming benefits not available from substitutes for human milk to the infant and mother. This policy is also supported by the Association of Women's Health, Obstetric and Neonatal Nurses, the American College of Obstetricians and Gynecologists, The American Academy of Family Physicians, and the World Health Organization. Goals of the US national health policy statement *Healthy People 2010* included 75% of mothers initiating breastfeeding, with 50% of mothers' breastfeeding their infant at 6 months of age. In support of these opinions, state legislatures have enacted laws that specifically allow women to breastfeed in public, and have exempted breastfeeding from public indecency laws. In 2006, 74% of US mothers initiated breastfeeding, and 43% were breastfeeding at infant's 6 months of age.

In a 2006 study conducted in New York City with 4,207 Mexican Hispanics, non-Mexican Hispanics, and non-Hispanics mothers, an infant with a foreign-born parent was associated with a dramatic increase in the likelihood of breastfeeding. There was an 85% reduction in the odds of breastfeeding by mothers born in the USA compared to mothers foreign-born. The study showed that for every year of US residency there was a 4% decrease in the odds of breastfeeding. Similarly, another study in low-income mothers ($n=490$) of Mexican descent that showed that increased years in the USA were associated with decreased likelihood to initiate breastfeeding, and shorter duration of exclusive and any breastfeeding. Using cross-sectional data from 33,121 children aged zero to 5 years, immigrant women in each racial or ethnic group had higher breastfeeding initiation and greater duration rates compared to native-born women controlling for socioeconomic and demographic differences. In this study, higher acculturation rates in Hispanic and non-Hispanic women were associated with lower breastfeeding rates. Large data base statistics from the 2003 Canada Community Health Survey showed that 85% of all mothers attempted to breastfed, although many stopped within the first month, and less than half continued to breastfeed at least 6 months. Exclusive breastfeeding for 6 or more months was associated with mother's age, education, household income, and was more common among immigrant than non-immigrant women. Not surprisingly, the practice of breastfeeding has been associated with improved outcomes for infants of immigrant mothers whose families frequently experience low levels of food security. Breastfeeding has been found to be initiated by 83% of immigrants. Breastfed infants were less likely to be reported in fair/poor healthy, and were less likely to have had a history of hospitalization.

The role of acculturation in immigrant women and its impact on breastfeeding continues to be examined. A study that evaluated the impact of prenatal education on breastfeeding showed that measures of household income were significant and positively associated, and that maternal acculturation levels were negatively associated with breastfeeding. This is in conflict with an older study of 962 low-income immigrant women in New York City. When controlled for smoking, intent to work, age, social support, and attitudes toward breastfeeding, acculturation did not automatically lead to decreased breastfeeding in immigrant women, and rather higher acculturation levels led to increased likelihood of receiving support from family, friends, and health care providers. This social and emotional support increased intent and duration of breastfeeding.

The prenatal intent to breastfeed has shown to be predictive of action and duration of breastfeeding. Other factors associated with breastfeeding intention include previous experience, age, maternal parity, living with a partner, and education. However, having been breastfed as an infant, prior breastfeeding experience, or having a breastfeeding friend or relative outweighs other contributing variables. In interviews with 382 women, foreign-born women were significantly more likely to intent to breastfeed compared to US-born women. County of origin, and having breastfed a previous child were significant predictors of intent to breastfeed.

Some concern has been expressed between the US practice of rooming-in on the postpartum floor that fosters a new mother's independence as a caregiver to her newborn, versus a conflicting cultural practice of giving the new mother time to recuperate and being attended upon by her family. Some cultures feel that the postpartum period is the most vulnerable time of a woman's life and that rest is crucial for future emotional and physical well-being. The demands of establishing breastfeeding need to be combined with the cultural needs to be cared for by the new mother.

Breastfeeding in the United Kingdom has been studied and contrasts the English belief that breastfeeding is rarely done in public and is an activity that society requires to be hidden from view, to the African societal practice that the breast is readily available to the infant and women can nurse their infants without leaving the worksite. In traditional Somalia, an extended family provides the new mother with a 40-day lying-in period of nurturing. Older and more experienced family members provide maternal behaviors for the new mother to model. Migration is largely done for economic reasons with the anticipation of securing paid employment. Breastfeeding may become more challenging if the woman works outside the home. This employment affects traditional perspectives on breastfeeding.

In an interview study with 19 Vietnamese immigrant mothers it was demonstrated that migration changed traditional health practices normally given to the new mother that can last 1 month to 100 days. In their home country new mothers receive a series of prescribed rituals that include rest and traditional perfumed steam baths meant to restore the *heat* lost in the process of childbirth, and helps them transition into motherhood by an established rite of passage. The lack of receiving these rituals lead the mothers to feel that she would be vulnerable to *cold* illnesses. It is thought that breastfeeding requires *vital energy* that may not be replenished after childbirth if ritual practices are not received. In addition, immigration to a new country may prevent the new mother from receiving the traditional meals composed of herbs and special meats which are thought to help produce *fresh*, nourishing milk. New immigrant Vietnamese mothers stated that breast milk was the best nourishment for their infants but felt that their personal breast milk was not good because traditional rituals were not followed.

In another study with Chinese immigrant mothers ($n = 506$) in Australia examining the intention and duration of breastfeeding, findings showed that health care providers may have an influential role contributing to a tenfold greater chance of initiating and sustaining breastfeeding. Support of new mothers' partners also contributed to intent and duration of breastfeeding, but only to those mothers who delivered in Australia, not China. Mothers who delivered in China relied on their mothers and female relatives for support. Those who migrated needed to rely on their partners as their relatives were not in proximity. In this study and in a study in Kenya ($n=444$), women's education level was positively associated with duration of breastfeeding. Well-educated women are reading more about the benefits of breastfeeding and returning to the practice of breastfeeding. Another study finding that complements previous research shows that immigrant and non-immigrant women, whose postpartum hospital stay is longer because of delivery by cesarean section, have greater access to education instruction, and have more time to be guided toward successfully establishing breastfeeding.

Holistic and culturally competent health care includes the incorporation and value of beliefs, traditions, and rules of behavior among racial and ethnic groups of people. Lessons learned include the effectiveness of using prenatal interventions to increase the prevalence of exclusive breastfeeding among Latina and other immigrant mothers. Prenatal and postpartum education should encourage the continuance of ethnic maternal practices of breastfeeding, while supporting concepts of respect for culture, the importance of family, trust, and the development of personal health care provider–client relationships. Attention to any prenatal or postnatal ritual practices that are thought to be needed for the production of good maternal milk needs to be incorporated into the plan of care for expectant and new mothers. Immigrant mothers may be lacking in the amount of social support received in their new maternal role due to their new place of residence. Friends and family may be far away. In addition, immigrant mothers may receive less support from health care providers, possibly due to language differences, and less instruction may make them more vulnerable to free samples of breast milk substitutes. Programs that seek to promote breastfeeding need to compensate for this lack of support, and reinforce existing social networks. It is encouraging that in immigrants whose US-born female children become more educated and obtain a higher socioeconomic status, there is a greater return to breastfeeding.

Built Environment

Linda S. Martinez[1], Flavia C. Peréa[2], Uchenna Ndulue[3]

[1]School of Arts and Sciences, Community Health Program, Tufts University, Medford, MA, USA

[2]Department of Public Health and Community Medicine, Tufts University School of Medicine, Boston, MA, USA

[3]Nuestro Futuro Saludable, Community Health Program, Tufts University, Medford, MA, USA

The impact of the built environment on health has shifted from a focus on sanitation to the influence of man-made systems and structures on the health and well-being of communities. Of particular concern to public health practitioners is the role of the built environment in modifying, exacerbating, or protecting against health disparities. The poor, particularly those of minority status, are disproportionately exposed to the deleterious effects of the built environment, and face a corresponding increase in related disease morbidity and mortality. Among these groups, immigrant populations are of particular concern as they often are the vulnerable to exposure and, perhaps due to language and cultural barriers, may be disproportionately at risk.

Health and the Built Environment

Conceptualizations of the built environment have changed over time. Resting at the intersection of urban planning and public health, our understanding of the built environment has shifted with the parallel development of these two disciplines. Public health concerns over the built environment have often rested within the broader context of environmental health, and as such have historically been concerned primarily with preventing exposure to toxins and pollutants, often through zoning ordinances and regulation. However, as both fields have matured, the domain of environmental health has grown to encompass the broader health effects of the built environment.

The increased interest in the built environment has shadowed a general change in the structure of the built environment itself. In the early 1900s, densely populated urban spaces tended to be self-contained, walkable, and provided access to daily necessities, such as food stores and shops. However, with outward migration to suburban areas in the early 1960s, the construction of highway systems, and the enlargement of urban sprawl, the impact of the built environment on health has become increasingly more complex. The current scientific conceptualization of the built environment encompasses all human-modified structures and places such as homes, schools, workplaces, parks, industrial areas, farms, roads, and highways; essentially, the places where people live, work, and play. Despite the diversity of structures that fall under the term, the built environment can be examined through housing, transportation, and neighborhood which provide a useful lens to examine the impact of the built environment on health.

A significant body of literature has examined the impact of housing conditions on health. While the interactions between housing and health are complex, it is generally recognized that inadequate housing can expose residents to allergens, mold, lead, pests, and result in negative health outcomes from asthma and respiratory infections, and cardiovascular disease. Similarly, transportation has been linked to negative health outcomes. In areas with high traffic density and crowded streets, air pollution is a persistent concern. Like inadequate housing, air pollution is associated with respiratory and cardiovascular morbidity. Additionally, transportation issues can decrease physical safety by increasing motor vehicle and pedestrian accidents. Lack of appropriate or accessible transportation may prevent residents from access to crucial services such as health care facilities, exercise facilities, supermarkets, and recreational spaces, leading to negative health outcomes.

Neighborhood characteristics such as walk-ability, availability of green spaces such as parks and playgrounds, access to needed facilities such as schools, police, supermarkets, and hospitals all affect health. The obesogenic nature of the modern urban built environment is also of great concern to public health practitioners, policy makers, and researchers. The growth of urban sprawl and the increase in the number of miles Americans must travel daily have all led to a decrease in physical activity. Physical inactivity has long been known to be associated with an increased risk for many health conditions including diabetes, hypertension, colon cancer, and coronary heart disease. The literature indicates that elements of the built environment can serve to provide avenues for physical activity or to prevent productive physical activity. Neighborhood factors also influence how residents respond to and recuperate from adverse health events, either physical or mental. Finally, elements of the built environment can influence levels of social capital and social cohesion.

While the above research suggests that the built environment directly impacts human health, of greater importance is the mechanisms by which these factors aggregate toward disparities. In an effort to tease out the multiple interrelated factors that the built environment serves to ameliorate or exacerbate, *The Social Determinants of Health and Environmental Health Promotion* (*SDOH &EHP*) model demonstrates how features of the built environment interact with social, economic, and political processes to promote health inequities. Of note in this model is that the built environment serves as an intermediary between macro-level causes of health disparities (i.e., ideologies and historical conditions) and proximate factors that lead to the aforementioned negative health outcomes (i.e., stressors, and health behaviors). This framework serves as a useful tool in examining how the built environment contributes to health disparities among new immigrant populations.

Immigrant Health and the Built Environment

Immigration patterns in the United States have experienced significant changes over the past century. At the turn of the twentieth century, primarily European immigrants composed over 13% of the population. Subsequently, the proportion of foreign-born peoples in America declined to approximately 5% of the population in the 1940s as post-World War II immigration policies restricted the influx of immigrants. However, in 1965, federal legislation eased immigration quotas and opened immigration opportunities to other countries. The resultant immigrant boom in the 1980s and 1990s – a functional doubling of the foreign-born population of America – resulted in a very different demographic of immigrants. These "new immigrants" originated outside of the traditional European regions and instead hailed from Latin America, the Caribbean, Africa, and Asia.

The new immigrant communities flocked to urban centers, such as Boston, Chicago, New York, and San Francisco. Yet since land use, and consequently many features of the built environment, have always been political decisions, those lacking political voice (i.e., immigrants) are often clustered in the least desirable, and consequently least healthy, spaces. Consequently, many immigrant populations are vulnerable to excess disease morbidity due to the built environment.

The *SDOH & EHP* model provides insight into how environmental injustice can disproportionately affect immigrant populations in urban areas and otherwise. Persistent sociopolitical inequities can manifest themselves through the built environment and result in health disparities. For example, economic and historical conditions can push immigrant populations to reside in affordable yet substandard housing leading to the negative health outcomes.

Examining the morbidity rates experienced by immigrant populations provides a clue as to how the built environment might affect health. Physical characteristics of the built environment can affect rates of obesity. New immigrants generally have lower levels of obesity than their US-born counterparts; physical inactivity might account for this increase. However, the impact of physical environmental characteristics on physical activity is unclear. Some studies have found that the reasons for physical inactivity among this population concerned aspects of the built environment including transportation, lack of facilities, cost, and safety. Conversely, other studies have shown that social environmental factors such as knowing people who exercise and having a supportive family structure as well as level of acculturation has a much stronger effect on physical activity. It is also important to note that different immigrant groups may possess different concepts of what constitutes physical activity. Though immigrants might not engage in physical activity during their leisure time, their daily tasks and chores might be highly active. Yet, even in such cases the perception of the built environment might discourage leisure-time activity.

Another domain where the built environment may play a strong role is the area of mental health. Generally, immigrants have better overall mental health status than native-born residents, however this is not consistent among all subgroups, varies by psychiatric disorder, and changes with time spent in the United States. In a nationally representative survey, researchers have found that a perceived lack of neighborhood safety was positively associated with mental health outcomes such as depression, anxiety, and substance use disorders. Similarly, the built environment is thought to play a role in acculturative stress, as living environments can impact acculturation.

Finally, the built environment might be implicated in several other health outcomes of immigrants. Regarding asthma, studies have suggested that while some immigrants are less likely to develop symptoms of asthma than their US-born counterparts, asthma rates vary widely between racial and ethnic groups. Regarding violence, the social and physical context of the built environment has been linked to rates of youth violence. For example, easy access to alcohol and lack of role models in professional occupations have been associated with youth violence.

Bureau of Immigration and Customs Enforcement

Kathrin Mautino
Mautino & Mautino, San Diego, CA, USA

The Bureau of Immigration and Customs Enforcement is the original name of the Immigration and Customs Enforcement (ICE). ICE, Customs and Border Protection (CBP), and United States Citizenship and Immigration Services (CIS) are the three organizations formed from the former Immigration and Naturalization Service (INS) when that agency was absorbed into the newly created Department of Homeland Security (DHS) in 2003.

For many years prior to 2003, critics of the INS complained that it was a dysfunctional agency, being charged with both enforcing the immigration laws and providing immigration benefits. The critics claimed that the enforcement mentality crept into adjudicating benefits, resulting in harsher standards than were required by the law. In addition, monies received by INS through increased fees originally designated to improve service often were appropriated for enforcement. With the formation of DHS, government officials took the opportunity to break the INS into component organizations with supposedly clearer missions.

Initially, there was a great deal of confusion as to which new agency had jurisdiction over various aspects of immigration law. Eventually, it became clear that ICE was responsible for the enforcement of the immigration laws within the United States. ICE officers are responsible for worksite visits, visiting jails and prisons, and otherwise looking for individuals in the United States in violation of the law. ICE officers also include the attorneys responsible for representing the government before the Executive Office for Immigration Review.

As the internal enforcer of the immigration laws, ICE is responsible for referring cases to the Executive Office for Immigration Review, Office of the Immigration Judges, commonly referred to as the Immigration Court. The Immigration Court can remove or deport an individual who was inadmissible when he/she applied for entry into the United States. An individual who (1) has a communicable disease of public health significance, (2) is an immigrant who has failed to have the required vaccinations, (3) has a physical or mental disorder that may pose or has posed a danger to the self or to others, or (4) is a drug abuser or addict, is inadmissible to the United States. Thus, if an individual, at the time of entry into the United States, was in one of these classes, ICE may place the person in removal proceedings, in some cases even if the individual entered the United States many years before.

One of the most active and growing sections in ICE is the fugitive unit. ICE officers in this unit are responsible for locating and removing individuals who have been ordered deported or removed but have not left the country. Although some are violent criminals, ICE has been criticized that many of those it targets have no criminal history. ICE has also been criticized for making collateral arrests of other individuals who happen to be present at a home or other location where ICE is looking for an individual.

ICE can make worksite raids of locations suspected of hiring a large number of illegal immigrants. In May 2008, ICE agents arrested over 400 individuals suspected of being in the United States illegally at a meat packing plant in Postville, Iowa. Individuals who used a social security number not their own were given a choice: be prosecuted under a federal identity theft statute and risk a 2-year prison sentence, or plead guilty to a lesser charge and face automatic deportation. One year later, the United States Supreme Court held that using someone else's social security number to obtain employment was not in and of itself sufficient to satisfy the identity theft statute. The Postville raid was criticized not only for ICE's treatment of those detained but also for its economic and psychological effect on the local community.

Cambodia

Christopher A. Kenedi[1], Kristen G. Shirey[2]
[1]Auckland District Health Board, Auckland, New Zealand
[2]Departments of Psychiatry and Behavioral Sciences and Medicine, Duke University Medical Center, Durham, NC, USA

The health of Cambodian immigrants cannot be separated from the political history and the impact of the Khmer Rouge whose rule saw the deaths of approximately 21% of the Cambodian population – 1.7 million people – between 1975 and 1979. A 2005 community survey of Cambodians who had immigrated to the USA before 1993 reported that 99% had experienced near-death due to starvation and 90% had a friend or family member murdered.

Background

Most Cambodians consider themselves to be Khmers and descendants of the Angkor Empire that was the dominant force in Southeast Asia for hundreds of years from the tenth to the thirteenth century. The empire declined over the next 500 years and the country was invaded and sacked by various neighbors, although a monarchy endured. In the nineteenth century, attacks from the west (Thai) and the east (Cham/modern-day Vietnamese) led to Cambodia seeking French protection and becoming a part of French Indochina. Vichy French Colonial administrators were allowed to maintain control of Cambodia during most of World War II, and unlike Vietnam there was little impact from the Japanese occupation. Cambodia gained independence from France in 1953 and remained a constitutional monarchy until open conflict with the communist (Maoist) Khmer Rouge began in 1970. Some scholars believe the US intervention in Cambodian politics supported an unpopular government that endorsed the US war effort in Vietnam, but made Cambodia more susceptible to the Khmer Rouge guerillas. Fighting continued until the Khmer Rouge gained control of the country in 1975 – at the same time the North Vietnamese gained control of South Vietnam and unified their country.

Khmer Rouge and Genocide

Within days of capturing the capital, Phnom Penh, the Khmer Rouge led by Pol Pot began to locate and kill military and political leaders, monks, teachers, doctors, scientists, lawyers, engineers, and anyone who wore glasses; these were all people thought to be contaminated by capitalism. Because ammunition was in short supply, the majority were killed by stakes or bludgeoned to death with iron bars after they had been forced to dig their own graves in what became popularly known as "The Killing Fields." Hundreds of thousands of people were known to have died in this manner based on excavated gravesites.

Based on large-scale "experiments" that Pol Pot had carried out on villages the Khmer Rouge had captured in previous years, he believed that society had to be radically destabilized to break all previous bonds and ensure absolute loyalty to the communist party. The campaign was called "Year Zero," a takeoff on the ideals of the French Revolution. To accomplish this, the cities and villages were emptied to become ghost towns and the population forced into the countryside despite signs of an oncoming famine in the wake of the civil war. The displacement campaign was organized to remove traditional bonds such as family, village ties,

Sana Loue & Martha Sajatovic (eds.), *Encyclopedia of Immigrant Health*, DOI 10.1007/978-1-4419-5659-0,

and faith in Buddhism. The farming practices proved to be poorly planned and executed due to the lack of expertise by the Khmer Rouge administrators. This led to an ongoing agricultural catastrophe, resulting in famine and starvation across the country.

The Khmer Rouge administration was an ally of the People's Republic of China. Cambodia was invaded by Vietnam (a client state of the Soviet Union) in 1978 and despite a limited Chinese invasion of Vietnam in 1979 to support their Cambodian allies, the capital Phnom Penh fell to the Vietnamese in the same year, ending the genocidal reign of the Khmer Rouge 4 years and almost 2 million lives after it began. During the 1980s, the Khmer Rouge operated as a guerilla movement from the jungles of Western Cambodia and sometimes across the Thai border. Ten years of ongoing civil war ended with a peace agreement in 1991 that was policed by 20,000 UN Peacekeepers, although sporadic fighting continued for 8 more years. The last remnants of the Khmer Rouge surrendered in 1999. Since the peace accords in 1991, there have been elections in 1993, 1998, 2003, and 2008 that have been generally peaceful – with the exception of a coup in 1997.

Despite increasing security and political stability, the scars of the Khmer Rouge linger on in many Cambodians' minds. There is almost no access to mental health resources within Cambodia. Posttraumatic stress disorder and other mental illnesses appear to have a high prevalence among the generation of Cambodians that survived as well as those that perpetrated the genocide and conflict.

Gang Rape

Because of the genocide of the 1970s and the conflict that followed, 50% of Cambodia's population is less than 21 years old. They tend to have limited education and skills training because most of the teachers were killed by the Khmer Rouge, schools were destroyed, and the following decades of conflict resulted in limited investment in an education infrastructure. Combined with the intentional destruction of Cambodian culture by the Khmer Rouge and the social structure that was lost with it, this has led to some challenging social trends. One is an increasing recognition of the widespread practice of "bauk," which translates to "plus" in Khmer. It is a practice of group sex that appears to be gang rape more often than not. The process involves a group of – up to a dozen – youths luring a woman, usually but not always, a prostitute to a room. The expressed sentiment is that they are paying "full price" so it is cheaper to split the cost. There appear to be no prosecutions for bauk despite it being well documented. One survey of 580 youths aged 13–28 in Cambodia reported that only 13% of men and 13% of women felt it was inherently wrong; 33% of men and 41% of women felt bauk was dangerous mostly because of STD transmission; 13% of men and 8% of women said gang rape was okay because the women were prostitutes and see "many men" anyway; and 13% of men and 17% of women said it was better to happen to prostitutes than "other women." Thirty-four percent of high-school students said they knew at least one person who had participated in bauk. Sixty percent of university students said they knew of someone who had participated. One trend noted anecdotally by women's-rights NGOs is that non-Khmer-speaking women (prostitutes or not) seem to be more common targets of bauk/gang rape, perhaps because their foreignness/otherness as immigrants appears to make it more acceptable to the men involved.

Trafficking

Another issue that comes along with a large population of unskilled Cambodian youths is unemployment and a susceptibility to human trafficking. Human trafficking is a form of exploitation that involves controlling and transporting people through the use of force, deception, or coercion. It is reported to be the third most profitable criminal activity in the world after drug and gun smuggling, and resulted in estimated worldwide profits of $31 Billion USD in 2008. Cambodian men, women, and children are trafficked for sexual and labor exploitation in Thailand, Malaysia, Macao, and Taiwan. The traffickers are reportedly organized crime syndicates, parents, relatives, friends, intimate partners, and neighbors. Cambodian men are trafficked into commercial fisheries, seafood-processing plants, and for farm, industrial, and construction labor. The trafficking of women commonly occurs for exploitation as sex workers.

It is also common to find Vietnamese and Chinese women trafficked into Cambodia working as prostitutes, commonly from ages 15 to 18. This is partly so not only because agents in both places act as way-stations to move the women on to industrialized nations, but also because within the local sex industry of each nation the foreign women are perceived to be more compliant and less resistant when they are in a strange country with an unfamiliar language, customs, and geography. In a foreign land they will be unaware of any resources to help them escape and may be subject to prosecution as illegal immigrants if they approach the police. Psychologically, they feel isolated and may see their captors as their only hope for survival. Even their employers or customers, who do not speak Khmer, may not realize that they are unwilling participants. In Cambodia, a local nongovernmental agency study found that 76% of trafficked children sent to Thailand came from families who owned land, 93% owned their own house and had no debt on the land or house, and 47% stated that their mother was the facilitator. Young Cambodian girls who are virgins are also highly sought after by traffickers, as clients will see them as being free from HIV or STDs. They are also thought to convey increased vigor to their male clients, an animist belief common throughout eastern Asia. Reports state that they are bought for a “week of use” and confined to a hotel or guesthouse room for the duration.

Landmines

Other residual effects from the conflicts include the remaining land mines and unexploded military ordinance that many of the different warring groups (US, Vietnamese, Royal Cambodian, Thai, Khmer Rouge, and other military forces) in Cambodia left behind. Cambodia is one of the most heavily mined areas in the world. In 2009, more than 10 years after the last of the Khmer Rouge surrendered, the Cambodian Mine Action Centre found and destroyed 19,511 mines and 133,164 artillery shells and bombs. It is estimated that two to four million mines remain. Cambodia has one amputee for every 290 people, one of the highest ratios in the world. This is especially tragic considering the youthful demographic of the population. UNICEF estimates that children account for half of landmine casualties in Cambodia. Many of these victims will not have access to modern prosthetics and will be at a severe disadvantage for work in a crowded labor market. They also have no access to physical medicine and rehabilitation specialists that amputees in developed countries would normally see. These victims also have unmet mental health needs and commonly express symptoms of PTSD and chronic depression.

Refugees

From 1975 to 1993, over 500,000 Cambodians fled into Thailand and another 100,000 entered Vietnam. At least 300,000 of those Cambodians permanently fled the region with more than 179,000 ending up in the USA, 50,000 in France, and 45,000 in Australia. Most of the refugees left Cambodia after the genocide because the Khmer Rouge would generally not allow the population to leave Cambodia. For instance, only 300 Cambodians arrived in the USA in 1977. After the fall of the Khmer Rouge from power in 1979 and as the Vietnamese came into Cambodia, a large amount of the Cambodian population made their way westward. In 1979, 6,000 Cambodian refugees entered the USA. A year later, 16,000 more refugees followed. The year 1981 saw the largest number of Cambodian refugees enter the USA, 27,100.

The Cambodian refugees who fled to Thailand overwhelmed resources at the border. In 1979, an international response led to the opening of several refugee camps within Thailand for some 160,000 refugees; another 350,000 lived in Thailand outside of the camps. Several hundred thousand returned to Cambodia after the arrival of United Nations Peacekeepers in the 1990s.

Gangs

Cambodian refugees resettled in the developing world have been associated with limited assimilation to their adopted culture and a higher rate of gang activity. This is thought to come from a series of factors: poor skills base on arrival, difficulty learning a language, familiarity with weapons, a higher rate of untreated mental illness and desensitization to violence, lack of parental guidance and role models, and settling in low-income/high-crime neighborhoods where some communities may have the need to band together to protect themselves. In Los Angeles 46% of Cambodians were found to be living below the poverty line as opposed to 27% of Vietnamese. Cambodians who have had negative experiences with the Khmer Rouge and then in refugee camps before arriving in the USA often show a fear of and distrust towards authority. This may make them less prone to cooperation and more likely to turn within their own community for support and perceived protection.

In the USA, gang-associated violence or misdemeanor crimes of suspected gang members can be a cause for deportation if immigrants have not achieved US citizenship, which many Cambodian immigrants in the USA have not. This had not been an issue in the past, as prior to 2001 there was not a treaty regulating deportation. The number of deportees is rising with several thousand pending return to Cambodia, despite the fact that many speak Khmer poorly or are not acclimatized to life in Cambodia. This is of concern to health care workers who treat suspected gang members or drug abusers who may be at risk for deportation.

Health Care in Cambodia

In addition to problems arising from the Khmer Rouge genocide and displacement, Cambodia faces problems that similar developing nations have to contend with, such as corruption, infectious diseases, poverty, and a significant lack of basic infrastructure. In developing countries, local economics determine illness exposure, and Cambodia is not an exception. Seventy-five percent of the country is engaged in agriculture and 35% of the population lives below a very marginal poverty line. Stability is beginning to pay off, however, the government-funded public health system is reportedly ineffectual, with up to 100% of the funds and equipment lost to corruption and diverted to private clinics – NGOs are stepping in to provide networks of clinic and birthing services.

Cultural Issues

Cambodian men are the traditional heads of household, but women have always had a role as "purse keepers" and masters of the household budget in Cambodia. After the genocide and years of war, in many households divorced, widowed, or separated women are accepted as the head. Age has traditionally been very important in Cambodian culture. Extended families often look to an older parent or grandparent for adjudication or structure and for Cambodian refugees; this can be stressful as the younger generation may be more likely to adapt to local customs. Younger members of refugee families may be expected to act as caregivers, translators, and transportation assistants for older family members requiring medical care. This can set up situations where health care is neglected, as older members feel they do not want to intrude or cannot ask younger members to help them access care.

Respect for the elderly is essential in a Cambodian family setting, and the oldest members should be greeted first and last in a family meeting. Communication can be very frustrating for Western-trained health care workers as it is unusual for older Cambodians to respond negatively or say "no." Synonyms for no may be a lack of response to the question, statements such as "it's ok" or "no problem," or even an unconvincing "yes." It is generally of little value to press directly for answers.

Emotion, including anger, frustration, or loud, cheerful, or overly familiar behavior, is often out of place and Cambodians, like Thai, prize equanimity in the face of distress and confrontation. Translators may have difficulty conveying tone or Western concepts in psychological or psychiatric assessment. It is important that health care providers address these challenges in communication; using a translator that is incompatible for gender, age, or other reasons will lead to false or limited information.

Children

Cambodians see compliments or unnecessary attention to children as bad luck. Cambodian society also sees corporal punishment as a common and acceptable method of feedback. Cambodians in Western society may be distressed at the lack of restraint and structure that schools provide and sometimes blame this for the high rate of gang involvement described above. Childhood immunizations are generally accepted.

Physical Touching

Greeting is by the *Sampeah* gesture, pressing the hands together and bowing the head. The bottom of the foot is considered unclean and should never be pointed at a Cambodian. Touching of the head is thought to impact the soul, and should be done only after obtaining permission during a physical examination.

Names and Language

The Khmer language places the family name ahead of a given name and both are used in many cases to show respect within a family and by strangers. Women usually keep their father's surname after marriage. Names of Cambodians in Western Arabic spelling are usually adaptations that were taken on arrival at refugee centers in Thailand or on arrival to their adopted country. Different family members may have slightly different spellings if they arrived separately. The Khmer language is not always as precise as Western languages in terms of medical symptoms. For instance, "Krun" is commonly translated as fever, but may actually refer to malaise, "hot and cold," or flushing. However, "Krun jang" usually refers to high fevers and rigors and is associated with malaria.

Traditional Medicine Practices

Although Cambodians are primarily Buddhist, there is an extensive range of animist and Chinese influences. Cupping, acupressure, acupuncture, massage, and traditional medications such as bark or animal products may be used for a variety of ailments. It is not uncommon to mix traditional therapies with alcohol. Spiritual practices are wide and varied; tattoos may be used for protection, amulets may be thought to convey healing powers or protection, and "Yuan," inscriptions over windows or doors, may be used for protection against spirits.

Cambodians may use a combination of traditional, spiritual, and complementary medicine practices and see no sense of exclusivity about them. It is common that they associate medications with symptoms of distress and stop the medications when the symptoms alleviate.

Mental Health

A report in the *Journal of the American Medical Association* stated that 62% of Cambodian refugees who came to America to escape the Khmer Rouge are suffering from posttraumatic stress disorder. Another 51% suffer from severe depression.

Mental illness in the Cambodian community is often only addressed indirectly and reluctantly. Animist influences suggest it is due to spirit possession and Buddhist influences suggest a role for bad karma from previous acts and shame, both leading to stigma within the community. Initial presentations for mental distress will often be to local Buddhist religious figures and traditional medicine practitioners. Only if these are unsuccessful will an attempt generally be made to engage Western practitioners. In a 1985 California survey conducted on the mental health of Southeast Asian refugees, 84% of Cambodian households had at least one member under a physician's care in comparison to 45% of Vietnamese households. This is thought to reflect psychiatric as well as psychosomatic issues from past traumatic experiences.

A number of case reports discuss specific PTSD symptoms surrounding episodes of cannibalism that were witnessed or experienced by child and adult survivors of the Khmer Rouge and the famine that resulted.

Culture-Bound Syndromes

"Koucharang," or "thinking too much illness," is associated with past trauma and symptoms of headaches, behavioral changes, and other somatic complaints.

"Khyol," or "wind illness," may also refer to dizziness and fever, but commonly describes a disturbance of balance that can be due to a variety of illnesses.

"Sore neck syndrome" may entail headaches, blurry vision, tinnitus, dizziness, and palpitations/shortness of breath. This is thought to be a manifestation of panic disorder.

Pregnancy and Childbirth

Traditionally childbirth was at home, but among refugees and in Cambodia this is switching to hospital-based midwives or birth attendants (chmop). There is often a strong preference for female attendants. Delivery is thought to leave women susceptible to cold. Cambodian women are anecdotally noted to be stoic during childbirth.

Infections

Cambodia is noted to have a very high burden of tuberculosis (TB) with 64% of the population infected and an average annual death rate from TB of 13,000 people. Cambodian refugees are at even higher risk of infection due to crowded conditions in some camps. Multidrug resistance is known within Cambodia and some refugees may have been partially treated due to being moved between camps in Thailand. Infections remain the leading cause of death and disability in Cambodia according to the World Health Organization.

The current HIV prevalence rate is estimated at 0.8% as of 2007. However 40–50% of the prostitutes in Cambodia are thought to be HIV positive, and Cambodian emigrants thought to have practiced prostitution should be tested for a range of sexually transmitted diseases including HIV, syphilis, gonorrhea, and chlamydia. Other infections seen in refugees and Cambodian immigrants include: amebiasis, angiostrongyliasis, anthrax, capillariasis, chikungunya, cholera, cryptococcosis, cryptosporidiosis, cysticercosis, dengue, Japanese encephalitis, filariasis, gnathostomiasis, helminthiasis, hepatitis B (15% of the population in some studies), leishmaniasis, leprosy, leptospirosis, malaria, melioidosis, mycetoma, strongyloidiasis, trenatodes, tropical sprue, typhus, and yaws.

Cambodians are at also at a distinct risk for oral cancer associated with betel leaf exposure that is commonly chewed and kept like loose tobacco as a quid at the gum.

History

Canada's history spans thousands of years – from the Paleo-Indians to the present day. Aboriginal people inhabited Canada for millennia, evolving trade networks, distinct spiritual beliefs, and social hierarchies. Long since faded before the arrival of the first Europeans, some of these civilizations were discovered through archaeological investigations. Through the years, various treaties and laws have been enacted between European settlers and the Aboriginal populations.

In the late fifteenth century, French and British explorers settled along Canada's Atlantic coast. After the Seven Years' War, in 1763, France ceded to Britain nearly all of its North American colonies. Shortly thereafter, Canada was formed as a federal dominion of four provinces. This marks the beginning of a rapid accumulation of provinces and territories and of increasing autonomy from the British Empire. Complete autonomy came with the Statute of Westminster of 1931 and was finalized in the Canada Act of 1982 – which severed all remnants of legal dependence on Britain's parliament.

Over the centuries, aspects of Aboriginal, French, British, and more recent immigrant customs have melded to form a rich Canadian culture. Canada has been influenced greatly by the United States; the two countries are similar in terms of geography, linguistics, and economics. Post–World War II, Canada has been committed to a policy that espouses socioeconomic development domestically and multilateralism abroad, contending that broad goals – such as nuclear disarmament – are best addressed with the cooperative assistance of many nations.

Today, Canada is comprised of ten provinces and three territories and is governed as both a parliamentary democracy and a constitutional monarchy with Queen Elizabeth II as its head of state.

Geography

Canada's national motto is "from sea to sea," as it includes most of the northern portion of North America, occupying 41% of the continent. In terms of total area, Canada is second only to Russia. Its territory spans an immense distance, from the Pacific Ocean to the west, the Atlantic Ocean to the east, the Arctic Ocean to the north, and the contiguous United States to the south. The country covers 9,984,670 km^2, with a land mass of 9,093,507 km^2. The northernmost settlement in the world is found in Canada, at the Canadian Forces Station (CFS) Alert. It is positioned on the northern tip of Ellesmere Island, just north of Alert, Nunavut – a mere 834 km from the North Pole.

Culture

Historically, Canadian culture was influenced heavily by European traditions, in particular those of Great Britain and France. Over time, aspects of the cultures of Canada's Aboriginal peoples and immigrant populations have become part of the fabric of the broader Canadian culture. The Aboriginal peoples include members of the *First Nations*, a term of ethnicity that refers to those whose ancestry is characterized as belonging to the indigenous peoples of the Americas. Canada's Aboriginal peoples are neither *Inuit* (Arctic-situated) nor *Métis* (mixed European-First Nations ancestry). Today, there are more than 630 recognized First Nations governments or bands spread across Canada; approximately 50% of its nearly 700,000 peoples are located in Ontario and British Columbia.

The Canadian government has influenced the culture in specific ways, one of which is through the use of Crown Corporations, Canada's various government-sponsored programs, laws, and institutions that promote and affect the culture through media endeavors such as the Canadian Broadcasting Corporation and the National Film Board of Canada. The government promotes numerous events that support Canadian traditions. Also, the government has tried to shape the culture going forward by regulating various media by setting and enforcing legal minimums on Canadian content. They accomplish this through the efforts of oversight bodies such as the Canadian Radio-television and Telecommunications Commission (CRTC). The CRTC is responsible for the regulation of all Canadian broadcasting and telecommunications activities. The best-known of these regulations is known collectively as the Canadian content rules. Canadian content, or CanCon, refers to the requirements that radio and television broadcasters must broadcast a certain percentage of content that was contributed to by persons from Canada. The rules apply to specialty channels as well, and they extend to the nature of the content itself. The CanCon rules are controversial, with one side contending that they preserve the legacy of a rich heritage that is uniquely Canadian, and the other contending that the rules are undemocratic and allow for the trampling of individual consumers' rights.

As Canada's territory was developed later than other European colonies in the Americas, symbols of pioneers, trappers, and traders were important in the early development of Canadian culture. Francophone is used to describe a natively French-speaking person, whether referring to individuals, groups, or places. The term refers specifically to people whose cultural background is associated primarily with the French language, regardless of ethnic and geographical differences. The Francophone culture beyond Europe is the legacy of the French colonial empire and the Belgian colonial empire.

The British conquest of Canada in 1759 brought a large Francophone population under British rule, and the migration of Loyalists from the 13 Colonies brought in British and American influences, thus creating the demand for compromise and accommodation. Comparatively, Canada's initial interactions with First Nations and Inuit populations were relatively peaceful as compared to the United States' initial interactions with its native peoples. Combined with an economic structure that developed later than other European interests, this served to allow the native people of Canada to have a significant influence on the national culture while simultaneously preserving their own unique identity.

Multiculturalism thrives in Canada and is manifest in various regional, aboriginal, and ethnic subcultures – such as the French Canadian of Quebec and the Celtic influences in Nova Scotia and Newfoundland. The Quebec Act of 1774 was an act of the Parliament of Great Britain; it outlined procedures for governance in the Province of Quebec. Key among the Act's components was the restoration of the use of French civil law for private matters, while the English law was preserved for common law, including criminal prosecution. The Act is viewed as critical to French Canada's early history.

Canada's multicultural heritage is protected Section 27 of the Canadian Charter of Rights and Freedoms, a bill of rights entrenched in the Constitution of Canada. In this section is written that interpretation should be consistent with the preservation of the multicultural heritage of Canadians. In many of the major cities, Montreal, Vancouver, and Toronto, multiculturalism is robust and part of the cultural norm, with diversity uniting the community.

Political System

The Canadian government is unusual in that it borrows from both the British and American models of government; it is both a federal system of parliamentary government with strong democratic traditions and a parliamentary democracy. At the signing of the Constitution Act, 1867, governance was established as a constitutional monarchy, wherein the Canadian Crown acts as the core of Canada's Westminster-style parliamentary democracy. In a constitutional monarchy, a monarch (an individual who rules for life) acts as head of state (the official leader of a nation) within the guidelines of a constitution, which can be written, unwritten, or blended. A constitutional monarchy differs from an absolute monarchy in that an absolute monarch is not legally bound by a constitution of any form and serves as the only source of political power.

The Crown is likened to a corporation, with the monarch at the center and the power of the whole shared by multiple institutions of government that act under the sovereign's authority. In this way, the Crown is the foundation of Canada's executive, legislative, and judicial branches. Aspects of governance are detailed in the Constitution of Canada. Notably, included in the document are items that have been developed over hundreds of years such as written statutes, court rulings, and conventions.

The head of Canada's executive branch is the king or queen of the United Kingdom, entrusted with powers over the legislative and judicial branches. Historically, this position is honorary rather than enforced, though should they decide, the monarch could assert considerable power over Canada. As they are geographically quite far apart, the monarch appoints a Canadian governor-general to oversee the executive powers. Although the executive branch typically bows to the will of parliament and the constitution, it does so by tradition rather than law.

Economy

Canada, one of the world's wealthiest nations, has the ninth largest economy worldwide and is a member of the Organization for Economic Co-operation and Development and Group of Eight. Canada resembles the USA in its market-oriented economic system and production pattern. As of November 2010, Canada was still recovering from the recent global financial crises; its national unemployment rate was 7.6%, with a range of 5.0% in Saskatchewan to 13.8% in Newfoundland and Labrador. In 2008, Canada had 69 companies on Forbes's list of the 2,000 largest companies in the world. As of 2008, Canada's total government debt burden was the lowest in the G8.

Canada has considerable natural resources, for example, the fishing industry (British Columbia) and the oil and gas industry (Alberta, Saskatchewan, Newfoundland, and Labrador). Northern Ontario holds numerous mines, and historically the fishing industry has been of chief importance to the Atlantic Provinces. Mineral resources include coal, copper, iron ore, and gold. The Canadian economy relies heavily on the international trade of its natural resources. In 2009, agricultural, energy, forestry, and mining exports accounted for nearly 60% of its total exports, while machinery, equipment, automotive products, and other manufactures comprised 38% of exports. The United States is Canada's largest trading partner, accounting roughly for 73% of exports and 63% of imports.

Healthcare

Healthcare is delivered through a publicly funded system that is, for the most part free at the point of use, with most services provided by private entities. The system is guided by the Canada Health Act (CHA) of 1984. The CHA contains the stipulations with which the provincial and territorial health insurance programs must conform to receive federal payments. Criteria include universal coverage without co-payments for all "insured persons" for all "medically necessary" hospital and physician services.

The government establishes quality controls through federal standards; however, it is not involved in day-to-day care. Providers are responsible for handling insurance claims against the provincial insurer; the patient is not involved in the claims process. Private insurance is involved minimally in the overall health care system. Although costs are paid primarily through funding from income taxes, three provinces impose an additional monthly premium.

Pharmaceutical medications for the elderly or indigent are covered by public funds or through employment-based private insurance. To control costs, drug prices are negotiated between the federal government and suppliers. If a patient wishes to see a specialist or is counseled to see a specialist, a referral can be made by the family physician. Emphasis is placed on preventive care; annual checkups are encouraged.

Canada's Immigration Policy and Trends

Relative to its current population, Canada accepts more than twice as many legal immigrants than the United States. Boasting the world's second largest land mass, Canada has had a longstanding immigrant-friendly migration policy. In the 1960s, two key developments had far-reaching effects on the country's policy: the establishment of a point system that favors the highly skilled and the abolishment of provisions that allowed for the screening out of non-Whites. These events provided the possibility of admission to minorities who had been shut out previously. A large wave of immigrants quickly followed, with Chinese, Indians, and Filipinos arriving in the greatest numbers.

With the second largest land mass worldwide and a population only one-ninth that of the USA, Canada has tremendous growth potential. The point system has served to influence positively public perception of immigration. It promotes the theme that Canada is receiving immigrants that it needs, immigrants that are vital to its growth and economy. Other factors that support immigration include: children of immigrants typically do well academically and socially; Canada's economic downturn has been fairly mild in comparison to other developed countries; and the virtual absence of illegal immigration has removed a dominant source of the conflict that surrounds immigration in other countries such as the United States.

Multiculturalism is pervasive throughout Canada, permeating a political culture that is accommodating and attractive to immigrants. While intense debates over immigration are seen in many developed nations, from Australia to Sweden to the USA, Canada is nearly devoid of such anti-immigration sentiment. In fact, few nations accept more immigrants per capita. Recently, the Canadian province of Manitoba petitioned and won the right to bring greater numbers of foreigners in. As they select ethnic and occupational groups judged most likely to stay, currently approximately 600 immigrants each month arrive in and around the province.

Cancer

Ellen Schleicher Pliska
Family and Community Health, Association of State and Territorial Health Officials (ASTHO),
Arlington, VA, USA

Cancer Prevalence

In 2007, there were over 12 million new cancer cases worldwide, with 5.4 million diagnosed in developed countries and 6.7 million diagnosed in developing countries. Globally, there were approximately 20,000 cancer deaths per day. Of the 7.6 million deaths per year, 2.9 and 4.7 million occurred in developed and developing countries, respectively. In developed countries, the three most common cancers among men were prostate, lung, and colorectal, and among women are breast, colorectal, and lung. In developing countries, the three most common cancers among men were lung, stomach, and liver, and among women were breast, cervix, and stomach.

There are regional differences in cancer types depending on the availability and quality of prevention and treatment services, prevalence of risk factors, age of population, and reporting mechanisms. Rates of specific cancers in regions are crucial as the incidence of cancer for new immigrants closely mirrors their home country's rates. Cervical cancer is the most common cancer of Eastern and Southern Africa, Central America, and South Central Asia. Breast cancer is the most common cancer in Northern and Western Africa, South America, Western Asia, and Northern and Western Europe. Prostate cancer is the most common cancer in the Caribbean and North America. Lung cancer is the most common cancer in Southeast Asia, Eastern and Southern Europe, and Micronesia. The remaining regions of the world have the following most common cancers: Kaposi sarcoma (Middle Africa), stomach (Eastern Asia), colon and rectum (Australia/New Zealand), and oral cavity (Melanesia).

Cancer Incidence and the Healthy Migrant Effect

Data from the US National Institutes of Health's Surveillance Epidemiology and End Results (SEER), a dataset of regional cancer registries in the USA and other countries, found that cancer rates from new immigrants to the USA were the same as rates from their native country. Latino immigrants to the USA suffer from relatively rare cancers in their new country but have lower rates of common cancers. However, the immigrants' future generations experience similar cancers and cancer rates as the host country. In their move to Western countries, within a generation immigrants from Africa and Asia have the same cancer rates as that of their host country, even when rates in their country of origin are low. Also called the healthy migrant effect, new immigrants often are healthier and less likely to die from cancer. Assimilation to the new country's pollution levels, diet, smoking, and other behaviors over time changes one's susceptibility to cancer over the life span.

Disparities

Tobacco Use and Cancer

Tobacco use is one of the greatest risk factors for cancer. Differences in tobacco use between developed and developing countries are great: adults in developing countries use tobacco nearly 1.5 times greater than developed countries. However, there is a large variation among regions and countries and frequency of use. While Asian-Americans have the lowest smoking rates in the USA, Asian immigrant groups have the highest smoking rates of all US residents, ranging from 34% to 43% for Asian immigrants versus 10.4% for US-born Asians.

Smoking cessation programs are unevenly accessed by immigrant populations, despite their desire to quit. Latino smokers in the USA are half as likely to have ever used nicotine replacement therapy compared to Whites. Barriers to accessing these programs include lack of insurance, lack of awareness of the benefits of a cessation method, and receiving no information on how to quit from a physician.

Diet and Colorectal Cancer

Colon and rectal cancer (CRC) is the fourth and third most common cancer worldwide for men and women, respectively. However, CRC incidence is markedly higher among developed countries (third and second most common) than developing countries (fifth most common for men and women). Immigrants from countries with lower CRC rates continue to have lower rates after they migrated to a high CRC country. However, the immigrant's offspring experiences similar to or higher than the country's nonimmigrant populations.

Changes in CRC rates over the generations point to dietary changes. CRC risk factors include a diet high in animal fats and low in fiber, fruits, and vegetables. Other risk factors include alcohol use, obesity, physical inactivity, and smoking. Acculturation to a new country's diet, such as Asian and South Asian immigrants' children in the USA, increases their CRC risk.

Preventive Care

Unfamiliarity with prevention and early detection of cancer prevents many immigrants from being screened. Without symptoms, many foreign-born populations feel they do not need to visit a physician. When a doctor does not recommend regular examinations, cancer screening is often viewed as pointless. In studies on cervical cancer, foreign-born women said that women only go to the gynecologist when they had pain, unexplained bleeding, or were pregnant.

Viruses cause approximately 18% of cancers globally, with a larger percentage (26%) affecting developing nations than in developed countries (8%). Cancers such as cervical, liver, and stomach cancers and Burkitt's lymphoma are all caused by viruses. Vaccines for the human papillomavirus (HPV), the virus that causes cervical cancer, and hepatitis B and C, the viruses that cause liver cancer, are available but are often expensive and difficult to find in developing countries. Immigrants without these vaccines may migrate to a new country already infected with the virus or have no knowledge of a vaccine that can protect them.

Barriers to Care

Cultural Beliefs and Cervical and Breast Cancer

Cultural beliefs play a large role in cervical and breast cancer screening. Women from many cultures believe cervical cancer is caused by sexual activity and lack of hygiene and not the human papillomavirus (HPV). Latina immigrants are most likely to associate cervical cancer with lack of genital cleanliness after sex. Other thought causes of the cancer include sex during menstruation, sex at an early age, rape, and general poor hygiene. Mexican- and Salvadorian-born women report physical trauma to the breast, from accidental bumps to falling on something sharp to rough breastfeeding, can cause breast cancer.

Breast and cervical cancer is also associated with karma or fate. In these cases, foreign-born women feel that those with cervical cancer are being punished for improper behavior. Younger Asian and Pacific Islander immigrants associate cervical cancer with promiscuity. Women from Southeast Asia and Cambodia linked cervical cancer to karma and were less likely to be screened. Foreign-born Latinas are more likely than native-born Latinas to feel that God gives people breast cancer for leading bad lives. Many cultures feel that following behavioral standards and norms will keep the body healthy. Foreign-born physicians may also hold these views and not recommend Pap smears and breast exams for younger, unmarried patients.

Foreign-born women with fatalistic attitudes associated with breast and cervical cancer are less likely to be screened for breast and cervical cancer. Latina immigrants are more likely to believe that having cancer is a death sentence. Holding fatalistic views make immigrants less likely to seek preventive care. Screening is seen as pointless if cancer is unavoidable.

Acculturation

The length of time immigrants spend in their host country affects the probability they will be screened for cancer. For all cancer screening, naturalized citizens are more likely to be screened for cancer than noncitizens of the same nationality. Women residing in the USA less than 10 years were up to 20% less likely to receive cervical cancer screening than women residing longer. Latina women who spoke mostly Spanish are the least likely immigrant group in the USA to have had a Pap smear in the last 3 years. The more acculturated an individual is, the more likely they will be screened for cancer.

Language and Health Literacy

Speaking the host country's dominant language and being able to understand health information and services greatly affect access to care. Studies show that language barriers with a health care provider lower patient satisfaction and increase feelings that his or her questions and concerns were not addressed. Women who do not speak the host country's native language are less likely to receive breast and cervical cancer screening according to guidelines. While hiring interpreters decreases language barriers, the delays caused in scheduling and recruiting can lead to stress for both the patient and the provider.

Likewise, while patient education materials are often written in multiple languages, they are seldom written at or below a sixth-grade reading level. Knowledge of cancer screening guidelines is a strong predictor of being screened for cancer among all immigrant groups. Korean immigrants were three times more likely to have regular Pap regular screenings if they knew the recommended Pap smear guidelines. Both language and lack of health literacy are a major obstacle to education on cancer risks, prevention practices, and the benefits of screening.

Geography

Physical location can determine the likelihood of receiving cancer-related services. Immigrants living in urban locations, while commonly more equipped with cancer screening facilities, often face barriers with transportation and parking costs and availability and scheduling of services. Neighborhood safety of affordable services may be a factor in obtaining screening and treatment.

Immigrants living in rural areas face a different set of obstacles. In remote areas of many countries, health services may be few and far between, requiring the patient to travel hours for appropriate services. Lack of public health infrastructure in these areas puts the burden on the individual to find cancer-related information.

In large countries, like the USA, there may also be regional differences in cancer care. Mexican women were found to have different cancer screening rates across different states within the USA. With each state governing their own public health infrastructure and differing access to local resources, a country may have varying resources and barriers to care for immigrants.

Insurance Access

Access to health care insurance in countries like the USA is vital to accessing a continuous source of care. Compared to the native-born, immigrants are more likely to be uninsured and less likely to have been treated by a physician in the last year. While the uninsured rate for US-born citizens is 13.4%, naturalized citizens, foreign-born individuals, and noncitizens were uninsured at 17.9%, 33.6%, and 43.6%, respectively. The uninsured are less likely to have had routine examinations, including cancer screening tests. Uninsured patients, in general, are more likely to be diagnosed with late-stage cancer than those with insurance.

Private insurance is often expensive, the number one reason for being uninsured. Immigrants are less likely to have employer-based insurance and insurance coverage through a spouse. While legislation like the US Patient Protection and Affordable Care Act, enacted in 2010, provides assistance for citizens and legal immigrants to purchase health insurance through an employer or a health insurance exchange, it does not provide assistance to undocumented immigrants. Private health insurance also commonly requires a co-pay, which is often cost prohibitive to low-income immigrants.

In the USA, immigrants' access to federal programs is dependent on their immigrant status and income. Legal permanent residents (LPRs) – immigrants legally granted the privilege of residing permanently in the USA – with 40 work quarters (10 years of work) are eligible for Medicaid, a health program for low-income families. Noncitizen nationals (people born in American Samoa or Swain's Island), members (born outside the USA) of Indian tribes, and members of Hmong or Highland Laotian tribes that helped the US military during the Vietnam era who are legally living in the USA, their spouses or surviving spouses, and dependent children are eligible for Medicaid given they meet other income requirements. Asylees, refugees granted asylum, Cuban or Haitian entrants, Amerasian immigrants, and LPRs with a military connection are eligible for Medicaid benefits without a waiting period.

The State Children's Health Insurance Program (SCHIP), a health insurance program for low-income children, gives access to children of LPRs after the first 5 years of residency. Some states opt to use state money to cover children of LPRs during the waiting period. Refugee children are eligible for SCHIP during the first 7 years of their residency.

The majority of immigrants in the USA do not qualify for Medicaid; these populations have minimal options for cancer care. The Emergency Medicaid Treatment and Active Labor Act (EMTALA) requires hospitals and medical facilities to provide emergency care to individuals regardless of citizenship status, legal status, or their ability to pay. Emergency Medicaid does not cover patient's needs after treatment, including follow-up appointments, long-term medication, and follow-up tests. Community health centers are required to give care to everyone regardless of their ability to pay. While neither EMTALA nor community health centers are required to collect citizenship status, undocumented immigrants are less likely to seek care if they think they may be asked for documentation.

Continuity of Care

Uninsured patients are significantly less likely to have a continuous source of care. The uninsured are more likely to visit community health centers, urgent care centers, and emergency rooms – facilities that are not equipped to handle long-term diseases like cancer. Having a continuous source of care, no matter the type of doctor, increases a patient's access to preventive health care. Korean and Filipino women with a prior preventive health exam were three and five times more likely to have been screened for breast and cervical cancer than women without a checkup. Similarly, women seeing a doctor for their current pregnancy were nearly 250% more likely to have ever had a Pap smear and over 775% more likely to have had one within the last 3 years. Immigrants without a regular source of care are more likely to rely on emergency rooms when their condition becomes unbearable and commonly miss routine cancer screenings that could find cancer at a more treatable stage.

Low Socioeconomic Status

Immigrants' socioeconomic status – an intersection of income, education, and occupation – heavily affects their ability to access cancer screening and treatment. Co-pays associated with health insurance, designed to prevent overuse of services, can be a deterrent to care. Even when health care is free, there are other costs that may make screening prohibitive. Cambodian immigrants in the USA reported that lack of affordable transportation to services was one of the biggest reasons for not receiving cancer screening.

Immigrants tend to work in the lowest paying jobs without the option to take time off for doctor appointments. Rates of cervical cancer incidence increase with lower socioeconomic status across all ethnic groups. Being poor is one of the biggest predictors of a late-stage cancer diagnosis. Often, immigrants must choose between health care and other necessities, such as food or heat, or between getting care and losing their job. Regardless of country of origin or ethnicity, people with low socioeconomic backgrounds have worse cancer outcomes.

Cancer Health Disparities

Claudia Baquet[1], Shivonne Laird[2]
[1]Department of Medicine, University of Maryland School of Medicine, Baltimore, MD, USA
[2]Formerly of Office of Policy and Planning, University of Maryland School of Medicine, Baltimore, MD, USA

Immigrants to the USA may have health-related protective and/or detrimental health behaviors, cultural beliefs that contribute to their perception of health and health care, their view of the disease called cancer, or preexisting conditions. It should be noted, however, that the new resources available in the USA, the resident culture of Americans and assimilated migrants, and the immigrant experience itself may affect their health outcomes and health-seeking behavior over time. Thus, health outcomes found in donor countries do not necessarily correspond to outcomes for migrants to the USA.

Cancer is a group of diseases characterized by abnormal cell growth and spread or metastasis. There are over 100 different types of cancer. Cancer is the second leading cause of death in the USA and accounts for significant morbidity and mortality globally. The National Cancer Institute (NCI) defines "cancer health disparities" as "differences in the incidence, prevalence, mortality, and burden of cancer and related adverse health conditions that exist among specific population groups in the United States." Cancer survivorship disparities are included in this definition.

Health disparities are defined as "differences in the incidence, prevalence, mortality, and burden of diseases and other adverse health conditions that exist among specific population groups in the United States."A health disparity population is one in which there are significant differences in the overall rate of disease incidence, prevalence, morbidity, mortality, or survival rates in the population as compared to the health status of the general population.

Complex and interrelated factors contribute to the observed disparities in cancer incidence and death among racial, ethnic, and underserved groups including immigrants. Health behaviors, cultural factors and language barriers, health care access, satisfaction with health care, and risk/exposures from the "parent country" all have significant influences on cancer disparities. When describing, monitoring, and addressing cancer disparities for immigrants, it is critical to consider worldwide cancer rates in the parent country as well as US rates. Contributing factors include:

- Major risk/exposures including tobacco use, occupational exposures, SES, alcohol intake, viral (EBV, HBV, BCV, HPV)
- Health care seeking and access to health care
- Advanced stage at diagnosis
- Culture, language, and beliefs
- Participation in clinical trials
- Discrimination in the health care delivery system
- Biology

Immigrant Factors

Identification and understanding of factors unique to immigrant communities are essential to address cancer health disparities in such richly diverse communities.

- *Migration factors* and related differential risk/exposures and generational issues: documented for many immigrants including Japanese immigrants, Latinos, and some African immigrants.

- *Acculturation*: Documented for Latino/Hispanic communities especially for dietary patterns and nutritional consumption.
- *Language and cultural influences*: Related to access to health care, health literacy, treatment regimen, and medication compliance. It is also related to gender factors for Latino and Asian females who often prefer a female health care professional.
- *Discrimination, satisfaction with health care, and racial/ethnic concordance between patient and provider*: Documented for Latino/Hispanic, Asian, and African immigrants.

Cancer incidence patterns among first-generation immigrants are often nearly identical to those of their native country. Through subsequent generations, these patterns evolve to resemble those found in the USA especially for hormone-related cancers, such as breast, prostate, and ovarian cancer and neoplasms of the uterine corpus and cancers attributable to westernized diets, such as colorectal malignancies. Longer residence in the USA appears to lead to lower rates of cancers attributed to Asian diets, such as stomach cancer associated with the highly salted and nitrite-containing foods common in Asia. Studies have documented the following:

- Known viral-related cancers include primary liver cancer caused by hepatitis B and C.
- *Helicobacter pylori* related to stomach cancer incidence.
- Cervical cancer caused by human papillomavirus (HPV) has been documented as a worldwide cause of elevated cervical cancer rates in Latin America, Mexico, Africa, and parts of Asia.
- Environmental factors and cancer in immigrants: nasopharyngeal cancer associated with exposure to smoke from stoves used for cooking in the home and salivary cancer associated with cold, dark environments that produce vitamin A deficiencies.

Cancer disparities and immigrant studies have been reported, with an emphasis on environmental factors and cancer risk. This includes:

- First- and second-generation Japanese immigrants living in Hawaii
- Asian-American women
- Africans including primary liver cancer
- Vietnamese-Americans
- Hmong refugees from Vietnam, Laos, and Thailand settled in California
- Korean-Americans
- Pacific Islanders and Alaska Natives
- African and Asian men: cancer of the penis
- Asians and esophageal cancer and stomach cancer
- Migrant farm workers in California, many of whom were recent Mexican immigrants:
  - Lack of access to care, including screening programs and treatment was identified as a contributor to cancer disparities for migrant farm workers.
  - Higher incidences of brain cancer and leukemia were attributed to occupational exposures, particularly to pesticides.

Cancer mortality is related to the interaction of complex factors such as stage at diagnosis, cell type and tumor biology, access to quality oncology care, and follow-up. Cultural and language influences of new and existing immigrants to the USA are related to cancer outcomes.

Disparities in Racial/Ethnic Groups

Overall, African-American males develop cancer 15% more frequently than White males. African-American woman have a lower breast cancer rate, but higher death rate than White women. For all cancers combined, Blacks have the greatest burden, with incidence and death rates higher than any other racial/ethnic group, specifically a death rate 25% higher than Whites. Although Whites have the highest breast cancer rate, for all ages combined, of any racial/ethnic group, Blacks are more likely to die from this disease. This may be caused by lack of medical coverage and late detection, as well as unequal access to improvements in medicine. There is also some research that shows that Blacks and Latinas are more likely to have a more aggressive form of breast cancer than other races. Latinas and Black women also have the highest rates of cervical cancer, with Black women having a higher death rate. This high rate is due to the lack of screening and persistent infection with certain strains of HPV. African-American men have the highest incidence and death rate for prostate cancer, with a death rate twice that of Whites. Blacks have higher incidence and death rates of both colorectal and lung/bronchus cancers.

Latinas and Black women have the highest rates of cervical cancer, and though Black women have a higher death rate, Latinas have a higher incidence rate. This high rate is likely due to the lack of screening and persistent infection with certain strains of HPV. Latinos have the lowest rates of colorectal and lung cancer of any US racial/ethnic group.

Overall cancer incidence rates are lower for Asians and Pacific Islanders living in the USA than non-Hispanic Whites, with the exception of Native Hawaiian women, who have statistically higher all cancer combined rates than White women. The Asian and Pacific Islander (API) population have the highest rates of liver and stomach cancers. They suffer more often from cancers that are related to certain infections, though more study is needed.

Asian and Pacific Islanders should not be viewed as one, homogenous group, however, especially regarding cancer disparities. For example, Barry Miller and colleagues examined varying patterns in cancer incidence and mortality among the API population. A majority of the sample for this study was born outside the USA, with the exception of Native Hawaiians and Japanese-Americans. They found that liver cancer is highest among Laotian men, though liver cancer incidence and death rates were higher than non-Hispanic Whites for both men and women. The presumed cause was hepatitis B and C infection, which are endemic in Asian, Middle Eastern, and African countries. Laotian men also had the highest rates of liver, prostate, and stomach cancers, while Japanese men and women had the highest colorectal cancer rates. Stomach cancer rates were also high for many of the API groups, with the exception of Asian Indians/Pakistanis and Filipinos. Samoan and Native Hawaiian men were found to have the highest overall cancer rates, because of high rates of prostate and lung cancers, but they are not higher than those of White men. Lung cancer was among the four cancers most frequently experienced by all the API women groups, as was colorectal cancer (for those for whom they had enough data). Native Hawaiian, Samoan, and Tongan women have the highest overall cancer rates, higher even that White women. Breast cancer was highest among Native Hawaiian women. Vietnamese women were found to have higher rates of cervical cancer than White women, along with Kampuchean, Korean, and Laotian women. In another study, Chinese and several Southeast Asian immigrants have also been found to be at increased risk for nasopharyngeal cancer, with suggested causes including high consumption of preserved foods from an early age.

Alaska Natives have higher rates of colon and rectal cancer than the national average. American Indians have the lowest cancer survival rates of any US ethnic group. Native American data are not representative, but they have been shown to have higher rates of kidney and renal pelvis cancers than other racial/ethnic groups.

Eleven million cases of cancer occur annually worldwide, six million of them in low- and middle-income countries. In recent years, four million deaths from cancer have occurred each year in low- and middle-income countries. High smoking rates in these countries have made lung cancer the most common form. Of the approximately 1.1 billion smokers in the world, 80% of them live in low/middle-income countries. In developing countries, 26% of all cancers are attributable to infectious agents, compared to about 8% in high-income countries.

Nearly 300,000 women die every year from cervical cancer every year, 85% of them from low/middle-income countries; the likely cause is infection with one of several strains of human papilloma virus (HPV). Disparities in cancer outcomes worldwide pertain to children as well as adults.

One hundred and sixty thousand children worldwide are diagnosed with cancer; currently, 80% of US children under 15 are cured, while 80% of children in low/middle-income countries die because of late diagnosis and lack of treatment. In developing countries, most cancers may already be incurable when first noted, because cancer stage at time of detection is typically much further advanced than in wealthier countries. Patients in low/middle-income countries also tend to have additional health problems that may make their recovery from cancer more difficult.

Approaches to Address Cancer Disparities in Immigrants

The unique cultural and cancer patterns of immigrants require careful strategies and program development to successfully address cancer disparities in such diverse communities. Going beyond translation services is mandated. Assuring culturally competent and relevant prevention, screening and early detection and quality treatment necessitates bidirectional community engagement between communities and the health care delivery system. Models such as WINCART, AANCART, Redes En Accion, and the New York Center for Immigrant Health's Cancer Disparities Program are examples of community engaged and tailored programs, including for immigrants, which address cancer health disparities for diverse communities.

Cancer Incidence

CLAUDIA AYASH
New York University Langone Medical Center, CORE (Cancer Outreach, Outcomes, and Research for Equity) Center, New York University Cancer Institute, New York, NY, USA

According to the current population survey, 28.4 million immigrants now reside in the United States, a 43% increase since 1990. Many immigrants that settle in the United States bring with them age-old traditions and practices that may be different from Western customs. Cultural factors may affect their risks for certain diseases such as cancer as well as impact their use of the American health care system. Therefore, the study of disease patterns in immigrant populations has become an important area of research in the field of public health. There are differences in the incidence, prevalence, mortality, and burden of cancer among specific population groups in the United States. This has created opportunities for research and much debate about the causes of health disparities between ethnic and racial groups.

Addressing cancer health disparities has become a priority for the United States government's principal agency on cancer research, the National Cancer Institute (NCI) and other major cancer organizations like the American Cancer Society (ACS), in addition to medical centers and community-based organizations. Cancer trends may give researchers some insight into how different aspects of culture like diet, exercise, and religious beliefs and practices may affect risks for cancer in addition to health care access issues. Studies have shown that cancer incidence patterns of immigrants tend to mirror those of their native countries. Through subsequent generations, however, cancer incidence patterns change to resemble those in the United States, particularly in cancers related to hormones, such as breast, prostate, and ovarian cancer and cancers related to Westernized diets, like colorectal cancers. Later generations tend to abandon some of their cultural practices and adopt an American lifestyle that typically includes a diet high in fat and processed foods. An example of this phenomenon is that Asians living in the Far East have lower incidence of breast and prostate cancers than their American counterparts. However, when Asians migrate to the United States, in time their risk of breast and prostate cancer becomes similar to those of people in this country. These changes typically start to take effect with the second generation and become more prominent by the third generation.

There are methodological issues that may impede research on cancer incidence among immigrant populations as well as cultural factors. The population-based Surveillance, Epidemiology, and End Results (SEER) program of the NCI is an important resource for the study of cancer incidence and prevalence among immigrant and minority populations. SEER collects and publishes cancer incidence and survival data including patient demographics, primary tumor site, tumor morphology and stage at diagnosis, first course of treatment, and follow-up for vital status from population-based cancer registries covering approximately 26% of the US population. Collecting information on place of birth is an important variable for studies of immigrants. Although these data are collected by SEER registries, the information is often missing for a significant number of patients. SEER registries rely on hospitals for this information, many of which do not have uniform data collection systems and birthplace information if often not included. Additionally, many immigrants do not know certain aspects of their medical history including their family history because of distance between family members and customs that may prohibit discussions about cancer diagnoses. They may not know if any of their relatives had cancers that could potentially put them at a higher risk of one day developing the disease. Knowing a patient's family history is important for research purposes and to also help practitioners to determine a patient's risk for familial cancers and an appropriate screening schedule.

Health disparities research will likely continue to be a priority in areas with large immigrant populations. Understanding incidence rates among different populations is important to help health practitioners and health educators to develop tailored culturally appropriate education and early detection campaigns in addition to effective treatments. Information gleaned from this research could also have far-reaching effects by improving cancer outreach and treatments efforts worldwide through international collaborations.

Cancer Mortality

Melina Arnold

Department of Epidemiology & International Public Health, School of Public Health, Bielefeld University, Bielefeld, Germany

Cancer mortality is determined by the risk of developing cancer (cancer incidence) and factors that influence the survival after cancer diagnosis. Some cancers, such as colorectal or breast cancer, are better detectable and treatable than others as opposed to, for example, liver, stomach, and pancreatic cancer, which are less curable. Survival from the former can be influenced by adequate prevention, screening, and therapy. Disparities in cancer mortality and survival may therefore be ascribed to differences in (i) disease susceptibilities, (ii) exposures to carcinogens, (iii) access to cancer prevention and (iv) quality of treatment.

Cancer burden, particularly cancer mortality, shows substantial variation within and across populations. Individual and area-based differences in socioeconomic position – comprising education, occupation, income, housing situation and social environments – are associated with poor access to prevention measures, suboptimal treatment, and follow-up as well as a higher mortality within certain population groups. Disparities in cancer mortality across populations, for example, between allochthonous (immigrant) and indigenous (native) people of a country may reflect the importance of another prognostic factor: ethnicity. Several studies suggest negative correlations and a close connection between the two, since immigrants are often likely to be socially disadvantaged in their country of residence. In this context, immigrants are defined as persons or groups that leave their country of origin in order to settle permanently in another, whereas ethnicity corresponds to a social construct that is based on shared beliefs, views, lifestyles, and cultural habits – mostly also common origin. Thus, immigrants usually belong to (or consider themselves members of) a certain ethnic minority group and are therefore of "foreign ethnicity."

In less well-developed regions of the world, infectious diseases still dominate as primary causes of disease and death. However, due to the epidemiologic health transition, low-income countries undergo a shift of global burden of disease, entailing ageing populations and an increasing occurrence of chronic conditions like cancer. Still, cancer incidence is rather low in these countries, but cancer mortality plays a big role in comparison to more developed regions. Immigrants from non-Western/low income countries retain some features of their countries of origin and carry their cancer risk profile (characterized by low incidences but high mortality) to their new country of residence, where they face new exposures and environments. Several studies confirm that migrants show substantial risk diversity in comparison to the indigenous population and indicate elevated risks for cancers that are associated with infections, like cervical, liver, or stomach cancer. Those risks strongly relate to exposures experienced in early life/childhood and thus underscore the importance of the life-course perspective in carcinogenesis. Lower risks are observed for lifestyle-related cancers such as breast, colorectal, or prostate cancer.

Several studies show that African Americans are disproportionally more likely to develop and to die from cancer than any other ethnicity. This applies to all cancer sites combined as well as in particular to cancer of the esophagus, oral cavity, stomach, liver, and prostate where large discrepancies exist and risks are often more than twice as high compared to Whites. Moreover, even mortality from cancers associated to lifestyle factors is elevated in this population group (i.e. breast, lung, and colorectal cancer); however, this pattern is more pronounced among men. Migrants from Asia often exhibit high mortality rates for cancers of the oral cavity, nasopharynx, stomach, and liver. Similar observations have been made for immigrant populations residing in European countries. South American migrants were found to be more likely to die from cancer of the nasopharynx, stomach, liver, gallbladder, and cervix as well as Hodgkin's disease; migrants from Turkey show high mortality rates for cancer of the nasopharynx, stomach, liver, thyroid gland, and Hodgkin's disease in comparison to autochthonous populations of their western host countries, respectively.

Key factors that may explain disparities in cancer mortality across ethnicities are differences in stage of disease at diagnosis as well as treatment, compliance, and survivorship.

Cancer Stage at Diagnosis

Cancer burden could be decreased significantly if patients with cancer would be detected and treated early and thus more effectively. Early detection implies recognizing symptoms in due time and immediate seeking of medical care. Regular attendance in screening programs helps identifying early or pre-cancerous stages for some cancer sites, before any obvious symptoms occur.

Several studies report that immigrants are more likely to be non-attendees in screening programs and tend to present at later and less curable stages of cancer than indigenous populations of their host countries.

There are various reasons for non-attendance, the most important barriers being personal (literacy, language skills, health knowledge), cultural (religious beliefs, differences in health seeking behaviors, perception of symptoms), and financial (health insurance status) factors. Personal beliefs about illness, especially culturally determined disease perception, have been found to have a major impact on the time of first diagnosis, survival, and mortality.

Treatment, Compliance, and Survival

Adequate treatment and care are essential to reduce cancer mortality. This especially applies for cancers that have high cure rates when detected at an early stage and treated according to best practice (such as breast and colorectal cancer). Cancer patients require continuous medical care and psychosocial support on how to maintain physical, emotional, social, and spiritual health and how to cope with long-term effects of therapy. Response to illness and coping mechanisms vary across ethnicities and can influence the success of treatment and may distinguish outcomes. Sociocultural factors are very important in decision-making processes: they may determine adherence to treatment and willingness to develop health-maintaining behaviors as well as personal allowance for appropriate follow-up, surveillance, and post-treatment monitoring.

Studies show that immigrants are all too often less likely to receive appropriate cancer care. In this regard, survival is especially poor for cancers that require complex and costly therapies (e.g., stomach cancer and leukemia). It has also been observed that cancer patients with migration backgrounds are more likely to be affected by treatment complications and are less likely to adhere to medication regimens. For example, Chinese American women decline therapy more often compared to White women and women of other ethnicities. Especially among women, often other obligations, such as care giving, family, or employment, dominate over the need for the own medical care, amplified by logistic factors like extra costs, difficult transportation, and additional time expenditure. Furthermore, evidence suggests a high prevalence of comorbidities in immigrant groups, possibly entailing poorer health outcomes and poorer cancer survival.

Ineffective and insufficient treatment often results from inadequate communication between health care providers and patients. Consequently, patients with limited literacy and language skills do not always receive proper information about treatment options, possibly leading to suboptimal treatment choices. Moreover, the provision of culturally sensitive support and treatment for minority cancer patients is often hampered by the lack of relevant information available to clinicians and oncologists. Treatment plans have to incorporate culturally relevant differences in care seeking and disease coping.

In conclusion, ethnicity and immigration status represent important prognostic factors for cancer survival, and disparities can partly be explained by diverse cancer risk patterns, a later stage at diagnosis and differentials in treatment and care. Thorough research has been dedicated to the role of socioeconomic determinants on cancer mortality, but the independent effect of ethnicity stays unclear and still needs to be evaluated. Differences in cancer mortality between populations may underscore existing inequalities in early detection as well as treatment and require culturally sensitive prevention programs, targeting high risk groups. Ethnic inequalities in cancer mortality are not yet adequately documented and require careful surveillance and action.

Cancer Prevention

Melina Arnold, Oliver Razum
Department of Epidemiology & International Public Health, School of Public Health, Bielefeld University, Bielefeld, Germany

Cancer is one of the most important causes of death worldwide. Cancer burden, however, varies widely across geographical regions as well as across ethnic groups. According to the World Health Organization (WHO), many cancers are associated with risk factors such as smoking, excessive alcohol consumption, certain dietary patterns, and lack of physical activity. Others are caused by infectious agents. Many cancers are therefore partly preventable. In general, cancer prevention is achieved on different levels and comprises (1) the complete prevention of the disease using methods that avert the exposure to risk factors (primary prevention), (2) early detection of disease and the limitation of its effects after diagnosis (secondary prevention), and (3) the avoidance of further disabilities in persons diagnosed with cancer (tertiary prevention).

Assuring equality with regard to healthcare services and access to preventive medicine is sought by many industrialized countries and is gaining political importance. Quality of and access to healthcare are important preconditions for health and should be free from bounds to socioeconomic position and ethnic origin. Nevertheless, disparities attributable to social determinants such as education, occupation, social status, housing, and the degree of integration in social environments exist and result in social gradients of health within countries. Concomitance of low socioeconomic status (SES) and (a foreign) ethnicity, corresponding to cultural differences and cross-country variations, are known to amplify health gaps in populations.

The coherent roles of social and cultural determinants need to be disentangled in order to appreciate the detached impact of culture on health. Ethnicity is a social construct, referring to one's sense of identity in a cultural group or society. Unlike race, ethnicity is not restricted to phenotypes and is motivated by sharing certain views, lifestyles, and cultural habits. Immigrants of non-Western origin often represent ethnic minority groups in their countries of residence and share cultural identities as well as common ideals and goals. Their individual health care needs require careful analysis and need to be addressed by sensitive targeting of prevention programs.

There may be differences in cancer risk across ethnicities, meaning immigrant groups, and causal factors which determine those differences. Additionally, there are barriers in access to cancer prevention that immigrants might face. We propose how ethnic minorities should ideally be targeted with respect to cancer risk reduction.

Cancer and Culture: Disease Susceptibility, Perception, and Healthcare Utilization

Immigrants are equipped with unique constellations of disease risk patterns and exposures experienced before, during, and after migration. Many cancers are still relatively rare in non-Western parts of the world as compared with industrialized countries where cancer ranges among the most common causes of death. Immigrants are exposed to sudden changes of environmental risk factors between their home and their host country while their genetic disposition and cultural habits persist. Favorable risks of immigrants mostly result from persistence in healthy behaviors, for instance dietary or reproductive patterns. Elevated cancer risks among immigrants are known for cancers related to infectious diseases, experienced in early life and childhood, such as stomach, nasopharyngeal, or liver cancer. In addition, cancer mortality shows different patterns and often suggests poorer survival among persons from ethnic minority groups. Lower survival may be due to a lower participation in prevention programs, hindering early detection in this group, possibly leading to disparities in access to care and treatment.

Immigrants are not a homogeneous group. Ethnicity implies diverse concepts of and attitudes toward health that have an impact on the individual utilization of health care services. Cultural roots determine disease perception and coping patterns; both need to be considered when planning preventive measures and deciding on treatment options. Prevention measures should initially focus on barriers that inhibit the uptake of adequate health care, and on ways to overcome those difficulties. Language barriers, low health literacy, insecure or unstable insurance situations, unfamiliarity/distrust with new health care structures and systems, as well as the pursuit of religious beliefs and other cultural aspects may hamper access to healthcare. These aspects need to be addressed by developing special prevention strategies.

Disparities in Cancer Care and Cancer Prevention

Low participation in primary prevention and screening programs is associated with a late-stage cancer diagnosis and poorer survival. This has particularly been observed in migrant and ethnic minority groups.

Barriers that are relevant in many ethnic minority groups are *personal and cultural beliefs* and related behavioral patterns. A very important factor is poor knowledge of the local language. Factors that also play major roles are a general fear of a cancer diagnosis and fear of pain. Lack of awareness of the need for testing due to the absence of symptoms or an inherent dislike of the idea of being screened also contribute to lower uptake of prevention measures in these groups. Many women claim other priorities in life such as strong family obligations and often fear loss of privacy or embarrassment during examination. In addition, ethnic minorities often follow alternative medicine approaches and have fatalistic views toward cancer, perceiving it as a result of personal fate.

Social networks can have a considerable impact on personal decisions in the clinical context. Families or cultural communities may determine attitudes and adherence toward interventions.

Economic barriers are ubiquitous in immigrant populations and may hamper access to cancer prevention services. Unstable insurance coverage as well as additional costs for screening and vaccinations influence screening uptake, in particular among immigrants who are often affected by social deprivation and a higher risk of poverty.

Access to care is additionally affected by the *sex and ethnicity of the health care provider*. Especially, immigrant women with strong religious beliefs often only accept physical examinations by female practitioners. Furthermore, practitioners with foreign backgrounds themselves may not recommend cancer screenings to women because they do not want to intrude on their modesty. Many immigrant groups show a general mistrust toward Western medical systems, as well as a greater degree of dissatisfaction with their physicians.

Primary Cancer Prevention

Primary cancer prevention aims at the complete prevention of disease, applying measures that reduce the exposure to risk factors. It addresses lifestyle as well as environmental risk factors (e.g., diet, physical activity, and occupation) and should particularly stress exposures to infectious agents that are more prevalent in ethnic minority groups and may cause cancer.

Awareness and acceptance of different prevention measures differ between ethnic groups and are strongly linked to health policies. Targeting ethnic minority groups according to their needs is one of the major goals of public health and health service research. This demands knowledge of risk factors that are relevant in immigrant populations and tailoring prevention programs in order to limit ethnic inequalities in cancer risk.

Infections

Infections, predominantly experienced during early life, may play a causal role in carcinogenesis in later life. Immigrants originating from countries where particular infections are highly prevalent may become infected in childhood and develop disease after migration to the host country. This risk mainly affects first generation migrants whereas it appears to fade in their offspring and following generations.

Epstein-Barr Virus (EBV)

EBV is an ubiquitous herpes virus in humans and is involved in the causation of cancers of the lymphatic system (Burkitt's lymphoma, non-Hodgkin lymphoma, Hodgkin lymphoma), as well as nasopharyngeal and other oral cancers. EBV is most prevalent in equatorial Africa and other developing countries primarily tropical regions, and often infects HIV-infected individuals. EBV is transmitted by oropharyngeal secretions. Vaccines against the virus are currently being developed.

Hepatitis

Hepatitis is the most common chronic infectious disease in the world. Chronic forms can cause cirrhosis, failure, and cancer of the liver, often leading to death. It is highly endemic in parts of East Asia, sub-Saharan Africa, and Latin America. Immigrants from high risk countries are disproportionally affected by hepatitis B (HBV) and C (HCV) infections. The prevalence of HBV infection among Asian Americans is up to 10%, while only 0.1% of White Americans are affected. Liver cancer is thus the most significant health disparity affecting Asian Americans in the US.

HBV infection is preventable and vaccination against the infection can lower the risk of liver cancer. There is still no vaccine against HCV. HBV transmission occurs through blood and infected bodily fluids. Mother-to-child transmission in the uterus during birth represents the most common mode of infection in many Asian populations. HCV is less contagious than HBV and mostly transmitted by injection drug use.

Immigrants are often less likely than the majority of the population to receive vaccinations and blood screenings against hepatitis. There is a link between the knowledge of prevention, the level of educational attainment, and the decision to receive vaccination against HBV. Many Asian immigrants in the US are not fluent in English, which affects their ability to communicate with their primary care providers, often leading to the avoidance or delay of visits. Financial aspects certainly also contribute to lower participation in high risk immigrant groups.

There is a clear need for prevention programs targeting high risk groups such as Southeast Asian migrants and increasing the awareness of the connection between hepatitis and cancer. For example, the *San Francisco Hep B free campaign* promotes routine blood tests, improves referral and access to care for people with chronic hepatitis, and supports the expansion of hospital services offering low cost or free screenings and vaccinations for HBV as well as adequate monitoring. Prevention measures for immigrants should focus on both families' and individuals' susceptibility to the virus and enhance awareness and motivation for screening and vaccination.

Helicobacter pylori (*H. pylori*)

H. pylori infection is a risk factor for developing peptic ulcer disease and stomach cancer. Its distribution varies geographically. Incidence is highest in developing countries whereas it is low in high-income countries. *H. pylori* infection is relatively common in non-Western immigrant groups who are accordingly at increased risk to develop stomach cancer. The mode of *H. pylori* transmission is still unknown, but the infection is typically acquired in early childhood. Crowded, unhygienic living conditions, and social deprivation are known to foster *H. pylori* transmission.

Early detection and eradication of the virus would, if possible, be a sensible prevention strategy against stomach cancer. *H. pylori* can be diagnosed by checking for dyspeptic symptoms (stomach-related problems) using noninvasive such as blood antibody and stool antigen tests or invasive tests such as biopsies and tissue (histologic) examination.

Human Papilloma Virus (HPV)

The human papilloma virus (HPV) is typically transmitted through sexual contact. Persistent infection with one genetic type can, in rare cases, cause cancer in most cases of the cervix. The incidence of HPV infections is high among young, sexually active adults (aged 15–24) but varies greatly across populations, being highest in South Asia, sub-Saharan Africa, and Latin America.

Newly developed HPV vaccines prevent infection from HPV types 16 and 18, accounting for up to 70% of cervical cancers. Vaccination is usually offered to girls starting at age 12, although implementation and administration vary greatly across countries. The introduction of HPV vaccines has caused controversy among clinicians and researchers. The protective effectiveness as well as the ideal age for administration, the number of necessary vaccinations, and the risk of side effects are still under debate.

A survey from the UK revealed a much lower awareness of HPV and a significantly lower acceptability of HPV vaccinations among immigrant women, compared to the majority population. Very low levels of awareness and acceptance were found in mothers of South Asian and African origin. Differences in cultural views toward a vaccination against a sexually transmitted disease might partly explain this pattern. It has been observed that parents with strong religious beliefs and cultural views were less likely to accept HPV vaccinations. Their concerns were most often based on social or religious reasons such as a belief that sex-related topics are taboo, monogamy, refraining from sex before marriage, a fear of promiscuity, and a fear of side effects.

Environmental Carcinogens and Important Lifestyle-Related Factors

In general, immigrants experience low risks of cancers that are associated with a Western lifestyle. This especially applies to breast, colorectal, and prostate cancer. Cultural views and behavioral patterns also impact on health-related habits such as physical activity, dietary, and smoking patterns.

Tobacco smoking prevalence differs substantially by ethnic group, gender, age, socioeconomic position, as well as geography. Several cancers, most importantly lung and bladder cancer, are strongly attributed to tobacco smoking. A high smoking prevalence in male and low-income immigrants has been observed in several studies. Tobacco use is widespread and significantly elevated in Asian Americans and migrants from Eastern European countries, compared to the indigenous population of their host country. In many ethnic minority groups, smoking is often an important part of social functions and events. Currently, there are few smoking cessation programs that specifically target immigrants. Some studies indicate a high probability for relapse among migrants that take part in smoking cessation programs.

High alcohol consumption is associated with many cancers. Many immigrants from Muslim countries, however, are likely to be total abstainers and thus at low risk for these cancers.

Dietary patterns (e.g., salt, meat, fat, and fruit/vegetable intake) and obesity are important risk factors for the development of cancers of the digestive system such as cancer of the stomach, esophagus, colon and rectum, gallbladder, and pancreas. Immigrants often show healthy dietary patterns, such as greater fruit and vegetable intake, and a strong familial persistence in different nutritional habits retained from their country of origin. In contrast, obesity has been noted to be high and increasing in many immigrant groups. This may be caused by a lack of traditional foods at affordable price and a gradual adaptation of Western dietary patterns. Dietary prevention programs require sensitive communication as well as motivation and should put emphasis on the nutritional value of cultural dishes and healthy nutrition. Often, immigrants exhibit lower degrees of physical activity compared to the native population of their host and their home country. Physical inactivity contributes to higher rates of obesity and may be involved in the development of colorectal, gallbladder, and kidney cancer.

Reproductive factors play an important role in the occurrence of breast, cervical, ovary, and testicular cancer. Immigrant women are more likely to have more children and to breastfeed and are less likely to use oral contraception or hormone replacement therapies after menopause, compared to the majority population. These protective factors are associated with a decreased risk of breast and other cancers of genital organs.

Most environmental and lifestyle-related factors and habits are hard to change, not only in ethnic minority groups. Cultural and religious beliefs affect behavioral patterns and determine lifestyle, diet, and sexuality. Some studies suggest a lack of adherence to medical advice regarding lifestyle and nutrition in immigrant groups. Prevention programs need to target high risk groups such as immigrant smokers, increase awareness of the link between lifestyle and cancer, and should operate on the community/family level.

Secondary Cancer Prevention

Immigrants are more likely to receive a late-stage cancer diagnosis in comparison with the majority population. This could be due to a low uptake of secondary cancer prevention measures, such as screening, aiming for early disease detection, and the limitation of disease effects after diagnosis. Secondary cancer prevention programs are particularly important in ethnic minority groups, because they often underutilize preventive care or fail to make return medical visits, and often lack cancer awareness. However, a higher participation in screenings has been observed in immigrants who spent a higher proportion of their lifetime in the host country and an increasing uptake the longer their duration of residence. This probably is a result of an acculturation process that is related to increasing trust and familiarity with health care structures in the host country.

Early detection during routine screenings for breast, cervical, colorectal, and prostate cancer represents a key factor for better survival in high risk groups. Cultural barriers to screening programs and suggested remedies are summarized in Table 1.

Breast Cancer Screening

Breast cancer is the most common malignancy among women worldwide. However, its frequency varies widely by country and population. Whereas the incidence in more developed regions of the world is 67.8 per 100,000 women, it is less than half in less developed regions (23.8 per 100,000). Breast cancer mortality is 18.1 and 10.3 per 100,000, respectively. There is evidence that reproductive factors partly determine the breast cancer risk. This comprises the age at first birth, the number of children, the age at menarche/menopause, and the use oral contraceptives and/or hormones during menopause. Other established risk factors for breast cancer are familial susceptibility and excessive alcohol use.

Breast cancer prevention focuses on screening. The most common methods of screening are mammography and breast self-examination. Since the introduction of breast cancer screening, the incidence of breast cancer increased whereas mortality decreased due to detection at earlier stages, implying a better chance for survival. Recent studies, however, have cast some doubt on the effectiveness of breast cancer screening.

Breast cancer screening is usually recommended to start between age 40 and 50. Some studies on breast

Cancer Prevention. Table 1 Cultural barriers to established cancer screening programs and suggested remedies

Type of screening	Barriers	Suggested remedies
Breast cancer	Perception of absence of symptoms, claiming health	Policies that alleviate women's anxiety
	Misconceptions, cancer fatalism, fear of possible diagnosis	Identification and elucidation of misperceptions, fear, and fatalism
	Patriarchal values, modesty	Encouragement of presence of family members during screening
	Strong religious beliefs	Employment of female practitioners who understand the role of cultural beliefs, especially the expression of modesty
	Fear of loss of privacy, embarrassment	Faith-based settings as venue for cancer education programs
	Distrust in system and clinician	
Cervical cancer	Fear of loss of privacy, embarrassment	Increasing awareness, clarification of misconceptions
	Aversion to invasiveness of Pap smear	Education of medical providers to recognize cross-cultural differences in health care to enhance their competence in engaging with minority women during medical encounters
	Modesty, strong cultural views	Involvement of family members in decisions and allow for their presence during screening
	Poor communication with providers	
	Prohibitions against examination by male health care providers	
	Competing life priorities (e.g., familial responsibilities)	
Colon cancer	Embarrassment of receiving digital rectal examinations/colonoscopy	Increasing awareness, cancer education
	Strong cultural beliefs	Offering alternative tests

cancer screening uptake in ethnic minority groups reveal large ethnic disparities and a rather passive attitude of migrant women toward screenings. Foreign born women are less likely to attend screenings and show lower referral and detection rates compared to native-born women. Furthermore, a clear association between age and health screening attendance (the higher the age, the lower the attendance) was found in immigrant women. Reasons for nonattendance with screening were particularly ascribed to patriarchal values (men as decision-makers), embarrassment, and modesty.

Cervical Cancer Screening

Cervical cancer is the second most common cancer in women from less developed regions (incidence 19.1 per 100,000) and fourth in females from developed regions (incidence 10.3 per 100,000). Mortality from cervical cancer is 11.2 per 100,000 in less developed regions and 4.0 per 100,000 in developed regions. The main known risk factor for cervical cancer is HPV infection. In many countries, the cervical Pap (Papanicolaou) smear test is used in women aged 30–60 in order to identify abnormal cells that can turn into cancer. The implementation of Pap smears is believed to have significantly reduced incidence and mortality of cervical cancer in many Western countries, but randomized controlled trials have not yet confirmed this assumption.

In many countries, screening uptake in immigrant women is far below target and significantly lower than in the majority population. Reasons for nonparticipation in cervical cancer screening are mostly related to language problems, dissatisfaction with practitioner, and the absence of symptoms. Religion also may play an important role. Among all US ethnic groups, Asian American women have the lowest participation rates, apparently determined by strong cultural views.

Colorectal Cancer Screening

Colorectal cancer is much more common in developed regions, being the second most common malignancy in females and the third in males. Incidence is 40.0/26.6 per 100,000 in more and 10.2/7.7 per 100,000 in less developed regions (females/males). Mortality is 17.7/12.3 and 6.2/4.7 per 100,000, respectively. Colorectal cancer is associated with dietary and environmental risk factors, such as a high intake of meat and unsaturated fat as well as physical inactivity. Screening is recommended starting around age 50 using fecal (stool) occult blood tests (FOBT) or endoscopic exams (colonoscopy or sigmoidoscopy). These measures require resources that are not available to everyone.

Colorectal cancer screening uptake varies significantly across ethnic groups and tends to be lower in immigrants than in the native population of their country of residence. For example, uptake was found to be very low among Asian Americans. However, screening patterns converged toward that of the majority population with increasing time of residence in the US.

Prostate Cancer Screening

Prostate cancer is far more common in more developed regions compared to less developed regions (incidence 56.2 vs. 9.4 per 100,000; mortality 13.5 vs. 5.2 per 100,000). Causes of prostate cancer are still poorly understood; however, a family history of prostate cancer seems to play a role. Certain ethnic groups such as African-Americans are disproportionally affected.

Prostate cancer screening is routinely done by digital rectal exams (DRE) and increasingly by prostate-specific antigen tests (PSA) which measures the level of PSA in the blood. However, there is no continuing evidence of decreases in mortality from prostate cancer due to screening.

In conclusion, immigrants are significantly less likely to attend cancer screening services than natives of their host country. This has various reasons, mainly differences in cultural views, disease perception, and health care utilization patterns. Identifying and addressing cultural barriers helps to reduce existing disparities in survival and to keep mortality low.

Tertiary Cancer Prevention

Screening alone does not ensure the improvement of cancer survival. What follows the initial diagnosis and how patients with a positive test result are treated is very important. Appropriate care, therapy, and diagnostic follow-up as well as rehabilitation are crucial for optimal health outcomes.

Some studies report a lower likelihood of receiving stage-appropriate treatment and a less frequent adherence to recommendations for follow-up care in immigrant populations. This may subsequently lead to poor clinical outcomes and lower survival.

The Challenge of Providing Culturally Sensitive Cancer Prevention

The goal of cancer prevention in immigrant populations should be to perpetuate – and if possible expand – advantageous lifestyle factors and to provide culturally adequate access to care. Culturally sensitive cancer prevention incorporates diversity of cultural beliefs, experiences, perceptions, norms, values, and behavioral patterns. Implementation demands a general awareness of cancer risk diversity and cultural aspects of cancer in every expert involved in cancer care, education, and research. Providing culturally sensitive cancer prevention is the key to diminish inequalities and increase access as well as awareness.

Before planning for new prevention measures, it is important to collaborate with ethnic minority groups in order to assess their understanding and opinions on existing cancer prevention programs. Best practice definitions and guidelines could be useful in order to ensure greater consistency of use and implementation of culturally sensitive cancer programs.

Cancer prevention needs to be encouraged by increasing awareness, by promoting the necessity for screenings, and by providing adequate cancer information and education. Educational materials should be developed together with members of ethnic minority groups in order to incorporate cultural beliefs in multilingual health messages that are accessible to those with limited literacy skills. High risk groups should be targeted and the stigmatizing nature of disease perceived by some ethnic groups needs to be addressed. Equal access to preventive medicine should be enhanced by providing comprehensive, well-coordinated, affordable, and culturally appropriate cancer care. Treatment plans should be developed together with the patient and other family members. Research on cancer disparities should be promoted and the inclusion of ethnic minority populations in clinical trials should be supported in order to learn more about the efficacy of treatment options for immigrants.

Cancer Screening

James Ted McDonald
Department of Economics, University of New Brunswick, Fredericton, NB, Canada

Cancer screening refers to a set of medical procedures intended to identify the presence of cancer before any symptoms appear, and can include physical exams, laboratory tests, and medical imaging. Regular screening offers the potential to reduce both cancer mortality and morbidity since treatment options and survival are related to stage at diagnosis for almost all forms of cancer. Estimates of the premature deaths that could have been avoided through cancer screening vary from 3% to 35%.

Screening guidelines for the detection of the most commonly occurring cancers are well established, and while national health agencies such as the US National Cancer Institute (NCI) periodically review these guidelines in order to ensure that the guidelines reflect the latest research, there is little debate about the overall importance of regular cancer screening. Most developed countries actively maintain screening registries for two types of cancer affecting women – breast and cervical cancer – in order to alert women to the importance of regular screening and to remind them to get screened.

Adherence to screening guidelines has been found to vary significantly by demographic factors such as race as well as by socioeconomic status, with screening less likely to occur among individuals in lower socioeconomic groups. Given the continued high levels and changing ethnic composition of immigrant inflows to the United States, Canada, the UK, and other countries that have significantly altered the demographic profile of these countries, the use of regular cancer screening by immigrants has become an issue of significant interest and importance to policymakers and health care professionals.

Theoretical Determinants of Cancer Screening

A variety of theoretical frameworks has been advanced to help explain possible differences in cancer screening among different subpopulations. One commonly used model is an adaptation of the Andersen framework of health service use that identifies three types of factors likely to be important determinants of an individual's demand for health services: predisposing factors such as age and sex; needs factors such as health status and awareness of cancer and screening, and enabling factors such as income and education, health insurance, and community resources. For immigrants, the use of cancer screening can also be reduced by barriers arising from difficulties with host country language and unfamiliarity with the host country health system. Immigrants' social and ethnic backgrounds can give rise to differences in attitudes about cancer and cancer screening. For example, traditions of modesty among some Asian and Hispanic populations might lead immigrants from those regions to avoid certain physical examinations. This discussion implies that patterns in cancer screening may vary significantly across immigrant subgroups even after accounting for differences in age, education level, income, and other factors. In addition, immigrants' participation in cancer screening could also increase over time following migration, as language barriers are overcome, experience with the health system is gained, and as attitudes and behaviors increasingly reflect host country norms.

Data on the Incidence of Cancer Screening

Most empirical evidence is based on two main types of data. The first type includes population-based self-reported surveys such as the National Health

Interview Survey in the USA and the Canadian Community Health Survey in Canada. The second type includes smaller scale interview-based surveys of particular ethnic groups. In some jurisdictions, researchers may also have access to administrative data on cancer screening that are drawn from cancer screening registries.

Screening for Cervical Cancer

Cervical cancer is one of the most preventable forms of cancer, and deaths from cervical cancer have declined by approximately 70% since the mid-twentieth century, due in large part to the introduction of the Papanicolaou (Pap) test. The Pap test is an easily implemented and widely accessible form of cancer screening, and systematic population-wide screening has been organized by government and nongovernment agencies at all levels. Current guidelines from both the US National Cancer Institute and Health Canada suggest that adult women aged 21–65 have a Pap smear test every 1–3 years, depending on prior history and risk factors.

Regardless of data type, the evidence points unequivocally to the fact that immigrant women have significantly lower participation in regular cervical cancer screening than nonimmigrant women. This result has been established for most ethnic groups of immigrants and in a number of immigrant-receiving countries. Importantly, while demographic and socioeconomic characteristics are well-established determinants of cervical cancer screening rates, lower rates of regular screening among immigrants are not explained by differences in these factors between immigrant and nonimmigrant women.

Analyses based on population survey data indicate rates of Pap smear testing that are lowest for immigrants recently arrived from developing countries, with rates of testing in the last 3 years in the order of 30–50% less than for comparable nonimmigrant women. In contrast, immigrants from other English-speaking developed countries have been found to have screening rates generally comparable to nonimmigrant levels. There is also evidence that rates of testing increase with additional years in the immigrant's new country, a result consistent with a process of acculturation to host country attitudes, as well as improved familiarity with and access to the health system. However, immigrants from Asian ethnic backgrounds do not necessarily reach nonimmigrant rates of cervical cancer screening even after many years in their host country.

More narrowly focused analyses of specific subpopulations of immigrant women suggest factors that help to explain differences in cervical cancer screening between immigrant and nonimmigrant women. For immigrant women from China, Korea, and other Asian countries, lack of knowledge of cervical cancer risk factors and of cervical cancer screening guidelines are important determinants of lower screening rates. The nature of the doctor–patient relationship is important for Asian, Hispanic, and Haitian women, including the physician's degree of cultural awareness, the presence of a female doctor, and the communication of guidelines by the doctor to the patient. More generally, characteristics of the health system are important among various immigrant subpopulations in the USA, with both a single source of primary care and having health insurance being associated with higher screening rates.

Screening for Breast Cancer

Breast cancer is a common disease and leading source of cancer mortality among women. It is estimated that one of every nine women will develop breast cancer during her lifetime, while one of every 25 will die prematurely from malignancy. It is well established that early detection is essential to the effective treatment of the disease. Detection modalities include clinical and self breast examinations and mammography, though it is mammography use that has been the main focus of research in the literature. Evidence indicates that regular mammography screening among older women could reduce breast cancer mortality by one third, and current screening guidelines published by Health Canada recommend biennial mammography for asymptomatic women aged 50–69 years. Although the benefits of mammography screening are less clear for women aged 40–49, some Canadian provinces (NS, Alberta, BC) include these women in their provincial recall and screening programs.

As with cervical cancer screening, rates of mammography screening are lower among immigrant women to the USA, Canada, and other developed countries than for nonimmigrant women, and the gaps are not accounted for by differences in demographic and socioeconomic factors. Low screening rates are of special concern for particular immigrant subgroups such as Filipina women, who experience higher mortality rates from breast cancer than from any other disease. In contrast to what is found for cervical cancer screening, evidence is mixed about whether gaps in regular mammography screening narrow with years in the host country, although some studies find such patterns for immigrant women in the USA and Australia.

Research on various immigrant subgroups identifies a number of characteristics associated with lower mammography screening rates that are more prevalent among immigrant than nonimmigrants. These include having no regular source of health care services, low education level, poor English language skills, a lack of knowledge about breast screening modalities, and a lack of health insurance. Other research has also established that certain cultural views such as traditions of modesty are associated with lower incidence of mammography screening.

There is less evidence available on other modalities of breast cancer screening including clinical breast exams and self-exams, although some research suggests that greater acculturation of immigrant women and more time in the host country are both associated with a higher incidence of breast self-exams and clinical breast exams. Interestingly, one study of Chinese women in San Francisco found that while knowledge of breast cancer and the importance of self-examinations was high (81% of women), adherence with recommended guidelines was markedly lower (54% of women).

Screening for Colorectal Cancer

In Canada, colorectal cancer is the third most common cancer, accounting for more than 12% of cases of cancer in both sexes, while in the USA, colorectal cancer is the fourth most common cancer. Given the occurrence of this form of cancer, research over the past decade has examined the merits and effectiveness of periodic screening in the asymptomatic population. A variety of means are available to screen for colorectal cancer, including fecal occult blood testing, sigmoidoscopy, and colonoscopy. For people at normal risk of colorectal cancer, annual or biennial testing using fecal occult blood testing (FOBT) and sigmoidoscopy are recommended for men and women aged 50–75 years. There is insufficient evidence to include colonoscopy as an initial screening test of people in this age group.

While the research on the incidence of colorectal cancer screening among immigrants is limited, US evidence suggests that most subgroups of immigrants by region of origin have lower incidence of screening than nonimmigrant individuals. Similar results are found for South Asian immigrants in the UK. As with other forms of cancer screening, demographic and socioeconomic factors have been established as important correlates of colorectal cancer screening but lower incidence of screening among immigrants is not explained by differences in these factors between immigrants and nonimmigrants. Furthermore, additional years in the host country appear to increase rates of cancer screening, which approach those of the nonimmigrant population. Having a regular health care provider is also positively associated with the incidence of colorectal cancer screening.

Screening for Prostate Cancer

Two types of screening for prostate cancer in men include digital rectal examination (DRE) and prostate specific antigen (PSA) measurements. Both types of screening have been shown to increase the early detection of clinically significant prostate cancer. However, available research is ambiguous about whether early detection and treatment leads to any change in the natural history and outcome of prostate cancer. Thus, different health agencies in the USA and Canada vary in terms of recommendations for their use among asymptomatic men over 50 years of age, and there is no general consensus on appropriate guidelines for regular screening. Some health agencies such as the United States Preventative Services Task Force recommend against screening for prostate cancer in men aged 75 years or older.

Researchers studying the incidence of screening for prostate cancer among immigrant men have noted significant variation in the regular use of both DRE and PSA screening across immigrant subgroups even after controlling for demographic characteristics and access barriers. Immigrant men in the USA who originated from Trinidad, Haiti, and Eastern Europe were all less likely than US-born White men to obtain regular screening for prostate cancer. Education and access to medical care were also important determinants of the incidence of prostate cancer screening.

Conclusions

A robust result of the extensive research on immigrant cancer screening is that rates of screening for the most commonly occurring types of cancer are significantly lower for most immigrant subgroups than for nonimmigrants, and these gaps are not explained by differences in demographic, socioeconomic, or geographic factors. Policies to encourage greater participation in cancer screening by immigrants may need to be tailored to the characteristics of specific immigrant subpopulations, particularly recent immigrants.

Cardiovascular Disease

SUJATHA SANKARAN
Division of Hospital Medicine, Department of Medicine, University of California San Francisco (UCSF), San Francisco, CA, USA

Globally, cardiovascular disease is the number one cause of death, and in 2005, cardiovascular disease caused 30% of all deaths worldwide. Cardiovascular disease is a category that encompasses a myriad of disorders of the heart and blood vessels, including coronary artery disease, cerebrovascular disease, peripheral vascular disease, infectious diseases of the heart, and congenital heart disease. Coronary artery disease is an impairment in the coronary blood vessels that are responsible for supplying blood to the heart, and disruption in this circulation can in turn lead to heart attacks. Similarly, cerebrovascular disease causes an impairment of blood flow to the brain, resulting in strokes, and peripheral vascular disease causes disruption of blood to body organs and extremities, resulting in organ dysfunction and pain.

There is a large body of evidence that supports the causal role of a number of risk factors in increasing the risk of cardiovascular disease related events, such as heart attacks and strokes. These cardiovascular disease risk factors are hypertension, diabetes, hyperlipidemia, tobacco use, and obesity. The global rise of cardiovascular disease can be largely attributed to the increase in prevalence of modifiable risk factors due to shifts in lifestyle such as immigration from smaller rural communities and villages to larger urban settings. With these shifts comes an increased risk of tobacco use, diets high in sodium, saturated fats and carbohydrates, and sedentary lifestyles, in turn leading to an increase in rates of hypertension, diabetes, hyperlipidemia, tobacco use, and obesity. With this increased prevalence of risk factors comes an increase in heart attacks and strokes. Because of the large environmental component to cardiovascular disease, immigration plays a vital role in the global rise of cardiovascular disease.

Immigration also plays a central role in the rates of congenital, metabolic, and infectious diseases of the heart. Maternal health and perinatal care are important determinants of cardiovascular morbidity and mortality in newborns. Maternal health and perinatal care are largely dependent on the social and economic conditions of different societies, and cultural norms and values and immigration status play an important role in the amount and type of pre- and postnatal care mothers receive. This in turn impacts the prevention and management of congenital heart disorders.

Endocrine and metabolic disorders such as thyroid disease and vitamin deficiencies may also cause heart dysfunction. There are a number of infectious diseases that lead to heart dysfunction, including a parasitic disease such as Chagas disease and bacterial diseases of the heart valves such as endocarditis. The prevalence of infectious causes of heart disease differs widely based on geographical location, and immigration status plays a vital role in the development of these disorders.

The Global Rise of Cardiovascular Disease

Cardiovascular diseases are responsible for more deaths worldwide than any other cause. An estimated 17.1 million individuals died from cardiovascular illnesses in 2004. This accounted for 29% of all global deaths. By 2030, approximately 23.6 million people will die from cardiovascular diseases each year, maintaining cardiovascular disease as the number one cause of death in the world. It is estimated that the largest percentage increases in death will occur in the Eastern Mediterranean region, and the largest number increases in death will occur in Southeast Asia. Income levels play a large role in both the prevalence of cardiovascular disease and the mortality rate of cardiovascular illnesses. Eighty-two percent of cardiovascular disease deaths occur in low- and middle-income countries.

In the United States, 31% of the population has cardiovascular disease, and 34.3% of annual deaths are due to cardiovascular causes. In Canada, in the year 2000, 34% of male deaths and 36% of female deaths were due to cardiovascular diseases, and cardiovascular diseases cost the Canadian economy approximately $18.4 billion annually. In the United Kingdom in 2003, there were 233,000 deaths due to cardiovascular disease and 38% of all deaths were from cardiovascular diseases. Death rates from cardiovascular disease are generally decreasing in developed nations – in the United States, from 1996 to 2006, death rates from cardiovascular disease declined by 29.2%. Over 80% of global deaths from cardiovascular disease occur in low- and middle-income countries.

The number of years of productive life lost to cardiovascular disease will increase by 20% in 2030 as compared to 2000. The rate of increase in cardiovascular illness is much higher in developing nations as compared to more economically developed nations. In Portugal, this 30-year rate of increase is 30% – in South Africa it is 28% and in Brazil it is 64%. The 30-year increase in risk of cardiovascular-related mortality in China is 57% and in India, it is 95%. In India, currently 10–12% of the population has cardiovascular disease. It is estimated that India bears 60% of the world's coronary heart disease burden. The rate of heart attacks in South Asians in the United States is double that of the American average. There are more individuals with cardiovascular diseases in India and China than in all economically developed nations of the world combined.

In Europe, each year cardiovascular disease causes over 4.3 million deaths, which is 48% of the total number of deaths in Europe. Cardiovascular disease is the main cause of death in women in all European countries, and is the main cause of death in men in all countries except France, the Netherlands, and Spain. Each year, cardiovascular disease costs the European Union approximately €192 billion.

There are likely multiple reasons why cardiovascular disease prevalence and death rates are higher in low- and middle-income countries as compared to higher income countries. Individuals in low- and middle-income nations have more exposure to cardiovascular disease risk factors and have less access to preventive methods as compared to higher income populations.

Preventive measures to detect risk factors and provide early interventions that in turn prevent morbidity and mortality related to cardiovascular disease are much scarcer in economically disadvantaged regions.

In general, people in lower income nations die younger from cardiovascular diseases when compared to people in higher income nations. These deaths of individuals in their most productive years in turn lead to increased poverty. Cardiovascular diseases are predicted to reduce GDP between 1% and 5% in low- and middle-income countries experiencing rapid economic growth. For instance, China is predicted to lose $558 billion due to loss of income in people with cardiovascular diseases.

The sex distribution of cardiovascular disease is roughly equal at this time, but in many countries, women experience a disproportionately higher risk of dying from cardiovascular disease compared to men. The rates of cardiovascular disease death are increasing at higher rates in women as compared to men in many economically emerging countries, such as China and Brazil.

Cardiovascular Disease in Immigrant Populations

Numerous studies have been conducted to determine whether there is a relationship between immigration status and incidence of cardiovascular disease. These studies have consistently shown that first-generation immigrants have cardiovascular disease rates that reflect their countries of origin. After two to three generations, however, several studies have shown that cardiovascular disease rates in immigrant populations tend to match those of the adopted country.

One study in 2008 in Sweden showed that Iranian immigrants had higher rates of cardiovascular disease than their native Iranian counterparts. Similarly, a study in 2006 showed that Chinese immigrants in New York City have a higher rate of cardiovascular disease than native Chinese from the same community. These results are consistent even after adjustments were made for income level and age. Similar studies in Indian, Pakistani, and West African populations have showed that both emigration from rural areas to more developed urban settings as well as emigration from developing to developed nations result in increased rates of cardiovascular disease rates. This likely is the result of increased rates of risk factors such as obesity, tobacco use, Westernized diets, and sedentary lifestyles in urban populations.

In the United States, individuals of South Asian descent have a fourfold higher rate of coronary artery disease as compared to the general American population. This is independent of the individual's immigration status – first-, second-, and third-generation South Asian immigrants all have a consistently increased rate of cardiovascular disease prevalence and mortality. In South Asians, more than 30% of deaths from heart attacks occur in those younger than 65, a rate double that of the United States national average. This increased risk of cardiovascular disease has also been noted in South Asian immigrants in the United Kingdom. According to the British Heart Foundation, the death rate from coronary artery disease is 46% higher in South Asian men and 51% higher in South Asian women than in the UK population as a whole – this, again, is the case among both first- and second-generation South Asian immigrants. However, data from California have shown that South Asian women are the only ethnic group in California that has experienced an increase in mortality due to cardiovascular disease.

Immigrants from Latin America to the United States have increased rates of cardiovascular disease when compared to native Latin populations. This could be at least partially due to health policies in Latin American countries. For example, Brazil has been cited as a model for effective cardiovascular disease prevention in Latin America. Brazil has been a world leader in promoting programs that reduce obesity, including national food and nutrition policies to promote healthy eating habits and lifestyles that lead to cardiovascular health.

In the United States, there is a marked difference in cardiovascular disease rates across different ethnic groups and immigrant communities. Among Caucasians, 12.1% have heart disease, 6.5% have coronary heart disease, 23% have hypertension, and 2.7% have had a stroke. African American populations have lower rates of heart disease and coronary heart disease than their Caucasian counterparts but higher rates of hypertension and stroke. Ten percent of African Americans have heart disease, 5.6% have coronary heart disease, 31.8% have hypertension, and 3.6% have had a stroke in the past. In contrast, Latinos in the United States have lower rates of cardiovascular disease, and 8.1% of Latinos have heart disease, 5.7% have coronary heart disease, 21% have hypertension, and 2.6% have had a stroke. Native Americans and Alaska Natives have higher rates of cardiovascular disease, and 12.1% have heart disease, 6.6% have coronary heart disease, 25.3% have hypertension, and 3.9% have had a stroke in the past. South Asians in the United States have the largest rates of cardiovascular disease of any subgroup, with rates of developing coronary heart disease ranging from 18% to 25%.

Cardiovascular Risk Factors in Immigrant Populations

Hypertension

Globally, high blood pressure, or "hypertension," causes approximately 7.1 million deaths each year. Hypertension, if left untreated, is a risk factor for strokes and heart attacks. It is estimated that about 62% of strokes and 49% of heart attacks are caused by hypertension. It has been predicted that the prevalence of hypertension will increase to 1.56 billion people by the year 2025. Currently, about 15–37% of the global adult population has hypertension, and in the United States about 140 million people suffer from hypertension. Throughout the world, it is believed that a significant percentage of hypertension is undiagnosed. Of the diagnosed cases of hypertension, it is thought that more than half of all hypertensive patients do not receive adequate treatment.

In India and China, there has been a rapid rise in the prevalence of hypertension over the past 20 years, and a concomitant increase in rates of stroke. These increases correlate with a shift from rural to urban lifestyles and mirror the increases in rates of hypertension in Chinese and Indian immigrants in the United States and the United Kingdom. In contrast, studies have shown that rates of hypertension are higher in native Mexicans than in first-generation Mexican immigrants to the United States. Despite the lack of consistent health care coverage in Mexican immigrants, rates of diagnosis and treatment of hypertension appear to be better in Mexicans living in the United States as compared to native Mexicans.

In Africa, the prevalence of hypertension is estimated at approximately 20 million people. The hypertension-related stroke rate is higher in Africa than in other regions of the world, and victims of hypertension-related stroke in Africa are relatively young. There is a lower rate of hypertension in Africans and first-generation African immigrants to the United States when compared to African Americans who have lived in the United States for several generations. This difference exists even when there are corrections for body mass index and age.

There is a well-established relationship between increased salt intake and hypertension. Numerous studies have also shown that tobacco use, alcohol use, and sedentary lifestyle can lead to increases in blood pressure. It is likely that development of hypertension is multifactorial and that inherent ethnic differences, varied patterns of exercise, diverse dietary habits, and differences in alcohol and tobacco use all contribute to increased rates of hypertension. Because immigrants often bring with them dietary and social habits from their native cultures, there is a complex interplay between genetic and lifestyle factors that determine rates of hypertension in immigrant populations.

Hyperlipidemia

High blood cholesterol or "hyperlipidemia" is another important risk factor for cardiovascular disease. Three components of cholesterol are measured to determine overall cardiovascular risk – LDL or low-density lipoprotein, increased levels of which lead to an increase in heart disease; HDL, or high-density lipoprotein, a component that can actually protect individuals from cardiovascular disease if high enough; and triglycerides, a component that is also linked to cardiovascular disease. Hyperlipidemia is estimated to cause about 4.4 million deaths every year, and is directly responsible for 18% of strokes and 56% of coronary heart disease globally. Diverse studies of immigrants have shown that there is a strong environmental component to hyperlipidemia, and rates of hyperlipidemia rapidly change as patients emigrate to another country and dietary patterns change. A study in Israel published in 1960 showed that immigrants from areas where typical diets are high in fruits and vegetables and low in animal fat have much lower rates of hyperlipidemia. This study also showed how, as immigrants' diets change to match local patterns and include increases in consumption of foods high in saturated fat, cholesterol levels also increase. Another study in 1985 showed that Japanese immigrants to Brazil had lower levels of HDL, the component of cholesterol that is protective against cardiovascular disease, when compared to native Japanese. Another study in Costa Rica in 2002 showed that as Chinese immigrants increased their consumption of animal protein, rates of hyperlipidemia increased. As with hypertension, there appears to be both inherent ethnic differences in rates of hyperlipidemia and a strong contributing lifestyle component.

Obesity

Obesity, defined as an unhealthy weight that adversely affects an individual's health and well-being, has a strong and well-established relationship with cardiovascular disease. There is a direct correlation between increases in body mass index, a common measure of weight, and cardiovascular illnesses. As BMI levels and abdominal circumferences increase, the prevalence of hypertension, high blood glucose levels, hyperlipidemia, and low HDL cholesterol levels increase. The rates of overweight and obesity are rising dramatically throughout the world. This is thought to be due to increasingly sedentary lifestyles as well as dietary factors.

In immigrant communities in the United States, studies have shown a direct correlation between the number of years of residence in the United States and increases in rates of overweight and obesity. A study in 2004 showed that after adjusting for age, socioeconomic and lifestyle factors, living in the United States for 10 years or more is associated with significant increases in the levels of overweight and obesity. Immigrants in the United States were also noted to be less likely than US-born individuals to discuss diet and exercise with clinicians. The study showed that only 8% of immigrants who had lived in the United States for less than a year were obese, but that 19% of individuals who had lived in the United States for at least 15 years were obese.

Another study in September 2009 looked at immigrants in the United States, and noted that the sons of immigrants had higher rates of overweight and obesity than their American-born counterparts. It was found that 34% of kindergarten-age immigrant boys were obese or overweight compared with 25% of the sons of native-born Americans. By age 13, 49% of sons of immigrants are overweight or obese as opposed to 33% of natives. This difference was independent of socioeconomic status and was more pronounced in children whose parents did not speak English. It is thought that a combination of easily available and inexpensive high-calorie, low-nutrient foods and beverages and the fact that often new immigrants are not aware of the risks of unhealthy lifestyle choices likely contributed to this effect.

One of the most important causes of overweight and obesity in immigrants is lack of education about the adverse effects of obesity and the contribution of diet and exercise to moderating weight. Another small study in 2009 showed a direct correlation between education and rates of obesity in immigrants – immigrants with advanced degrees were less likely to become obese, while immigrants without advanced degrees were more likely to become obese after 5 years in the United States. The other factors influencing rates of obesity in immigrants are perceived health status and body image. In many resource-poor cultures, overweight and obesity are associated with economic success, and physical activity is associated with blue-collar jobs and poverty. Other cultures associate overweight and obesity with good health and in some cultures individuals who are overweight or obese are considered more "marriageable." One study of Latina immigrant women in 2006 showed that the majority of women in the study associated overweight and obesity with attractiveness and were reluctant to lose weight because of perceived unattractiveness to men.

Diabetes Mellitus

Currently, it is estimated that there are approximately 150 million people worldwide with type II diabetes, and this figure is expected to double by 2025. About 58% of global diabetes mellitus is attributable to overweight or obesity. Rates of death from diabetes mellitus are also increasing.

In general, immigrants from the developing world to more economically developed regions have higher rates of diabetes than native populations. One study in 2006 in Sweden showed that immigrants from non-European countries had higher rates of diabetes than native Swedish populations or immigrants from European countries. Another Dutch study showed that immigrants from Suriname, India, Turkey, and

Morocco to the Netherlands had higher rates of diabetes than their native counterparts. This tendency is independent of rates of overweight and obesity. A study of Ethiopian immigrants in Israel in 2005 showed a growing prevalence of type II diabetes. In Canada, individuals of aboriginal, Latino, Asian, South Asian, or African descent have been noted to be more vulnerable to diabetes.

It is very well documented that South Asian immigrants have a much higher rate of diabetes mellitus than the general nonimmigrant population in developed nations. In the United Kingdom, studies have shown that the Bangladeshi and Pakistani communities have a disproportionately high level of diabetes when compared to Caucasians. In the United States, South Asian immigrants are seven times more likely to have type II diabetes than the general population, and in New York City, Indian immigrants are at a greater risk of hospitalization from diabetes than other immigrant groups. Studies in New York City have also shown that South Asian immigrants have a rate of diabetes that is almost three times higher than the rate for other Asian American immigrants in New York City. Another study in 2009 showed that 28% of Bangladeshis living in New York City have diabetes. South Asian immigrant women in New York City have the highest prevalence and highest increase in prevalence of gestational diabetes mellitus.

There is also evidence that immigrants with diabetes have poorer glycemic control than their native counterparts. A study in 2008 in Ireland showed that non-White immigrants to Ireland had poorer glucose control than native Irish individuals with diabetes mellitus. Factors that are thought to play a role in higher rates of hyperglycemia in immigrant diabetic patients include lack of education about the consequences of untreated diabetes and the importance of medication compliance, and lack of information about appropriate food and diet choices. Studies have shown that a strong family support system and targeted culture-specific education can have a significant impact on rates of cardiovascular disease.

Finally, immigrants who arrive in the United States at younger ages are more likely to become overweight with increasing time in the United States as compared to immigrants who come to the United States at older ages.

Tobacco Use and Immigrants

Currently, there are about 1.3 billion smokers in the world, and this number is projected to rise to 1.7 billion by 2025. Smokers in general have death rates two to three times higher than nonsmokers. A joint study by the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) showed that smoking causes a 100% increase in the risk of stroke and coronary heart disease, a 300% increase in the risk of death from undiagnosed coronary heart disease, greater than a 300% increase in the risk of peripheral arterial disease, and a 400% increase in the risk of aortic aneurysm.

In the United States, the rates of tobacco use in 2000 were 13.7% among Asian and Pacific Islanders, 19.1% among Latinos, 25% among non-Hispanic Whites, 24.7% among African Americans, and 40% among Native Americans and Alaskan natives. Various studies have looked at tobacco use rates among different immigrant populations in the United States. One study of Chinese Americans in Texas showed that while smoking rates were significantly lower in Chinese Americans as compared to the general Texas population, the smoking rate among recent immigrant men was higher. Twenty-eight percent of immigrant Chinese men smoked, as compared to 20.6% of the local population. In contrast, US born Chinese American smoking rates are comparable to those of the local American population. In Latino populations, studies have shown that adolescents are particularly vulnerable to tobacco use, and that there is a strong connection between poverty, unemployment, high school dropout rates and tobacco use. One study in California in 1993 showed that disadvantaged Latino youths were three times more likely to use tobacco than non-Latino youths. South Asian individuals in the United States have lower rates of smoking than other Asian groups.

The tobacco epidemic is affecting an increasing number of children and adolescents. Tobacco use in children and adolescents is highest in the Americas and Europe, where it is approximately 20%. Cigarette smoking is higher among young people in the Americas and Europe, while use of other tobacco products is higher in South East Asia and the Eastern Mediterranean. Everywhere, tobacco use is significantly higher in boys than in girls.

Infectious Diseases of the Heart in Immigrant Populations

Infectious diseases that affect the heart are an important cause of morbidity and mortality in immigrants. In particular, two infectious conditions – Chagas disease and rheumatic fever – are commonly responsible for cardiovascular disease in immigrant populations. Chagas disease is transmitted by the protozoan parasite *Trypanasoma cruzi.* Infected insects take blood meals from humans and their domestic animals and deposit parasite-laden feces. The parasites are then transmitted to humans through breaks in the skin, mucosal surfaces, or conjunctiva. Transmission also occurs congenitally or through blood transfusion or organ transplantation. Once an individual is infected with *T. cruzi*, there is no way to eradicate the infection. Longstanding *T. cruzi* infection can lead to the serious cardiac disease of Chagas disease. Ten to 30% of individuals with chronic Chagas disease develop clinical manifestations of the disease. The most serious cardiac complication is an inflammatory cardiomyopathy that results from the presence of parasites in the heart. This cardiomyopathy results in congestive heart failure, causing symptoms of severe shortness of breath, decreased exercise tolerance, and swelling in the lower extremities. Cardiac rhythm disturbances can also occur.

While the rates of cardiac disease due to Chagas disease are low in the native population of the United States, there has been a notable increase in the number of people with complications of Chagas disease in the last few decades due to immigration of people from endemic countries. It is estimated that now approximately 13 million people from endemic countries live in the United States and 80,000–120,000 of these people have chronic *T. cruzi* infection. Approximately two thirds of these individuals are from Mexico.

Acute rheumatic fever is another infectious cardiac disease that is common in immigrant populations. Streptococcal throat infections are sometimes followed by rheumatic fever, typically beginning about 2–3 weeks after the initial streptococcal infection. In about half of patients with acute rheumatic fever, inflammation of the heart called carditis can follow, and carditis leads to heart failure in some patients. Rheumatic fever can also damage heart valves. In the United States, rheumatic fever is most common in recent immigrants from developing countries in which there is poor access to antibiotics.

Conclusions

Immigration status plays a large role in the development of cardiovascular disease. Shifts from rural to urban lifestyles and changing patterns of diet and exercise are largely responsible for the development of cardiovascular risk factors that in turn lead to coronary heart disease. Perinatal, metabolic, and endocrine causes of heart disease also are affected profoundly affected by immigration status. Immigrants without appropriate access to regular medical care are more likely to experience the sequelae of various cardiovascular illnesses. Cardiovascular disease rates are determined by a complex set of cultural, biological, and social factors, and immigration status is intimately tied to these factors. In order to adequately identify and treat cardiovascular illness in diverse populations, it is vital that this cultural milieu is recognized and considered. This will become even more imperative as increased immigration and globalization lead to increasingly heterogeneous populations throughout the world.

Cardiovascular Risk Factors

Homer Venters
Division of General Internal Medicine, New York University School of Medicine, New York, NY, USA

Cardiovascular (CV) disease remains the single greatest cause of mortality in developed nations and is fast rising as a major cause of mortality elsewhere. While many developed nations have begun to address CV disease and the associated population risk factors, few resources are dedicated to identification and modification of CV disease risk factors elsewhere. Immigrants face multiple challenges addressing CV disease risk factors; many developing nations may fail to identify CV risks within immigrant populations and when these risks are identified, access to care, beliefs systems inconsistent with the Western medical model, and competing (non-health related) priorities may interact to make CV risk factor identification and modification difficult. Additionally, the CV risk profile that immigrants arrive with will change over time, often to include a more sedentary and stressful lifestyle and less healthy diet.

Two important questions regarding immigrants and CV risk are whether one's status as an immigrant confers inherent CV risk and whether ethnic or geographic variation changes the relative importance of various CV risk factors. These questions touch on the basic conundrum of medical providers, public health workers, and policy makers. How are immigrants different than other patients and how specialized do health care services need to be in order to address their unique health issues without recreating services that already exist elsewhere and for which specialization is not beneficial?

Immigration clearly imparts stressors that may contribute to CV risk. The psychological stress associated with migration has been linked to increased CV risk and for immigrants leaving their country of origin after traumatic events, either natural or man-made, this stress translates to heightened CV risk. In addition to the psychological stress associated with immigration, the transition to a new country almost certainly interrupts normal diet and activity level.

Some ethnic and regional groups of immigrants have been reported to possess inherently increased CV risk profiles. For example, multiple reports have identified increased rates of insulin resistance, diabetes, and other CV risks among Asian and Pacific Islander immigrants to the United States, Brazil, and other nations. Other groups of immigrants that have been identified as having particularly high CV risk profiles include

It is likely that the most significant cardiovascular risk factors among immigrants stem from variables that are unrelated to immigrant status. One of the single largest studies to examine cardiovascular disease predictors among multiple national and ethnic groups was the INTERHEART study. This case-control study was conducted in 52 countries and identified 9 easily measured risk factors that account for over 90% of the risk of acute myocardial infarction (AMI) among patients presenting with their first AMI at 262 participating centers. These risk factors (smoking, lipids, diabetes, hypertension, obesity, diet, physical activity, alcohol consumption, and psychosocial factors) were analyzed for approximately 12,000 cases and 9,000 controls. Conventional wisdom has held that these traditional risk factors might account for only 50% of AMI risk and that these risk factors might vary widely in their predictive power across geographic regions. Surprisingly, these nine risk factors proved remarkably consistent in their predictive powers of AMI in both men and women as well as across the 52 nations of Africa, Asia, Australia, Europe, the Middle East, and North and

South America where subjects participated. One geographic dichotomy that INTERNEART reported was the much earlier presentations of AMI among men (8–10 years versus women) and in the regions of Africa, the Middle East, and South Asia (10 years versus all other regions).

While most studies compare the CV risks of immigrant to a native-born cohort, a key consideration is whether the immigrants' CV risks are truly acquired or not. For example, smoking among immigrant populations appears to mirror rates from the country/region of origin. Immigrants moving from low to higher smoking prevalence nations (such as Africans living in Europe) appear to conserve their low prevalence status while immigrants making the opposite transition appear to similarly continue their high rates of smoking. Given projections that global smoking rates will continue to rise and soon account for 10% of all deaths, these observations may not hold and immigrants from less developed nations may arrive with additional CV risks.

Unlike smoking, rates of diet and physical activity appear to change relatively quickly with immigration. Multiple studies have examined the role of new dietary habits among immigrants as well as the changes in physical activity and mental health. Immigrants from Africa to Europe may have lower rates of smoking but higher rates of physical inactivity and higher BMI than their native-born cohort. These changes in risk profile likely result in physiological consequences such as increased atherosclerosis changes over time. Additional information may be gained from knowledge of migration within nations that replicates external migration. For example, an analysis of CV risk factors among Tanzanian men and women who migrated from rural to urban setting revealed increased weight and decreased physical activity but mixed changes in cholesterol and diet (more red meat but also more fresh fruit and vegetables). In some cases, such as that of emigration from the former Soviet Union to the United States, the dietary and activity changes may actually improve CV risk from baseline.

For policy makers, public health professionals, and medical providers, a central challenge is how to communicate CV health knowledge to immigrant patients and work to promote healthy living. Multiple studies have documented that immigrants acquire CV risk factors associated with the diet and level of activity, but to date, the evidence concerning targeted interventions is mixed. Since most of these interventions are small community-based programs, rigorously evaluating their effectiveness is often a challenge.

One challenge to these interventions is difficulty in targeting the intervention to a particular immigrant community. Some immigrant groups are well-acquainted with the Western medical model and long-term health risks and disease progression may be widely accepted concepts. Such groups may include immigrants moving between developed nations or those migrating from nations with established primary care systems. For many immigrants, however, the notion of CV risks and decade-long developments of CV disease is quite foreign. Many immigrants from developing nations are familiar with medical care, providers, and medication as interventions for urgent or emergent problems such as trauma, seizure, and complicated childbirth. For these immigrants, traditional beliefs and practices are often very intact when they arrive in a new home country. These traditional concepts of disease, and the traditional healers that offer services in the new country, must be integrated into any efforts to educate or otherwise engage immigrants about CV risk. Such an undertaking may be too great a challenge for primary care providers and concerted community and public health campaigns are often needed. Traditionally, public health interventions with immigrants in developed countries have focused on infectious disease, such as screening for tuberculosis, HIV, and parasitic infection. While these diseases remain important, similar efforts must be made to communicate abut CV risks and disease in immigrant communities.

Another challenge that may impair CV risk reduction strategies among immigrants is the presence of more pressing needs. In developed nations, newly arrived immigrants face a dizzying array of social services and regulations that they must navigate in order to secure basic food, shelter, and employment. For immigrants arriving or staying in a new country without proper immigration status, the need to avoid detection (and detention/deportation) by immigration officials may supersede almost all other needs. For immigrants who do seek to engage with medical care, it is most often on behalf of their children, who may require certain medical documentation for school registration, and for whom medical care may be more accessible. Communities that have successfully engaged with immigrants concerning CV risks have done so by providing care in a convenient manner (i.e., in a mosque or taxi garage or school) and without any threat of immigration or police presence.

CV risks among immigrants are essentially like those of nonimmigrants, an aggregation of dietary, lifestyle, and genetic components as reported in the INTERHEART and other studies. The unique concerns for promoting CV health among immigrants are how to identify changing CV risk profiles and engage immigrant communities on these risks and their modification. Several levels of intervention are required for meeting this goal. First, leaders in immigrant communities must be enlisted as advocates for promotion of CV health. Next, public health institutions must target their CV risk reduction campaigns toward the immigrant groups in their communities with programs that are rooted in familiar language and concepts. Simple, protective interventions such as smoking cessation, increased daily intake of fruits and vegetables, and moderate physical activity can be incorporated into most belief systems and concepts of health. Finally, primary medical care must be available to immigrants so that their physicians can perform adequate CV risk assessment and discuss CV risk modification.

Caregiving and Caregiver Burden

Brandy L. Johnson
Rynearson, Suess, Schnurbusch & Champion, L.L.C.,
St. Louis, MO, USA

Caregivers or, as they are known in some countries, careers, are people who are responsible for looking after, tending to, or aiding others who suffer from illness or disability. While there are numerous formal sources of care, such as nursing homes, assisted living communities, rehabilitation hospitals, and home health care, most caregiving occurs informally and at home. Likewise, although there are professional caregivers who get paid for their services, caregivers are more often unpaid family members or friends of the individual requiring care. Parents, spouses, siblings, and adult children are often informal caregivers. The care recipients can be of any age and are often ill, injured, physically disabled, mentally ill, mentally disabled, or elderly. Family members and friends commonly step into the role of caregiver out of love, respect, commitment, and/or a sense of duty or responsibility for the care recipient.

With advances in medical science, the populations of many countries have seen an increase in longevity for the elderly, ill, and disabled. This has created an increased need for caregiving. In 2004, it was estimated there were 44.4 million caregivers in the USA The UK reported six million caregivers in 2001. In the same year, there were 481,579 caregivers in Scotland. As caregiving is very personalized, the amount of care provided, as well as the type of care provided, varies with each care recipient. The care recipient may need full-time care, requiring the caregiver to be present for forty or more hours a week. Other care recipients may need as little as a few hours a week. Depending upon the care recipient's needs, the caregiver may have a full or part time job in addition to aiding the care recipient. In recent years, employers have begun to work with caregivers by offering more flexible hours, job sharing, the ability to work from remote locations, and leaves of absence.

Most caregivers are women. A study performed by the National Alliance of Care Giving and American Association for Retired Persons (AARP), released in 2004, showed 61% of caregivers in the study were women. Male caregivers are more likely to provide care to other men. Female caregivers also tend to provide a greater number of hours of care and a higher level of care.

Caregiving is extremely individualized. It can be relatively undemanding, highly demanding, or anywhere in-between these extremes. The care may be as minimal as grocery shopping, paying bills, driving to an appointment, and/or housekeeping. However, the care could be comprehensive and require assistance with cooking, feeding, dressing, bathing, wound care, transferring/lifting, and management of medical equipment like catheters, wheelchairs, respirators, or oxygen tanks.

As well as assisting in activities of daily living, caregivers often play other roles. Caregivers are usually advocates for the medical management of the care recipient. The provision of care requires that caregivers understand the care recipient's illness, disability, or medical condition and participate in the treatment or management of it. Caregivers often dispense medication and provide both reassurance and emotional support to the care recipient. They may also be in charge of, or assist with, the care recipient's finances and upkeep of the household.

Informal caregiving may be coupled with formal caregiving, depending on the needs and resources of the care recipient. For example, the recipient may attend adult day care or have a home health nurse who only performs specific tasks related to the care recipient's medical needs. The care recipient may have a housekeeper, driver, or the ability to utilize community transportation services to attend appointments. When this occurs, informal caregivers are required to coordinate the sources of care to ensure all the care recipient's needs are met.

An individual's need for care can occur quickly, such as when there is an accident, or may develop over time. A care recipient's need may also change as a disease progresses. Individuals who suffer from Alzheimer's or dementia may be able to function relatively well in the beginning, requiring little to no care, and progress slowly toward a need for around the clock care. Caregivers must adjust to meet the needs of the care recipient and, when necessary, consider whether more formal care is required. When the needs of the care recipient become greater than the abilities and/or resources of the caregiver or caregivers, a decision must be made regarding whether to turn to institutionalization of the care recipient.

Caregiving can be a rewarding experience. Although caregiving can be complicated and demanding of time and resources, many caregivers find a sense of purpose stems from the act. In fact, a 2007 nationwide survey by *Caring Today* magazine revealed, in the USA, nearly 80% of family caregivers found the experience to be emotionally rewarding. Caregivers also often find their bond with the care recipient strengthened through the caregiving experience. The caregiver may also develop increased self-esteem through the provision of care. These positive findings can be characterized as caregiver gain.

While some find caregiving to be a positive experience, others find the opposite. Caregiving, especially if the care recipient's needs are highly demanding, can be extremely stressful. The stress (physically, emotionally, and financially) experienced by those who provide care to the ill, disabled, and elderly can be characterized as caregiver burden. Caregiver burden is also known as caregiver syndrome, caregiver stress, caregiver distress, and caregiver strain.

Caregiver burden is the result of more than the need to provide care. The way the caregiver approaches the task can affect how he or she feels about the role. Many times the role as caregiver is unexpected, unfamiliar, and unwanted. If the caregiver feels he or she had no choice in assuming the role, it is more likely there will be anxiety and a negative attitude on the part of the caregiver. There may be feelings of resentment toward both the role as caregiver and the care recipient. Additionally, the nature of the relationship between the caregiver and care recipient before the need for care arises can affect how the caregiver feels about his or her role. When the caregiver and care recipient have a good relationship before the need for care arises, the caregiver may feel more positive about his or her role. Conversely, when the participants have a bad or shaky relationship before the need for care arises, the caregiver may experience a greater amount of anxiety, bitterness, or resentment.

The effect of caregiving on the caregiver's relationships with others can add to caregiver burden. The majority of caregivers have a spouse and children. Caregiving can cause strain on marriage and relationships with children, friends, and coworkers. When the care recipient is also a member of the caregiver's family, caregivers may find their relationships with other family members are also strained. The caregiver may feel other family members are not providing the additional aid they should. Disagreements may arise between family members, especially siblings, concerning the type of care being provided, the manner in which the care is provided, use of the recipient's resources, or whether the recipient should be institutionalized.

In addition to the strain on relationships, it is not uncommon for the caregiver's social activities to diminish. Social isolation leads to feelings of loneliness, guilt, and resentment. The caregiver may feel anger over losing time with others, the ability to engage in hobbies or favorite past times, and free time. Such isolation, and the resulting feelings, can lead to depression and/or anxiety. Studies have shown caregivers suffer from a higher incidence of depression than control groups. If the caregiver has few coping skills, the burden felt can be magnified.

Caregivers often neglect their own mental and physical health while caring for another. Caregivers are twice as likely to report a physical or mental health condition. Caregivers have been found to have a reduced immune function and slower healing of wounds. Viral illnesses tend to last longer in caregivers than non-caregivers. Studies have also found higher mortality and morbidity levels in caregivers who perceive greater stress in the provision of care. One study found elderly spouse caregivers who experienced caregiver burden had a 63% higher mortality risk than the control subjects.

The amount of caregiver burden that is experienced by caregivers can be affected by the culture from which they belong. In some cultures, the caregiver does not differentiate this role from their other daily activities. Instead, it is perceived as a part of life. The Chinese culture, for example, views caregiving as just another part of family life. Caring for family is considered part of filial piety, or respect and love for one's parents and ancestors. The Hispanic or Latino culture is very similar. The concept of *familia* dictates family members are morally responsible to help each other. Thus, members of this culture are raised to expect the need to aid family members when problems arise with their health, finances, or other life issues. The African-American culture has been found to have comparable values.

Caregiver burden can have an effect on both the caregiver and the care recipient. As the caregiver declines, the quality of care to the recipient may also decrease. The care recipient may be exposed to the caregiver's negative attitude and resentment. This can lead to guilt and resentment on the care recipient's behalf. Moreover, the possibility of abuse, verbally or physically, increases when the caregiver is under, or perceives, a larger amount of stress and anxiety.

When considering caregiver burden, consideration must be given to what is occurring financially, socially, physically, and psychologically for both the caregiver and the care recipient. Once all of this is considered, steps can be taken to reduce the burden on the caregiver. Respite can provide the caregiver with a break from the provision of care. The caregiver can use the time to relax, take care of his or her own needs, spend time with friends or family, and engage in hobbies or favorite past times. Aid from other family members, support groups, and the utilization of community support programs can also help reduce the caregiver's burden.

The stress experienced by caregivers can be reduced further by having legal documents that outline the care recipient's wishes. Discussion of the care recipient's wishes coupled with legal documents like advanced directives, wills, powers of attorney, and Do Not Resuscitate (DNR) orders helps alleviate the stress that accompanies a caregiver having to make financial, health care, and end-of-life decisions for the care recipient. It can also prevent conflict among family members who have different ideas concerning the care recipient's finances, treatment, and end-of-life decisions. Open and frank communication between the caregiver, the care recipient, and other members of the family about the conditions under which the recipient would be institutionalized can also serve to reduce the burden experienced by the caregiver.

Unlike in the past, individuals today have an increased longevity. Technology and medical advancements permit many people who once would have been institutionalized to live at home. These factors, along with the rising cost of health care, have increased the need for family and friends to provide care for the ill, elderly, and disabled. Along with the increased need for caregivers is an increase in the burden they may experience. While caregiving can be stressful and demanding, it can also be a rewarding and fulfilling experience. However, caregivers should know their limits, develop additional coping skills, and be aware of the resources available to them financially, emotionally, and in the community. Caregivers must also learn to balance their roles as a skilled caregiver, friend, spouse, parent, employee, and family member. Caregivers that are successful in doing this are more likely to view caregiving experience in a positive light and provide a higher quality of care.

Celiac Disease

Melanie Athey
Department of Psychiatry, Case Western Reserve
University School of Medicine, Cleveland, OH, USA

Celiac disease (also known as celiac sprue, nontropical sprue, and gluten sensitivity enteropathy) is an autoimmune disorder that damages the villi (small, fingerlike projections) in the small intestines and interferes with the absorption of nutrients from food. In individuals with celiac disease (CD), a negative reaction of the immune system is triggered by gluten, a protein primarily found in wheat, barley, and rye. When individuals with CD ingest gluten, their immune system responds by attacking and damaging the lining of the small intestine. This damage impairs the body's ability to absorb important vitamins, minerals, and other nutrients properly, leading to malnutrition and other conditions. Developing CD requires a genetic predisposition, exposure to gluten through digestion, and a trigger to start this abnormal reaction from the immune system. Common triggers include stress, trauma, or possibly infection. CD is permanent and damage to the small intestine will occur every time gluten is consumed, regardless if symptoms are present or not. Left untreated, individuals with CD may develop further complications such as diabetes, infertility, neurological disorders, osteoporosis, thyroid disease, and cancer. Strict adherence to a gluten-free lifestyle is the only known treatment for CD. CD was once believed to only affect populations of European descent. Due to this belief, the majority of research for CD was focused on individuals of European origin until the late 1970s. Today, researchers consider CD to be a worldwide health problem with evidence of it affecting all ethnic populations, without exception. CD is common in developing countries where the major diet staple is wheat, posing a challenging health problem for individuals requiring a gluten-free diet.

In addition to the misconception of CD only affecting Europeans, it was also thought of as a childhood disease presenting exclusively with GI (gastrointestinal) symptoms. It is now recognized that the disease is a multi-symptom, multisystem (organ) disease that can be triggered at any age. There are over 300 symptoms that may be associated with CD. The classic symptoms for CD include: chronic diarrhea/constipation, abdominal pain, bloating, and weight loss. More common but seemingly unrelated symptoms include joint pain, infertility, anemia, tingling/numbness, dermatitis, depression, irritability, and headaches. The symptoms of CD vary considerably from person to person, as does the severity of symptoms. To further frustrate patients and physicians, CD may present different symptoms at differing times within an individual's lifetime. For example, at age 20, GI symptoms may be present, while years later, at age 35, the same individual may experience joint pain, fatigue, or anemia, without GI issues. Others with CD may not experience any symptoms at all. With such a wide variety of symptoms associated with CD, coupled with many symptoms mimicking numerous other health issues, an accurate diagnosis can be time consuming, frustrating, and difficult. On average, it takes 10 years from the onset of symptoms for an individual with CD to be appropriately diagnosed.

Initial screening for CD is done through blood tests. The major tests that are available for CD screening include blood tests such as the IgA tissue transglutaminase antibody (also known as the TTG), the IgA anti-endomysial antibody, and the IgA antibody to deamidated gliadin. If these tests suggest CD, a small intestinal biopsy should be done, which is absolutely required to establish a definite diagnosis of CD. Individuals should not start a gluten-free diet prior to confirming the diagnosis of celiac disease by small intestinal biopsy. This is because the damage to the small intestine that is caused by gluten can heal when gluten is removed from the diet, therefore potentially causing a false-negative test result.

CD is the most common genetic autoimmune disorder in the United States today. It is also the most underdiagnosed autoimmune disorder and considered a hidden epidemic by many celiac specialists. CD affects approximately 1% of average, healthy Americans. This means that more than three million people in the United States are living with CD and 97% of them are undiagnosed.

Celiac disease predominately affects people of European descent (30% of Europeans currently carry the gene for celiac disease), but recent studies show increased prevalence of CD worldwide. It is a global health concern that affects both developed and underdeveloped countries. No continent nor ethnicity has been spared of this disease. Information, awareness, and support are all necessary factors for every individuals managing CD. In Finland, England, and Australia, celiac disease awareness is more advanced than in the United States and other countries. For example, health policy makers in Finland set out to achieve high detection rate by training health personnel, and advocating blood tests for people known to be at risk for developing celiac disease. However, individuals with CD living in the United States have more food options than ever. Once only available through mail order or in health food stores, gluten-free foods are now mainstream, providing celiac suffers with more food options than ever before. Many restaurants offer gluten-free menus, making dining out a possible option for individuals with CD, an option that was not long ago unheard of for individuals with such dietary constraints. Sales of gluten-free foods increased 74% from 2004 to 2009 in the United States and the gluten-free market is expected to reach $2.6 million in sales by 2012.

Many individuals experience several different emotions after being diagnosed with CD. Following a strict gluten-free diet for life can feel overwhelming. Individuals with CD must not only give up common foods such as bread, pasta, and pizza, but also have to be aware of items that may contain hidden gluten, such as lip balm, vitamins, and medicines. It is, however, a very a promising time for individuals with CD. New research results and information are becoming more accessible. Adhering to a gluten-free diet is challenging, although it is becoming easier as more and more gluten-free products come to market. The prognosis for CD is excellent in individuals that remain gluten-free. The small intestine will steadily heal and start absorbing the needed nutrients, and most individuals report an improvement with symptoms immediately after gluten has been removed from their diet.

Central America

Amy N. Sharpton
Department of Veterans Affairs, Louis Stokes DVA Medical Center Cleveland, Brecksville, OH, USA

Location

Central America is a region of the continent of South America. It is situated between the southern border of Mexico and the northwest border of Colombia. Most often Central America is understood to include the nations between Mexico and Colombia, including Belize, Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua, and Panama. There is some disagreement, however, as some geographers classify Central America as a large isthmus, in which case the boundaries include the portion of Mexico that lies east of the Isthmus of Tehuantepec, including: the Mexican states of Chiapas, Tabasco, Campeche, Yucatán, and Quintana Roo.

Geography

The region covers 524,000 km^2. Its population was estimated at 41,739,000 as of 2009, with a population density of 77 people/km^2. The land mass is recognized as the isthmus of southern North America, with boundaries that can be traced from southern Mexico's Isthmus of Tehuantepec, running southeastward to the Isthmus of Panama, where it connects to the northwestern portion of South America at the Colombian Pacific Lowlands. The furthest reaches of Central America can be seen to the north at the Trans-Mexican Volcanic Belt and the Gulf of Mexico, to the southwest at the Pacific Ocean, and to the northeast at the Caribbean Sea.

Central America is active geologically, with periodic volcanic eruptions and earthquakes. For example, in 1976, 23,000 persons were killed when Guatemala was devastated by an earthquake. Nicaragua's capital city, Managua, was the site of two catastrophic earthquakes in 1931 and 1972. Approximately 5,000 perished in the latter quake. Volcanic eruptions are common. As a consequence, fertile soils from weathered volcanic lavas have made it possible to sustain dense populations in the agriculturally productive highland areas.

Central America has many mountain ranges; the longest are the Sierra Madre de Chiapas, the Cordillera Isabelia, and the Cordillera de Talamanca. Fertile valleys lie between the mountain ranges and offer an attractive climate in which much of the population is concentrated. In fact, most of the population of Honduras, Costa Rica, and Guatemala live in valleys. Valleys are suitable also for the production of coffee, beans, and other crops. As part of the Mesoamerican Biodiversity hotspot, Central America holds greater than 7% of the world's biodiversity, featuring many species from the Nearctic and the Neotropic ecozones. The most biodiversity is found in the southern countries of Costa Rica and Panama, followed by the northern countries of Guatemala and Belize.

Recently, deforestation has been a concern for the region of Central America. The UN reports that despite efforts to arrest the decline, Central America had the highest rate of forest loss in Latin America for the decade 2000–2010. Over that same decade, the average annual rate of forest cover loss was 1.19% in Central America, compared to 0.13% globally, while Central America's forested area shrank from 54 million acres in 2000 to 48 million acres in 2010. The chief cause of deforestation in the region is conversion of forest land due to urbanization and agriculture; reportedly 90% of the wood removed in the region is used for fuel. It is reported, however, that a variety of practices are being developed to avoid deforestation, such as emission reduction projects, forest fire control efforts, and improved stoves.

History

Due to the Spanish conquest in the sixteenth century, most of Central America had a similar history – the exception was British Honduras. To the English, the land was called *British Honduras*; to the Spaniards and Guatemalans, the land was called *Belice*. In 1973, independence from Great Britain was earned, and the name "Belize" was adopted. From the sixteenth century through 1821, Central America formed the Captaincy General of Guatemala, or the Kingdom of Guatemala – formed by the states of Chiapas (now part of Mexico), Guatemala (including present day Belize), El Salvador, Honduras, Nicaragua, and Costa Rica. Officially, the Captaincy was part of the Viceroyalty of New Spain; however, it was administered not by the viceroy or his deputies, but by an independently appointed Captain General headquartered first in Antigua, Guatemala, and later in Guatemala City.

In 1821 a congress of Central American *criollos*, persons of Spanish heritage born in Latin America, declared their independence from Spain. Independence was short-lived; however, as on January 5, 1822, the leaders in Guatemala welcomed annexation by the First Mexican Empire of Agustín de Iturbide. When Mexico became a republic in 1823, it acknowledged Central America's right to determine its own destiny. On July 1, 1823, the congress of Central America declared absolute independence from Spain, Mexico, and any other foreign nation, and a republican system of government was established and the nation of Central America was formed.

The Constitution for the Federal Republic of Central America was signed in 1824; the nation was comprised of Guatemala, El Salvador, Honduras, Nicaragua, and Costa Rica, with an additional state – Los Altos – being added in the 1830s. Although Central American liberals hoped the new country would evolve into a modern, democratic nation, the Union dissolved in civil war, beginning when Honduras separated from the federation on November 5, 1838. The federation faced significant obstacles such as strong opposition by conservative factions allied with the Roman Catholic clergy, deficient transportation and communication routes between states, a broad lack of commitment toward the federation, and poverty and extreme political instability.

Although various attempts have been made to reunite Central America, none has succeeded for any length of time. While reunification lacks popularity with the leaders of the individual countries, the concept arises occasionally. Today, all five nations fly flags that have incorporated the old federal ornamentation of two outer blue bands bounding an inner white stripe.

Demographics and Ethnicity

The Central American population has grown rapidly over the last 60 years, with an estimated population in 2007 at over 40 million, up from 10 million in the early 1950s. On average, the population density is 77.3 inhabitants/km^2, though the population is distributed very unevenly across the region.

Spanish, the dominant language of the region, is the official language in six of the nations, while English is the official language of Belize and along much of the Caribbean Coast. Many of the native tribes speak only their native tongue, though some speak Spanish and others speak more than one native language. In some areas of Central America, many indigenous languages still exist; for example, there are 23 different Mayan dialects spoken in Guatemala. In other Central American countries, indigenous languages are now less prevalent.

Central America is comprised of a large percentage, nearly 70%, of persons who are of mixed ancestry. It is estimated that approximately 60% of those with mixed ancestry are of mixed European and American Indian descent; they are called *ladinos* in Guatemala and *mestizos* elsewhere; with an additional 5% descended from European and African ancestors, referred to as *mulattoes*; and 1% descending from a mix of native and Black ancestors. The original indigenous population, *Amerindian*, comprise 20% of the population. Those of strictly European ancestry make up approximately 12%, with the remainder claiming descendency from Chinese and East Indian indentured servants. The population is distributed unevenly across the region, with one-third in Guatemala, one-sixth in El Salvador, one-sixth in Honduras, one-eighth in Nicaragua, one-tenth in Costa Rica, and one-twelfth in Panama. A very small percentage, less than 1%, resides in Belize.

The native populations were converted to Catholicism during the Colonial Period. Catholicism has remained the majority religion of the region, ranging across Central America from 80% to 90%. The Catholic faith was blended into the religious practices of the native peoples, and their original beliefs and rituals have become a part of the Catholic faith of the region.

Culture

Central America has a rich cultural heritage that includes influences from the Maya, Olmec, Teotihuacán, Toltec, Aztec, and other Mexican civilizations. From approximately 2000 BC, the Maya occupied the Yucatán and adjacent parts of Central America. Their greatest achievements included their elaborate calendar, writing, palaces and temple pyramids with vaulted rooms made of limestone, polychrome pottery, stone stelae, and stylized wall paintings and bas-reliefs. Maya architectural styles are found in three regions: the Petén district (Uaxactún and Tikal); the cities of the river valleys, such as Piedras Negras and Palenque; and the cities of central and North Yucatán (Uxmal).

To the west, in the area of Veracruz and Tabasco, Mexico, the Olmec civilization developed in the Preclassic period. The finest Olmec art was produced between 800 and 400 BC. The Olmec are noted for the excellence of their stone carving; frequently, they used a motif combining human and jaguar features.

Much to the west of the Olmec and Maya civilizations, dating from the first century AD to 700 AD, the Teotihuacán civilization formed – with the peak of its artistic expression occurring approximately between 300 and 700 AD. The Teotihuacán produced extraordinary architectural achievements including monumental pyramids, temples, and processional roads. The site of Teotihuacán was destroyed by invaders around 700 AD.

The two centuries following the fall of Teotihuacán are characterized by the absence of a single dominant force, with a multitude of warring factions vying for power. Eventually one group, the Toltec, made their capital northwest of Teotihuacán at Tula and reigned approximately from 900 to 1,200. The Toltec dominated much of Mexico until they were defeated in the mid-1100s. During their reign they invaded Maya country, in particular Chichén Itzá. The Toltec's cultural influences are revealed in the pyramids at Tula and Chichén Itzá, with their deep colonnades, their decorative bas-relief, and their many sculptured structural elements.

Following a period of anarchy after the destruction of the Toltec's, the Aztecs rose to power. By 1344, at the site of present-day Mexico City, they had founded Tenochtitlan, their grand capital, which became one of the architectural wonders of ancient America. Aztec art developed a unique character, drawing on the traditions of conquered areas, but under the influence of the harsh Aztec religion as well. The importance of human sacrifice in the cult of the war god, Huitzilopochtli, permeated life and art, and representations of skulls, hearts, hands, and sacrificial scenes were common.

The Aztecs sculpted magnificent works made of stone; pieces were large and elaborate. One such example is the statue of the earth goddess Coatlicue, which features intertwined serpents and a necklace of human hearts and hands. Less ominous subjects, such as the plumed serpent, Quetzalcoatl, and various animals, were carved in a smooth, compact style. Feather work, jade carving, gold work, extraordinary ceremonial vases, and superb textiles were produced by the artisans of subjugated groups. Aztec power over Central Mexico extended until the arrival of Cortés in 1519.

Modern Central America is undergoing considerable change – culturally, politically, and economically. With efforts toward cooperation, if not unification, communication between states has increased over recent decades. Four countries, Guatemala, El Salvador, Honduras, and Nicaragua, are undergoing a process of integration and have formed The Central America Four or *CA-4*, which has introduced common internal borders. The policy of common internal borders enables the citizens of the four signatory states to freely move across borders, without restrictions or checks. Foreign nationals who enter one of the signatory countries can travel to other signatory states also without having to obtain additional permits or to undergo checks at border checkpoints. The CA-4 Agreement is similar to the Schengen Agreement in Europe in that it establishes a harmonized visa regime for foreign nationals traveling to the area. Belize, Costa Rica, Panama, and Dominican Republic join the *CA-4* only in matters of economic integration and regional friendship.

Economy

There is significant economic diversity within the Central American countries. Nicaragua is the least developed as reflected in rates of infant mortality, adult literacy, and GDP, common indicators of development. Panama and Costa Rica are more developed. Although Panama has the highest GDP per capita, Costa Rica is considered to be the most developed of the Central American countries due to its relatively high GDP per capita and has the best indicators of the Central American countries for life expectancy at birth, infant mortality rate, and adult literacy rate.

Historically, Central American trade has been highly dependent on two exports – coffee and bananas. In fact, during much of the twentieth century, coffee was the single largest Central American export. The export of bananas has been critical to the economies of Honduras, Panama, and Costa Rica. The United States and Central America have strong trade agreements. The United States was the main importer of Central American products during the twentieth century. In recent decades, Central America has had success in diversifying its exports and is now less dependent on bananas and coffee. Furthermore, the region has sought to diversify its trading partners as well.

At times the countries that comprise Central America have sought to promote mutual economic development. In 1960, with the chief goal of economic growth, Guatemala, Honduras, El Salvador, and Nicaragua created the Central American Common Market (CACM). However, CACM suffered from political disagreements, culminating in 1969 in a war between El Salvador and Honduras. The conflict resulted in slowed economic cooperation in all of Central America. In recent years, efforts have been made to increase economic integration among the Central American nations.

Health

As with many developing regions of the world, there are significant disparities in health equity across Central America. Public health campaigns were widely implemented first by the Pan American Sanitary Bureau and the ministers of health of Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua, and Panama. They were instrumental in the creation of the Institute of Nutrition in 1946, which was inaugurated formally in September 1949. The Institute orchestrated pioneering clinical and epidemiological studies and interventions. A primary goal was identifying and correcting dietary deficiencies in the region, and the Institute developed some of the first studies on the chemical composition of foods used by the population. Today, the Institute is known as the Instituto de

Nutritión de Centro América y Panamá (INCAP) and serves as a Pan American Health Organization (PAHO)/World Health Organization (WHO) Regional Center.

Migration

Central America has experienced high rates of migration for generations, including rural-to-urban and regional migration as well as emigration abroad, predominantly to the United States. Before the 1980s, a decade wrought with armed conflicts in the region, Central America drew little global or hemispheric attention in terms of migration. In this period, however, the region became a geographic bridge to North America as migrants from South America sought to enter the United States. Furthermore, Mexico has become the main transit country for Central Americans headed north.

Emigration abroad has produced a range of profound changes within Central America, including economic dependency on remittances, an exponential increase in the volume of international phone calls, and – from fashion to governance – the importation of outside tastes. While Central America is a junction of numerous migratory flows, migration does not affect the region uniformly. The more conflictive zones and countries in the region, such as the civil strife in El Salvador, Nicaragua, and Guatemala for example, have experienced significantly higher rates of emigration than rates in the more stable countries of Panama and Costa Rica.

Colonized by the Spaniards in the 1500s, Central America was chiefly a subsistence agricultural zone; that is, any agricultural economy in which the crops and/or animals are used nearly exclusively for local or family consumption. As such, the *Kingdom of Guatemala* provided far fewer riches than other Spanish colonies. Though independent as of 1821, the region's livelihood did not change substantially until the late nineteenth century when coffee and other export crops were introduced. The reforms at that time privatized communal lands and displaced thousands of peasants. Equally important, however, is that the policies catalyzed a pattern that endures today – oligarchic control of the land and the armed forces, while much of the population fights to overcome perpetual poverty. This combination of agricultural labor needs with people displaced from the land produced seasonal, rural-to-rural migration – a pattern that endured into the second half of the twentieth century.

In the 1960s, several Central American countries attempted industrialization. However, the divided class structure persisted and became the impulsion for revolutionary and civil warfare in the region during the 1970s through the early 1990s. Warfare not only killed thousands and displaced millions, but also institutionalized a migration pattern to the north – a pattern that until this time had been very minor. Massive refugee flows moved through the isthmus into the United States and, to a lesser extent, Mexico, Costa Rica, Canada, and Belize. Until then, Central American emigration had consisted of small numbers of professionals, skilled laborers, and domestics. Internal labor migrations became increasingly dangerous as a result of the region's conflicts. Thus, regional economies suffered, inciting combatants and noncombatants alike to flee. Figures derived largely from the 1990 US census suggest that more than a million Central Americans fled their homelands and sought asylum in the United States during the turbulent decade of the 1980s.

Regional Migration

In 1970, approximately half of all Central American emigrants relocated to other Central American countries, while half moved out of the region. By 1980, however, the proportions had altered dramatically, with 80% leaving the region. In fact, by 1990, 93% of all Central American migrants left the region. Information on extraregional migration flows is much more readily available, although there is some notable research on Nicaraguan migrants emigrating to Costa Rica and, to a lesser degree, migrations of Guatemalans and Salvadorans to Belize. Intraregional migration is an area that calls for further study. For example, there is growing evidence of migrations of Nicaraguans and Hondurans into El Salvador spurred by the late 1990s postwar economic recovery in that country – a rebound financed in large part by remittance dollars from Salvadorans living in the United States. Additionally, the Panamanian economy attracts a modest number of Central American migrants; the number of Central American foreign born rose 11% between 1990 and 2000.

Cervical Cancer

Steven P. Wallace[1], Gloria Giraldo[2]
[1]Center for Health Policy Research, School of Public Health, University of California Los Angeles (UCLA), Los Angeles, CA, USA
[2]School of Public Health, University of California Los Angeles (UCLA), Los Angeles, CA, USA

Cervical cancer is the seventh most common cancer worldwide and the third most common among women. In 2008, there were 529,000 new cases of cervical cancer and 275,000 deaths worldwide. Cervical cancer arises in the epithelium after persistent infection with one or more oncogenic types of human papilloma viruses (HPV). The resulting precancerous lesions can progress to invasive cervical cancer over a period of 10–20 years if not identified and removed in a timely manner. The main risk factors are therefore HPV infection and a lack of screening with early treatment. The established identified cofactors that increase the risk of cervical cancer are long-term use of hormonal contraceptives, high parity, tobacco smoking, and coinfection with HIV. Common factors that contribute to most of these risks are low education and poverty.

Epidemiology

It is estimated that among women worldwide with normal cytology about 10.4% are positive for cervical HPV DNA. HPV and cervical cancer are unequally distributed globally with a high concentration in the Global South. The prevalence of HPV is higher in less developed countries (15.5%) than in more developed countries (10.0%). Women in Africa have the highest HPV prevalence (22.1%), followed by women in Central America (20.4%). In contrast, women in South America and North America have a lower prevalence (12.3% and 11.3%, respectively).

While the geographic pattern of cervical cancer generally follows the HPV pattern, cervical cancer screening and treatment inequities modify the pattern somewhat. Approximately, 85% of the cervical cancer cases occur in low-income countries where cervical cancer accounts for 13% of all female cancers. In Africa, the age-standardized incidence rate (ASR) is 29.3 per 100,000 with an ASR of 42.7 in Eastern Africa. Central and South America have ASRs around 30 while the rate in Asia is 15.4 (26.6 in South Asia). In contrast, the cervical cancer ASRs in North America, Japan, Australia, Western Europe, and Northern Europe are all below 10.

The slow conversion of an HPV infection to cervical cancer provides a long window for action. Early detection methods and curative treatments were introduced in the 1950s in developed countries, leading to falling cervical cancer rates in most parts of the world. The high incidence and mortality rates in low-income countries are mainly due to the lack of or ineffective screening programs, in addition to elevated disease burdens, a lack of basic health care services for women, and to general barriers to access and utilization of health care.

Cervical Cancer in the Context of Migration

The low international migration rates of residents of the poorest nations result in most migrant women coming from countries with middle incomes and an intermediate risk profile for HPV and cervical cancer. When they settle in high-income countries, those migrant women are often the focus of special efforts to screen, diagnose, and treat HPV and cervical cancer because their rates are noticeably higher than the average of their new homelands.

Screening

Data from high-income countries with large immigrant populations consistently show that screening rates are lower for immigrants than for the native born, and that Asian immigrants have particularly low rates.

The majority of the 40 million immigrants in the USA come from Latin America (54.6%) and East and South Asia (17.6%). One study found that 18.6% of recent immigrant women (those who have lived less than 25% of their lives in the USA) and 9.9% of more established immigrants had *never* received a Pap test in their lifetimes, compared to 5.8% of US-born women. The highest rates of never being screened were for women born in India who had lived less than 25% of their lives in the USA (recent immigrants, 43.7% unscreened) and those who had lived more than 25% of their lives in the USA (established immigrants, 25.0% unscreened). The study similarly found high non-screening rates among immigrant women from Mexico, with 32% of recent immigrants and 16.6% of established immigrants reporting that they had *never* been screened for cervical cancer. There was a consistent trend among immigrant women of increasing "ever screened" rates as they lived a longer portion of their lives in the USA. When the rates were adjusted by socioeconomic factors, the adjusted prevalence of never receiving a Pap test was highest among women from Asia, Southeast Asia, and India (19.6%); followed by women from South America (12.7%), Mexico (11.2%), the Caribbean (11.0%), Europe (9.9%), and Central America (9.2%).

Immigrants constitute 20.8% of Canada's total population. While the largest number of foreign-born persons is from the United Kingdom (UK), the largest migrant groups since the 1990s have been from China, India, and other Asian nations. A study of immigrants in Canada found that White English-speaking foreign-born women have the best Pap smear screening rates (only 3.8% never screened and 16.1% screened more than three years previously or not at all). These percentages were similar to the rates for White native women. In contrast, other groups of immigrant women reported high rates of never having been screened: 34.3% of South Asians, 30.1% of Arab/West Asians, 25.5% of Southeast Asians, and 17.5% of Hispanics. The authors concluded that Pap testing for Hispanic immigrant women and White women from continental Europe eventually reaches, and in some cases surpasses, that of Canadian born White women. Immigrant women from Asia, however, never reach the cancer screening rates of native-born women even after living many years in Canada.

Immigrants in Australia constitute 26% of the total population and mostly come from the UK, New Zealand, China, and India. Several studies have shown that migrant women in Australia had significantly lower levels of screening compared with the native-born population, with only 39% of Thai women reporting regular Pap tests and Vietnamese women being at 10–12% points lower than the general population in cervical cancer screening rates. Similarly, the odds ratio of reporting ever having a Pap smear were significantly lower for migrants from Southern Europe, Southern Asia, the Middle East, and Southeast Asia compared to Australian-born women.

While culturally based notions of modesty, embarrassment, and fatalism have been extensively studied as possible contributors to lower screening rates, it is important to note that most of these studies have not controlled for cohort and history effects. The Pap smear was introduced in 1949 and gradually became part of the routine care for women in developed countries. On the other hand, in low-income countries cervical cancer prevention programs compete with many health priorities in the midst of major financial constraints and have been plagued by ineffectiveness or limited to coverage in urban areas. Therefore, some cohorts of immigrant women lack familiarity with Pap testing, resulting in a lack of knowledge about the test and its purpose. However, increased education, the utilization of community health workers and interpreters, accessible transportation and child care, and most importantly, access to healthcare, have been shown to increase rates of Pap screening among immigrant women.

Incidence

Immigrants in high-income countries tend to exhibit cervical cancer rates that are between that of the country of origin and the receiving country.

In the United States in 2007, the age-adjusted cervical cancer incidence was 7.9 for non-Latina White women, 10.7 for Latinas, and 7.0 for Asian American women. Just over half of Latina adults were immigrants and almost 80% of adult Asian American women were immigrants. The higher rate of cervical cancer for Latinas than Whites is the opposite of the pattern for most other cancer sites. In addition, Latinas living in heavily low-income Latino neighborhoods, which are also primarily immigrant communities, have higher odds that both cervical and breast cancer will be detected at a later stage compared to those living in neighborhoods with a lower proportion of Latinos. This suggests that barriers to screening, noted above, have a consequence on the severity of cervical cancer when it is identified.

Immigrants to the USA from other low and middle-income countries also have high incidence rates. For example, in Miami, Florida the cervical cancer rate is highest among recent Haitian immigrants with an estimated incidence of 38 per 100,000. According to the Pan American Health Organization (PAHO), Haiti has the highest cervical cancer rate in Latin America and the Caribbean at 93.8 per 100,000 women. Laotian women have the highest rates among Asian American women with a cervical cancer incidence rate of 24.8; reliable data from Laos is not available.

Cervical cancer rates in Canada among refugee women 45–64 years of age exceed rates among their Canadian counterparts. Refugee immigrants had an elevated incidence of cervical cancer with a standardized incidence ratio of 1.58 to native Canadians. Among non-refugee immigrant women of the same age, the rate was no higher than among native Canadian women. The majority of refugee immigrants originated from Southeast Asia and South and Central America, while non-refugees are from Northeast Asia, Middle East, North Africa, and Western Europe.

In Sweden, there is an increased risk of cervical cancer among women who immigrated to Sweden at age 50 or higher and who were born in Asia, South America, Poland, Bosnia, Eastern, and Southern Europe; there was a decreased risk among women born in Turkey. The observed risk for women over 50 corresponds to the incidence rate of country of birth of the immigrants. These results also suggest that these women are not fully benefiting from screening programs due to differences in socioeconomic position.

Survival and Mortality

A comprehensive study of cervical cancer survivors in California found that a lack of English proficiency and Latin American origin were associated with lower levels of physical, social, and sexual well-being. Among cervical cancer survivors, the disease and its treatment appear to place additional demands on monolingual Spanish-speaking survivors and their families, including difficulty in accessing appropriate follow-up medical and psychosocial care that results in a poorer overall health-related quality of life. These outcomes underscore the greater disease-related burden of cervical cancer among immigrants and low-income survivors.

Mortality rates in the USA for the period of 1985–1996 showed that there was a marked difference in cervical cancer mortality rates between immigrant and native-born women, primarily among Latina and Asian and Pacific Islander women (AA/PI). The ratio of mortality rates between foreign born and US born was 4.11 for Latina women and 1.40 for AA/PI women. More recent data show that Latina women continue to have increased cancer mortality rates compared with non-Latina women. From 1998 to 2003, Latinas had increased cervical cancer mortality rates compared to non-Latina White women. A more concerning finding was that among Asian–Pacific Islanders and Latinas over the age of 50, the rates of invasive localized cervical cancer declined and regional and distal invasive cervical cancers increased, signifying a late presentation at diagnosis. There is a lack of studies on cervical cancer mortality among immigrants from other countries.

Conclusion

Most published studies have been conducted in developed nations where there are large numbers of immigrant populations. They reveal that immigrant women tend to lag behind in screening and have higher cervical cancer incidence rates than native-born populations.

For most immigrant populations, high socioeconomic position, having health insurance (or access to healthcare), younger age, higher education, speaking the main language in the host country, having a usual source of health care, and spending more time in the host country are associated with increased cancer screening likelihood.

Studies in California, where 27% of the total population is foreign born, show that near parity in cervical cancer screening has been reached among most groups of women. According to the 2007 California Health Interview Survey, 91% of US-born women between the ages of 21–64 received a Pap test in the past 3 years, compared with 92.3% of women born in Mexico and 80.3% of women born in Asia and the Pacific Islands. These results are to a large extent attributed to the successful implementation of a government sponsored cancer control program in the state that provides free screening and treatment to low-income women regardless of their immigration status. This success provides additional support to the many studies that conclude that the sociodemographic variable most strongly associated with screening and screening maintenance is healthcare coverage and access to care.

Survival and mortality have been studied less often for immigrants, although some studies report higher mortality; there is less conclusive evidence about differentials in survival length and outcomes. When multivariate analyses were conducted that adjusted for socioeconomic differences and access to care, differences between immigrant and nonimmigrant populations in screening, incidence, and mortality usually disappeared, indicating that socioeconomic differences and differences in access to care are the most influential causes of variation in the cervical cancer care continuum for all women regardless of migration status.

New technologies developed for cervical cancer prevention and control pose great opportunities and challenges in order to expand access to the new vaccines and detection technologies to the women who are most at risk. Newly developed vaccines for the most prevalent strains of the HPV virus may make prevention easier, especially in countries with less developed health care systems. But cost of a complete series of vaccinations ($375) remains a barrier since it is more than the entire per person national health care expenditures of the poorest countries of the world and will compete with other priorities in middle-income countries.

Cervical cancer prevention requires age appropriate interventions in order to be effective; women who are already affected by HPV need to be monitored while young women may be targeted for vaccination. Data show that many populations are receptive to vaccination of young girls. According to the 2007 California Health Interview Survey, 60% of US-born parents expressed interest in having their daughters vaccinated against HPV or had already had them vaccinated. Asian-born parents had the same level of interest (59%) and Mexican-born parents in the state had among the highest level of interest (70%).

US immigration policy briefly (2008–2009) required that women aged 11–26 have the HPV vaccine to obtain permission to immigrate. The controversy over this requirement highlights the concerns over costs, coercion, and the portrayal of immigrants as vectors of disease in relationship to cervical cancer. Finally, although low-income immigrants tend to fare poorer in terms of cervical cancer screening, as well as higher incidence and higher mortality compared to their native-born counterparts in some countries, access to care, access to new vaccines, and novel testing methods have the potential to bring health equity to all women.

Chain Migration

Bin Yu
Rhode Island College, Providence, RI, USA

Chain migration is a social process that is more complex than a simple mechanical process of people migrating. Sociological factors such as social networks are the key during the chain migration process. It is common for some scholars to refer to *chain migration* in the context of *social network* which usually operates within a social network that includes family, friends, community, etc. However, the term *chain migration* usually refers to the migration chain that operates within family members only. Most research on chain migration has focused on the operating mechanism of chain migration and its demographic and socioeconomic impact on the destination countries on a macro level. Some research has examined chain migration at local levels.

During a typical chain migration process, the initial immigrants migrate to a destination country on their own, although they have no family ties there. These initial immigrants will migrate either driven by the *socioeconomic factors* (such as wages, employment potentials, etc., as validated by all of the economic and sociological immigration theories), or by *non-socioeconomic factors* (wars, natural disasters, refugee and asylum policies, etc., as validated by all of the non-socioeconomic theories). They are either *voluntary* or *involuntary* (or *forced)* migrants, depending on their situations. The key is that these initial immigrants make the move on their own; there is no family tie in the destination countries. Therefore, migration for them usually has a high price, both *economically* (in terms of financial cost) and *noneconomically* (in terms of the disruption of their family lives and the cultural shock associated with migration). Once they arrive at their destination countries, they will settle down and start bringing their family members over by sponsoring them. The potential *cost* of the future migration of their family members and relatives is substantially lower. With these initial immigrants anchoring at the destination countries, it is relatively easier for them to arrange for the migration of their family members and relatives. The growth and expansion of *migration chains* will reduce both the *costs* and the *risks* for future migrants, potentially making it virtually risk free and almost cost free, as they can diversify their household labor and earnings after their family members and relatives have joined them in their new countries.

At the same time, the migration chains are also regulated by the emigration policies of the countries of origin and the immigration policies of the countries of destination – that is the non-socioeconomic aspect of the immigration process. For example, some European countries do not have family-unification-specific immigration laws similar to those in the USA. The differences among the immigration laws contribute to the differences in immigration patterns between US and European countries.

Generalized Chain Migration Process

The generalized chain migration process consists of three phases: the initiation phase, the family unification phase, and the family reproduction phase.

The *initiation phase* of the chain migration process is the migration of the initial immigrants or *principal immigrants,* who are sponsored by nonfamily entities. The nonfamily entities include employers who sponsor immigrants as professional immigrants (or through investment as investment immigrants); the government that sponsors immigrants as refugees, asylum-seekers, or diversity immigrants; and US-born citizens who sponsor immigrants as foreign-born spouses. Theoretically, undocumented immigrants could also be considered initial immigrants because they might obtain legal immigration status and someday sponsor family members.

The *family unification phase* of the chain migration process is the *cumulative* migration of family members. During this phase, all prospective migrants immigrate under the sponsorship of previously migrated family members. Migration chains are usually established through the sponsorship of family members who were sponsored by other family members, and so on. It is important to understand that the original principal immigrants usually sponsor their immediate family members only, and they usually do not and cannot sponsor other relatives, such as nieces and nephews, of their family members. These relatives can, however, be sponsored by the other family members who were sponsored by the principal immigrants. These relatives, once they arrive at the destination country, can also later sponsor their own immediate family members. Therefore, the chain migration process can progress to bringing more *derived* family members into a country. However, the principal immigrants are in fact truly *responsible for* all of the derived family members. This is the phase where the Immigration Unification Multiplier (IUM) is defined. *IUM* measures the multiplier effect of the chain migration during this immigration unification process.

The *family reproduction phase* of the chain migration process is the settlement stage of the immigrant family, during which the immigrant second-generation will be born in the destination country. In this phase, immigrant fertility plays a significant role in affecting the size of the second-generation immigrant population. As immigrants arrive from different countries, their respective fertility patterns will have various chain migration multiplier effects that Immigration Reproduction Multiplier (IRM) can measure.

Major Factors Affecting the Chain Migration Process

During the chain migration process, the strength and length of the migration chains will be determined by several key factors, such as the total number of principal immigrants, the size and structure of immigrant families, and the immigrants' fertility patterns.

The total number of principal immigrants is the most important factor during the chain migration process because the number is actually the total number of migration chains to be initiated. Since each migration chain will have its own family network to sponsor future family immigrants during the complete chain migration process, larger numbers of migration chains will mean a larger number of family members could be potentially sponsored. Therefore, the greater the number of principal immigrants, the greater the number of migration chains that will be generated during the process and the greater the potential number of future family immigrants will be.

Since each future family immigrant could be sponsored either directly by a principal immigrant or indirectly by other family immigrants (who were sponsored by the original principal immigrant), the size and structure of the immigrant family will determine the potential size of the eventual migration chain. Every such sponsorship is a chain migration event that will result in bringing an additional family member into the destination country. Since each newly sponsored family immigrant could later also initiate his or her own migration sub-chain (for a spouse, children, parents, siblings, and in-laws), these migration sub-chains, combined with the all other migration sub-chains originated from the same principal immigrant, are the basic elements of the large family migration network or the complete migration chain. The potential total number of family members to be sponsored is directly linked to the family sizes of these immigrants, which is determined by the culture of their countries of origin. The larger the immigrant family is (determined by the culture in their own countries), the larger the total number of family immigrants and the stronger and longer the migration chain will be.

Immigrant fertility is another very important factor that will have major impact on the chain migration process after immigrants (both principal and family immigrants) settle down in the destination country. Immigrants with higher fertility rates will produce more children, while immigrants with lower fertility rates will produce fewer children. Since various cultures in the countries where the immigrants are from all play significant roles in shaping the immigrant fertility, immigrants from different regions/countries usually have quite different immigrant fertility patterns in producing immigrant children. Therefore, various immigrant fertility patterns decide the total number of second-generation immigrants in the destination country. The higher the immigrant fertility rate, the greater the immigrant second-generation population will be, if the immigrant population size is the same.

At the same time, other socioeconomic and non-socioeconomic factors also have major impacts on the process of chain migration, and the actual realization of the chain effects could differ greatly among various immigrant groups. Other possible determinants include:

- The *attractiveness* of the destination country

  The more attractive the destination country is relative to the country of origin, the more family members will want to be part of the chain. According to existing research on international migration, developed countries are highly attractive to immigrants from underdeveloped or developing countries.
- The *openness* of the immigration policy of the destination country

  The more open the immigration policy of the destination country is, the greater the potential for more chain effect during the chain immigration process. While most European countries are among the least open in terms of immigration policies, the USA is one of a few top countries with very open immigration policies.
- The *culture* factor of the immigrant home country

  Assimilation is one of the most discussed topics in international migration research. During the assimilation process, the greatest challenge for immigrants is usually the process of cultural adaptation and adjustment. The degree of successful cultural adaptation and adjustment of earlier immigrants will have major impact on the migration decisions of potential future immigrants within the chain migration process.

Measuring the Migration Chain

Measuring the impact of chain migration is very complicated. The current available indicators are the Immigration Unification Multiplier (*IUM*) and the Immigration Reproduction Multiplier (*IRM*). Both are the components of the Immigration Multiplier (*IM*).

The *Immigration Unification Multiplier* (*IUM*) is the total number of first-generation immigrants each principal immigrant generates. The IUM reflects the total number of future immigrants who come to the host country through the family unification process as a result of the admission of one principal immigrant (who was not him or herself sponsored for a family reunification visa by any previous family immigrant). The IUM value is, therefore, the multiplier factor that measures the family reunification process in migration chains. Since principal immigrants are part of the first-generation immigrants, the value of the Immigration Unification Multiplier (*IUM*) will have to be 1 or greater. The extreme case of the *IUM* being 1 would mean that the principal immigrants migrate to the destination country all by themselves without sponsorship of any of his/her family members. In reality, however, immigrants will most likely sponsor some of their family members. Therefore, with the assumption that the additional family members will join the principal immigrants, we should always see a value greater than 1 for the *IUM*. Since the family reunification process is heavily influenced by the immigrants' cultural backgrounds (such as family size, family values, etc.), it is easy to suggest that the larger the immigrant family is and the stronger its family values are, the higher the *IUM* value it will have, and the stronger the chain effect of the migration chain will be in the form of Immigration Unification Multiplier.

The *Immigration Reproduction Multiplier (IRM)* is the combined total of the first- and the second-generation immigrants that each first-generation immigrant generates. The value of IRM is the multiplier for measuring the family reproduction component of the chain migration process. Since all first-generation immigrants are responsible for all of their immigrant children (i.e., the second-generation immigrants), the Immigration Reproduction Multiplier (*IRM*) will also have to be 1 or greater. If, in an extreme case, the *IRM* is equal to 1, it means that the principal immigrants (and their sponsored family members, if *IUM* is greater than 1) will not produce any children in the destination country after their migration. In reality, immigrants do usually have children in the destination country. Therefore, we can use this new indicator to measure the fertility component of the chain immigration process, because producing children in the destination country is the final phase of the migration chain. Usually, the higher the immigrant fertility rate, the higher the *IRM* value, and the stronger the chain effect of the migration chain in the form of the Immigration Reproduction Multiplier will be. As some research suggests, when children are born in the destination country, immigrants tend to stay there permanently. This fertility component in chain migration process is very important.

The IM, therefore, indicates the total number of all future immigrants who are directly or indirectly sponsored by one principal immigrant, and the total number of all second-generation immigrants who are born to all of these immigrants. For example, higher IUM indicates higher sponsorship rate, and thus stronger family unification multiplier effect of the chain migration; higher IRM indicates higher fertility rate, and thus stronger family reproduction multiplier effect of the chain migration. With clear multiplier effects from unification and from reproduction, we will have the overall IM and can assess the overall multiplier effect and its impact of the chain migration process.

Chaldean Americans

Andrea M. Przybysz
Case Western Reserve University School of Law,
Cleveland, OH, USA

In the Detroit metropolitan area, an estimated 490,000 individuals refer to themselves as Chaldeans. While most people in the Detroit area are accustomed to the term, due to small populations elsewhere, few individuals outside the area have heard the term. Even fewer individuals know the full definition of what it means to be Chaldean or the history behind Chaldean Americans.

Chaldeans are commonly thought of as Christian Middle Easterners, but this definition lacks precision. More specifically, Chaldeans are Roman Catholic individuals who have immigrated from the northern Tigris-Euphrates Valley, the area historically known as Mesopotamia, and presently known as Iraq. It should be acknowledged that while Chaldeans compose only about 10% of Iraq's population, the vast majority of Iraqis living in America are Chaldean.

As a result of the early promise of Detroit's auto industry, the vast majority of Chaldeans living in America reside in Detroit, with small communities also appearing in Chicago, Illinois; El Cajon, San Jose, and Turlock, California; and Oaxaca, Mexico. Of the Chaldeans living in Detroit, nearly 95% of people can track their ancestry back to the Tigris-Euphrates town of Telkaif.

At the same time that auto incentives drove the first Chaldeans to Detroit in the late 1800s, many Chaldeans left Telkaif for Mosul, Baghdad, Basra, and Beirut. But, by the time Chaldean Americans settled and found success in Detroit, many encouraged their families and friends to join them. This second coming started the process of chain migration, which continued with wavering intensity through the 1960s.

While newly arriving Chaldeans viewed Detroit as a hospitable economic environment, the Detroit's large Catholic population also drew Chaldeans in. Though the majority of Iraqis are practicing Muslims, Chaldeans are Roman Catholics, thought to have been converted by the missionary St. Thomas the Apostle in the early part of the first century. Until the arrival of St. Thomas in the Tigris-Euphrates Valley, the Chaldean people followed Nestorius, a patriarch of Constantinople who led the Church of the East and taught that Jesus was not simultaneously God. Aside from this division, Chaldean people followed the teachings of the Roman Catholic Church. In 1445, the Church under the leadership of Pope Eugenius IV and the Nestorians reconciled their differences: the Church agreed to permit a new Catholic rite, the rite to hold mass in Aramaic, and the Nestorians agreed to accept Jesus as God. Those Nestorians who refused to accept the Church's terms continue to belong to the Church of the East.

Unlike the majority of Iraqis who speak Arabic, the ancestral language of Chaldeans is Aramaic, commonly known as the language Jesus was thought to have spoken. Despite being better educated and from wealthier families than their Chaldean counterparts who immigrated in the early and mid-part of the twentieth century, most recent Chaldean immigrants do not speak Aramaic. The loss of the Aramaic language among modern Chaldean immigrants is considered a grave loss and can primarily be attributed to the fact that the Iraqi school system requires school to be taught in Arabic.

Following the Gulf War in the 1990s, the USA has seen fewer Iraqis and Chaldeans immigrate. Because many Chaldean families had sons and nephews on both sides of the Gulf War, fighting for the USA on one hand, and Iraq on the other, many families suffered devastating psychological effects. The result of this so-called brother versus brother combat left many Chaldean families who identified first and foremost as Americans without a sense of home or belonging. The result of this impact can arguably be seen today where Chaldean and Arab Americans continue to be cautious of anti-Arab attitudes by limiting the extent to which they are willing to acculturate. Instead, many Chaldeans and Arabs elect to live in close proximity to one another.

Due to continued stigma associated with mental disorders in Middle Eastern culture, less acculturated Chaldeans face major obstacles in admitting problems and seeking mental health services. In Chaldean culture, it is still believed that mental disorders cast shame upon the family. Unfortunately, these negative attitudes toward mental health greatly undermine the work many Middle Eastern refugees need. Many Middle Eastern refugees come to America after having witnessed serious atrocities, political unrest, and in some cases, even torture. More acculturated individuals similarly face problems due to the creation of a public identity to minimize ethnicity when desirable and a private identity to be used around family and friends. These negative attitudes pose further risks when considering that Chaldean Americans who seek out proper services do so in the context of there being little empirical research on the culturally relevant services needed.

Chemical Exposure

Doug Brugge
Department of Public Health and Community Medicine, Tufts University School of Medicine,
Boston, MA, USA

There are over 80,000 chemicals in use in the USA and it is safe to say even more if one were to do a global inventory. In addition, there are many more chemicals that people are exposed to that are generated by combustion and other reactions in the environment. Combustion products, smoke of various sorts, can by themselves be composed of thousands of chemicals. In contrast, only a small number of these chemicals have been thoroughly tested for their toxicity and an even smaller number are regulated in terms of human exposure or environmental release. Thus, it is almost impossible to comprehensively review chemical exposure in general, let alone for immigrants. However, some broad strokes of understanding are possible.

Chemicals come in three basic forms: gases, liquids, and solids. The form that a chemical takes will influence how it might or might not get into the body. Gasses or very tiny suspended particles of liquid or solid can be breathed in. Inhalation is a critical entry path because the lungs provide an easy surface onto which chemicals can be deposited or be absorbed into the blood. Liquids and solids may be ingested. The gastrointestinal tract is more protective than the lungs in terms of penetration into the blood, but depending on the nature of the chemical, it may be absorbed to a greater or lesser extent.

The skin is another route of entry and is most easily penetrated by fat-soluble substances such as organic solvents. Many potentially hazardous substances will not easily pass through the skin, although some, such as acids, can cause direct damage to the skin on contact. In addition, some chemical substances will cause harm if they penetrate the skin physically, such as depleted uranium shrapnel fragments that may remain lodged internally in combat veterans leaching uranium into the body.

The chemical structure of a substance is highly deterministic of its toxicity and ability to enter the body. As suggested above, a fat-soluble compound, such as benzene, which is found in the gasoline that we put into our cars, has numerous properties that contribute to its toxicity. It is a liquid, but evaporates easily to form vapors that can be breathed in. It is fat soluble and can pass through the skin on contact and enter the blood and travel through the body. Benzene is an acute toxin and can cause drowsiness, dizziness, rapid heart rate, headaches, tremors, confusion, unconsciousness, and even death in a short time at high doses. But it is also a well-established carcinogen and can cause a specific type of leukemia (acute myeloid leukemia) following years of low-grade exposure.

The settings in which people are exposed to chemicals are also quite varied. Some people are exposed at work, others at home or during recreation. There may be exposures at school that are not present at home or vice versa. There may be chemicals in the food that we eat, pesticides for example, and in the water we drink, arsenic being one. Particularly in industry, mining, construction, and other manual jobs there can be toxic chemicals that are part of the job, such as silica dust or various solvents. In other settings, restaurants for example, there will be chemicals from the combustion associated with cooking and tobacco smoke (if it is not banned), even though we think of these as "safe" occupations. Some chemicals in the home are a legacy of the past, an example being interior lead paint, while others are introduced to address a problem, such as pesticides used to kill cockroach infestations.

Because there are so many chemicals and they each have their own properties and toxicities it is impossible to remember all of them. Even an expert will need to seek documentation of what is known about a chemical that they have not already investigated. The first problem is to find out what the chemical is. This may not be easy; but many consumer products and substances used in the workplace have labels on the container that give the chemical names. Also, in the USA and many other countries workplaces are required to retain and provide to workers Material Safety Data Sheets that have information about chemicals. Other sources (listed at the end of this entry) include the Agency for Toxic Substances and Disease Registry's Toxicological Profiles and the National Institute of Occupational Safety and Health's Pocket Guide to Chemical Hazards.

A couple of examples will provide a sense of how chemical exposure might be higher for some immigrant populations.

Nail salon workers in the USA are staffed heavily by Vietnamese immigrants, perhaps making up a majority of these workers. While nail salons are not industrial and may not be considered hazardous occupations by many people, they use products that contain many toxic chemicals, including solvents, resins, acids, and plasticizers. While there is little question that Vietnamese immigrants in the USA will have higher exposures to these compounds, it is unclear to what extent this is affecting their health because of the paucity of studies on this occupation. The few studies to date have depended largely on surveys and observation and do not directly monitor exposures or measure biomarkers or long-term health outcomes.

Southeast Asian immigrants to the USA often come from rural villages. Due to their experience and comfort with fishing and hunting, their low-income status, and the general acceptability of fishing in the USA, many will fish for food. However, in industrialized areas, fish may be contaminated with chemicals that bioaccumulate, such as methyl mercury or polychlorinated biphenyls (PCBs). Bioaccumulation is a process by which certain chemicals, often fat soluble, increase in concentration as they move up the food chain to higher order predators. If humans are at the top of the food chain, then they may be consuming and thus bring into their bodies these substances. Indeed a study by Schantz et al. found elevated levels of some of these pollutants in Southeast Asian immigrants who fish.

A classic example of chemical exposure in immigrants is farm worker exposure to pesticides. Many farm workers are immigrants, documented or not, and many are migrant in that they move to follow the available work. Farm operations commonly use pesticides to control insects and other pests and herbicides to control weeds. While there are a large number of chemicals that are used for these purposes, the toxicity of some of them are well understood, raising concerns about occupational exposure.

Numerous studies have confirmed what is clear simply from observation, that many farm workers are exposed to pesticides on a regular basis and that they receive little or no training or protective equipment.

Farqhar et al. studied Oregon indigenous farm workers who mostly did not speak English or Spanish and found that 48% worked with pesticides (probably an underestimation) and that only 57% received any training. Arcury et al. reported findings in 2009 from a study that measured urinary concentrations of six metabolites of organophosphate pesticides. Frequency of detection of the pesticide metabolites ranged from about 8% at the low end to over 78% at the high end and reported that these metabolites increased during the farm work season.

Studies have also associated pesticide exposure in farm workers with biological harms, including genetic damage. Our understanding of the mechanism of action of the organophosphate and *N*-methyl-carbamate types of pesticides is highly developed. We know that these substances inhibit a specific enzyme in the body, cholinesterase, and that their immediate, acute/short-term, effects are primarily on the nervous system. Long-term associations include increased risk of developing cancer. Indeed, the leading edge of research on the biological effects of these pesticides is now investigating and showing that some genetic/biological traits interact with pesticide exposure to modify their impact on enzyme activity.

In the USA, regulation of occupational exposure of farm workers to pesticides is through the Environmental Protection Agency rather than the Occupational Health and Safety Administration. This, combined with the exclusion of agricultural workers from many labor laws and the often undocumented status of these workers, places severe barriers on the ability of immigrant farm workers to be afforded basic protections from chemical exposures that are hazardous to their health.

At the more local level of workplace practices aimed at reducing chemical exposure, a 2009 report by Pechter, Azaroff, Lopez, and Goldstein-Gelb addresses the use of hazardous cleaning products for Janitors in Massachusetts, USA. This project, engaged the workers, their union, and a local nonprofit called the Massachusetts Coalition for Occupational Safety and Health. Using a survey and having workers show and describe the substances they were using at work, it was possible to identify products that were the most hazardous, misused, or not needed. Supervisors responded to this effort with a number of changes aimed at reducing exposures and addressing health complaints.

While the examples given above only scratch the surface of chemical exposures to immigrants, many more of which are probably not even identified let alone studied, they illustrate that there are distinct aspects of chemical exposure for at least some groups of immigrants. There is a need for more research as well as increased education of immigrant populations about chemical exposures and health.

ABDUSAMAD DUSTOV
Department of Nuclear Medicine, Gastroenterology Institute of the Academy of Sciences of the Republic of Tajikistan, Dushanbe, Tajikistan

Twenty-four years have passed since the time when the world was shaken by the damage at Chernobyl nuclear power station, the fatal consequences of which many thousands of people now feel. A tragic fate overtook 1,800 citizens of the Republic of Tajikistan who participated in the response to the disaster. The effect on the environment of the Chernobyl atomic catastrophe has been investigated many times, and from different points of view, since the accident. But investigations of the effects of different radiation doses on the human immune system have not been studied.

In our Institute in Dushanbe, we examined approximately 750 people who had taken part in the liquidation of Chernobyl between 1994 and 2006. The psychological, digestive system, and immune responses of these people, who directly took part in the liquidation, were assessed. The investigation began eight or more years after the catastrophe. All of the patients were investigated and treated in our hospital, opened after the Chernobyl disaster.

This work characterized the immune status of 350 individuals who participated in the 1986–1990 cleanup work of the Chernobyl nuclear power plant explosion. The level of immunoglobulin (IgA, IgG, and IgM), the numbers of peripheral blood leukocytes, lymphocytes, T-lymphocyte and their subpopulations (CD3+,CD4+, CD8+),B− lymphocytes (CD19+), and natural killer cell (CD16) were determined in the peripheral blood.

Most of our patients were sent by general physicians to us for psychiatric consultation about psychological and psychiatric problems. The doses received by our patients depended on the time at which they began their work in the contaminated area and its duration. The first signs of disorders appeared at the end of 1986 among 45% of our patients. It took 1.5–2 years or more for these disorders to appear. The average age of our patients was 30–45 years at the time. Most of them had similar multiple complaints: headache, dizziness, fatigue or chronic tiredness, poor concentration and lack of attention, memory loss, irritability, sometimes anger, mood swings, anxiety, exhaustion after physical and mental activities, high blood pressure, respiratory deregulation, feelings of hopelessness and worthlessness, and lack of libido. They also had a high sensitivity to loud noises, bright light, and high temperatures. The overall symptoms of these patients were so similar, that we call this syndrome: "Cerebrasthenic post Chernobyl Syndrome." In some cases, the cerebrastenic syndrome developed into an encephalopathic syndrome. The pathological change in these cases included autoimmune, neuro-immune reactions and biochemical changes. At the same time, most of our patients suffered from various somatic diseases.

The results of psychological examination of those patients indicated poor attention, lack of concentration and attention, memory loss, mental exhaustion, and reduction of mental ability. Eighty percent of the patients had a very high level of anxiety. Some patients could not even remember their phone numbers or what they just had read in the newspaper. Sometimes they did not remember where they were going. More than 85% had changes in their character, and 96% had low levels of self-esteem and self-evaluation.

At our Institute, we saw many patients, and we realized that it was very difficult, and sometimes impossible, to sort out all these symptoms. Psycho-organic syndromes can evolve in three stages:

- The first is mild, with asthenia or cerebrasthenia, reduced emotional ability, decreased physical working ability, changes in mood, poor attention, lack of concentration, and memory impairment.
- The second stage is moderate, which includes all of the first stage, plus personality changes, irritability,

Chernobyl Sequelae. Table. 1 Parameters of immunity and biochemical parameters in blood of the liquidators

	Control group	Liquidators	*P*
T-lymphocytes suppressors	2.0 + 0.08	1.37 + 0.07	$P < 0.01$
Immune complex	1.88 + 0.12	3.35 + 0.25	$P < 0.05$
IgA	2.65 + 0.2	1.86 + 0.2	$P < 0.05$
IgM	1.24 + 0.15	0.78 + 0.1	$P < 0.01$
IgG	15.8 + 1.1	10.3 + 1.1	$P < 0.01$
Protein	74.0 + 0.59	66.1 + 0.4	$P < 0.01$
Bilirubin	20.5 + 0.3	25.5 + 0.6	$P < 0.01$
Cholesterol	4.11 + 0.4	3.86 + 0.5	P > 0.1
AsAT	125 + 11.9	156 + 11.8	P < 001
ALAT	280 + 12.3	380 + 13.1	P < 0.001

dysphasia, periods of anger and psychotic-like states.

– The third stage is severe, with important aggravation of the symptoms of the first and second stage, plus instability.

Clinical and psychological examinations allowed us to describe a specific "cerebrasthenic Syndrome" as the first stage of organic mental disorders. The diagnosis, the prevention, and the treatment of neuropsychiatric syndromes, especially those related to radiation and to acute radiation sickness, are of great interest and they need to be analyzed and studied further.

In 350 liquidators from Chernobyl, we found a significantly decreased number of CD16+ cell (natural killer), of CD4+ and CD8+ T-lymphocytes. In Chernobyl cleanup workers there was variation in the number of T-lymphocytes. Levels of IgG and IgM were significantly decreased in persons who worked in Chernobyl in 1986 during the first month after the accident. For the T-lymphocytes suppressors, there is a similar situation: a decrease of the T-helpers which increases the defense mechanism against various infections, and an important increase of T-lymphocytes suppressors, which reduces these deference mechanisms. Our results clearly reflect an impaired immune system in the Chernobyl cleanup workers even 10–14 years after the nuclear accident (Table 1).

The liquidators from Chernobyl had a reduced IgG (gamma-globulins), pointing to a reduced reaction of their immune system. They also have low doses of Cs 137 in their bodies. We also found an increase in the number of circulating autoantibodies in the blood of these liquidators: These are very complex, very pathogenic proteins, which induce several autoimmune disorders in various organs.

In conclusion, the immune systems of liquidators from Chernobyl have been impaired. We find various disorders of the immune system in these people.

Child

MARJORIE NIGAR EDGUER
Mandel School of Applied Social Sciences, Case Western Reserve University, Cleveland, OH, USA

Child immigrants are children who immigrate, as distinguished from children of immigrants, who are the children of adult immigrants (and may be immigrants themselves, or may be born in the country to which the parents have migrated). A child who immigrates is born in one country and at some point following their birth migrates to another country to live. Child immigrants usually move to a new country (the “receiving country”) with their parents and/or other family members, but may migrate alone for a number of reasons (see Unaccompanied Minor entry). Child immigrants constitute a special population of immigrants because they have not reached the age of legal adult status in the receiving country, so they do not have the ability to make legally binding decisions for themselves but need to rely on adults to act for them. They are also a special population because of child development: they are experiencing many significant biological transformations physically, cognitively, and emotionally. They are a diverse group, representing many different sending and receiving countries, and having a multitude of reasons for migrating. Many aspects of the child immigrant experience are important: their status within the receiving country, especially regarding citizenship; their interactions with the child systems in the receiving country, especially education systems; and their roles within and the dynamics of their family systems.

National policies of receiving countries vary widely regarding child immigrants. Policies regarding immigrant integration in the receiving country may relate to supportive services, educational services, or immigration status. National attitudes regarding immigrants also impact the experiences of child immigrants. Receiving countries tend to be European Union (EU) countries or North American countries (the United States and Canada). Policies regarding immigrant children vary widely from country to country. In the United States, the 14th Amendment to the Constitution states that anyone born or naturalized in the United States is considered a citizen; thus children of immigrants who are born in the United States are citizens of the United States. Because the United States recognizes dual citizenship in certain cases, children born in the United States to immigrant parents may be able to maintain a legal connection to both their parents’ sending country and the United States. In Germany, historically, citizenship was only granted through a blood relationship to a German citizen. Recently, the law has been amended so that some children born in Germany to immigrants are eligible for German citizenship. But dual citizenship is still not recognized in Germany, so youth with immigrant parents have to choose a citizenship as young adults. Immigrant children will find themselves with similar choices as other children of immigrants: policies in the receiving country may support maintaining their connection to their sending country, but more often the policies will encourage establishing themselves in the receiving country by cutting ties to their sending country.

Child immigrants are often eligible for a multitude of services to ease the transition to the receiving country. Services to support the transition include language classes, educational support programs, preschool programs, vocational training programs, and translators. Immigrant children are eligible and expected to participate in the compulsory educational opportunities available to children of their age in the receiving country. Depending on their educational experiences in their sending country, they may or may not be prepared for the educational opportunities they find in the receiving country. They may need educational support to catch up with their peer group academically. Children may also be eligible for medical services, either short term or long term, depending on the receiving country.

Children who immigrate may have families that are well educated, with many socioeconomic resources in both the sending and receiving country, or their families may have less education and fewer resources than the average family in either sending or receiving country. Immigrant children will be presented with different opportunities, based on these factors. But regardless of socioeconomic differences, immigrant families tend to value education, and immigrant children tend to internalize this value and work hard to succeed in the educational system of the receiving country.

Recent research in the United States and Canada that has focused on child immigrants has found that in general immigrant children tend to do well, surpassing the academic achievements of native born children and overcoming risk factors related to neighborhood poverty and violence. Immigrant youth tend to be healthier physically, including reporting less obesity, asthma, or school absenteeism, and less risky behaviors (drug and alcohol use, sex, delinquency, or violence). While different ethnic groups report some differences in specific patterns, in general, immigration is a protective factor for children. Research in Europe has suggested less positive outcomes: immigrant children in Europe are less likely to be fluent in the language of the receiving country and less likely to experience success in the educational systems at the same rate as native born children. Some studies have shown that immigrant youth are more likely to be involved in violent behavior than native youth. It would be important to know more about the differences that have been reported regarding immigrant youth outcomes, so that the appropriate interventions can be implemented.

Child Abuse

Susan Hatters Friedman[1], Joshua Friedman[2]
[1]Departments of Psychiatry and Pediatrics, Case Western Reserve University School of Medicine, Cleveland, OH, USA
[2]Department of Pediatrics, Te Puaruruhau Child Protection Unit, Starship Children's Hospital, Auckland, New Zealand

Child maltreatment includes several distinct but sometimes co-occuring acts: physical abuse, emotional abuse, sexual abuse, and child neglect. *Child physical abuse* consists of intentional or reckless injury including cuts, bruises, fractures, thermal burns, at times with violent forces such as hitting, kicking, slapping, throwing a victim. For infants, shaking and/or impacting the head has been recognized as shaken baby syndrome, non-accidental head injury and abusive head trauma. Among and within various cultures, corporal punishment is considered distinct from physical abuse, as intentional infliction of physical pain as part of discipline with the goal of changing behavior (e.g., smacking and spanking). *Child sexual abuse* involves sexual activity of a child with an older child or adult— and can include indecent exposure/viewing genitalia, viewing pornography, producing child pornography, intentional sexual activity in view of a child, inappropriate touching, sexual contact, requesting or coercing such contact, as well as encouraging masturbation or prostitution. *Child neglect* is generally conceptualized as the parents or guardians not providing for the child's physical necessities, including food, shelter, or clothing; their needs for medical treatment; their emotional needs for nurturing; or their educational needs. Neglect also includes any failure to act or omission which presents the child with an imminent risk of serious harm. Child abandonment, when done illegally (rather than through Safe Haven type programs), may be considered child neglect. *Emotional abuse*, more difficult to define, co-exists with other forms of child abuse but on its own may include intentional or reckless devaluation of a child's human worth and/or violation of individual rights by terror, exploitation, threat, isolation, insult, humiliation, rejection, or failing to care or give affection. Overall, the bulk of substantiated cases of child abuse are child neglect, followed by physical abuse and sexual abuse, but there is concern of under reporting and lack of detection.

The occurrence of child abuse is multifactorial. Some of the risk factors for perpetration of child abuse include being a single-parent, being in an abusive relationship, substance abuse, and severe socioeconomic stress. Prior abusive or neglectful behavior increases risk, as does parenting skill problems. Special needs children are more likely to be victims.

Younger children are at highest risk of fatality. In the vast majority of cases, parents or persons *in loco parentis* are the perpetrators and the abuse most frequently takes place in the home. However, extended family and even community members such as teachers or religious leaders are perpetrators in some cases.

Child abuse was not recognized as a public health concern until the 1800s. Many societies had protection for the safety of animals prior to protection of children. There has been ambiguity across cultures and nations, and even across generations, regarding what is considered to be abuse and what is considered to be within the range of normal or acceptable parenting practices. In the 1920s a Declaration of the Rights of the Child was drafted. The United Nations Convention on Rights of the Child, borne out of decades of revisions of the aforementioned Declaration was opened for ratification by the United Nations in 1989. It was signed by the US Secretary of State in 1995, but unlike 194 countries of the world, the US has as yet failed to ratify. The Articles lay out the social, political, cultural, economic, and civil rights of children. Several countries have made various forms of corporal punishment illegal, yet others view this parental right preferentially. As an example, Sweden, over a decade ago passed a law that children must not be physically punished or humiliated.

As of 2007, over 20% of American children had parents who immigrated. Immigrants and their children potentially face many stressors such as lack of family, financial and/or social support, and these may elevate the risk of maltreatment.

Several American studies have considered child maltreatment reports from immigrant families in Los Angeles County (California). A study of 221 Chinese immigrant families found that the most common type of maltreatment was physical abuse of children. Another study considered rates of abuse among 170 Korean immigrant families. They found that Koreans were similarly more likely to be accused of physical abuse. This most frequently occurred in situations in which corporal punishment gone wrong. When psychological abuse occurred, it was often in the context of witnessing domestic violence. Still another LA study considered 243 case files of Cambodian refugee families. They found that compared to other Asian and Pacific Islander ethnic groups, Cambodian cases were more frequently reported. Parents often suffered substance abuse (more common in the fathers) or mental illness (more common in the mothers). The Cambodian refugees were more likely to be reported for neglect (compared to other Asian and Pacific Islander groups). Overall, however, it has been noted that the reported rates of child maltreatment among Asian Americans is low; this may be due to protective factors, or may be related to lack of disclosure of abuse.

Community support may help decrease risk of child maltreatment. Parenting education with specific knowledge of the culture has been recommended as a prevention effort.

Medical problems after the abuse or neglect will vary depending on the sort of abuse or neglect specifically suffered. Shaken baby syndrome is a form of inflicted traumatic brain injury based on shaking trauma to the infant's brain. Other children may suffer broken bones or organ damage. In addition, whether due to direct medical causes or psychological reasons, some may suffer chronic pain as adults.

Among child victims of abuse, there may be psychological consequences in addition to medical complications. Anxiety, depression, and posttraumatic stress disorder are psychiatric disorders, which may occur among victimized children. In addition, decreased self-esteem, disorganized attachment styles, and acting out behaviors may be seen. They may experience difficulty trusting others. Childhood victims of sexual abuse are at elevated risk for the development of borderline personality disorder. Emotional scars as well as physical scars need considered.

For some, in later life, a pattern of abuse is carried on through the generations. There is an age-old pattern that women often become perpetual victims in later relationships and that men often become the abusers, perpetuating the cycle of violence. Early diagnosis and treatment may help prevent furthering this cycle.

Thus, medical treatment and psychological treatment are often both indicated for victims. Medical treatment may occur in a hospital or as an outpatient, depending on both safety and the severity of the injury. Children may participate in psychotherapy, play therapy, or group therapy, depending on what is recommended for their individual situation and developmental level.

Teachers, medical professionals, police officers, legal professionals, and other professionals are often required to report cases suspicious for abuse to the appropriate agencies, often called "Child Protective Services" (CPS) or a "Children and Family Services." Other concerned members of society may also report. CPS will determine whether investigation is warranted, and if so, a case worker will be assigned. Though parents have rights, the State or Nation generally has the authority to intervene in cases in which parents fail to protect their children's safety or well-being. Recently, social services have the imperative to learn to improve practices in a culturally competent manner with immigrant and minority families.

Specific concerns identified within immigrant communities related to whether to report child abuse have included, among others, fear of government intervention or deportation, differing cultural norms of acceptable parenting behavior, and lack of social support. For example, immigrants to New Zealand may be surprised to learn that only children over age 14 may be left home alone. They may be considered to have neglected their children though their behavior was consistent with what they considered normal in their community of origin. Immigrants may have diverse customs and approaches to child discipline, child monitoring, and cultural practices in illness (e.g., cupping).

When there is concern of abuse or neglect, CPS and associated services make a safety plan, and determine whether remaining in the home is appropriate. If not, the child may be cared for by safe relatives or within the foster care or group home system. Immigrants who are lacking the social support network and kin from home may find their child removed to the foster care system, whereas their native counterparts see the child cared for by a grandparent.

Other potential complications with involvement of CPS related to immigrant status include lack of knowledge of immigration law/transnational issues, religion, culture, lack of appropriate resources, and bias. There has been a lack of sufficient research in this area, and CPS workers may find themselves unprepared for complicated cultural issues. Better practices include consideration of cultural competency, consular relations, potential for transnational placement with relatives, and provision of interpretation services.

Foster care systems may suffer some racial or ethnic disparities in delivery of care. The aforementioned study in Los Angeles also found that the Chinese children of immigrants were less likely to be removed from their home than non-Chinese children. Criminal and civil court cases may be initiated. Many cases go through the court system, and children may be removed from the parent's care temporarily or in some cases, permanently.

Parents, in collaboration with CPS, are often prescribed a "case plan" which they must complete for custody or reunification with the child to occur. Case plans may include such directives as attending drug treatment, psychiatric treatment, and parenting classes. If the child has been put in out-of-home placement, initial visits with the child may be supervised by CPS or other professionals.

In sum, in the late nineteenth century, Western civilization acknowledged child abuse and neglect as unacceptable, and by the late twentieth century recognized its manifestations and clearly codified social responsibility toward children, the criminality of the acts, and the imperative to further improve detection and service. Meanwhile, anthropological exploration of the process of raising children within many of the world's cultures overturned conventional wisdom of an extant universal standard of child maltreatment. Indeed, the rights of children vis-à-vis the rights of the group vary by society, and change over time; cultural rationalizations for acceptable treatment of children heed the perceived conditions for survival. As cultural idiosyncrasies ranging from tolerant and permissive to authoritarian and restrictive have been revealed across the world's cultures, there has been concomitant effort globally to root decisions regarding child protection in the child's "best interests" and to innervate culturally competent child advocacy. However, raising children by weaving diverse cultural norms into a novel social fabric burdens immigrant families and the social institutions of destination states in consideration of child abuse and neglect.

Child Development

Marjorie Nigar Edguer, Maureen Riley-Behringer
Mandel School of Applied Social Sciences, Case Western Reserve University, Cleveland, OH, USA

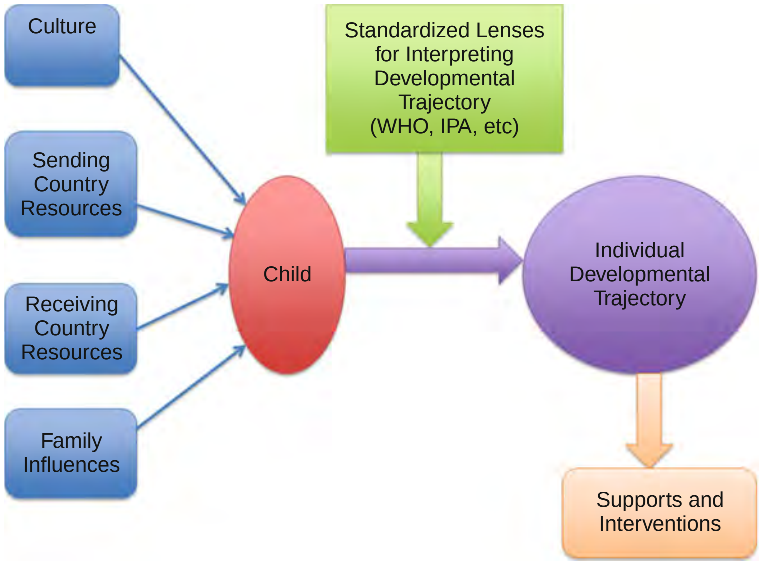
Introduction

Child development and immigration have a multifaceted relationship. It is important to understand this relationship to grasp the experience of child immigrants and develop appropriate supports/interventions. Key aspects of immigration that affect child development include the following: sending country characteristics, family, receiving country characteristics, and cultural expectations of both the sending and receiving countries. Sending country characteristics are the resources, health, safety, and education of the country of origin. Family includes kinship dynamics, resources, and separation(s). Receiving country characteristics include resources, health, safety, and education of the new country. Cultural expectations focus on attitudes, behavior, and beliefs regarding biopsychosocial development, social stratification, developmental milestones, and the interaction of these with other influences. Due to these influences, child immigrants will progress in unique, individual ways that need to be assessed and understood in order to support their optimal development. The concept of an "individualized child development trajectory" refers to the projected developmental pathway given those influences that impede/enhance that child's overall growth; while there may be many generalizations regarding developmental expectations, it is important to consider which of these are relevant for this particular child (Fig. 1). This concept is important for all children, but particularly relevant for immigrant children, as a multitude of influences surround the immigration experience.

One in five children in the USA is an immigrant, resembling rates in most high-resource, developed nations. Immigration usually occurs from low- to high-resource nations. Children/adolescents constitute a special subgroup of immigrants because they are still developing physically, cognitively, socially, and emotionally, and lack adult rights. For example, children/adolescents are dependent upon the adults around them to meet basic needs (e.g., shelter, food, clothing, and safety). Dependence on adults varies by both the age of the child and their cultural context. Based on this dependency, children/adolescents may immigrate because of a decision by their parents. They may also immigrate after becoming refugees in their sending country. Children and adolescents' experiences are impacted developmentally: their understanding, insights, ability to act, and motivations will vary at different developmental stages. Additionally, children and adolescents have particular vulnerability because their physiological and psychological development may be changed by trauma, and incorporating new influences may change their previous sense of identity.

Immigration poses a significant transitional event, regardless of the dynamics preceding it. Children and adolescents are learning how their world works, and what is valued by their world. Immigration means that there have to be shifts in this knowledge and understanding. Their ability to make these shifts, and learn how their new world works, will be instrumental in their ability to successfully transition to a new country. Immigrant children's ability to successfully transition will have long-term impacts for them, their families, and their new countries. Intervention with child and adolescent immigrants has to be grounded in both developmental processes and have awareness of the impacts of immigrant children's experiences on overall growth and well-being (see Fig. 1).

Much of the research regarding child and adolescent immigrants has found conflicting results, possibly because it fails to integrate the multiple dynamics that impact the process. Some research has found that child and adolescent immigrants are more at risk for problems. Other research has found that immigration is a protective factor for children and adolescents. The reality is that there are multiple aspects that influence the experience of immigrant children and adolescents: biological and psychological child/adolescent development, immigrant status, ethnicity or culture of origin, culture of migration/host society, and individual family culture. Research often uses single measures for complex concepts, like preferred language as a measure for acculturation. Acculturation is defined in a myriad of ways, and has been conceptualized very differently depending on the theoretical model. Simplistic



Child Development. Fig. 1 Individualized developmental trajectory model definitions and models fail to give an accurate picture because they only look at one aspect of the experience. Many immigrant children experience stress and are also doing well on many measures (e.g., academic grades, graduation rates, delinquency, or risky behaviors). Each of these reinforces the importance of considering the child's individualized developmental trajectory.

Potential Influences: Sending Countries

Resources

Sending countries tend to be limited-resource nations. The literature links children failing to meet their developmental potential in limited-resource countries to factors of poverty, health-related issues, and barriers to education. An estimated 200 million children under the age of 5 are failing to grow healthily and meet their developmental potential, leading to devastating short- and long-term implications for the value of human capital. An interdependent relationship exists among domains of child developmental growth and family preservation, all of which are affected by aspects of living in poverty (i.e., joblessness, migration), experiences of health-related issues (i.e., malnutrition, infectious diseases), and encounters with barriers to education (i.e., school access, child labor). Lack of these resources can be the primary reason families immigrate from limited- to higher-resource countries. Although the developmental effects experienced may follow that child to a new country.

Economics

Raising children in limited-resource countries can present many barriers to accessing resources to meet needs of the developing child. A parent's/provider's competence in supporting his or her family is vested in his or her ability to meet primary needs. Some countries in transition face a restructuring labor market, lack available jobs, or experience a shortage of workers with adequate skills to fill available positions, which may influence a family's decision to immigrate. Unemployment often prompts temporary (i.e., migration, child labor) or permanent family separations (child relinquishment related to death of parent(s), abandonment, or inability to meet children's primary needs).

Youth may feel some pressure to work to promote preservation of their families. In Central Asian culture, there has been an increase in individuals between ages 15 and 19 being employed. Reportedly, youth in this age group feel financial pressures to support their families financially and question the value of higher education. Millions in Asian cultures have also gone outside of their countries' borders in order to find jobs and decrease family poverty. Employment migration, in some cultures, serves the purpose of raising families out of poverty, aiding them in remaining preserved long term. It is typical to live in a multigenerational family home where kinship care supports children in their parents' absence. For immigrant families, there may have been a history of temporary migration and separation prior to immigration. This will impact relationships following reunification and immigration.

Health/Safety

Health-related issues in low-resource countries can be detrimental to children reaching their developmental potential. Common issues are malnutrition, infectious diseases, lack of access to health care, growth stunting, impaired cognitive functioning at work/school, and costly use of healthcare services. Intrauterine growth restrictions are most common in low-resource countries, primarily from malnutrition and infections. Research links this to low birth weight at delivery, lower cognitive scores, decreased problem-solving abilities, and other growth restrictions having impacts as late as adolescence/adulthood. Processes during brain growth have consequences for later cognitive functioning (e.g., school readiness, later academic performance). Children with stunted growth reportedly have a less positive affect, decreased playfulness, and increased likelihood for insecure attachment versus non-stunted children. Ongoing hunger and malnutrition is another threat to children's developmental potential, reportedly perpetuating poverty by leading to a poor physical condition, impaired cognition/school performance, and more need for healthcare services. Although children may have access to nutrition and health care following immigration, the long-term consequences of the earlier deprivation often follow immigrant families to their new countries.

Limited-resource sending countries have greater exposure to infectious diseases (e.g., malaria, HIV/AIDS). Inadequate general healthcare services compound long-term detriments of infection on children's development, often accompanying them beyond their immigration. The literature notes that children who survive severe malaria have been found to have varying degrees of neurological impairments, deficits in hearing, memory, attention, neurological effects (fine/gross motor), speech and language, and nonverbal developmental domains. Globally, over two million children under the age of 15 and more than ten million people between 15 and 24 years are HIV positive. Many children are orphaned and vulnerable (OVC) following parental death from HIV/AIDS. Nations' infrastructures have been severely impacted by the epidemic, resulting in the loss of a generation usually at their peak for economic and societal production.

Armed conflicts affect the safety of over one billion children globally. There are many impacts of war such as injury, death, orphanhood, maiming, abduction, rape, children used as soldiers, posttraumatic stress, denial of humanitarian access, and geographic displacement. Even when children and their families immigrate to a peaceful receiving country, they can suffer many long-term physical and emotional ramifications from the effects of war.

Education

Children from limited-resource countries often experience disadvantages or losses related to their education prior to immigrating. Receiving a basic education is many times beyond reach for millions of children due to families' inabilities to afford school fees (i.e., uniforms, school supplies, and books), lack of access to facilities in remote areas, few educational facilities being equipped with water/sanitation systems, and fear for children's safety due to civil conflicts/natural disasters. Discrimination against indigenous populations/minorities, children with disabilities, and students touched by the AIDS crisis often exclude some children from receiving an education in limited-resource countries. Teacher mortality rates in sub-Saharan Africa are particularly high due to the AIDS epidemic. Schools often have to share available educators who travel from community to community to meet children's needs on a part-time basis. Many of these children struggle with language and math, receiving fewer than 800 hours of instruction a year, learning in crowded classrooms, in inadequate learning environments.

Immigrant children coming from limited-resource countries are also often deprived of the right to an education in their sending countries due to gender inequalities. It is common for families to remove them from school to help support the family through child labor. Poorer families have greater difficulty in managing risk (i.e., by having savings/eligibility to borrow) related to downturns that can threaten family preservation. Girls often bear the brunt of education loss due to family poverty, with it being the norm for parents to send their male children to school if a choice must be made. This lack of prior education or substandard education by the receiving country's expectations may place an immigrant child at a disadvantage following immigration. This disadvantage may be very difficult to overcome.

Potential Influences: Family Dynamics

Kinship Dynamics

Most limited-resource countries remain preindustrial economies, lacking financial surplus to provide structured social welfare systems to care for the needs of their countries' vulnerable populations. In preindustrial societies, family dynamics encompass the larger, extended kinship network. These networks provide for the primary physical, emotional, and financial needs of the collective. The ideology of patriarchy also plays a role in gender power differentiation within the family network.

Resources/Separations

When a nuclear family leaves its country of origin through immigration, it often separates from the extended kinship group that once served as its social welfare-based system of safety nets. Once in receiving countries, immigrant families reportedly feel a sense of uncomfortable physical, emotional, and financial exposure without the safety net that they once were accustomed to having. Many times, parents of children will immigrate in advance for financial purposes, while children remain in their country of origin in kinship care with the extended family. Parents travel for employment purposes to raise money to bring the rest of the family with them or simply to send funds back to the larger kinship network for a better life. Millions of parents in Asian cultures leave their homes, with or without their children, to find better-paying jobs than in their countries of origin.

Potential Influences: Cultural Expectations

Cultural expectations have a major influence on how child development is viewed. Different cultures have different expectations regarding dependency, independence, passivity, aggression, assertiveness, language acquisition, and motor skills. These expectations may also vary depending on the age of the child and on cultural values and beliefs. Childhood can be conceptualized as a position in a social structure, which will vary depending on the social structure. Different cultures have different social structures and thus view childhood and adolescence differently. Different countries assign or legislate different expectations for children and parents. Nations decide what the rights of children and parents are, what responsibilities each has, limit or regulate their power, and decide on the age that children can legally engage in work for pay. Nations also decide on resource allocation for children (education, health, etc.). Many of these assignments are based on cultural beliefs and expectations.

When children immigrate, they are likely to move from one set of cultural expectations to a different set of cultural expectations. A child and his or her family may attempt to maintain the cultural expectations of their sending country, leading to conflicts with different systems in the receiving country. An example of this would include situations in which immigrant families do not enroll adolescents in school, expecting them to care for younger children or to bring in a wage. If a family has different developmental expectations regarding independence and interdependence than the larger surrounding culture, institutions (and representatives of the institutions) may judge the child to not be meeting developmental norms.

While every culture will have some specific differences in the expectations of children and adolescents, there are some general patterns regarding sending countries and receiving countries. Receiving countries are more likely to use "Western" concepts about the role of children as innocent and needing protection, whose place is one of safety: with family and in some kind of educational setting. In most receiving countries, child populations are declining except among immigrant groups. Sending countries may have similar expectations; or they may see children as having more freedom and not needing to meet the more rigid expectations for different genders that will exist after puberty in that culture; or they may see children as economic resources to be used for the benefit of adults. Sending countries are more likely to have poverty, forced migration, or war, which have a large effect on children because of their vulnerability. Receiving countries and sending countries often have different developmental expectations based on sex or gender. Sending countries tend to be more agrarian, and have more traditional division of labor and very different role expectations for males and females. Most sending countries value having many children, and value male children more highly than female children because both of these increase the economic options and standing of the family. Sending countries usually do not have policies that support gender equality. Receiving countries tend to have similar role expectations for male and female children, and usually have policies that regulate gender equality.

Culture has a strong influence on parenting practices, including the value that parents place on education, how parents discipline their children, what is seen as appropriate behavior for a child, the role of extended family, expression of emotion, sleep patterns, social skills, and coping styles. Cultural expectations can influence even a habit like nail biting, and how parents understand and respond to the habit. A child or adolescent who had different expectations in their sending culture may resent the new expectations of their receiving country. The difference in cultural expectations can also lead to conflicts between the child and family, if one or the other adopts the expectations of the receiving country while the other seeks to maintain the expectations of their country of origin. The different expectations between sending and receiving countries may cause confusion, conflict, or stress for immigrant youth and families. It is important to be able to understand the different cultural expectations and how they are influencing a particular child and family.

Potential Influences: Resources in Receiving Country

Resources

Resources in receiving countries impact child development through a variety of ways, including what resources actually exist, what mechanisms are used to distribute resources, the families' skills and abilities to access resources, and belief systems (both the immigrants' and the receiving countries') regarding resources. Resources in this context are not limited to those that are natural or raw, which may be in abundance in both receiving and sending countries. "Resources" reflects the amount of goods and services produced, which tend to be highest in wealthy nations, which also tend to have an abundance of well-developed systems for their distribution. Those resources in receiving countries with the most impact on child development include employment and social supports, health care, and housing and education systems.

Economics

The economies of receiving countries with their high-resource status do not usually mirror those of sending countries; immigrants may not be well prepared for the differences they encounter. Economic systems include employment and social supports, health care, and housing. Employment supports refer to job availability, job training, and having a living wage, as well as supports that effect parents' ability to both work and parent. These supports may be difficult for immigrant families to understand and access, which effects the family's economic status and further opportunities. Immigrant families are more likely to have a lower socioeconomic status, and to live in neighborhoods with more violence and other problems. While immigrant families tend to have protective factors regarding the effects of poverty and neighborhoods, they are still disadvantaged. Health care includes the quality of medical care, prevention and intervention, as well as its accessibility. Housing refers to the quality, safety, and affordability of available living accommodations. Social supports include unemployment benefits, family allowances, disability and sickness benefits, housing benefits, and other forms of social assistance. Each of these supports may be differentially accessible to immigrants. The institutionalized systems may be difficult for immigrant families to understand, impacting their use of support systems in the receiving country. In turn, these can all impact immigrant child development.

Education

Education systems affect child development by their ability to teach skills that children need to meet the demands of their environment and prepare them for adult life. For most receiving countries, this includes literacy, job skills, and cultural norms. Children may have not been in a formal education setting prior to immigration, or the education system of the receiving country may be different in its structure and expectations from those of the sending country. The education system in the receiving country may have difficulty assessing and educating the immigrant child due to language differences. The need to function in a nonnative language will lead to stress. There may also be tension for immigrant youth related to minority status. There may be disparities between educational domains for the immigrant child (e.g., high math and low reading scores) that can impact the child's sense of self-efficacy, and their developmental trajectory.

Lenses for Interpretation

Impacts of earlier discussed detriments to child development are typically evaluated over a growth continuum that ranges from infancy through adulthood in which milestones are measured by physical, emotional, and social markers. When markers go unmet, a child's full developmental potential may not be reached, leading to short- and long-term consequences. Primary, generalized tools used to measure whether children are reaching their developmental potential are the World Health Organization's (WHO) Growth Standards and the International Growth and Development Criteria (IDGC). Both sets of criteria are endorsed strongly by the International Pediatric Association (IPA). Child development theories that are often used to conceptualize psychosocial growth of children include Erikson's psychosocial stages of development, Piaget's cognitive stages of development, and Vygotsky's sociocultural perspectives on cognitive development. Theories relating to acculturation and independence/interdependence are also helpful in understanding the development of immigrant children.

WHO and IGDC

These growth standards serve as a framework for healthy, physical child growth and development to guide parents and pediatric professionals. The WHO Growth Standards are endorsed by the International Pediatrics Association (IPA), which encompasses several guiding pediatric organizations in the world. The International Growth and Development Criteria (IGDC) differ from WHO Standards as they standardize physical, emotional, and cognitive domains for a given chronological age. Both are based on long-term studies of infants/children and are multiculturally/socioeconomically applicable. These milestone-accomplishing approaches base standards on families' having ideal access to resources, a nurturing primary caregiver, and an environment in which children are most likely to reach their developmental potential. The WHO tool is gender specific, detects undernutrition and obesity, good healthcare practices (i.e., immunizations), and appropriate growth criteria for children aged 0–60 months. It offers percentile and z-score curves for length/height-for-age, weight-for-age, weight-for-length, weight-for-height, and body mass index (BMI)-for-age (see "Further Resources" to access these standards).

Child Development Theories

Theories of child development are used to assess psychosocial–emotional growth in children and tend to be based on the cultural expectations of high-resource nations. Three examples of commonly used theories are as follows: Erikson's psychosocial stages of development, Piaget's cognitive stages of development, and Vygotsky's sociocultural theory of development. Professionals in education, government, and mental health settings use such theories as lenses to view individual children and their development. A brief summary of both Erikson's and Piaget's models of development can be found at http://psychology.about.com/od/developmentalpsychology/a/childdevtheory.htm.

Erikson's and Piaget's models are very structured, noting a sequential nature to each developmental stage. While they are important lenses by which to view child development, the impacts of immigration must also be factored into children's psychosocial and emotional growth trajectories. This is especially true when the culture, values, and experiences of the sending country differ from those of the receiving country.

Vygotsky's sociocultural theory of development proposed that children's cognition and learning form through the continuous interplay of social interactions and culture. Vygotsky stressed the importance of language as an expression of culture and values. Differing from other developmental theorists, Vygotsky did not use formal stages in his model, but spoke of "zones of proximal development," that is, skills that children are capable of achieving, but cannot do without adult guidance. This emphasizes the role that culture plays in child development, and the range of behavior that children present, based on their culture. His concept of "scaffolding" children's behavior, teaching them the skills that they need in a society, is also important for professionals working with immigrant children to keep in mind.

Theories of acculturation inform professional understanding of immigrant child development. Originally, acculturation theories focused on the adaptation of the immigrant to a new cultural context. Current models of acculturation have evolved from more simplistic origins, proposing categories that include integration, marginalization, assimilation, separation, fusion, and other strategies. They also highlight varying degrees of resiliency in immigrant children where some may/may not experience adjustment problems regardless of category. Cultural tenets regarding independence and interdependence also play a role in the immigrant child's developmental processes. These concepts serve as a framework for immigrant child development by providing a context within which development takes place. Most sending countries value interdependence. Receiving countries typically emphasize independence, which is evident in both Erikson's and Piaget's developmental stages. Valuing either independence or interdependence affects the behaviors, relations, boundaries, and skills that children learn. The developmental progress of immigrant children is often judged on the basis of the receiving country's expectations of independence. Clearly, the integration of developmental concepts from both sending and receiving cultures is important for professionals working with immigrant children to use in assessing development.

Conclusion

A myriad of influences impact the healthy growth of immigrant children making it imperative that those medical, mental health, and education professionals working with them understand their complex set of developmental needs. Devising an individualized child developmental trajectory that encompasses sending country characteristics, influences of the family, receiving country characteristics, and cultural expectations of both the sending and receiving countries will support immigrant children in reaching their full developmental potential.

Child Health and Mortality

Mary Lou de Leon Siantz
Office of Diversity and Cultural Affairs, University of Pennsylvania School of Nursing, Philadelphia, PA, USA

Demographics

Nearly 3% of the world's population migrates, with one out of three persons around the globe undergoing migration. Children of immigrants are the fastest growing group in the US population under 18 years of age, with one in five children the child of an immigrant. While immigrants are 11% of the US population, children of immigrants make up 22% of the 23.4 million children under 6 years of age. As of 2005, nearly one-fourth (23%) of children lived in an immigrant family. This explosive growth, combined with the large numbers (40%) originating from Mexico, and additional areas that include 10–11% each from the Caribbean, East Asia, or Europe combined with Canada and Australia; as well as 5–7% each from Central America, South America, Indochina (Cambodia, Laos, Thailand, Vietnam, or West Asia); and 2–3% from Russia and Africa. As a group, immigrant children are changing the racial and ethnic composition of US children for the present and adults in the future. These children are also among the poorest segment of the population, with one in four immigrant children living in poverty. Their families are among the poorest, least insured, or educated with limited, or no access to health care. Poverty is a social determinant that negatively impacts health across the lifespan.

Immigrant Children's General Health

Children of immigrants are likelier to be in "fair" or "poor" health than children of natives, with their health declining more rapidly as they age. Seven percent of immigrant children under 11 have been reported to be in fair or poor health which rises to 13% among 12–17-year-olds. Poor health status increases with poverty. While 12% of poor immigrant children 5 years or younger have been reported in fair or poor health, poor health status increases to 19% among adolescents, 12–17 years.

Immigrant Infant Health

The rate of low birth weight and infant mortality are two common indicators of infant health. Findings based on linked birth/infant death data sets for a number of immigrant subgroups that include Mexican, Cuban, Central/South American, Chinese, Filipino, and Japanese have documented that children born in the USA to immigrant mothers are less likely to have low birth weight and to die during the first year of life than children born to native-born mothers from the same ethnic group. While other factors may be involved, cigarette smoking, alcohol consumption, and weight gain during pregnancy are critical determinants of difference between immigrant and native-born women and their infant's low birth weight and mortality. Since the 1980s, research has supported the "immigrant paradox" that despite risk factors that include higher poverty rates, lower education, and less access to health care, some immigrants have better birth outcomes than the native born. The immigrant paradox is most consistent with Hispanic immigrants; however, some of the largest differences in low birth weight and infant mortality rates have occurred between foreign and US-born non-Hispanic Blacks.

Congenital Anomalies

Asian American children have a lower prevalence of congenital diseases and chronic conditions in general. Among Hispanics, the incidence of congenital anomalies is no greater than in the general non-Hispanic White population. About 2% of newborns have a major malformation, with an additional 3% having such conditions discovered in later childhood. According to the American Academy of Pediatrics, immigrant children may not be screened at birth for diseases such as congenital syphilis, hemoglobinopathies, and inborn errors of metabolism.

Immigrant Preschool Health

Untreated health and developmental conditions that occur during infancy may continue during the preschool period of 2–5 year of age. The child's living environment is critical to his or her cognitive and social-emotional development not only during infancy, but also during the preschool period. Exposure to toxins such as lead can lead to developmental problems if left untreated. Unintentional injuries from accidents will also negatively impact a child's overall growth and development and especially effect children living in poverty. Consequently, screening and follow-up for developmental problems is recommended.

Asthma

Asthma is the leading pediatric chronic condition of the USA. A growing body of evidence documents a disproportionally higher lifetime asthma prevalence among children born in the USA compared to those born elsewhere. While a relatively low prevalence of asthma exists among Hispanic children as a group, Puerto Rican children have been found to have the highest prevalence compared with children in all other racial and ethnic groups. Among Asian immigrant subgroups, a wide variation can be found in the prevalence of asthma, with Filipino children born in the USA having similar rates of asthma compared with children of Black, American Indian, or Alaskan Native heritage. Asian Indian children born in the USA have a much lower asthma rate.

Interactions among genetic, environmental, and social factors have been associated with differences in the prevalence of asthma among immigrant children. Children from immigrant families with asthma often experience additional factors that exacerbate their condition. These may include pollen-sensitive forms of asthma, with migration from tropical to a temperate climate with higher and more seasonably varying pollen rates which can worsen the condition. Exposure to viral pathogens to children not previously exposed can precipitate asthma. Cultural beliefs may also affect the etiology and treatment among immigrant families.

Chronic Health Conditions

While children of immigrants in general have better health outcomes compared to children born of US parents, it is unclear whether the immigrant paradox applies to children with chronic conditions. For example, compared to asthmatic children of US-born parents, asthmatic children of immigrant parents are more likely to be uninsured, lack a usual source of health care, report a delay in medical care, report no visit to a physician, or no emergency room visit for asthma in the past year. Asian Indian children have the lowest percentage of chronic conditions.

Immigrant School-Age Health

School health issues for immigrant children range from childhood nutritional challenges that include nutrient deficiencies, obesity, diabetes, as well as infectious diseases like tuberculosis, and dental caries. Health issues of school-age children from 5 to 11 years of age are a continuation of those that were identified during the infant and preschool period with untreated chronic medical conditions such as asthma negatively affecting a child's overall educational potential and development. Immigrant children whose parents lack health insurance are especially vulnerable since this limits their access to health care, needed medication, equipment, and monitoring of the condition. While low-income immigrant children 6–11 years of age are less likely to have more behavioral problems than native children, advantages have been found to worsen with time, with no differences found among low-income children 12–17 years of age.

Infectious Disease

Infectious diseases commonly found among immigrant children and adolescents are often easily treated and rarely pose a public health threat to the school community. Children with latent TB infections may attend school, pending evaluation and treatment with skin testing recommended for students coming from endemic countries. High rates of intestinal parasites, such as giardia, are found in some immigrant populations. Children with symptoms that suggest a parasitic infection or those in situations that pose a high risk of infection or transmission in institutional care settings may warrant screening and treatment or even empiric treatment with antiparasitic medication. A less common infection includes hepatitis B among children from endemic countries. Skin infections such as fungal infections, scabies, and lice are seen in newly arrived immigrants.

Children of migrant farm workers are at increased risk for respiratory and ear infections, bacterial and viral gastroenteritis, intestinal parasites, skin infections, lead and pesticide exposure, tuberculosis, poor nutrition, anemia, undiagnosed congenital anomalies, developmental delay, intentional and unintentional injuries, as well as occupational injuries and substance abuse.

Dental Health

Tooth decay is not only the most common chronic illness among children, affecting five times as many children as asthma but the most unmet health need among children. Decayed teeth retain bacteria that can be spread throughout the body and increase a child's susceptibility to other problems which include ear and sinus infections. Oral disease can affect children's growth, speech development, nutrition, learning, and overall quality of life. The American Academy of Dentistry recommends that all children have a dental care visit within 6 months of the eruption of their first tooth. Dental problems are common among immigrant children. Elementary school–aged immigrant children have been found to have twice as many dental caries in their primary teeth as their US counterparts. Immigrant children have been found to be twice as likely as native children to receive no preventive dental care.

Nutritional Deficiencies

Anemia and micronutrient deficiencies, especially of iron, zinc, and vitamin A, are common health problems among refugee and immigrant communities. Iron deficiency anemia has been found among high-risk age groups such as toddlers/preschoolers and early adolescents from developing countries. Anemia and iron deficiency may be compounded by lead poisoning.

Obesity and Diabetes

Among school-age children, obesity has emerged as a significant problem affecting long-term health. Mexican-American and Puerto Rican children are significantly more obese than non-Latino White children. Both of these Latino subgroups demonstrate increased fat deposits in the trunk which has been associated with higher cardiovascular disease in adults. This higher prevalence has been found to start as early as 6–7 years of age and continues through adolescence and adulthood. This high rate of obesity is of concern with its increased risk for cardiovascular disease and association with Type 2 diabetes. Mexican Americans are at particular risk for Type 2 diabetes.

Type 2 Diabetes

As a consequence of the high rates of obesity, many US adolescents are beginning to suffer from diseases that have traditionally been diagnosed in adulthood. The average age of onset of Type 2 diabetes is currently 13, and minorities with the disease suffer greater rates of complications and early death than their non-Hispanic White peers. Type 2 diabetes occurs when the body does not make enough insulin or does not adequately utilize the insulin that is produced (this is called insulin resistance). Type 2 diabetes increases the adolescents' risk for serious complications including, heart disease (cardiovascular disease), blindness (retinopathy), nerve damage (neuropathy), and kidney damage (nephropathy). Nonetheless, the risk of Type 2 diabetes can be cut by 58% simply by decreasing dietary saturated fat and engaging in at least 30 min of moderate to vigorous physical activity every day. Parents, educators, and public health officials need to find new ways to engage immigrant youth in healthy lifestyles within their own cultural context.

Immigrant Adolescent Health

Adolescence in the twenty-first century is defined as the period from puberty onset to societal independence and includes the development of sexual and psychosocial maturity during that stage. Adolescence not only harbors immense health risks but also vast opportunities for sustained well-being through health education and prevention. In order to provide a comprehensive view of adolescence, health and physical development cannot be overlooked. These two factors drive the developmental changes that are experienced during this vibrant period and the sustained consequences over time of health choices. The mental health, nutrition, and risky behaviors are special challenges among immigrant adolescents.

Mental Health

Immigration imposes unique stresses on children and families resulting in depression, grief, and anxiety. Current research on depression in immigrant adolescents is inconclusive, with some studies showing higher rates of depression in this population, and others showing lower rates. Hispanic immigrants, especially of Mexican origin, have the highest prevalence of depression. Research in Texas has documented that 31% of Mexican adolescent girls experienced depressive symptoms, compared to 16% of non-Hispanic White girls. Data from the National Center for Health Statistics in 2000 found an increased risk for suicide in this population, with 20% of Hispanic adolescent girls attempting suicide compared to 9% of non-Hispanic White girls. The rates of death from suicide are much higher for boys (83%) than girls (17%), but girls are more likely to report attempting suicide than boys in data from the Centers for Disease Control and Prevention. Regardless, depression is a serious health risk among adolescent immigrants. Among Hispanics, foreign-born youth (first generation in the USA) have been found to experience lower self-esteem and higher levels of suicide thoughts, while those born in the USA of immigrant parents show more serious health risk behaviors and conduct problems. It is worth noting that depression increases the risk for serious depression later in life, and is associated with poor health outcomes, such as risky sexual practices, pregnancy, violent behavior, and suicide. Recognizing depression in the adolescent could prevent further, more severe depression later in life, and other serious negative outcomes.

Nutrition

Overall, the nutritional status of foreign-born children upon entering the USA is associated with their socioeconomic circumstances in their country of origin. Limited data exist on nutritional status in general. More is known about Hispanic and Asian children than about children from Eastern Europe, Russia, Africa, and the Middle East. While foreign-born Hispanic adolescents have lower rates than their US-born counterparts of risk of overweight, the rates for foreign-born youth are very high. The most recent data report that nearly half of adolescents aged 12–19 are at risk for overweight, while more than one-fourth of Mexican-origin boys of all ages and one fifth of girls are overweight.

Data concerning the nutritional status of Asian children in immigrant families are limited and complicated by the diversity of Asian countries that send children to the USA. Understanding the economic, nutrition, and health conditions of their country of origin is critical to evaluating their nutritional status. Available data document the initial consumption by Asian children in immigrant families of traditional foods as part of the dietary intake with a transition to an American diet occurring over time. Among Southeast Asians, high levels of anemia have been found with limited intake of iron-rich food and possible gastrointestinal bleeding due to active parasitic infection.

High-Risk Behavior

Research has documented high rates of tobacco use, alcohol consumption, and substance abuse among Hispanic adolescents. Other studies have documented an association between high risk behaviors and acculturation. With increased acculturation, Hispanic girls engage in sexual activity at earlier ages and are more likely to give birth outside of marriage and to drop out of school. Increased risk for HIV/AIDS cannot be overlooked among immigrant adolescents as they acculturate and engage in substance abuse and sexual activity over time. The most frequently cited risk factors for sexual risk taking behavior are early exposure to sexual pressure, depression, and low social support. Violence as a source of injury and death among immigrant adolescents cannot be overlooked. It has become a major public health problem among adolescents in the USA. Poor urban young men of color, especially Latinos and African Americans, are especially at risk for violence.

Mortality among Hispanic adolescents is associated with homicide and unintended injuries. According to the National Center for Health Statistics, Latino adolescents have a rate of death from homicide that is higher than for non-Hispanic Whites. Some of the violence is due to gang activity with the developmental needs of adolescents for peer acceptance and social support, especially among marginalized immigrant youth. Gangs provide feelings of community acceptance and belonging. More research is needed to address violence prevention that is culturally tailored and developmentally appropriate to the immigrant adolescent subgroups of the USA.

Substance abuse increases with acculturation. Hispanic adolescents who are more highly acculturated to American culture report increased substance abuse with some variation by country of origin. In general, high-risk behaviors have been found to increase for each generation for adolescents with origins from Mexico, Cuba, Central and South America, China, the Philippines, and Canada with findings inconclusive. More research is needed to examine the association between acculturation and high-risk behaviors of adolescents including the identification of cultural factors that could protect immigrant teens from such behaviors over time.

Child Health Care Access

Shalini G. Forbis
Division of General & Community Pediatrics,
Department of Pediatrics, Wright State University
Boonshoft School of Medicine, Dayton, OH, USA

Access to health care remains a critical issue for underserved children, particularly for children from immigrant families. The causes of decreased access to health care differ for immigrant children. Recent studies indicate that one in five children in the United States live in immigrant families. The immigration status of these children varies widely. Some of these children are immigrants themselves and were born abroad and others are US citizens themselves (the majority). Immigration status factors play a role in their access to health care. In addition, immigrant children have differing demographic profiles from other minority children. For instance, they are more likely to come from settings with married parents and more likely to live in a multigenerational family. Because of differing immigration status of children from immigrant families, their barriers to access to health care vary. The specific areas within access to health care include health insurance coverage and then ability to access that care, particularly primary care, dental care, and vaccinations.

Insurance coverage remains a critical issue for immigrant children in the United States. There have been gains in coverage in the past two decades with rates of un-insurance dropping from 19% to 15% by the mid-2000s. One third of all uninsured children in the United States are from immigrant families. This phenomenon has been seen both for children in families where all members are citizens as well as for children who are citizens with noncitizen parents. However, for children who are immigrants themselves and live in immigrant families the gap is widening, with levels of uninsured children rising from 44% to 48%. Under federal law, the Personal Responsibility and Work Opportunity Act of 1996, all legal immigrants (including children) are barred from Medicaid or SCHIP coverage during their first 5 years in the country. As of 2007, 22 states cover legal immigrants during this 5-year period utilizing state funds. However, there is significant variability as to what benefits are available from state to state.

In addition to access to insurance coverage, immigrant children experience other issues related to access to health care. In one national study, >25% of noncitizen children did not have a usual source of health care as compared to 18% of citizen children in noncitizen families and 6% for US children in citizen families. This is well short of the Healthy People 2010 objective of 97% of all children having a usual source of care. Half of these noncitizen children had not seen a doctor or dentist in the past year. Despite the lack of primary care, these children are also less likely to be seen in the emergency department. However, there is a study that determined that when immigrant children are seen in the emergency department, they have higher medical expenditures. This may be due to families seeking medical care at later stages of illness due to lack of primary care access.

Another access issue that is well documented in the medical literature is access to immunizations. Healthy People 2010 set goals of: (a) 90% up-to-date for individual vaccines and (b) children are 80% up-to-date with the series 4DTP/DTaP (diphtheria, tetanus, whooping cough/pertussis), 3 IPV (inactivated polio vaccine), 1 MMR (measles, mumps, and rubella), 3 Hib (Hemophilus meningitis), 3 HBV (hepatitis b), 1 Prevnar (pneumococcal meningitis) (4:3:1:3:3:1) by 36 months of age. However, noncitizen children are less likely to be adequately immunized and have demonstrated decreased rates of vaccination for hepatitis B and *Haemophilus influenzae* type b. This decreased immunization rates may be a consequence of a lack of primary care and can lead to increased risk of developing serious illnesses including meningitis hepatitis B.

Another significant barrier for many immigrant families is related to communication. Immigrant children with insurance coverage are still less likely to receive medical care than their insured nonimmigrant counterparts. Language barriers may play a significant role in this, particularly for recent immigrant families. Studies of Latino families demonstrate that language barriers play a significant role in creating a barrier to accessing care for their children. These families face many barriers when encountering the health care system. These barriers start with the first encounter which typically involves (depending on their level of English proficiency) scheduling appointments. This will require an interaction with a receptionist to discuss the nature of the appointment and potential times. During a visit, a parent may have to fill out paperwork, sign consent-to-treat forms, provide medical information to multiple providers, receive health education and complete billing information. Depending on the setting and location, there may be bilingual staff; if not, there are a variety of methods for approaching families with limited English proficiency. For hospital-based settings, there may be availability of medical translators or of calling a translator service and utilizing a two head set phone with the health care provider, parent, and then a translator on the other end of the call. In community-based settings where translation services are not readily available and may be prohibitively expensive, providers will often utilize informal services of family members of the patient (sometimes older siblings) or staff who may have limited experience with the language. Lack of consistent reimbursement for translation services is a barrier for these families as well as for health care providers to utilize trained medical translators.

In addition to the aforementioned barriers, immigrant families may perceive discrimination in the medical settings. This may be due to lack of language skills, or may be related to cultural differences. In addition, cultural differences may create misunderstandings. Finally, there may be concerns related to immigration status, particularly for undocumented families. These families may be concerned that their immigration status may be reported to immigration authorities and they may face such negative consequences as deportation.

Despite these documented barriers to access to health care, there are data to suggest that these children may be healthier than nonimmigrant children of similar socioeconomic status. This is known in the literature as the "health immigrant phenomenon or paradox". This has been demonstrated most consistently among Hispanic immigrants. One example of this phenomenon is that the prevalence of low birth weight is less common among immigrant Mexican-American women when compared to that of mothers who are US-born Mexican Americans (8% versus 12%). Some of this disparity is due to factors such as alcohol and tobacco use. Similar results have been demonstrated for infant mortality rates within the Black community. Children born to African women have decreased infant mortality rates when compared to African American women (10.5 versus 12.9 per 1,000 births). Analysis has demonstrated a clear role for immigrant status in this circumstance. Unfortunately, there is less research supporting a similar effect continuing into later childhood due to the difficulty of this research. Research for other immigrant groups is limited.

Children from immigrant families that may either be citizens or immigrant themselves face many barriers to accessing and receiving health care in the United States. These barriers may include lack of insurance coverage, access to needed and required immunizations, lack of primary care and dental care, and language barriers. Those who work with immigrant children should understand their individual state's benefits for immigrant children and assist with accessing insurance coverage as well as primary care. In addition, health care providers should be sensitive to the many barriers these families have when accessing and utilizing the health care system.

Child Labor

Marisa O. Ensor
Department of Anthropology, The University of Tennessee, Program on Disasters, Displacement and Human Rights, Center for the Study of Youth and Political Conflict, Knoxville, TN, USA

Child labor remains a widespread and persistent socio-economic reality for many young people around the world. United Nations Children's Fund (UNICEF) estimates that 158 million children aged 5–14 are engaged in child labor – one in six children worldwide. Children are involved in many different forms of work, and work relations between children and adults can vary from complete subordination to relative autonomy. The single biggest sector of child labor is in agriculture – where children either work on family farms or work, often part-time, on other local farms. There are also many child laborers who do domestic work or who work in the service sector, factories, or in office environments. Some forms of child labor are exploitative and abusive, either because they are inherently so, or because of the young age and immaturity of the child workers involved. These "worst forms of labor," as they have been termed by the International Labor Organization (ILO), include bonded labor; prostitution; child soldiering; or other extremely hazardous, unhealthy, or personally dehumanizing forms of work. While not all kinds of child work are necessarily harmful or incompatible with access to good-quality education – as often articulated by children themselves – age-related conditions may make children more susceptible than adults to certain work hazards and health and safety risks.

Working Children in Cultural Context

Work has traditionally been an integral feature of the lives of most of the world's children. Historical and cross-cultural comparisons of children's work show enormous variation in the nature and intensity of what children are expected to do, the contexts and relationships within which work is performed, and the social perception and valuation of children's work. Policy standpoints on the employment of children and young people are based, implicitly or explicitly, on models or theories of childhood. In turn, conceptualizations of childhood, and of acceptable forms of work for children at different ages and genders, are mediated by cultural and socioeconomic factors.

The idealized image of the emotionally priceless but economically useless child – the "sacred child syndrome" – of upper- and middle-class Western society rarely exemplifies the daily reality of children around the work. Even in the Global North, many children resent the prolonged dependence resulting from what they see as a questionable and unnecessary exclusion from socially relevant work. Children's work contribution often constitutes an essential part of a household survival strategy. For children in especially difficult circumstances such as in the aftermath of disasters, conflict, displacement, or economic crises, the prospect of gaining some control over their own lives and having access to an independent source of income can be both household-sustaining and self-affirming. On the other hand, these situations also create an increased potential for children to be compelled to engage in hazardous labor in an effort to ensure their own survival and that of their families. Their mental and physical health and well-being may be compromised as a result.

Health Issues of Child Labor

Children and adolescents have particular anatomical, physiological, and psychological characteristics associated with their stage of development that may make them more vulnerable to work-related hazards than adults. While scientific studies regarding young workers' susceptibility to the wide range of potential risks to which they may be exposed in their work places are not yet common, some conclusive evidence of a link between age and vulnerability is already available.

Some epidemiological studies suggest that children exhibit more severe lead toxicity at lower levels of exposure, and tend to absorb higher amounts of lead than adults do at the same level of exposure. They could also be more vulnerable to pesticide exposure (a particularly alarming finding, given that agriculture constitutes the single biggest sector of child labor), asbestos, and ionizing radiation. An endocrine system compromised before full adulthood may result in hormonal imbalances and cause negative effects on sexual maturation.

Young children breathe faster and more deeply and have a higher metabolic rate and oxygen consumption than adults. Their greater intake of air per unit of body weight results in an increased absorption of fumes, gases, air pollutants, and other potentially harmful particles often found in certain work environments.

Young workers are believed to be more susceptible than adults to hearing loss induced by exposure to high levels of noise pollution – as would be the case in work performed in certain industrial or other environments. Children also have lower heat tolerance and are thus subject to higher risk of heat stress at work. Other studies indicate higher rates of injury-related disability among young workers when compared to adults due to more frequent cases of musculoskeletal problems and accidents. Injuries to ligaments and growth plates are particularly dangerous in children and can result in a condition known as osteochondroses (localized bone tissue death), potentially leading to limbs of unequal length. Carpal tunnel syndrome, tendonitis, and long-term back strain are additional concerns.

Particular attention needs to be paid to the so-called "worst forms of child labor" which, by their very nature, are especially harmful to children, and categorically condemned by international labor and human rights instruments. Their negative consequences for children are often psychological in addition to physiological.

Worst Forms of Child Labor

The International Programme for the Elimination of Child Labour (IPEC) was created in 1992 to spearhead the International Labor Organization's (ILO) efforts against child labor. The primary policy instruments related to these efforts include the ILO Convention 138, the UN Convention on the Rights of the Child, and the ILO Convention 182. The link between child labor and health issues is clearly established in these provisions.

The ILO Convention 138, also known as the Minimum Age Convention, seeks to regulate the intensity of work (generally measured in hours) at various age thresholds. Article 1 of this Convention requires ratifying nations "to pursue a national policy designed to ensure the effective abolition of child labour and to raise progressively the minimum age for admission to employment or work to a level consistent with the fullest physical and mental development of young persons." While the Convention provides that "[n]ational laws or regulations may permit the employment or work of persons 13–15 years of age on light work which is not likely to be harmful to their health or development; and not such as to prejudice their attendance at school" (Article 7[1a and b]), a higher minimum age of 18 years is established for "work which by its nature or the circumstances in which it is carried out is likely to jeopardize the health, safety or morals of young persons" (Article 3[1]).

Taking a rights-based approach, the UN Convention on the Right of the Child (CRC) addresses child labor by recognizing "the right of the child to be protected from economic exploitation and from performing any work that is likely to be hazardous or to interfere with the child's education, or to be harmful to the child's health or physical, mental, spiritual, moral or social development" (Article 32[1]). The CRC further calls for children to be protected from a variety of exploitative activities including the use of children in trafficking of illicit drugs (Article 33); child sexual abuse and commercial sexual exploitation (Article 34); the abduction, sale, or trafficking of children (Article 35); and the use of children in armed conflicts (Article 38).

The ILO Convention 182, adopted at the International Labor Conference in June 1999, commits ratifying nations to "take immediate and effective measures to secure the prohibition and elimination of the worst forms of child labour as a matter of urgency" (Article 1). This Convention categorically condemns certain forms of child labor, which have come to known as "unconditional worst forms of child labor." These include the sale and trafficking of children; the use of children in forced and bonded labor; children in armed conflict; the commercial sexual exploitation of children in prostitution and pornography; and children in illicit activities such as drug trafficking.

While the ILO has the lead responsibility for regulating child labor issues, other UN agencies engaged in poverty reduction, education, and children's rights also have a key role to play in addressing the underlying factors that give rise to child labor. These include the United Nations Children's Fund (UNICEF), the United Nations Educational, Scientific, and Cultural Organization (UNESCO), and the World Health Organization (WHO). Further, although child labor does not appear explicitly in the Millennium Development Goals (MDGs), strong linkages between addressing child labor and fulfilling other goals are evident. These include poverty reduction (MDG 1); education for all (MDG 2); gender equality (MDG 3); combating HIV/AIDS (MDG 6); and a global partnership for development (MDG 8).

The important role played by nongovernmental organizations, trade unions, and child-advocacy and other organizations involved in activities concerning working children must also be recognized. Lack of coordination and disagreements among these organizations over the most appropriate objectives and strategies to pursue can, however, undermine their effectiveness. The major challenge in the coming years will be to better integrate child labor issues into the relevant frameworks at international and domestic levels. Measures to promote the physical and psychological recovery of children who have fallen victim of harmful forms of child labor must be an integral component of these efforts.

Conclusions

Child labor is a complex and multifaceted phenomenon requiring systematic attention to the socio-economic, cultural, and physical environment in which children live and work. While the institutional, legal, and human rights frameworks regulating child labor issues have been increasingly strengthened in recent decades, and some progress is already evident, child labor remains a concern of immense social and economic proportions. Millions of children are forced by necessity or circumstances to work too much at too young an age, or under particularly exploitative circumstances. In 2006, IPEC estimated that about 126 million children were engaged in various types of hazardous work worldwide. While there are encouraging trends in a number of nations – Brazil, Mexico, Turkey, and Vietnam, among others – child labor rates remain persistently high in much of the work. Although not enough is yet known about the links between age-related vulnerabilities and specific work hazards, it is clear that special health risks should be taken into consideration when prioritizing definitions of work appropriate for children and adolescents, and in enforcement of minimum-age regulations.

Child Rearing

Sarah Lytle
Department of Psychiatry, University Hospitals Case Medical Center, Cleveland, OH, USA

Child-rearing practices vary widely based on cultural beliefs, education, and economics. Immigration and acculturation can affect child-rearing abilities and practices as immigrant parents face unique challenges. These include, but are not limited to, poverty, unemployment, access to public health services, limited transportation, isolation, and incomplete command of the native language. One of the goals of many immigrant families is to provide a better life for their children, but immigration is often stressful for immigrant families and children. Studies have shown that circumstances associated with being an immigrant can undermine the parenting role. Immigrant parents may want to preserve their cultural identity and traditions and their children's awareness of their former country, but also want their children to assimilate into the new country.

Child rearing in infancy begins as people in contact with the child, typically a mother or mother-figure and family, interact with the newborn. The transition from being a woman to being a mother may be an isolating experience for some immigrant women. New immigrant parents often find that they have limited social support when it comes to caring for their new child and for themselves. Even in the hospital after delivery, some cultures ascribe to specialized diets after birth, which are generally not provided in western hospitals. The social isolation can be significantly different from what they would have experienced in their native country, as some cultures place an emphasis on the family and provide significant emotional and physical support to new mothers. Lack of this support and social isolation can lead to early struggles with anxiety and depression, which may have an adverse effect on parent–child interactions. Compounding this problem, lack of knowledge of resources as well as stigma associated with mental illness often inhibit people from seeking help.

As children enter the school system, child-rearing practices can affect the child's progress. Some cultures place a strong emphasis on education; however, the parent's ability to communicate with both the child and the school can affect how well the child is able to take advantage of educational opportunities. Immigrant parents may have limited access to information about their child's new environment and experiences. They may not understand the new educational system, may use their native countries education system as a model for the education of their children, or be unable to take full advantage of the new education system. The immigrant family may become more dependent on the school for the child's academic performance due to the language barrier or lack of understanding of the system. Studies indicate that in the United States, there are generally low rates of enrollment in early education programs, especially among low income families and those families with less formal education and/or command of the language. Sometimes immigrant parents are undocumented and may be wary of institutions like public schools for fear of deportation. At the same time, there may be pressure for the child to fulfill the parent's dreams which can place stress on the child.

Child rearing can be affected by traditional values of the parents and the new values being introduced by outside factors, like school. This dichotomy can lead to intrafamilial and intergenerational conflict. Studies indicate that children typically adjust more rapidly than their parents to the new country. This is referred to as the acculturation gap and has been found to be more pronounced in families where the parents are less educated. When this occurs, there may be some level of role reversal as the child's command of language surpasses that of the parent, and the child becomes responsible for communication with outside agencies like schools, banks, or grocery stores. While this role reversal can weaken boundaries and lead to children being less likely to listen to or obey their parents, it can also have a positive effect whereby the child feels that they are contributing to the family and helping out their parents.

Different parenting styles have been described in the literature. These include authoritarian, permissive, and authoritative. An authoritarian parent stresses control and obedience and places little emphasis on child autonomy. A permissive parent allows children to make their own decisions and regulate their own behavior. Authoritative parents emphasize limit setting through reasoning, verbal give and take, clear instructions, and positive reinforcement. Studies indicate that parenting at either end of the spectrum (authoritarian or permissive) may adversely affect the parent–child relationship. However, some studies have shown that if the parenting style is congruent with the sociocultural environment, then there is no negative impact. This can become an issue when the parenting style of the immigrant no longer matches that of the new culture. For example, the Chinese parenting style is traditionally authoritarian. Upon immigration to a more liberal society, conflict may arise as the child sees other children having fewer limitations. Cultural differences related to corporal punishment can also affect child rearing in immigrants. Corporal punishment may be a normal child-rearing practice in some cultures and immigrant families may not consider this child maltreatment or abuse. Additionally, native law enforcement may not reinforce immigrant parent rules, thereby undermining the parent's authority. One study showed that immigrant adolescents had higher levels of psychological disorders and lower connectedness to families, and another suggested that family cohesiveness decreased after immigration.

Data indicate that immigrants tend to have a lower income than natives. Children of legal immigrants often have hardships in the areas of food acquisition, housing, and health care, and a greater percentage of immigrant children than native children live in poor families. Financial stress may require both parents instead of one to work, which can mean there is less often a parent home to be involved in child rearing. Often, immigrants are employed at levels below their education level and may suffer from hostility from the natives. Highly educated individuals often suffer financial and occupational difficulties, especially within the first few years of immigrating. Lack of employment or employment below the parent's education level can affect parenting as the breadwinner suffers in his role as the primary provider. This can create a tense atmosphere in the home. Socioeconomic disadvantage may lead to marital dissatisfaction, conflict, and aggression, which can adversely affect children. Unemployment and poverty can lead to grief, guilt, isolation, increased alcohol intake, increased risk of mental health problems, and neglect or punishment of children.

While immigration status can have many adverse effects when it comes to employment and finances, there are some positive outcomes. Immigrant women who must work or choose to work may become more independent, and these women may take advantage of a broader range of child care options and work opportunities than they may have had in their native country. Immigrant mothers may gain more decision making control and have multiple roles compared to their native country. Additionally, in one study, fathers reported immigration allowed them to spend more time with their children (because they were working less).

In addition to education and financial issues, certain countries may require detention of asylum seekers that do not have visas. Parents and their children can be held for months to years and may not have access to adequate physical and mental health services, education, housing, and hygiene. In addition, they may be exposed to violence and/or abuse. Adult asylum seekers have been shown to have high levels of anxiety, depression (including suicidal thoughts/intent), and posttraumatic stress disorder (PTSD), and this may affect their ability to care for their children. The children of such parents have been found to suffer behavioral regression, depression, anxiety, and suicidal thoughts.

Another event which may significantly affect child rearing in immigrant populations is raids on and/or deportation of illegal immigrants. One or both parents may be separated from their children for a period of time. While there may be a heavy reliance on extended family networks, children may be left to fend for themselves or other small children. Removal of the breadwinner can lead to decreased income (less access to food, etc.) and a more unstable home environment. It can also mean that the remaining parent must work, thereby altering the family dynamics as children are left without a parent at home. The loss of a parent or both parents can be difficult to explain to children and require adaptation to single parent families and stress associated with separation and finances.

While immigrant parents face many challenges, studies have shown that many immigrants and their families may stay away from public assistance and health services due to uncertainty. Some countries have implemented programs to aid immigrants with transition and parenting. Research indicates that programs like Strengthening of Intergenerational/Intercultural Ties in Immigrant Chinese American Families (SITICAF) tested in California, USA, which are family-based mental health programs, can be effective in reestablishing family connectedness and understanding. Canada and other countries offer educational programs for immigrants and their families on parenting and child development (for example, the Calgary Immigrant Aid Society) as well as offering family literacy programs. There remains room to make improvements to address and improve social isolation, transportation, employment, child care, partnership equality, and shared responsibility with family, neighbors, friends, and community.

Childhood Injuries

Elizabeth M. Valencia
Radiology Department, St. Joseph's Hospital & Medical Center, Phoenix, AZ, USA

Nonintentional childhood injuries are the leading cause of death and disability in children worldwide, responsible for 950,000 deaths, and of these 90% are preventable. In the USA, for every child injury death there are 34 children hospitalized and 1,000 children treated in the emergency department. Moreover, the health care burden attributed to non-intentional childhood injuries is nearly $300 billion each year, accounting for 15% of total medical spending for children between ages 1 and 19 in the USA. Efforts to decrease the morbidity and mortality led to an unprecedented World Health Organization Summit for Child Injury Prevention in 2005, which urged prevention and increased public awareness. While fire-related burns, falls, and poisonings are frequent causes, road traffic injuries and drowning are the source of more than 50% of childhood injuries. A brief synopsis of the injuries comprising this global public health epidemic is provided.

An estimated 720 children die daily, while ten million children are either disabled or suffer permanent disability due to child road traffic injuries each year. The main cause of death in children between the ages of 10 and 19 is road traffic injuries, which accounts for 22% of total unintentional childhood fatalities. Children are at increased risk because they share the roadway as pedestrians, bicyclists, and as passengers in cars. Immigrant children are at increased risk of pedestrian injuries in part due to cultural differences regarding roadway safety. Cross-walk improvements, bike path expansions, and neighborhood education on child roadway safety has helped reduce child pedestrian injuries. Other childhood injuries are due to inappropriate use of a car seat, or failure to wear a seatbelt or helmet. Improper installation of car seats results in high fatalities in children under the age of 8; however, appropriate car seat safety use can reduce fatalities by 71% in infants and 54% in toddlers. In addition, the overwhelming majority of bicycle fatalities involve non-helmeted riders, with nearly 47% of nonfatal hospitalized injuries resulting in traumatic brain injury. The use of helmets can reduce fatalities by 75% and head injuries by 85%. Also, globally, teenagers between the ages of 15 and 19 are at even greater risk for road traffic injuries because of increased propensity to speed, drive under the influence, failure to wear a seatbelt, and engage in other risky driving behavior.

Every day 480 children die as a result of drowning and near-drowning injuries result in serious neurological damage worldwide. Drowning is the leading cause of death in children under the age of 5 and accounts for 17% of total non-intentional childhood fatalities. In addition, there is a higher incidence of drowning among immigrant children secondary to lower rates of swimming proficiency among children and adults. Drowning can occur quickly within a few minutes and in as little as a few centimeters of water with infants. Overall, children are vulnerable to these injuries because our daily environment involves direct contact with water sources for essentials such as drinking, bathing, cooling, and water recreational activities. Bathtubs, buckets, toilets, swimming pools, and open water sites are common locations for drowning or near drowning. The bathtub accounts for more than 50% of all infant drownings under the age of 1. Further in the USA, 30 infants drown each year in buckets containing water for household chores. Meanwhile, children over the age of 4 are more susceptible to swimming pools and open water sites, with 300 pool drownings in the USA annually. Fenced pool enclosures can reduce child drowning and near drownings by up to 50%. In comparison, teenagers often succumb to water-craft-related drowning, often due to failure to wear a personal floatation device, which can reduce child drowning by 85%. Prevention strategies shown to reduce child drowning fatalities and near-drowning injuries include: child supervision near or in water, drainage of all unnecessary water accumulations, four-sided fenced pool enclosures, and use of a personal flotation devices at all times with all water-craft activities.

Similarly, 262 children die each day and 96,000 die yearly from unintentional burns worldwide. Each day in the USA there are 435 child burn injuries evaluated in the emergency department and there are two deaths. Further, the mortality associated with burns is 11 times greater in low- to mid-income countries compared to high-income countries. Daily interaction with heating, lightening, and cooking increases the likelihood of burns. For instance, the increased incidence of unintentional burns among immigrant children was often associated with food preparation. Burns are typically caused by scalding water or steam, electrical or chemical burns, and fires. Although scalds from tap water or steam constitute 75% of burns in young children, infants are at greatest risk of death due to smoke inhalation. Further, electrical burns from appliances or outlets cause 33% of burns in children under the age of 12 and residential fires cause the majority of child burn fatalities under the age of 9. Extensive rehabilitation and treatment are usually required for significant nonfatal burns. Prevention includes child supervision, child-proof lighters, anti-scalding faucet heads, lowering residential water heaters to 120°, and installation of smoke detectors on each residential floor. Specifically, fatalities can be reduced up to 82% with appropriate installed smoke detectors.

Child fall injuries are the fourth leading cause of death among children, with 130 deaths each day and 47,000 deaths per year worldwide. Moreover for every death, 690 children will miss school due to a fall injury. In the USA, on average there are 8,000 emergency room evaluations daily because of child fall injuries. Approximately 80% of fall injuries occur at home and 66% are falls from height. Meanwhile, among immigrant children, fall injuries are increased in the agricultural setting. Overall, children are susceptible to falls due to unrefined motor skills, their general inquisitive nature, and increased level of physical activity. Infants sustain most injuries from nursery furniture and baby walkers, while playground and window falls account for the majority of older children's injuries. In particular, playground falls result in 200,000 annual emergency room evaluations and 75% are due to head injuries. Prevention can reduce fall fatalities and injuries, with installation of window guards on multilevel floors, roof railings, safer play equipment with appropriate surface material, and other safe product modifications such as safety glass.

Child poisoning injuries account for 123 deaths each day and 45,000 deaths each year worldwide. In the USA, child poisoning accounts for 374 emergency room evaluations and two fatalities each day. Additionally, millions of calls are made to the poison control center each year. Children are vulnerable to poisoning because their physiology is less well developed which increases risk of toxicity. Ninety percent of poisoning fatalities and injuries occur in a child's residence due to household products and medications. The most common causes of poisoning are over the counter medications, prescription medications, household products, and pesticides. Meanwhile, 890,000 children suffer from lead poisoning, which delays growth and development, while carbon monoxide poisoning affects 3,500 children every year often due to improperly ventilated space heaters. Specifically, immigrant children are at increased risk of lead poisoning likely secondary to lead exposure from toys, pottery, jewelry, cosmetics, or herbal remedies from foreign countries. Prevention of child poisoning fatalities and injuries involves: storing medications out of the reach of children, having access to poison control center contact information, carbon monoxide detectors, undergoing health screenings for lead poisoning, and providing child education.

In conclusion, childhood injury is a health epidemic that results in significant loss of life. The *Report on Child Injury Prevention*, by the World Health Organization provides a comprehensive approach on reduction of child road traffic injuries, drownings, burns, falls, and poisonings. Together, prevention and public education can save an estimated 1,000 children from childhood injury each day.

Chinatown

Doug Brugge
Department of Public Health and Community
Medicine, Tufts University School of Medicine,
Boston, MA, USA

Chinatowns exist in many cities throughout the world, including Asian countries outside of China. They are usually urban and densely developed. Chinatowns serve as a cultural and commercial center for Chinese populations who have immigrated into predominantly non-Chinese areas. There are Chinatowns in Nagasaki, Japan; Bangkok, Thailand; Honolulu, Hawaii, as well as in Australia and Europe. In North America, Chinatowns can be found in Victoria, British Columbia and Toronto, and in the USA in San Francisco, New York, Chicago, Houston, Boston, Philadelphia, and elsewhere.

Because they serve as ethnic "hubs" that speak the language and provide food and goods that Chinese immigrants seek, the Chinatown community may be considered broader than simply the people who live there. It may also include the many Chinese (and others) who work and come to Chinatown to shop, eat, and visit. Thus, the community may be larger than the resident population. Also, the resident population in many Chinatowns has shifted over time. As the urban territory that they occupy may become prime real estate, pressures of gentrification and development may dislocate lower-income, working-class residents.

The health issues associated with Chinatowns arise primarily from the living and working conditions of residents and workers and infectious diseases that are prevalent in Chinese populations. However, it is critical to note that there has been too little investigation to date on health of Chinatown community members and there is a risk of overlooking health problems simply because they have not been documented.

A good example is asthma, which was largely not examined among Chinese immigrants to the USA until recently. When asthma was examined, Chinese children were found to have a substantial prevalence of asthma – above national averages. A specific event that may have affected respiratory health of Chinese immigrants was the 9/11 attack on the World Trade Center buildings in New York City.

Hepatitis B is endemic in China and, therefore, also a common condition in Chinese immigrant populations, including those in Chinatowns. Hepatitis B is transmitted via blood and body fluids, but in the Chinese context much of transmission may be from mother to child during birth or between family members. Because it is widespread in the Chinese community, there have been efforts to educate members about the disease and encourage screening and vaccinations. A consequence of high hepatitis prevalence is high liver cancer rates. Another infectious disease of particular relevance to Chinatowns and Chinese immigrants is tuberculosis.

Smoking prevalence is high among Chinese immigrant men, but very low among Chinese immigrant women. This is a pattern similar to many other Asian populations. Beyond the direct impact of smoking on the health of the smoker, who is at increased risk for cardiovascular disease, lung and other cancers, chronic obstructive pulmonary disease and other illnesses, second-hand smoke exposure poses a significant risk to wives (or other family members). Lung cancers among Chinese immigrant women are a notable outcome of this exposure.

The environment and context of the Chinatown itself may also be important to consider. While there has been limited research in this area, there are some indications of health impacts arising out of the built environment. Many Chinatowns have heavily traveled streets and some have adjacent highways. Thus, exposure to air pollution from motor vehicles is a potential concern that may merit further attention. Local "hot spots" of air pollution have been shown to exist near high traffic density locations. These pollutants are known to be associated with cardiovascular disease, lung cancer, and other illnesses. In addition to air pollution, traffic generates sound, perceived as noise by many, that is linked to a variety of adverse physiological outcomes, possibly through producing stress.

Stress may be an important exposure in Chinatowns. Besides traffic noise, there are other urban sources of sound. In Chinatowns that experience major construction projects, for example, there is considerable noise and vibration associated with these projects (and air pollution releases as well). In addition, crime, walkability (including pedestrian safety), and onerous work schedules in low-paying and often unpleasant or hazardous jobs add to stress. This may be an area deserving greater attention in future research efforts.

Traffic is also associated with motor vehicle–related injuries. A study conducted in Boston's Chinatown found that both in-vehicle and pedestrian injuries were associated with times of days and days of the week and with particularly complex (confusing) intersections. While many victims were Chinese residents, the drivers were mostly from outside the community. Cross times at signals were too short for the large elderly population to cross on the green light.

Crime, including violent crime and fear of crime, are common to many urban settings, but Chinatowns have been both subjected to stereotypes about being dangerous (mysterious) places and, because of their location in urban centers and near sources of crime, actually subjected to high crime rates. Again, crime produces stress that has health consequences, but crime also is directly harmful to health. For example, violent crime can lead to injuries, and drug use and prostitution spread infectious diseases.

Housing is another critical issue in Chinatowns. Quality, quantity, and affordability are concerns. Overcrowding is, as it is with many low-income communities, immigrant or not, a significant factor. Overcrowding is, of course, driven by housing costs and ability to pay so low-income immigrants, including those in Chinatowns, are at risk. Overcrowding, besides being stressful, also may increase the risk of transmitting communicable diseases and create conditions that attract pests. Pests and water damage, leading to mold growth, are also examples of deterioration of housing conditions that could put sensitive individuals, persons with specific allergies, for example, at risk of aggravation of underlying conditions such as asthma.

Working conditions in Chinatowns are also likely contributors to adverse health outcomes. While there has been far too little attention to the risks faced by low-income Chinese immigrant workers, recently, studies have begun to probe into this area. It is clear that many of the jobs these workers do, restaurant and construction work, for example, carry high risks. And it is likely that working long and unconventional hours increases health risks in this population, as it does in others.

Thus, Chinatowns have a mix of associated health concerns that are distinctive, but have not yet been fully elucidated. The lack of firm data creates a particular risk of misjudging the most salient health concerns in these communities. Many visitors are tourists looking for food or trinkets, who do not even realize that Chinatown is home to many people. There deserves to be more research to clarify which health concerns are most critical and how to address them.

Chinese

Rowena Fong, Albert Yeung
School of Social Work, The University of Texas at Austin, Austin, TX, USA

Introduction

About 15.2 million, or approximately 5%, of the population in the United States are of Asian descent, a number that is expected to grow to 20 million by the year 2020. Among the many diverse subgroups that make up the Asian American population, Chinese Americans represent the largest number (3.54 million), followed by Filipinos (3.05 million), Asian Indians (2.77 million), Vietnamese (1.64 million), Koreans (1.56 million), and Japanese (1.22 million). Chinese is also the second most widely spoken non-English language in the United States after Spanish. Eighty percent of the population of Chinese Americans are concentrated across five states – California, New York, Hawaii, Texas, and New Jersey – with California being the most populous, accounting for 40% alone. Within the Chinese American population, (non-native) immigrants make up 47%.

It is also important to distinguish the various subgroups that make up the Chinese immigrant population. These subgroups are largely formed around cultural and language differences based on their country of origin or regional location. Chinese immigrants from mainland China speak Mandarin; individuals from Taiwan speak Taiwanese and identify themselves differently from Mandarin-speaking Chinese; and Cantonese-speaking Chinese from Hong Kong and southern China share a regional ethnic identification (Guangdong). Chinese immigrants coming from other Southeast Asian countries may distinguish themselves based on their country of origin (in many cases Vietnam).

Health Status

In terms of life expectancy, Asian Americans have the highest life expectancy (85.8 years) of any other ethnic group in the United States, with Chinese American women having the highest life expectancy (86.1 years) within the Asian subgroups. Although there is a paucity of specific health status data on Chinese Americans, the Office of Minority Health, as well as other research studies, indicates that Asian Americans as a whole have lower risks for death and disease compared to Whites and other non-Asian minorities. Elderly Asian Americans also have disproportionately lower mortality rates compared to their White counterparts.

There is variability in health status within Asian subgroups with Chinese Americans ranking high in many categories compared to other Asian subgroups. Chinese were most likely to be within a healthy weight range; the least likely to be obese after Koreans; and 11% less likely than other minorities to be poor, although within Asian subgroups Chinese adults were more than twice as likely as Filipinos to be poor. Other health findings for Chinese Americans taken from the 2001 Health Care Quality Survey found that Chinese Americans were least likely among Asian subgroups to rate their health as fair or poor (11%) compared to 40% for Vietnamese and 29% for Koreans. Notwithstanding, there is also evidence of poorer health status in Chinese immigrants of lower socioeconomic status and those living in poverty. Trends in research data also indicate differences in disease incidence rates based on factors such as immigration status and acculturation. Findings show that foreign-born immigrants have better health status compared to their US-born counterparts; however, the differences in health status between groups diminish with increased years of residence, suggesting the influence of factors related to a Western lifestyle and environment.

Health Risk Patterns

While overall health statistics are generally higher among Asian Americans in general, the Office of Minority Health points out that the highest risks for Asian Americans are for heart disease, cancer, diabetes, stroke, and unintentional injuries (accidents).

Cardiovascular Disease and Stroke

Cardiovascular disease is the leading cause of death for Asian Americans as well as Chinese Americans in the United States, accounting for 28% of total deaths. However, there is a lack of studies specifically examining cardiovascular disease prevalence and risk among Chinese Americans. In China, the statistic is even more startling; mortality rates related to cardiovascular death accounts for over 40% of total mortality. In China, it has been found that the incidence of stokes were higher in China than in Western countries. Among Asian Americans, 6.9% have heart disease, 4.3% have coronary heart disease, 19.5% have hypertension, and 2.6% have had a stroke.

With respect to hypertension, which is strongly related to coronary and cardiovascular health, data from the Multi-Ethnic Study of Atherosclerosis (MESA) found that, among Chinese participants, the prevalence of hypertension is higher than among their White counterparts after controlling for age, body mass index, smoking, and prevalence of diabetes mellitus. However, it has also been found that being born outside the United States, speaking a language other than English at home, and living fewer years in the United States were associated with a decreased prevalence of hypertension. Research also reports that Chinese (17%) or Korean (17%) adults are less likely than Filipino (27%) and Japanese (25%) adults to have ever been told that they had hypertension.

Cancer

Health research has shown that Asian Americans generally present the lowest incidence of cancer compared to non-Hispanic Whites. Research looking at age-adjusted cancer incidence and mortality rates of Asians residing in California from 1997 to 2001 showed that Chinese presented the lowest incidence rates for all types of cancers studied. Other research findings on cancer incidence and mortality rates among five Asian subgroups in California found that Chinese Americans present the lowest rates of all cancers combined compared to Korean, Filipino, Vietnamese, and Japanese ethnicities.

While some data shows that Chinese Americans have some of the lowest, age-adjusted incidence and mortality rates for all types of cancer as a whole, other studies show that Chinese Americans are at increased risk for cancers of the colon and lung, and have the greatest risk for cancers of the liver. Incidence patterns for liver cancer in Chinese Americans are associated with Hepatitis B, although liver cancers in Whites are associated with alcohol. Incidence rates for cancers of the colon, liver, and lung were high in Chinese Americans compared to the other Asian subgroups. In particular, Chinese women were found to have the highest lung cancer incidence and mortality rates of all the Asian ethnic subgroups in California; Chinese men had liver cancer incidence and mortality rates more than twice as high as in Japanese men. Also, Chinese men have the third highest incidence and mortality rate for colorectal cancer among the Asian ethnic subgroups.

These findings are consistent with other reports investigating the incidence of prostate cancer in men across 15 countries; Chinese men have the lowest incidence rates which contrast with Black men in the United States who have mortality rates 12 times higher than Chinese men in Hong Kong. These findings offer additional support for research findings, which identify China as having the highest death rates for liver cancer compared to 50 other countries. China ranked high in death rates associated with cancers of the esophagus and stomach; conversely, death rates for prostate and breast cancers ranked the lowest among the 50 countries.

Sharp differences exist in incidence and mortality rates for certain types of cancers for Chinese living in the United States compared to Chinese living in Asia. Cancers of the colon, breast, and prostate all show higher rates in Chinese American immigrants living in the United States compared to those living in China. Such contrasts in incidence rates imply possible risk factors associated with a Western lifestyle or environment.

Diabetes

Data based on Family Core and the Sample Adult Core components of the 2004–2006 National Health

Interview Survey found a prevalence of diabetes among Chinese to be 6%. Worldwide incidence rates of insulin dependent diabetes mellitus (Type 1) show that China has the lowest rates of Type 1 diabetes compared to 100 other populations in both adults and children. However, despite the very low rates of diabetes in China, the World Health Organization predicts a two- to threefold increase in prevalence rates of diabetes within the next few decades.

Tobacco

Tobacco use behaviors from the National Center for Health Statistics indicate that most Asians report never having smoked; Chinese American adults are most likely to have reported not smoking (84%) compared to Korean adults (65%). Among Asian smokers, Korean adults (22%) were two to three times as likely to be current smokers as were Japanese (12%), Asian Indian (7%), or Chinese (7%) adults. Another study noted similar findings where Chinese Americans reported lower rates of current smoking behavior compared to Whites, as well as other Asian subgroups except Japanese. Among Asians generally and Chinese in particular, smoking is largely associated with males than females. However, smoking behavior also varies based on acculturation. Research looking at four Asian subgroups finds that more acculturated youth and less acculturated male adults have higher smoking rates. For females, the opposite is true – smoking behavior is more highly associated with greater acculturation. Also, smoking behavior was associated with low education, use of non-Western physician or clinic, lack of knowledge of cancer and health risks, and being foreign born rather than US born.

Health-Seeking Behaviors

Health-seeking behaviors of Chinese immigrants are a complex process that is influenced by demographic, financial, and cultural barriers. Generally speaking, health-seeking behaviors are heavily influenced by degree of acculturation. The more highly acculturated the Chinese immigrants are, the more positive attitudes they have toward healthcare services and higher levels of actual service utilization. Chinese immigrants also suffer disproportionately from a lack of knowledge of health issues and awareness that symptoms are signs of a health problem. For instance, research looking at cardiovascular health and disease awareness among Chinese immigrants finds low awareness of warning symptoms of heart attack and stroke and what to do in response in a hypothetical situation.

The process of health seeking involves acknowledging that symptoms are severe enough to seek treatment. In terms of symptom severity, Chinese immigrants often delay accessing formal healthcare services in lieu of home remedies and traditional forms of medicine. When Chinese immigrants do access formal healthcare services, they often present with more severe symptoms when other more culturally acceptable forms of treatment have been exhausted. For most Chinese people, this pathway to accessing Western healthcare treatment is rooted in the desire to keep problems and issues secret within the family.

Chinese cultural values and norms influence the perception and interpretation of physical symptoms as well. As opposed to interpreting physical symptoms as a health or mental health problem, individuals may perceive their problem as a spiritual condition or as a personal weakness or deficiency to be overcome. Moreover, Chinese culture imparts a tendency to minimize individual suffering and avoid dwelling on negative conditions; instead, willpower and personal determination are encouraged which may negatively impact their health-seeking behaviors.

Healthcare Service Delivery

Decades of research have reinforced common themes associated with healthcare service delivery for Asian minority populations. Persistent patterns of underutilization of healthcare service among Chinese immigrants are related to a lack of understanding in navigating the healthcare system, an inability to communicate effectively, and factors related to costs of healthcare and perceived benefits. Chinese families also have a tradition of utilizing family networks first to keep private concerns within the family. Underutilization of services by Chinese immigrants is strongly influenced by the stigma and shame associated with physical and mental illnesses. The association of illnesses with individual character flaws and personal weakness is still strong in immigrant Chinese communities, and the fear of shame and of “losing face” within the Chinese community keeps many families from seeking external social services.

Another problem is the issue of racial discrimination and stereotypes of the Asian "model minority." Perceptions of Chinese immigrants are shaped by the model minority myth which reinforces the notion that Asians as a whole have higher socioeconomic status, educational achievement, more stable families, and lower crime rates. This type of stereotyping ignores the heterogeneity within the various ethnic subgroups within the Asian population. It fails to recognize the bifurcation within the Asian population, polarized at the ends of the spectrum by those well educated, affluent, and upwardly mobile and by those uneducated, less acculturated, and of lower socioeconomic status. Thus, this misappropriated label applied to Asians serves to obfuscate the problems and needs that many Chinese immigrants and other Asian minorities face; and while population-level indicators may point to the overall success of Asians, it fails to call attention to the needs of many Asians living in the United States. In addition, research on the experiences of racial discrimination by Asian Americans found it to be associated with chronic health conditions such as heart disease, pain, and respiratory illness.

Barriers to Healthcare Utilization

The research evidence on the barriers to healthcare utilization among Chinese Americans is well established. Access to healthcare is influenced by the nature in which services are delivered. Often healthcare facilities are not located near areas populated by Chinese immigrants. Immigrants of lower socioeconomic status may also lack access to transportation to access services. Low awareness of health issues and inadequate availability of healthcare services persists in Chinese immigrant communities due to limited access to health information presented in their native languages.

Cultural and social contexts also shape the way Chinese immigrants conceptualize their health, health problems, and utilization of healthcare services. An example of this can be seen by the manner in which many Chinese immigrants may conceptualize mental health problems as physical ailments caused by organic factors and describe their condition as such. This leads many individuals with mental health problems to present to healthcare providers in primary care settings. Also, the Chinese language does not have equivalent terms to describe some mental health terms like depression, so patients may use Chinese idioms and metaphors to describe their physical condition. Thus, the somatization of mental health problems, compounded by a lack of common terms used to describe mental health conditions, often results in misdiagnoses and ineffective treatments.

The role of language poses a major barrier in the overall quality of healthcare service delivery for Chinese immigrants. After English and Spanish, Chinese is the most common language spoken in homes in the United States. However, the absence of professional translators in healthcare settings exposes significant gaps in cultural competency with respect to the language barriers. This may cause Chinese patients to experience feelings of greater disconnect, suspicion of treatment and of their healthcare providers, and decreased levels of overall satisfaction with services. This is particularly true when there is also a practice of ad hoc use of translators and because there are different dialects of Chinese. Using the correct dialect is critical because speakers of one dialect usually will not understand another.

Barriers to healthcare utilization among Chinese-Americans are also created by the cost of insurance and healthcare. While Chinese Americans have been shown to have better overall health compared to non-Asian ethnic groups, they are also less likely to have healthcare insurance compared to Whites. With the perceived high cost of individual health insurance plans, many Chinese immigrants who work in smaller, family owned business, such as restaurants, grocery stores, etc., who do not have access to more affordable, employee-sponsored insurance plans opt to go without health insurance coverage or utilize public insurance if they qualify.

There needs to be more training and development of Chinese-speaking medical interpreters along with the promotion of greater diversity in healthcare staff. Ethnic matching and language matching in health treatments would facilitate trust building and might improve the utilization of services. Support for the development of community-based healthcare clinics to increase access would be helpful as well as the development of language-specific health promotion literature to be distributed among the Chinese populations in the United States to encourage them to get help for their health problems.

Chinese Exclusion Act of 1882 (U.S.)

Andrew Leong
College of Public and Community Service, University of Massachusetts/Boston, Boston, MA, USA

The Chinese Exclusion Act of 1882 (hereinafter "the Act") is considered as the first and only federal piece of legislation that prohibited a specific race, nationality, and ethnicity from entering the USA. Signed by President Chester A. Arthur on May 8, 1882, the Act excluded Chinese unskilled and skilled laborers from entry into the USA. Originally lasting a 10-year period, the Act was extended by the Geary Act in 1892, and thereafter extended indefinitely. The Act served as a starting point for the exclusion of citizens of other Asian countries from immigrating to the USA. Through a combination of other Asian exclusionary acts such as the Gentlemen's Agreement of 1907, Immigration Act of 1917, the National Origins Quota of 1924, and the Tydings-McDuffie Act of 1934, the legacy of the Chinese Exclusion Act of 1882 extended well beyond 1943, when the Act was finally repealed in a propaganda struggle against the Japanese during World War II.

The impact of the passage of the Act was felt immediately as Chinese immigrants who were considered laborers were categorically excluded. There was also ongoing litigation as to the re-entry rights for immigrants who were residing in the USA but were out of the country at the time of the passage of the Act. The trickle of immigrants entering thereafter consisted of merchants and students. The ultimate impact of the Act and its legacy Acts was the halting of Asian immigration. No other racial group has been singled out in such a systematic and blatant way for immigration purposes in US history. Though repealed in 1943, the ban on Chinese immigration and restrictions on immigration from other Asian countries continued for all practical purposes because the annual allotted immigration quota was so small (e.g., China 105/year) in comparison with huge quota for European countries (e.g., Germany 25,814). Not until 1965 was the institutionally racist "national origins quota" formula abandoned in favor of an immigration quota system that allocated an equal number for countries in the eastern hemisphere. The 1965 Act did not, however, cure the decades of Asian exclusion. Therefore, shortly thereafter a huge backlog of immigration applications existed for those countries that had been racially excluded. This is why the Asian Pacific Islander population is such a low percentage in the overall US population. For those Chinese and other Asians fortunate to be in the country prior to the passage of the Act, they were not allowed to become naturalized US citizens since the 1790 Naturalization Act had limited naturalization only to "free white persons." Even when people of African descent were allowed to become citizens of the USA through the passage of the 14th Amendment to the US Constitution in 1868, the ban continued against Asians. This ban was not lifted country by country until the 1940s and up to 1952, when the ban was removed finally for all Asian nationalities.

Although not nearly as infamous, the passage of the Page Act of 1875 did more to negatively impact the healthy development of family life and social formation in the Chinese community than other legislation. The Page Act was a federal law that prohibited the entry of Chinese, Japanese, and Mongolian contract laborers, and women for the purpose of prostitution, and felons. The section regulating the prohibition of prostitutes was applied against Asian women through a general assumption that Asian women were prostitutes attempting to enter the USA for immoral purposes unless they could prove otherwise. Whether it was cultural beliefs that women needed to stay behind in the home country to care for children and elders, or the enormous travel expenses, or the increasing anti-Asian hysteria, men were the primary immigrants in the nineteenth century. The many exorbitant fees levied upon each Chinese immigrant in the state of California alone became prohibitive to one working and living in the state, no less attempting to have a family life in the USA. With a huge disparity in the gender gap, these conditions became ripe for the prostitution industry. Such were the precursors to the passage of the Page Act. Health reasons were cited particularly for the regulation of Chinese brothels and eventually justifying passage of Asian exclusion Acts since Chinese prostitutes were looked upon as spreading venereal diseases and other germs amongst the White male population. The implementation of the Page Act greatly restricted the entry of Asian women into the USA. According to US Census data, the percentage of Chinese females in 1870 was 7.2% of the total Chinese population. By 1890 the figure dropped to 3.6%. The unavailability of Chinese women and thus potential mates served as a major impediment to the establishment of Chinese communities and a healthy family life. Many Chinese males working and living in the USA would travel back to China to get married, and possibly father a child but never or rarely have the occasion to see their family members due to restrictions on the exclusion Acts. Other Chinese males attempted to have family life in the USA but were forbidden from marrying White women due to various state anti-miscegenation laws as well as the federal Cable Act of 1922 (which had the effect of revoking the US citizenship status of any female who married an Asian man).

The Chinese Exclusion Act should not be considered only as a single piece of legislation, but as a culmination of a national anti-Asian movement and "Yellow Peril" xenophobia that started in the West Coast through a series of California state legislation that attempted to prevent and discourage Chinese immigration and democratic participation in everyday life. In California, there were head taxes for disembarkation from ships, special taxes and fees for Chinese in certain industries, laws that prohibited Chinese from testifying for or against Whites in court, and a tax on the Chinese for just residing in the state. Infamous cases such as *Ho Ah Kow v. Nunan* (a pig tail "queve" cutting ordinance against Chinese prisoners that had violated the "Cubic Air Ordinance" that forbid overcrowding housing conditions in San Francisco in 1870) and *Yick Wo v. Hopkins* (a series of San Francisco ordinances in the 1880s that regulated the licensing of the laundry industry operating out of wooden buildings) were initiated by local San Francisco officials under the guise of addressing health and safety issues while the ultimate impact was discriminatory practices against the Chinese only. Similar laws modeled after the Chinese Exclusion Act were passed in Australia (the Immigration Restriction Act of 1901) and Canada (the Chinese Immigration Act of 1923).

Christianity

Cristina Gavrilovici
Department of Legal Medicine, Medical Deontology and Bioethics, University of Medicine and Pharmacy "Gr. T. Popa", Iasi, Romania

General Issues

Christianity originated in the geographical area that is now known as the Middle East. Christianity arose in Palestine during the first half of the first century among the followers of Jesus of Nazareth, who was called the Christ. Christ's followers believed that He was the Messiah and the Son of God. Although Christ's first followers were almost exclusively Jews, this new faith spread quickly throughout the Mediterranean basin and soon attracted many non-Jewish converts. During the first three centuries, it remained a minority religion. The practice of the faith was prohibited by the Roman imperial government, and its adherents were often subjected to persecution. In the year 313, the Emperor Constantine declared Christianity to be a legal religion.

Christianity is a monotheistic religion that believes in one supreme God and is based on teachings from the Holy Scriptures. It comprises three major branches: Roman Catholicism and Eastern Orthodoxy (the two split from one another in 1054 AD), and Protestantism, which came into existence during the Protestant Reformation of the sixteenth century. Protestantism is further divided into smaller groups called denominations.

The fundamentals of the Christian faith can be found in the Old Testament; the New Testament, composed by followers of Jesus during the first century; and the patristic literature, which comprises the writings of early church leaders and theologians until the end of the fifth century. During this era, the beliefs and practices of the new faith were articulated and refined; such controversies included issues relating to the divinity of Christ and the nature of redemption. Gradually, a core set of beliefs developed within the orthodox structure and was promoted through church organization. Both the faith's doctrine and hierarchy were established by the late fifth century; both the doctrine and the hierarchy differ in some respects between Western Europe and the Byzantine culture of the East.

Christian identity is rooted in the experience of the Holy Spirit. Life is considered to be a sacred gift from God that should be protected, transmitted, cultivated, cared for, and fulfilled in God. For many Christians, the ultimate reality is the Holy Trinity: the Father, source of the other two fully divine persons; the Son, forever born of the Father; and the Holy Spirit, forever proceeding from the Father. Human beings are created as a composite of body and spirit, as well as in the "image and likeness" of the Holy Trinity. "Image" refers to those characteristics that distinguish humanity from the rest of the created world: intelligence, creativity, the ability to love, self-determination, and moral perceptivity. "Likeness" refers to the individual's potential to become "Godlike." The work of redemption and salvation is accomplished by God through the Son, the second person of the Holy Trinity who, with the exception of sin, took on human nature as the person of Jesus Christ. Christ taught, healed, gave direction, and offered Himself upon the cross for the sins of humanity. His resurrection allowed him to conquer the powers of death, sin, and evil.

Applied Christian Values

Christianity and the Principle of Justice and Equity

Even within a developed region such as Europe, disparities exist between different countries in terms of the quality of health care and the ability to access health care systems. Many relatively wealthy countries that are able to provide comprehensive health systems must nevertheless deal with issues of rationing and the fair distribution of resources. Therefore, the principle of equity is central to any consideration of health care.

Justice is both a social concept and an important Christian concept. Christianity does address the issues of equity and fairness in health care. The Holy Scriptures' focus on justice may be best understood by the modern reader as charity or love. The Old Testament reflects the concept of justice through its conferral of equal status of all men and women before God. Every human being is believed to have been created in the image of God; this quality belongs to all individuals, independent of any other differences. The Prophets repeatedly remind the people of Israel to do justice and that the true service of God is the pursuit of justice. Justice is primarily related to God. According to Christianity, human justice is a response to God's justice that human beings can experience between each other. However, Jesus ordered his disciples to practice strict adherence to this law, but asked them to go beyond the strict requirement of the law. Justice is not denied as an important value but love goes beyond justice demanded by law. Justice gives a person what might be considered to be due to him or her after weighing all relevant considerations. In contrast, love presupposes the implementation of justice and then may allocate to the individual more than would be demanded by justice alone. As an example, the Old Testament speaks of the Sabbath Year, during which the Israelites were to provide rest for themselves, their animals, their land, and forgive debts. In essence, the law functioned as a mechanism for the redistribution of wealth. In comparison, Jesus warned about the dangers of accumulating materially and asked individuals to distribute their wealth to the poor. This advisory was not for the purpose of effectuating social change, but was rather for the purpose of achieving spiritual perfection. The concern was not with equity, but with love.

Christianity and Caring for the Sick

From its beginnings, Christianity has been concerned with health and hospitality. Philanthropy and charity provided the foundation for the establishment of hospitals starting in the fourth century in the East, until modern times in the West. Medical tasks have often been central to the church's missionary efforts.

Christianity often views the source of suffering as outside of the sufferer. The source of an individual's suffering is often perceived to be the thing that is causing the pain, the pain itself, the individual's life circumstances, or a stroke of fate. On the other hand, suffering almost always involves a self-conflict. Both on a religious and a secular basis, it is not unusual for suffering persons to believe that their suffering is a form of selfless service to others. This is why the meaning is essential to suffering; the suffering associated with a threat to an individual's physical integrity necessarily raises the issue of the meaning of the pain and its implications. As an example, the crucifixion of Jesus, which was an evil, was transformed by God into

Christianity's central saving act and a demonstration of the power of love over suffering.

A Christian Protestant perspective asserts that God is in control and that there is a greater meaning or purpose in illness of which we may not be aware. Some Christian Protestants pray for miraculous cures as a sign of God's authority. Many believe that a miracle could occur but also believe that God works through human ingenuity and technology to cure illness and relieve suffering. Believers are warned not to attribute to physicians and medical interventions more power than they actually have and to remember that it is God who is in control.

Although Christian theology views physical health as important, it maintains that it may be an obstacle to the supreme good, which is believed to be spiritual health. It is believed that the soul is more valuable than the body, and that care for the body should not conflict with care for the soul. Christians are counseled to accept and appreciate both sickness and health. Sickness can correct or restrain one from engaging in sin, help an individual to increase patience and reduce pride, and facilitate the individual's reliance on God.

Within orthodox Christian theology, the origins of human death and disease are perceived as the consequence of divine judgment on human sin. When illness occurs, Orthodox Christianity affirms an ethical duty to struggle against sickness, which if unaddressed can lead to death. The moral requirement to care for the health of the body indicates it is appropriate to use healing methods that will enhance health and maintain life. Depending upon the particular denomination of Christianity, spiritual healing, such as prayer, and different forms of medicine may be utilized concurrently.

Christianity and End of Life Values

Christians have an obligation to attend to the sick and the poor of the community. To do so signifies not only Christian love but also a respect for life that is rooted in the belief that every human being was formed in the image of God. Accordingly, all human life is deemed to be of value, and therefore needs to be addressed with compassion and care.

Christianity maintains that we have a duty to protect the life given to us by God; accordingly, suicide, active euthanasia, and "mercy killing" are prohibited. However, there is a distinction between ordinary and extraordinary measures; a person is obligated to use ordinary measures but can choose whether or not to accept extraordinary measures.

A persistent theme in Christian reflection on death is the view that death serves to transform the individual into another form of existence; it is not the annihilation of the self. In other words, it is believed that the individual human being survives death, perhaps for all eternity. Death may represent a life that is free of sorrow, suffering, and separation. Some may believe that death does not have the power to cut them off or separate them from the life of the community and the life of God. Accordingly, death is viewed as a meaningful stage in the life cycle.

In general, Christianity traditionally defines death as the moment the spirit leaves the body. Signs of the spirit's departure include the absence of breathing, a heartbeat, and a pulse. Many Christian theologians have accepted a brain-oriented definition of death, sometimes analogizing this to the departure of the spirit from the body.

Christianity and Immigrants

Christianity and Immigrants' Integration into the Host Country

Some scholars have argued that after the first generation, immigrants in the United States would abandon their native languages and ethnic traditions but retain their religions and use religion as a way of melting into America's heterogeneous population.

In fact, religious identities may increase in importance among immigrants compared to its role in their nations of origin because of the role religion can play in preserving ethnic identities. Religion can be used not only to construct a religious identity, but also to develop or retain an ethnic identity. For example, studies involving Korean Christians have demonstrated how religious organizations can help to preserve ethnic traditions by combining and making religious and ethnic rituals synonymous. Campus-based evangelical Christian organizations have been shown to provide Asian Americans with cultural resources for reinforcing the image of Asian Americans as model minorities.

Churches may also serve as important social and educational centers that support the development and maintenance of relationships between individuals who speak the same language and share the same culture, thus providing group ties, identity, and acceptance. The practice of a religion in the destination country may also serve as an empowering resource for women, taking less patriarchal forms in organizations in the United States than in the immigrants' countries of origin. One ethnographic study demonstrated how a Taiwanese evangelical Christian church provided a space for women to construct a distinct sense of self as separate from the family.

Christianity also plays a role in developing social identity from a citizenship point of view. Development of an identity as a citizen first requires that one be a citizen. Gaining citizenship involves navigating the application process, which may be impeded by language barriers and other impediments to gaining legal status as an American citizen. Christian organizations often provide social service resources, such as assistance with learning the English language and help studying for the US citizenship exam. This has been demonstrated to be helpful in a study that was conducted with Asian Americans living in the five metropolitan areas with the highest numbers of immigrants.

The differences between the Orthodox and Catholic churches are important and may potentially influence the immigrants' lives. First, Eastern Orthodoxy never developed a worldwide central authority equivalent to the Papacy of Roman Catholicism. Orthodox Christians consider themselves to be part of one worldwide church that shares the same faith and sacraments; however, in church governance Orthodox Christianity is actually a unity of independent national churches. Unlike Roman Catholicism, Orthodox Christianity never developed an institutional unity that could transcend national, ethnic, and linguistic barriers.

Second, in the United States, Orthodox Christianity generally arrived later than Catholicism. Although monks from Russia established an Orthodox mission in Alaska in 1794, most Orthodox families came to America after 1900. They have integrated into American society more slowly than have Catholics because of the stronger ties between religious affiliation and ethnic community among the Orthodox. Ethnic consciousness appears even today to be more important for American Orthodox individuals than for Catholics. Further, various Orthodox church rules and traditions may contribute to Orthodox individuals' sense of ostracism from present-day mainstream American society. Thus, orthodoxy in the United States has supported more strongly the retention of immigrants' religious identity than their integration into the host country.

In the process of migration, a family or a person may lose a social network and the social and human resources on which they depend for both daily and long-term needs. An immigrant often experiences a sense of disorganization and disorientation that has been referred to as cultural exhaustion or shock. Others' behavior and symbols no longer mean what they meant before migration and the new immigrant must expend considerable energy to understand their meaning. Attending to the basic needs of housing, obtaining food, learning the banking system, and mastering English all require much energy. This sense of disorganization may diminish over time. The extent to which an individual experiences this sense of disorganization and confusion depends upon the individual's level of education, occupation, social status, formal social ties with the host country, personality traits, motivation for migration, and the extent of differences and similarities between the immigrant's country of origin and the receiving country. The immigrant's religion and religious community may serve as important sources of strength and may provide support during this period of difficulty.

Religious beliefs are powerful determinants of demographic events such as marriage, divorce, and childbearing. Religious teachings relating to partnership, sexuality, and fertility can affect demographic patterns both directly and indirectly. As an example, church leaders may oppose the use of contraceptives, which may impact the birth rate within a particular community. Accordingly, Catholics once had a significant fertility advantage over Protestants among White Christian Americans, but this advantage lessened during the second half of the twentieth century. Evangelical Protestants continue to have higher fertility rates than those from more liberal Protestant groups. In the United States, the high numbers of individuals immigrating from predominantly Catholic Latin America helped to mask conversions and departures from Catholicism to Protestantism and secular nonaffiliation.

Christianity and Immigrant Health

Many immigrants prefer to receive health information in a church setting. In the United States, the church has been found to be the most preferred location for attending a health education session compared to a community center, a hospital, or a local school. Studies have shown that churches and health care organizations can collaborate to implement successful health promotion programs and health education interventions. These programs and interventions focus on a wide range of health topics, such as smoking cessation, diabetes prevention, nutrition, physical activity, and cancer screening. Many church leaders provide immigrants with practical assistance, such as accompanying a church member to physician appointments, providing translation services, assisting with completing forms, etc., and consider this to be a core component of their Christian mission.

Over 70% of Koreans in the United States attend churches on a regular basis, in contrast to only 14–30% of Koreans residing in Korea. Therefore, Korean churches in the United States may play an important role in health research for this immigrant population.

Chronic Disease

Erin M. Fekete[1], Stacey L. Williams[2]
[1]School of Psychological Sciences, University of Indianapolis, Indianapolis, IN, USA
[2]Department of Psychology, East Tennessee State University, Johnson City, TN, USA

Immigrant status and nativity (i.e., country of birth) are strongly related to health, mortality, and incidence/prevalence of chronic illness. Compared to US-born, non-Hispanic Whites, immigrants tend to have a health advantage, including a longer life expectancy and lower mortality rates. However, in some cases immigrants from ethnic groups experience higher rates of chronic illness.

Chronic illness is characterized as any illness that persists over time and requires management through medical treatment (e.g., medication, surgery) or lifestyle changes (e.g., dietary changes, exercise). Many chronic illnesses are caused in large part by stress and poor health behavior choices such as having a poor diet, sedentary lifestyle, or other negative health behaviors such as smoking or drug/alcohol abuse. The major chronic illnesses attributed to lifestyle behaviors include heart disease, cancer, type 2 diabetes mellitus, and HIV/AIDS. Although medical treatment such as surgery or medication may be necessary, the main aspect of management for these chronic illnesses includes maintaining healthy lifestyle changes such as eating a healthy diet, getting adequate exercise, and medication compliance.

Heart disease. Heart disease is a major cause of death for many ethnic minority groups in the USA. New immigrants tend to have a lower risk of heart disease than minorities and nonminorities in their host country. However, over time this risk becomes similar to or greater than the risk of heart disease for native-born individuals.

Cancer. Overall, nativity and immigrant status do not appear to have strong links to cancer, but among different ethnic groups, the link between immigrant status and cancer is strong. In some cases, these links appear to be genetic, such as Asian immigrant's offspring tendency to have lower rates of ovarian cancer. In other cases, however, the links between immigrant status and cancer are due to poor health behaviors, such as higher rates of oral cancer in Asian immigrants from habitual use of tobacco, or higher rates of cervical cancer in Latino and Haitian women due to lower knowledge about and screening for HPV (human papillomavirus).

Type 2 diabetes. Research is mixed regarding the association between immigrant status and the development of type 2 diabetes, which occurs as a result of poor lifestyle behaviors. Some research suggests that nativity has protective effects, such that some ethnic groups appear to have lower rates of diabetes due to genetic factors. However, similar to heart disease, there is a general tendency for the incidence and prevalence of diabetes in immigrants to be highly correlated with incidence and prevalence of diabetes in their host culture.

HIV/AIDS. Research on the prevalence of HIV/AIDS in immigrant populations suggests that in general, immigrants and native-born individuals have similar rates of HIV-infections, although women from Sub-Saharan Africa tend to have higher rates of HIV/AIDS and Asian Pacific Islanders have lower rates of HIV/AIDS. Longitudinal data also suggests that many immigrants tend to become infected with HIV post-immigration.

Cultural Influences on Immigrants' Health

Although data clearly suggest that social and behavioral factors influence the incidence and prevalence of illnesses in immigrant populations, research on chronic illness still has a tendency to neglect the extent to which culture can influence an individual's chronic illness experience. Sociocultural theory provides a strong framework for understanding immigrants' chronic illness experience. Each culture has different values, beliefs, and normative behaviors that carry over into cognition, development processes, social functioning, and comprehension. Taken together, an individual's identity, self-image, and reality are a product of their culture. Thus, when immigrants are living with a chronic illness, the extent to which they identify with their native versus host culture (i.e., acculturation) can strongly influence how they understand, cope with, and manage their illness. In addition, their illness experience will also depend, in part, on the extent to which they are able to seek out adequate health care, have access to adequate health care, and receive quality health care that is sensitive to their cultural values and norms.

Acculturation and Chronic Illness in Immigrants

Acculturation is the process and result of an individual from a minority group adopting the cultural norms and beliefs of the dominant group or host culture. The stages of acculturation include contact, accommodation, and assimilation. Therefore, becoming acculturated includes behavioral and attitude changes such as changes in language preference, the adoption of common attitudes and values, and changes in political or ethnic identification.

Research generally suggests that immigrants are healthier than both their US-born counterparts and US-born Whites. This advantage is due, in part, to both a healthier lifestyle in their country of origin and selectivity of healthy immigrants. When immigrants first arrive in the USA, cultural factors such as religiosity or support networks tend to act as a buffer to the negative health behaviors and negative health events immigrants are exposed to (e.g., smoking, poor dietary behaviors). However, these health advantages tend to diminish as acculturation and duration of residency increase.

Health Behaviors and Risk Factors

A great deal of research finds a positive association between acculturation and the decline of health behaviors, including being overweight or obese, eating unhealthy foods, having a sedentary lifestyle, and engaging in negative health behaviors such as smoking and unsafe sexual practices. For example, as some immigrants become acculturated they have higher rates of being overweight or obese. As these negative health behaviors are primary causes of many major chronic illnesses, it is likely that as immigrants become acculturated their risk for developing heart disease, cancer, type 2 diabetes, and HIV increases as well.

Immigrants may have less knowledge about signs and causes of chronic illness due to language barriers and cultural beliefs. Some immigrants may not engage in preventive care, such as regular mammography or Pap smears, because they lack knowledge about the importance of the behaviors. There may be a lack of knowledge about where to obtain health care, fear of a language barrier between patient and provider, or fear of not receiving adequate care because of their inability to communicate effectively. In some cases, immigrants may be suspicious of their host country health care providers because the health care system in their host country is different than the health care system in their native country. As immigrants become acculturated, they may engage in better preventative health behaviors and illness management because their knowledge and trust of the host country's health care system increases.

Once diagnosed with a chronic illness, immigrants may have a difficult time making or maintaining lifestyle changes associated with illness management because of cultural influences, including traditional foods or religious beliefs. Immigrants with type 2 diabetes may modify their diet to an extent, but they may engage in deliberate deviations from their diet when culturally traditional foods, that are not necessarily healthy, are concerned. Many immigrants rely heavily on religious institutions as a means of emotional and instrumental support. Religious institutions often provide a sense of indirect social control in that members of the religious institution feel obligated to avoid behaviors that are not condoned by most churches, such as sexual promiscuity, excessive drinking, and smoking. As immigrants become acculturated, religiosity may become less important to them and therefore behaviors that were once restricted may no longer be seen as taboo.

Gender/Social Roles

Gender role theory suggests that men and women are socialized to engage in gender-specific behaviors from the time of childhood, and these behaviors often carry over into their adult behaviors and attitudes. Men tend to be independent and agentic, and are often seen as breadwinners of the family, whereas women are more often seen as communal as they engage in many of the caregiving aspects of the marital/familial relationships. In many Western and developed countries, it is becoming common for gender roles to be less pervasive in relationships and for men and women to be more egalitarian. However, in many traditional cultures, gender roles are still very persistent, and sometimes play a more dynamic role in the management of health and chronic illnesses.

Compared to non-Hispanic White cultures, Black and Hispanic cultures are generally more familial and have small, close-knit social networks. Immigrants coping with stigmatizing chronic illnesses such as HIV may not be able to disclose information about their illness to family members due to fear of rejection and social isolation as a result of the behaviors often associated with HIV-infection (e.g., homosexuality, drug use). As a result, immigrants may lack the social resources needed to cope with their illness, and they may also fail to engage in appropriate health behaviors such as medication compliance or attending regular health appointments in an attempt to hide their illness.

Many immigrant cultures place emphasis on the role of a woman as the caretaker of her family. As a result, the personality characteristic of unmitigated communion, or focusing on others to the detriment of the self, may be fostered in immigrant women. In this sense, immigrant women place so much emphasis on the health and well-being of their family that they do not tend to their own health care needs, including both preventive medicine and chronic illness management.

Health Care Utilization

The experience of chronic illness may be impacted by immigrants' utilization of health care. Although utilization of the health care system may be in part attributable to individual-level factors affecting the decision about whether or not to seek care, a number of factors at varying levels contribute to such utilization decisions and behaviors. In particular, not only are decisions impacted by structural factors like global access to care and the quality of the care once it is sought or received, but also the social and cultural context within the lives of specific immigrant groups.

Compared to nonimmigrants, immigrants are more likely to underutilize and delay the utilization of health care services. In addition, immigrants are less likely to discuss health promotion behaviors with physicians, and are less likely to get appropriate preventative services. For instance, female immigrants seek out preventative gynecological services less regularly.

A behavioral model of health services use, or the Anderson model, has been proposed to organize the themes of barriers to access and use of services. The model considers predisposing factors, enabling factors, as well as need. For instance, nativity, according to this model, is a predisposing factor to access and use of services, while health insurance and language, ease of making an appointment, and availability of providers are examples of enabling characteristics. Need might be based on illness and chronic illness as well as sex- or age-appropriate screenings and preventive care which can predict service use.

Access to Care

There is some evidence from nationally representative studies of US-born and foreign-born adults that having insurance and a usual source of care are less predictive of seeking both preventive and non-preventive health visits. Yet, other findings indicate that unmet medical needs are greater among those who lack insurance than among those insured – whether immigrant and nonimmigrant. Indeed, foreign-born individuals living in the US, and especially those who are noncitizens, are less likely to have health care insurance. This includes children as well as the elderly. Similarly, these individuals are less likely to have a usual source of care. This patterning corresponds with the trends found for rates of actual health care seeking; in particular, those who are noncitizens (undocumented and legal status) seek less health care than citizens. This is generally true for preventive care as well, such as mammography and Pap tests.

It is perhaps more even more difficult to access services when living in rural locations, where immigrants (e.g., Hispanics) are increasingly found. Thus, it may be that utilization of health care is attributable more to access, which is positively correlated with socioeconomic status. For example, after studies adjust for factors such as demographics, insurance, regular source of care, and other similar factors, immigrants appear equally likely to get preventive care.

It is also possible that acculturation issues and better health in combination with fewer health-enabling issues explain lower health care service use. These factors may be barriers to service seeking and many negatively impact the course of chronic illness. There may also be some fear on the part of the immigrant of negative or limited treatment due to their minority status. Data on African people living with HIV in the US have shown barriers to care that include individual perceptions such as fatalistic views about HIV and fear of isolation. Other barriers included fear of deportation and lack of knowledge of the health system and HIV-related services.

Quality of Health Care

In addition to understanding how health care access affects immigrants' chronic illness experience, it is also important to acknowledge immigrants' experience once inside the health care system. Quality of health care is the extent to which services are aligned with professional knowledge, and the extent to which individuals receive appropriate services in a competent and communicative way. To this end, typically expected characteristics of quality may include shared decision making between the patient and the health care provider, as well as sensitivity to cultural differences and concerns. Such quality is important because it contributes to a greater likelihood of continued service use and better health outcomes.

The Anderson model of service access and use includes quality of care. Considering the patient and physician interaction as a context for determining quality of care, specific indicators of quality might include patients' perceptions of (1) whether the doctor listened to the patient, (2) whether the patient understood the doctor, (3) whether the patient had questions that went undiscussed, (4) patient trust of physician, (5) whether the doctor treated the patient with respect, (6) whether the doctor involved the patient in decision making, and (7) whether the doctor spent the amount of time with the patient that is wanted. Considering the association between nativity status and patient perceptions of the patient–physician interaction, foreign-born, as compared to US-born individuals, are at increased odds of reporting their physician as not involving them in their care as much as they would have liked. In addition, foreign-born persons are at increased odds of reporting their physician did not spend as much time with them as they would have liked. Additional reports of research show that at times immigrants perceive health care as not helping to the fullest degree.

Given the role of language in communication, language differences and other cultural differences can contribute to immigrants' quality of care as well. Language appears to increase the difficulties with patient–physician communication when the patient is an immigrant. For instance, individuals who are less proficient in English tend to receive fewer of the appropriate tests and preventive screenings than those more English-proficient. Those less proficient in English tend to have worse health and more distrust that physicians understand their medical problems. Further, those who have difficulties with language and communication report less adherence to medical regimen and chronic illness management. Foreign-born individuals also are more likely to report perceived discriminatory experiences in the health care system; being non-White and a noncitizen is related to more such reports.

Other Cultural and Social Contexts

Several other factors related to cultural and social contexts might contribute to health care utilization and subsequently the chronic illness experience among immigrants. For example, lower service use and the fewer enabling factors to service seeking may be exacerbated within the social context of intimate partner violence in the lives of immigrants. Considering women in particular, partner violence puts immigrant women at risk for some chronic health conditions such as sexually transmitted diseases. Further, legal issues related to being undocumented may prevent these women from seeking health care. Moreover, in some cultures, partner violence may be perceived as extremely personal and not within the realm of topics to be discussed with health care providers. In this social context of private partner violence and a distrust of the health care arena, individuals may feel helpless to change their situations or appropriately handle other health-related concerns.

Immigrants' personal and familial relationships may contribute to health care use and the illness experience. Some research has shown, for instance, that immigrant women's adult daughters may play an important role in their health care and health care seeking. This pattern may be especially true when the daughter is more proficient in English language skills and is able to help navigate the health care system. In fact, some evidence suggests immigrants may connect with other immigrants as well as with family and friends to navigate the health care system. This solidarity may contribute to a greater likelihood of receiving adequate health care. Further, the challenges or barriers to care reported above may also apply to children of immigrants, whether or not they themselves have chronic conditions which require treatment. Thus, access to care and quality of care, as well as cultural issues contributing to perceptions of the health care system impact not only individual immigrants who may be suffering with chronic conditions but also can influence families as they navigate the health care system.

Another contextual reality for immigrants is that chronic illness is often comorbid with other illnesses, including mental illness. Mental health problems may be greater among immigrants particularly as they remain in their host country for longer periods of time. This link between acculturation and mental health perhaps reflects greater risk for psychiatric disorders with increased exposure to minority status. Further, immigrants' experiences of having less access to health care, less quality health care, and greater stigma and fear of deportation associated with health care, can contribute to greater psychological distress. Finally, in many cultures, mental health problems are not acknowledged or addressed. As immigrants acculturate to their host country, they may feel more comfortable seeking mental health treatment. Some variations in mental health patterns by gender and ethnic category exist, leading to the question of whether factors related to specific immigrant groups contribute to mental health. The National Survey of American Life found that Caribbean immigrant men fared better psychologically than their US-born Black counterparts, whereas Caribbean immigrant women fared worse as compared to US-born Black women.

The combination of increased mental health issues and lowered mental health care seeking could exacerbate the negative experience of immigrants with chronic illness. An increased focus on immigrants' health care needs and utilization in the context of mental health needs and care seeking seems necessary. In this realm of mental health and psychiatric care, it is perhaps an additional charge of the primary healthcare system to address such issues that are not traditionally in the preview of health care and yet may be ever present. Indeed, immigrants and US-born alike disproportionately use the general medical sector for treating mental health problems. Given the lowered utilization of mental health care, perhaps integration of psychologists into primary care could reduce the stigma associated with seeking care. To illustrate, Asian Americans experience various emotional or behavioral problems, and yet underuse existing mental health services except when culturally and linguistically sensitive. Culture-bound syndromes and misdiagnosis can occur. Due to Asian traditions of viewing the body and mind as one rather than two separate systems, individuals tend to focus more on physical than emotional symptoms, leading to overrepresentation of somatic issues. Perhaps the integration of psychology into primary care practice can address both the physical and mental health contexts.

Need for Cultural Competence in the Health Care System

It is important for researchers and health care professionals to understand that while immigrants and individuals from minority populations may integrate and incorporate beliefs from their host environment, they will retain some of their traditional beliefs and practices. As such, each ethnic and minority group within a larger culture develops a unique mix of social and cultural roles, expectations and beliefs, and frameworks that shape the health behaviors and health decisions of individuals coping with chronic illness. The differences in immigrants' and minorities' cultural belief systems may contribute to the health disparities seen in many immigrant and minority populations.

One way to address the health disparities seen in the incidence of, treatment for, and health care usage in chronic illness in minority populations is through increasing cultural competence in researchers, medical professionals, and health care providers. Cultural competence can be conceptualized as a systematic set of behaviors, attitudes, and policies that enable professionals or agencies to work effectively in culturally diverse settings. This can be implemented through cultural competence education in physicians and other health care professionals. Cultural competence can be best implemented and most effective if resources are available to provide appropriate care, medical professionals and health care providers know the population they are providing care to and respond to the needs of their patients appropriately, and health professionals are committed to providing high quality and comprehensive care across culturally diverse settings.

A potentially effective method for becoming knowledgeable about the population to whom physicians are providing care may be to conduct focus groups with individuals who experience challenges to seeking care and yet successfully navigate the health care system, obtaining care that is needed and helpful. This strategy has been used with results showing that many immigrants feel embarrassed, helpless, and discouraged from seeking care and yet can overcome obstacles into the system through solidarity with other immigrants, friends or extended family, and connections with health service personnel. These networks of care enabled Latinas to access a complicated health care system and offer lessons for providers and policy makers concerned with improving the delivery of care to this population.

Interventions

In addition to a call for cultural competency in the health care professions, research should also keep culture at the forefront of their research programs. Although the roles of culture and ethnicity are becoming common considerations for clinicians and researchers, few culturally sensitive interventions have been implemented. Instead, the traditional "one size fits all" method of interventions tends to prevail. Instead, researchers need to design interventions based on what types of interventions will work best for *whom* and *under what circumstances*. The process of conducting culturally sensitive research and interventions involves consideration of cultural contexts across all phases of the scientific research process, including ethnographic methods such as focus groups, translating measures into culturally appropriate language, data collection that includes comparison groups, and culturally appropriate analysis and interpretation of data.

Conclusions

Immigrants often experience lower rates of illness until they have acculturated to their host country. Many immigrants do not have or develop the knowledge about health and preventive behaviors needed to prevent many of the major chronic illnesses. Immigrants are less likely than nonimmigrants to seek out and utilize health care for a variety of reasons, many of which reflect challenges of being an immigrant such as less access to enabling characteristics to service use, and cultural and contextual issues. The challenges to needed care that immigrants encounter, particularly in combination with lower perceived quality of care, may further contribute to feelings of stigma and avoidance of the health care arena. These patterns could indicate an eventual negative health impact for immigrants, as lack of use of the health care system could contribute to an exacerbation of symptoms and health risk over time.

Additional conclusions based on limited but promising research, however, suggest that variations in health care–related factors may be indicated for specific immigrant groups, locations, or regions. Despite the challenges to health care, some immigrants do successfully navigate the health care system. These findings suggest the need for further investigation into the ways in which health care is accessible and of good quality for immigrants, as well as the characteristics of the immigrant groups who are successful at navigating the system. Information garnered from such investigation can be used to implement better health care situations for other immigrants.

Chronic Pain

Brandy L. Johnson
Rynearson, Suess, Schnurbusch & Champion, L.L.C.,
St. Louis, MO, USA

Pain is an unpleasant feeling, which can range from mild, localized discomfort to agony and is usually a symptom of some injury, disease, or disorder. Pain can be acute or chronic. Acute pain is typically a response to an injury and lasts only until the injury is healed. Unlike acute pain, chronic pain persists past the resolution of an injury or is the result of a longstanding condition. It can be a continuous discomfort of varying degrees or a recurrent pain. Depending on the doctor, chronic pain is diagnosed after the individual experiences the pain for between 3 and 6 months.

Chronic pain can stem from different sources and can be physical and/or neurological. Chronic pain can be caused by damage to, or inflammation of, the joints. Examples of this type of chronic pain are osteoarthritis and rheumatoid arthritis. Chronic pain can also result from nerve conditions. Individuals with diabetic neuropathy, failed back syndrome, or spinal cord injuries suffer from this type of chronic pain. Another common source of chronic pain is muscle conditions. Epicondylitis and temporomandibular joint disorder (TMJD) are examples of muscle conditions that can result in chronic pain. Organ damage can cause chronic visceral pain. Liver cancer, gallbladder disease, and bowel inflammation can result in visceral chronic pain. Studies have also suggested dietary deficiencies, specifically a lack of vitamin D, can result in a higher incidence of chronic pain. Such a deficiency may place immigrant groups at a greater risk for chronic pain. It has been theorized that immigrants are at a higher risk of 25-OH vitamin D deficiency due to darker skin color, low sun exposure, diet, and traditional dress.

In addition to injuries, chronic pain can result from a disease. Individuals with diseases such as cancer, AIDS, or multiple sclerosis usually experience chronic pain. Repetitive use can cause painful chronic conditions like carpal tunnel syndrome or cubital tunnel syndrome. Even the aging process can result in conditions that are painful and chronic, for example, degenerative joint disease, degenerative disc disease, and arthritis.

Some people, however, suffer chronic pain that does not have an identifiable source. Psychogenic or psycho-physiological pain does not have an identifiable source or the level of the pain being experienced exceeds any obvious cause. Examples of this type of pain include fibromyalgia and reflex sympathetic dystrophy.

The forms of chronic pain vary and can depend upon the cause of the pain. Symptoms can include muscle pain, cramping, spasms, soreness, and swelling. Some individuals suffer from headaches, migraines, joint pain, sciatica, and pain that can be sharp, aching, burning, and/or tingling. Chronic pain sufferers may experience weakness, easy fatigability, numbness, and a lack of energy.

Chronic pain is a very complex condition, as it often involves more than the mere pain symptoms experienced by the individual. Chronic pain often affects the individual emotionally as well as physically. Problems often experienced by individuals with chronic painful conditions include depression, anxiety, fatigue, a weakened immune system, and a decreased ability to sleep. Irritability, anger, and feelings of helplessness are also common in people with chronic pain. Individuals with chronic pain tend to be more aware of their physical conditions, their pain, and often worry about their pain or health. This creates a propensity for depression, fear, anxiety, and feelings of hopelessness and helplessness. As emotional states can affect how pain is felt, stress, anxiety, and/or depression can amplify the pain.

Chronic pain can affect how the individual sees himself or herself and the ability to participate in activities of daily living. It can reduce the individual's quality of life. Sufferers of chronic pain often see their relationships with family, friends, and even coworkers change or diminish altogether.

Chronic pain can be treated. However, the success of the treatment varies from individual to individual. The most common form of treatment for chronic pain is a medication regime. It is often recommended that sufferers of chronic pain take anti-inflammatory medication. Such medication can be purchased over-the-counter or in a prescription form. Aspirin and acetaminophen are also common over-the-counter medications used as part of a medical regime for chronic pain.

A chronic pain sufferer's medical regime will probably also include prescription medication. The type of prescription medication varies from patient to patient and is based upon the source of the chronic pain (i.e., joint inflammation versus neuropathic pain) and the patient's response to the medication. As with any medication, different individuals will respond to, and tolerate, the medication available in varying manners.

For nerve-related pain, the individual's medication regime may include tricyclic antidepressants, anticonvulsants, and/or antiarrhythmics. Although originally developed to treat conditions like depression and seizure, these classes of medications have proven beneficial in the treatment of nerve-related chronic pain.

Opioids, like morphine and oxycodone, are often part of a medication regime. The utilization of opioids to treat chronic pain is not without controversy. Prolonged use of this type of drug can lead to side effects and secondary conditions, such as loss of benefit, hyperalgesia (a condition wherein the person has an abnormally increased sensitivity to pain), and testosterone deficiency. Fifty-one percent of all patients utilizing opioids experience at least one adverse side effect. Moreover, as the medication is a narcotic, there is a higher potential for abuse as the individual's tolerance level increases. Tolerance to opioids tends to occur over a period of months to years. As their tolerance increases, many people will misuse the medication to achieve the desired effect. In the United States, between 1999 and 2006, opioid poisoning was noted to be the second leading cause of injury death, overall, and the leading cause of injury death in those between the ages of 35 and 54. Given the dangers associated with opioids, it has been argued they should only be included in a treatment regime if the medication is shown to both provide relief and increase the individual's level of functioning. Many practitioners are now requiring patients to enter into an agreement or treatment contract, whereby the patient agrees to the objectives of treatment, to refrain from obtaining medication from another source, and to use the medication only as directed.

In addition to a medication regime, there are other forms of therapy that should be included in the treatment regime for chronic pain. A home exercise program is highly recommended. A lot of people with chronic pain avoid additional movement and exercise due to the pain. It is generally agreed, however, that such a program helps prevent further weakness and deterioration. Regular exercise can also increase the individual's energy level, ability to sleep, and production of natural endorphins.

Hot and cold compresses are encouraged for individuals suffering from chronic joint or muscle pain. Massage is another treatment option people with chronic joint or muscle pain find beneficial. Acupuncture may ease chronic pain, especially in those suffering from headaches, low back pain, and osteoarthritis. Electrical stimulation, through a transcutaneous electrical nerve stimulation (TENS) unit or an implanted spinal cord stimulator, is an additional option for chronic pain sufferers. Finally, cognitive behavior therapy, psychological/psychiatric therapy, support groups, and stress management techniques are often utilized when treating chronic pain.

Cognitive behavior therapy teaches a chronic pain sufferer skills to help cope with the pain. Stress management techniques, such as biofeedback and relaxation therapy, aid the individual in learning to influence the body's physical response to pain. Psychological or psychiatric therapy provides the individual with a tool to help come to terms with the fact they will live with chronic pain, the changes that may occur in the ability to work, dependency, or relationships with others, and any resulting depression.

Depending upon their access to health care, immigrants may be able to try some, or all, of the above therapies. However, many immigrants do not have access to doctors willing to treat chronic pain and/or are able to afford prolonged treatments. Additionally, immigrant populations often tend to have less trust in the health care system and unfamiliar treatment regimes. Instead, immigrants may turn to therapies with which they have more cultural familiarity. For example, Chinese immigrants tend to be more familiar with acupuncture and, therefore, are more willing to undergo this form of treatment. Although acupuncture has been shown to provide some relief with certain types of chronic pain, it is possible that a higher degree of relief could be obtained with a different treatment or a combination of treatments.

When the treatment is not effective, the individual's problems are often compounded by secondary conditions. Depression, insomnia, fatigue, hopelessness, a loss of purpose, and a decrease in general physical functioning can all occur when an individual is not able to successfully cope with, and treat, his or her chronic pain. A downward spiral can result when chronic pain and these secondary conditions occur; each feeding off of the other. Suicide is not unheard of when the individual no longer feels he or she has any value, is a burden upon others, and cannot continue to cope with the pain. This is why treatment for chronic pain, as illustrated above, is often multimodal and should address more than the pain alone.

It has been estimated that chronic pain affects one out of every ten adults. In addition to the effect it can have both physically and emotionally, chronic pain can also have an effect on an individual's memory, concentration, or ability to problem solve (cognitive functioning). Studies suggest most people with chronic pain complain of cognitive difficulties. Specifically, problems with memory and attention were reported. The studies have suggested objective cognitive deficits in the domains of memory, attention, speed in performance of structured tasks, speed in responding to stimuli of a cognitive task, verbal ability, and mental flexibility.

As chronic pain, by its very definition, can last a long time, if not a lifetime, the costs for treatment of the condition can be quite high. The cost of treatment can, and does, affect the chronic pain sufferer's access to health care and medication. This is especially true when the chronic pain is so disabling that the individual cannot work. The effects of the cost of treatment for chronic pain and, therefore, the ability to access such care may not be as devastating in countries with some form of universal health care. However, in countries without universal health care, such as the United States, individuals with chronic pain may find themselves without access to health care and medication if they do not have access to insurance through a job or spouse, cannot afford the insurance, and do not qualify for Medicare or Medicaid.

Immigrant groups, especially undocumented immigrants, often have reduced access to the health care system. The cost of the prolonged treatment for a chronic condition also makes the care prohibitory for many immigrants. Additionally, even in countries that have a form of universal health care, language barriers and an inability to understand and navigate the health care system can further limit immigrants' access to care for chronic pain conditions.

The inability to access to health care and medication leaves an individual with few choices. Many turn to illegal drugs and/or alcohol. Self-treatment with alcohol is not a truly effective tool in pain management, as it acts as a depressant, effects the individual's mental and physical ability to function, and wears off after a relatively short period of time. Regular misuse of alcohol leads to the development of tolerance and, with prolonged use, painful conditions such as alcoholic myopathy, alcoholic neuropathy, and liver disease.

Marijuana is another drug that is turned to for self-medication. The act of buying and possessing marijuana is a crime in many countries. Additionally, marijuana use for chronic pain has drawbacks. Smoking marijuana can affect the lungs and prolonged usage can result in dependency and memory loss. However, studies have shown that the active ingredient in marijuana, tetrahydrocannabinol (THC), can have some benefits with regard to pain control. The medical benefits of the drug have resulted in legalization in some places. In the United States, several states have enacted, or are in the process of enacting, legislation permitting use of proscribed medical marijuana. Some countries, such as Canada and Austria, have made the use of medical marijuana legal. Other countries have essentially decriminalized it when used in small amounts for medical purposes. Medical marijuana is available in both cigarettes and pill form.

In summary, when the pain lasts for a prolonged period, it is classified as chronic pain. Chronic pain varies from individual to individual in both symptoms and severity. The underlying condition, therefore, must be considered when determining the best treatment approach. However, it is generally agreed the treatment regime should be multimodal and include more than pain medication. Chronic pain is not uncommon and can have life changing consequences. Consequentially, ensuring access to affordable health care is essential to providing individuals with chronic pain a positive quality of life.

Citizenship

Tambra K. Cain
Barrett, Twomey, Broom, Hughes & Hoke, LLP,
Carbondale, IL, USA

A citizen is a person who is a native or naturalized member of a State or nation and who owes allegiance to its government and is entitled to its protection. In some countries, individuals may also derive citizenship through their parents if the specified conditions are fulfilled. Citizenship means to have the status, rights, privileges, and duties of a citizen. Conversely, an alien is one who has citizenship in a country other than his or her residence. In addition to having the status of citizen or alien, a person may also be a national, which means a person who, while not a citizen, owes permanent allegiance to a country.

Each country has its own requirements to be a citizen. The Fourteenth Amendment of the United States Constitution provides that all persons born or naturalized in the United States, and subject to the jurisdiction thereof, are citizens of the United States and of the State wherein they reside. In the United States, the Immigration and Nationality Act of 1965 (INA) provides the guidelines for who is a citizen and who may become one. Also, in 2000, Congress passed the Child Citizenship Act (CCA), which allows any child under the age of 18 who is adopted by a United States citizen and immigrates to the United States to acquire immediate citizenship.

An individual is a natural citizen of the United States if the person is born in the United States; is born abroad to parents who are both United States citizens, one of whom has had a residence in the United States or one of its outlying possessions prior to the birth; is born abroad to at least one United States citizen parent who has been physically present in the United States or one of its outlying possessions for a continuous period of 1 year at any time prior to the birth of such person; or is of unknown parentage found in the United States while under the age of 5 years, until shown, prior to his attaining the age of 21 years, not to have been born in the United States. It should be noted that the specific requirements for deriving citizenship from a parent or parents have changed over time.

In most cases, a person seeking to become a United States citizen must have resided continuously within the United States for a period of at least 5 years, at least half of which must have been spent physically in the United States; have lived at least 3 months in the state in which the application for citizenship is being made; reside in the United States from the time he or she makes the application until the admission of citizenship; and be a person of good moral character, attached to the principles of the Constitution of the United States, and well disposed to the good order and happiness of the United States.

An applicant must understand the English language, including an ability to read, write, and speak words in ordinary usage in the English language. He or she must have a knowledge and understanding of the fundamentals of the history and of the principles and form of government of the United States. The language and governmental principles requirement shall not apply to any person who is unable to meet these requirements because of physical or developmental disability or mental impairment, is over 50 years of age, and has been living in the United States for periods totaling at least 20 years subsequent to a lawful admission for permanent residence, or is over 55 years of age and has been living in the United States for periods totaling at least 15 years subsequent to a lawful admission for permanent residence.

The right to become a naturalized citizen is not absolute. Citizenship can be refused. Any person who at any time during which the United States has been or shall be at war has deserted the military or has gone beyond the limits of the United States with the intent to avoid any draft into the military is permanently ineligible to become a citizen of the United States. No person shall become a naturalized citizen of the United States who advocates, or is a member of or affiliated with, any organization that advocates opposition to all organized government, or who is a member of the Communist Party or any other totalitarian party, or of any foreign state, or who, advocates or is a member of any organization that advocates the overthrow by force or violence or other unconstitutional means of the Government of the United States. However, any person who establishes that such membership or affiliation is or was involuntary, or occurred and was terminated prior to reaching 16 years of age, or that such membership or affiliation is or was by operation of law, or was for purposes of obtaining employment, food rations, or other essentials of living and where necessary for such purposes may be allowed naturalization.

Citizenship may also be lost. A United States citizen, whether by birth or naturalization, may lose his or her citizenship by obtaining naturalization in a foreign country after having reached 18 years of age, by making a formal declaration of allegiance to a foreign country, by serving in the armed forces of a foreign country if such armed forces are engaged in hostilities against the United States, by making a formal renunciation of nationality, by committing any act of treason against the United States, or by attempting by force to overthrow or bearing arms against the United States.

In 2008, 1,046,539 people became naturalized United States citizens. Of the people naturalized in 2008, 1,032,281 were civilians and 4,342 were military personnel; 121,283 petitions were denied. This is a marked difference from 1998, when 461,169 people became naturalized citizens, and 137,395 petitions were denied.

A person's citizenship status may impact the quality of life in many ways. For example, a person who is not a United States citizen may be limited in the types of employment available to him or her, certain governmental benefits, such as financial assistance and medical assistance, may not be available to a noncitizen; and if the noncitizen is in the United States illegally, he or she may be even more limited in access to employment or healthcare for fear of discovery and deportation.

United States Constitution, 14th Amendment

Civil Rights Act of 1964 (U.S.)

Bettina Rausa
Salk Institute for Biological Studies, La Jolla, CA, USA

On July 2, 1964, the US Congress passed landmark legislation called the Civil Rights Act. Signed by President Lyndon Johnson, the law made racial segregation and discrimination illegal in the USA. The Civil Rights Act had five major components: (1) it barred unequal application of voter registration requirements; (2) it outlawed discrimination in hotels, motels, restaurants, theaters, and all public places; (3) it encouraged desegregation of public schools and granted the US Attorney General the authority to file suits to force desegregation; (4) it authorized the withdrawal of federal funds from programs that practiced discrimination; and (5) it made discrimination in employment illegal for any business with more than 25 employees and created the Equal Employment Opportunities Commission, a body set up to review employment discrimination complaints.

The Civil Rights Act of 1964 was driven by a desire to improve the quality of life for African Americans and other minority groups in the USA. There was a significant buildup of events that preceded the passage of civil rights. Two of the earliest occurrences included large numbers of Black Americans moving into northern cities to live and work and Black soldiers serving in World War II. Prior to these two events, people in many parts of the USA, excluding the South where Black Americans predominantly lived, were mostly unaware of the issues that Black Americans faced and the important contributions they made during the war. In addition, even as early as 1945, legislation designed to enforce equality helped lay the groundwork for the eventual passage of civil rights legislation. For example, there were presidential orders that ended discrimination in the military and in federal employment, including work done under government contracts. In 1954, the Supreme Court made a critical decision that had enormous effects on the civil rights movement: it struck down legal support for school racial segregation in what was coined “separate but equal” in the case of *Brown v. Board of Education* in Topeka, Kansas. *Brown v. Board of Education* was born out of a demand for better conditions at schools for African American youth. Black children were segregated from White children in the education system: they were not allowed to attend schools near their homes and instead were bused to other schools. Often, those schools were inferior both structurally and in the quality of education. For example, teachers of schools for Black students were severely underpaid compared to other teachers, and teaching resources and materials were far fewer. However, as important as this case was in setting the stage for strong federal support for civil rights, *Brown v. Board of Education* did not address the treatment of African Americans.

In the early 1960s, Congress and President John F. Kennedy’s administration also made advances that added to the trajectory that eventually led to the passage of civil rights legislation. In 1961 and 1962, presidential executive action was taken to ensure minority rights in housing, transportation, education, and employment.

Social conditions during this period were also very influential. There were many protests and marches in cities and towns across the nation that brought attention to the concerns of and for African Americans on a number of social inequalities. These included how segregation prevented them from using public facilities on an equal basis with White people, and how they were restricted from using public transportation, parks, and restrooms, and their limited educational opportunities all based on years of systemic and accepted racism. Along with the protests and marches, boycotts and sit-ins were also carried out, many of which were organized by African American community and religious leaders and others. Dr. Martin Luther King, Jr., who became the most prominent Black leader of the Civil Rights Movement, led several boycotts and sit-ins. He lent much legitimacy and increased awareness and visibility of the civil rights movement across the nation. Although Dr. King and many other organizers and leaders insisted on peaceful and nonviolent demonstrations, many acts of violence occurred, including riots, often spurred by angry counterprotestors that required using federal troops to restore calm and order.

The nation's media outlets focused much attention on the social unrest and events, bringing scenes which often included beatings, protestors being sprayed with fire hoses and even killed, into the homes of Americans everywhere. It soon became undeniable that the social conditions of this period required government intervention. Congress and other elected officials could no longer ignore the social unrest. Churches everywhere and elected officials also became vocal on the issue of civil rights. National polls reflecting the positive attitudes of Americans toward racial integration had risen to 72% in 1963 representing a 30% increase over the last 20 years. President Kennedy began to come out strongly in favor of legislative action by Congress to address racial segregation in the USA. The Justice Department was tasked with the responsibility of crafting what would eventually become the Civil Rights Act. It was critical that this work was conducted in a bipartisan fashion, considering the concerns of both Democrats and Republicans, in an attempt to avoid filibusters or legislative defeats. Even though the polls showed that the vast majority of Americans favored ending racial segregation, not everyone was in favor of these changes. On June 19, 1963, a bill was submitted to Congress for a vote. The House of Representatives debated the bill, and nearly 100 amendments that attempted to weaken the bill were rejected. The House eventually passed the bill after 70 days of public hearings and 275 public testimonies. The bill then moved to the Senate where it was debated again at length under threats of filibusters by opposing senators, but it eventually passed with 289 votes and was signed by President Johnson on July 2, 1964.

In the following year, the US Congress also passed the Immigration and Nationality Amendments Act of 1965. Instead of using nationality and racial criteria to admit immigrations, this new legislation implemented a system based primarily on family reunification. The Civil Rights Act was a fundamental tool for the new immigration legislative and policy changes because for many, the new changes in immigration laws were seen as an extension of the civil rights movement. Foreign policy concerns were also considered as the USA preferred to be seen by other countries as a place where equality and respect for all people was the standard.

Civil War

Ryan C. W. Hall
Department of Psychiatry, University of South Florida, Tampa, FL, USA

At its simplest level, a civil war is defined as a conflict between opposing groups of citizens from the same country who are fighting over who has the legitimate right to govern. This definition does not necessarily take into account many of the complexities involved in modern civil wars, which may involve several groups located in the same geographic region of a country that have never seen themselves as sharing a common identity. Many of the most recent civil wars have begun following the collapse of a former European colonial system of government (e.g., Angola), the fighting produced by Cold War proxy conflict (Vietnam), and/or the end of the Cold War (e.g., Bosnia). The colonial system and the Cold War created strong central governments that maintained order, but at times arbitrarily nationalized various ethnic groups that oppressed other groups within the national boundaries (e.g., Rwanda with Tutsi and Hutu, Yugoslavia with Bosnians and Serbs). These "civil wars" occur in "nations" where the goal of the fighting is not simply to maintain political power (e.g., Khmer Rouge in the Cambodian civil war), but also to facilitate the ethnic cleansing of the region based on tribal identification (e.g., Rwanda), religious divisions (e.g., Bosnia), or longstanding historical grievances (e.g., Bosnia). Narcoterrorism has also produced civil wars in Latin America (e.g., Mexico, Colombia), as have radical differences between right- and left-wing forces attempting to govern (e.g., Chile, Argentina, Peru, Nicaragua, and Honduras).

Civil wars are often brutal, resulting in mass causalities, as seen with "the killing fields" of Cambodia, where over one million people were slaughtered, and the genocide in Rwanda, where an estimated 800,000 were killed. Such brutality leads to the commission of systemized war crimes intended to disrupt the cultural and personal identity of groups of people and to shatter their sense of self-worth and belonging. In Rwanda, there was the systematic rape of women and girls and the slaughter of males in an attempt to ethnically cleanse the Tutsi from the region. In addition, torture, beatings, and mental coercion are used to intimidate the remaining local populace and maintain power and control over their territory.

Immigrants from civil wars are often reluctant to discuss the torture that occurred because of their concern that such reports might affect their immigration status or produce some form of retaliation from their "home" country or countrymen.

Immigrants from civil wars present unique and complex challenges to the countries that provide them with asylum and naturalization. Depending on the nature of the conflict the immigrant is coming from, they often have few resources, little family/social support, and less education than traditional immigrants. Immigrants from civil wars also typically have greater need for health care services. Many have physical/traumatic wounds (e.g., amputees) and suffer from the long-term effects of malnutrition, infectious diseases (e.g., tuberculosis, cholera, leishmaniasis), and long-term psychiatric conditions (e.g., major depression, anxiety disorders, organic mental states secondary to head injury, and torture). Many studies indicate that the psychological effects caused by a civil war can persist for decades. The resulting effects produce long-term economic and social service problems for the host countries.

Civil war immigrants held in refugee camps prior to immigrating are at high risk for experiencing revictimization while in the camps, which further increases their likelihood of physical or psychiatric complications. Refugee camps are often crowded, disorganized, and may have serious problems maintaining adequate levels of sanitation and security. Individuals in refugee camps are often the victims of violent crime and sexual assault. The "legal limbo" that most camp refugees face adds additional stress on an already vulnerable individual. Fear of death, displacement, physical violence, rape, isolation, and return to the parent country all breed fear, anxiety, mistrust, demoralization, and marked feelings of uncertainty and helplessness in refugees, which can further compound or produce the most commonly experienced mental health problems seen in civil war immigrants, chronic major depression and posttraumatic stress disorder.

Other factors associated with higher rates of mental illness in civil war immigrants include: poor fluency in the language of the new country in which they settle; being single (e.g., widowed, separated, never married), unemployed, "retired," physically disabled/injured; and lacking financial resources (e.g., poverty). Older immigrants are more likely to experience these problems than younger individuals and also have more difficulty resolving them. The elderly have greater difficulty acculturating to their new country (e.g., learning the language, customs, and skills) and obtaining work or work at levels equivalent to that which they had before immigrating. They lose more during the process of immigration (e.g., position in the community, finances) and have more physical ailments and infirmities. All of these factors make their adjustment to their new society more difficult.

Providing medical and psychiatric care to immigrants who speak a different language is difficult. This is especially true for immigrants escaping a civil war who are often mistrustful of both foreigners, as well as their own countrymen. Trained translators are needed, but are often in short supply due to often large and unexpected influxes of immigrants and/or refugees. In general, it is best not to rely on family members to act as translators because the patient may be unwilling to discuss important concerns, painful recollections, failings, or symptoms to save face in front of their family or spare the family from learning about certain painful or humiliating information. Also, the family members serving as translators may not directly translate the patient's comments out of a need to protect the patient and/or family from embarrassment, retaliation, or possible deportation. Untrained third-party translators may understand both languages, but may not recognize the importance of repeating questions or responses verbatim, instead of summarizing. They may lack an understanding of medical terminology and may converse with the patient, inserting their own thoughts and opinions, rather than just translating what the doctor and patient are discussing.

Refugees from civil war may fear revealing information about themselves or making errors that could result in their return to their homeland and further prosecution, torture, or death. The fact that they fled and claimed special refugee status could in and of itself result in their imprisonment and/or death in some cases.

Cocaine

Beatrice Gabriela Ioan
Department of Legal Medicine, Medical Deontology and Bioethics, University of Medicine and Pharmacy "Gr. T. Popa", Iasi, Romania

Cocaine is a psychoactive drug, highly addictive, and one of the most dangerous and widely consumed drugs.

Cocaine is an alkaloid extracted from the leaves of *Erythroxylon coca* bush cultivated in South American countries. According to United Nations Office on

Drugs and Crime (UNODC), in 2008, the production of pure cocaine hydrochloride was of 845 tons, of which 51% originated in Colombia, 36% in Peru, and 13% in Bolivia. Currently, organized criminal groups in Colombia control the worldwide distribution of cocaine. Cocaine may also be obtained by chemical synthesis, but this method is more expensive and less common.

Most of the illicit trafficking of cocaine in the USA is held by the border with Mexico. On this route, Colombian traffickers use Mexican drug trafficking organizations to bring cocaine into the USA, to the South Texas region. However, in recent years, the quantity of cocaine seized on this route decreased sharply (from 22.656 kg in 2007 to 17,085 kg in 2009) as result of reduced cocaine production in Colombia, the joint efforts of the US and Mexican official agencies to reduce illegal cocaine trafficking, and diversion of the illegal cocaine trafficking to Europe. As a consequence, the availability of cocaine on the illicit US market decreased, and Europe became the most rapidly growing cocaine market. Currently, cocaine is distributed in the US illicit drug market mainly by Dominican, Colombian, and Mexican drug organizations.

Cocaine is illegally trafficked using various vehicles such as trucks, aircraft, vessels, and also by body packers. The body packer strategy consists of ingestion or introduction of small packages of drugs into the body in the vaginal or anal cavity, with the aim of transporting them into a foreign country, cocaine being the drug most commonly transported in this way. In recent years, trafficking cocaine by body packing method has become a common problem in European airports. People who take this route to transport drugs may be the country’s citizens, tourists, legal or illegal immigrants. The main danger faced by the body packers is death by overdose caused by breaking of the packages or drug diffusion due to the low quality of the cover of the pack.

The use of cocaine for its psychoactive properties has been documented for about 5,000 years, coca leaf chewing being a millennial habit among South American Indians and continued due to its stimulant, anorexic, and euphoric effects. In 1859, C. Niemann extracted the cocaine, as pure substance, from coca leaves.

In 1878, Bentley recommended the use of cocaine as a substitute in the treatment of morphine addiction, opening the way for a more dangerous addiction. In his paper *Uber Coc,* published in 1884, a botanical monograph containing data on the origin, stimulant and antidepressant properties of cocaine, Sigmund Freud recommended it for the treatment of psychiatric disorders such as: hypochondria, hysteria, and melancholia. In 1884, Karl Koller, an Austrian physician, demonstrated the local anesthetic effects of cocaine, which contributed to its widespread use in medical practice.

Following the alarming increase in cocaine use in the USA (a fivefold increase between 1890 and 1903), largely based on nonmedical consumption, it was classified in 1914 as a narcotic drug and included in the prohibited substances list. Currently, in the USA, cocaine is included in the Controlled Substances Act Schedule II (DEA. Title 21, Section 812.) due to its addictive potential and the possibility of its use in medicine as a highly effective topical anesthetic. Cocaine was also included in Schedule I of the Single Convention on Narcotic Drugs, issued by the United Nations in 1961.

According to the National Survey on Drug Use and Health conducted in 2008 in the USA, 5.8 million people aged over 12 years have used cocaine at least once in the past year and 1.1 million people over 12 years used crack at least once in the past year. Official statistics stress that cocaine and crack cocaine consumption in the USA has stabilized in recent years, albeit at high levels.

In the European Union countries, there has been an increase in the cocaine consumption over the last 10 years, cocaine being the most used illicit drug after cannabis. About 13 million Europeans aged 15–64 years have consumed cocaine at least once during their lifetimes. The highest prevalence of cocaine consumption during the last year was recorded in the age group 15–34 years (7.5 million). An increased prevalence of cocaine use in the EU is recorded in Spain, United Kingdom, Denmark, Italy, and Ireland.

With respect to immigrant populations, research shows that US Hispanics have a high rate of deaths caused by the consumption of drugs, especially marijuana and cocaine, and the Puerto Ricans show the most prevalent consumption rates. US Hispanic teens have higher cocaine consumption rates than White and African American teens (5.7% versus 3.8% and 2.2%).

Cocaine is a white powder with a specific odor. It can be taken by snorting, smoking, subcutaneous or intravenous injection.

Crack cocaine is the freebase cocaine which is taken only by smoking. The entry of crack cocaine into the US market led to lowered prices and increased the availability of the drug on the market, leading to expansion of cocaine consumption from high and middle classes of society to minorities in cities.

In the short-term, cocaine has psychoactive properties producing: euphoria, increased self-esteem, improved physical and mental performance, increased aggressivity, increased body temperature, blood pressure, and heart rate. Death may occur due to overdose by central respiratory depression or severe cardiac arrhythmia, or suddenly, during the first administration of the drug ("cocaine shock") due to the paralysis of the respiratory center in individuals with particular sensitivity.

Cocaine addiction, mostly at a psychological level, occurs after a few weeks or months of repeated intake of doses. At this stage, the cocaine addict suffers from hallucinations, perception and thinking errors, and behavioral disorders. After 5–10 years of cocaine use, the drug addict reaches a state of physical and mental deterioration, abandons her/his social and professional life, and may commit various felonies, such theft or violence, in order to get money for buying drugs.

Cocaine or crack use during pregnancy, often associated with a disorganized lifestyle and adverse environmental conditions (disharmonious parental relationship, stress, violence, poverty) may affect fetal development in variable degrees. Newborns may show: prematurity, low birth weight, small head perimeter, and various neurobehavioral deficits (so called "crack babies"). Cocaine-using pregnant women have higher rates of miscarriage and placental rupture at birth.

Children exposed to cocaine in utero are not a homogeneous group in terms of their short- and long-term physical and behavioral development. The environment in which the children grow up can affect their long-term development, the drug-induced biological vulnerability, making them more vulnerable to adverse environmental conditions. Poverty plays an important role in this relationship, and studies show that many children exposed to drugs in utero are from poor class of society. In some U.S. states, drug use during pregnancy is equivalent to child neglect or child abuse, which can lead to loss of custody.

Immigrant women often face financial problems, especially at the beginning of their stay in the host country. This limits their access to prenatal care and to treatment for addiction and may determine, along with cocaine abuse, damage to fetus. From a social perspective, their access to health resources is limited due to stigma associated with drug use in pregnancy. Illegal immigrant status, fear of expulsion from the host country, and the possibility of allegations of neglect or child abuse decrease the chances that pregnant immigrant women who use cocaine or crack cocaine can access the health care system and admit their drug addiction.

Cognitive Testing

Natasha T. J. Raming
The Institute for Palliative Medicine, San Diego Hospice, San Diego, CA, USA

Cognitive tests are used to assess cognition: the mental act of perceiving and manipulating information. Generally, cognitive tests measure two specific types of mental abilities, crystallized and fluid. Tests of crystallized abilities assess domains such as verbal knowledge, semantic memory, higher reasoning skills that involve conceptual relatedness, episodic memory, visual–spatial manipulation, mathematical ability, and executive function skills such as judgment and problem solving. Fluid abilities allow us to attend to, perceive, process, store, and retrieve information, and they are the means by which we collect, organize, and accumulate knowledge, the basis of crystallized abilities.

Cognitive Assessment

In the clinical setting, cognitive test data are used to assist in the diagnosis of conditions resulting from developmental abnormalities, traumatic brain injury, stroke, mild cognitive impairment, vascular or frontotemporal dementia; and neurodegenerative processes such as Alzheimer's, Parkinson's, or Huntington disease. In such cases, a cognitive assessment, consisting of multiple tests that measure mental processes associated with one or more specific domains, is conducted by a *psychometrist*, an individual trained in the administration and scoring of cognitive measurement tools. This assessment commonly takes place in a one-on-one interview, involving stimulus materials, paper and pencil tests, or a computerized presentation device. Materials are presented in a standardized manner and information about the participant's performance and reaction time is recorded. Following the interview, the results are analyzed and interpreted to determine the severity of impairment associated with a potential diagnosis and whether specific treatment or therapy is necessary.

Historically the development, use, and validation of cognitive tests focused on White, non-Hispanic, formally educated populations in the United States. Repeated testing and systematic study of cognitive measures have occurred more recently in African American and Hispanic groups. Normative data compiled from these studies allow for the development of statistical methods that are used to make adjustments to cognitive test data based upon age, education level, gender, and race. The use of normative data is the primary method for interpreting an individual's cognitive test scores and statistical applications based on such data are used to make predictive interpretations of one's cognitive abilities.

Diagnostic Use and Interpretation

Although cognitive abilities are considered to be universal and fairly uniform across all races, the development of such skills has not only a genetic basis, but is contingent upon environmental, social, and cultural influences. Systematic study of cognitive measurement and interpretation of data in highly diverse populations has not been prolific. Consequently, there are not sufficient normative data available for most immigrant populations, and interpretation of test results using existing normative data may not be appropriate because it does not account for the linguistic, educational, cultural, and socioeconomic differences between groups. Therefore, the diagnostic use and clinical interpretation of cognitive measures in this population can result in predictive validity errors. For example, cognitive test data are interpreted as a false positive, resulting in a neurologically intact individual being misdiagnosed as cognitively impaired or in the opposite case, a false negative indicating that an impaired person has no deficits.

Fairness and Bias

Ethically, the intention of cognitive assessment is to make a fair and accurate measurement of cognitive ability. In this context, fairness equates to the absence of bias, ensures equal treatment throughout the testing procedure, and allows for an opportunity to learn the material being tested and to receive feedback about test performance. Bias is the result of systematic error inherent in the design and administration of cognitive measurement tools or in the interpretation of test results.

Two specific types of bias that may be inherent in the test itself are referred to as "construct" and "differential item functioning" bias. Construct bias may result when a test is designed to measure a cognitive construct, or domain, that has specific cultural relevance and differs between groups. Consequently, the measurement tool cannot validly measure this domain without demonstrating between group differences. This is because individual test questions are highly sensitive and do not capture important aspects of the domain as they translate to each population, or this type of bias occurs when the question is too generally worded, the domain is measured in such a broad way that the test captures extraneous or irrelevant information.

Differential item functioning bias occurs within the individual test items themselves, resulting from poorly translated words or phrases, ambiguous meaning, and the inclusion of cultural connotations. The validity of a cognitive test is questionable when more than one population repeatedly produces scores that do not have the same meaning across groups. In other words, the cognitive test's ability to make fair, accurate, and valid measurement is lost in translation.

Instrument and administration bias are also threats to the fairness principle known as equitable treatment and stem from how the test instrument captures information (for example, use of pen and paper versus a computerized tool) and the environment in which it is administered (for example, not reasonably accommodating for a disability). Bias can arise when interaction and communication between the *psychometrist* and the individual being tested impede the administration of the measurement tool.

Due to the number of biases that arise from systematic error inherent in the design and administration of cognitive tests, it is important to take into consideration an individual's educational experience, language proficiency, and socioeconomic context when making interpretations and predictions about the results of cognitive assessment in diverse minority groups, including immigrant populations.

Cognitive Testing and Social Factors

Language

Age at the time of immigration plays a critical role in language acquisition; upon immigration, children are likely to receive exposure to the new language by way of education and social interactions, which facilitate engagement in the nonnative language. Early learners of a second language are likely to develop well-versed bilingual competency when they regularly engage in their native language with family and friends or act as translators for other native language speakers.

On the opposite end of the bilingual spectrum, older immigrants may have less exposure to the majority language depending upon their age, occupation, and social-cultural role in the family or community. To varying degrees, these factors limit exposure and engagement in the majority language; this situation may be further compounded by reliance upon translation and living in ethnic enclaves.

In cognitive testing language, comprehension and fluency are important variables to consider, not only in regard to the fairness of the cognitive test and differential item functioning bias, but the difference between the cognitive activity that is required of bilingual versus monolingual individuals. Bilingual individuals are required to suppress or control engagement in one language when they are being tested in another. This behavior requires cognitive control, and the amount of effort required may vary, depending on how efficiently the appropriate information is processed, accessed, and retrieved by the brain and whether or not there is interference from the suppressed language. On the other hand, the cognitive practice that bilingual persons engage in is also believed to be a benefit to various aspects of cognition such as semantic memory and executive function.

Socioeconomic Status

Socioeconomic status (SES) is not always considered when interpreting cognitive test scores in the clinical setting. Immigrant populations with low SES may not have access to appropriate education, be subjected to financial stress, unable to find substantial employment, or have limited access to health care. Low SES immigrants may experience heightened financial, psychosocial, and acculturative stress, and are at increased danger for the development of diseases that result in cognitive impairment. Some studies indicate that controlling for SES may normalize cognitive data sufficiently and perhaps be more important than controlling for race, thus reducing predictive validity errors in cognitive measurement tools.

Current Directions in Cognitive Testing

Research and Development

Currently, there is a cross-cultural focus on the development and use of specific cognitive tools, but research that specializes in cognitive assessment of immigrants and immigrant subgroups is not abundant. In order to validate specific tools in this unique population further research is needed, via one-on-one interviews or by working with focus groups, to learn more about how group members understand cognitive test questions and whether or not the information elicited by the test question is an accurate and valid assessment of the mental processes and domains being evaluated.

Furthermore, investigation in this area should take into account differences in cognitive test performance related to sex, age, and race, as well as environmental factors that are highly influential in immigrant populations, such as regional migration patterns, familial migration history, educational experience, language proficiency, and socioeconomic status. Such research would allow for the tabulation of population-specific normative data and allow for greater accuracy when comparing an individual's cognitive performance to that of their peers, thus ensuring a more accurate assessment of one's cognitive abilities.

Collectivism

Collectivism is a learned culture-derived value and psychological alterable characteristic that is often contrasted with the value individualism. The term, which refers to the need to fit-in, is also known as interdependence, and contrasts with the need to stand-out also known as independence. Researchers have developed the independence-interdependence psychological measure to understand the influence that culture-level socialization practices have on an individual's endorsement of independence-interdependence.

Cross-cultural psychological research, conducted for over 3 decades, suggests that individuals born and raised in China, Greece, and Mexico, on average, tend to score higher on measures of interdependence when compared to individuals of Caucasian descent from Germany, Great Britain, and the United States. It is posited that on average, China, Greece, and Mexico engender individuals who will value belongingness and in-group harmony. On the other hand, it is posited that, on average, Germany, Great Britain, and the United States engender individuals who value competition, agency, and a strive for achievement. Research also suggests that individuals born and raised in a collectivist culture can reject the value of interdependence in favor of independence, vice versa, or may favor an integration of both values.

As a result of the blurring of cultural boundaries brought about by innovations in communications and technology, societies are becoming increasingly culturally and linguistically heterogeneous. Consequently, researchers are increasingly interested in measuring immigrants' health. However, a more complete understanding of immigrant health issues has been hindered by the failure to recognize that culture can be operationalized and measured beyond broad indicators such as ethnicity or race. Typically, ethnic groups are perceived as homogeneous and static regarding values and beliefs. This preconceived "homogenization" has resulted in the inadequate exploration of within and between ethnic group differences regarding the endorsement of cultural values. Thus, it is important to assess the degree to which an individual endorses interdependence and the way other factors such as acculturation, gender, and socioeconomic status influence such endorsements. Even if an individual immigrates into an individualist culture from a collectivist culture, other factors will influence the degree to which the immigrant retains or sheds values derived from the culture of origin.

Health research aimed at improving immigrants' health can explore the role that the endorsement of interdependence plays in the conceptualization and assessment of health-related constructs. For example, an individual's belief in his/her own ability to adopt a healthy behavior, also known as self-efficacy, is perceived as influenced solely by psychological aspects, which are internal to the individual. However, a recent study indicates that the construct of self-efficacy can be expanded to include aspects external to the individual such as the amount of social capital available. Researchers have found that the availability of social capital influences the self-efficacy of individuals who value interdependence.

Colombia

Luis F. Ramirez
Quality Outcomes Training, Brecksville, OH, USA

Background

Colombia is located in the upper corner of South America, where it is bordered by Panama on the northwest, Venezuela and Brazil on the east, and Peru and Ecuador on the southwest. Colombia is considered by many to be one of the most beautiful countries in South

America due to the magnificent combination of mountains, valleys, and the coasts of two oceans.

The name of the country, Colombia, comes from Cristóbal Colón (English: Christopher Columbus), acclaimed as the discoverer of America; it was adopted by Francisco Miranda to all the territories under Spanish rule. In 1819, the Viceroyalty of New Granada, consisting of Colombia, Panama, Venezuela, and Ecuador, became known as the Republic of Colombia. After a series of political and demographic changes, this region became known in 1886 as the Republic of Colombia, the name which is retained to today.

The capital city of Bogota has more than seven million inhabitants. Cali and Medellín each claim two million residents. Barranquilla has a population of more than one million and Cartagena has close to a million residents. There are almost 46 million individuals in an area of 401.042 square miles.
