Foreword

In the waning weeks of 2004, the Routledge publishing company approached one of us, J. Baird Callicott, proposing a two-volume, A-Z encyclopedia of environmental ethics and philosophy. Routledge had just published *Environmental Philosophy: Critical Concepts in the Environment*, a five-volume reference work of about one hundred classic and important papers in environmental philosophy, edited by Callicott and Clare Palmer. Routledge thought that an encyclopedia covering the field more broadly and in a more summary way would be of complementary value. Editing a collection of one hundred or so previously published papers is one thing—picking the papers; writing five or six introductions—while editing an encyclopedia of more than three hundred newly written articles by at least half as many authors is quite another. The overused expression, "herding cats," immediately came to Callicott's mind, but he accepted the challenge—with fear and trembling—despite his doubts about being up to the task.

The first thing to do was to assemble an editorial board. Working with Clare Palmer had been pleasurable as well as productive, and so she was a natural choice. No one has a deeper knowledge of the field than Holmes Rolston III, the founding "dean" of the field and compiler of the extensive annotated bibliography on the International Society for Environmental Ethics (ISEE) website. So he too was a natural choice. Robert Frodeman had just joined the Department of Philosophy and Religion Studies at the University of North Texas, as its chair, that year—of which Callicott was also a member. Frodeman had recently helped to found a sister organization to ISEE, the International Association for Environmental Philosophy (IAEP), which had budded off from the Society for Phenomenology and Existential Philosophy (SPEP)—so he could bring the perspective of "Continental philosophy" to the project, complementing the Anglo-American background of the two other associate editors and the editor-in-chief. The four of us met in Boulder, Colorado—where Frodeman was summering and which is just down the highway from Fort Collins and Colorado State University, Rolston's headquarters—in June of 2005, to sketch a list of article titles and identify potential authors.

Then, without warning, in August of the same year, Routledge decided to get out of reference-book publishing altogether and cancelled the contract. Callicott experienced mixed feelings—disappointment and relief—but, perceiving the capital importance of the undertaking, Frodeman urged that we look for another publisher. The *Encyclopedia of Science, Technology, and Ethics*, edited by Frodeman's friend and associate, Carl Mitcham,

had just been published by Macmillan; and Frodeman himself was author of several of its articles. So, after consulting with Mitcham, Frodeman pitched the project to Hélène Potter of Thomson Gale, publisher of the Macmillan imprimatur, and she immediately saw its value and secured an offer to publish the *Encyclopedia of Environmental Ethics and Philosophy*, the Foreword to which you are now reading.

In addition to his philosophical background, Frodeman brought training in science (geology), and policy (U.S. Geological Survey) experience to the project that Callicott lacked; and so Callicott asked him to come aboard as co-Editor-in-Chief. At the urging of Hélène Potter, the scope of the encyclopedia was broadened from a more narrow academic and Anglo-American focus to something more international and also inclusive of a wide range of issues and policies, points which Frodeman also favored. So the board of Associate Editors was reconfigured to reflect the larger compass of the Macmillan-published encyclopedia. Palmer, an Associate Professor of Philosophy at Washington University of St. Louis, is British and, as founding editor of the journal *Wordviews, Environment, Culture, Religion*, brought both an international perspective and an expertise in comparative religion and culture studies to the project. We (Callicott and Frodeman) invited Paul Thompson, Professor of Philosophy and Agricultural Economics at Michigan State University and Bryan Norton, Professor of Philosophy in the School of Public Policy at the Georgia Institute of Technology, to join the board of Associate Editors because of their expertise—similar to Frodeman's in this regard—in the area of environmental policy: Thompson primarily in food and agriculture policy, Norton primarily in conservation and environmental policy. Moreover, the philosophical affinities of both Thompson and Norton were oriented toward the rich tradition of American Pragmatism. As Pragmatists, their commitment to an anthropocentric approach to environmental philosophy and a greater concern for outcomes than theories complemented the non-anthropocentric and more theoretical commitments of Callicott and Palmer.

Finally, we invited Victoria Davion, Professor and Chair of the University of Georgia Department of Philosophy to join the board of Associate Editors. Davion is a well-known and -respected ecofeminist philosopher and founding editor of the journal, *Ethics and the Environment*. She brought to the board of Associate Editors, not only a feminist perspective on environmental ethics and philosophy, but also an expertise in other kinds of related intellectual hybridity, such as Deep Ecology and the kind of activist movements they inspired, such as Earth First! We are deeply gratified that all accepted to serve and we deeply appreciate their individual and collective contributions to this work. Meanwhile, Rolston was in process of retiring from Colorado State, but agreed to remain in an advisory role as Editor Emeritus and Bibliography Editor.

The two Editors-in-Chief (EICs) and the four Associate Editors (AEs) met with in-house executives, editors, and staff at the Thomson Gale headquarters in Farmington Hills, Michigan in December 2006. (Afterward Thomson Gale became Gale, a part of Cenage Learning.) The company has a vast experience in seeing encyclopedias through the process from conception to publication and that process was explained in detail to all of us. An in-house editor, Jason Everett, was assigned to work with us from beginning to end. Basically, the six of us (EICs and AEs) have been responsible for the encyclopedia's intellectual content; the publisher's staff—led, in our case, by Everett—were responsible for everything else. Our responsibilities were both limited to and tailored to what we were competent to control, the intellectual content of the encyclopedia. And the in-house editors could be in total control of the process and not have it be mismanaged by a bunch of absent-minded professors—who were also doing full-time jobs in addition to all their encyclopedia work, including, in both Frodeman's case and Davion's, chairing the philosophy departments of large public universities.

The whole field, broadly conceived, of environmental ethics and philosophy was divided among the AEs, who thus became "Area Editors." Thompson's area included food and agriculture; Norton's (like the others, among other things) conservation and related

laws; Palmer's religion and the environment and things international, such as the Earth Charter; and Davion's modern philosophy, in which she has a strong background, as well as ecofeminism and various activist movements.

Every article in this encyclopedia has been reviewed, edited, and approved by one of the AEs and both the EICs. In some cases we rejected an article outright. In almost every instance the article was returned to its author for revision. Depending on the extent of the recommended revision, a revised article would go through either the whole review process again or a more cursory review by one or the other or both of the EICs.

As we went into 2008, with a publication date set for November 7 of that year, the editorial process kicked into high gear as deadlines loomed. By mid-June, Everett had managed—with much behind-the-scenes cajoling and sometimes a little extortion—to get all the articles submitted, processed, and sent to the typesetter. In the meantime, the EICs were working on the back matter and the front matter. Rolston had submitted his annotated bibliography and it remained to us to edit it. We had selected the primary documents and, at Everett's suggestion, we invited one of our UNT graduate students, Jonathan Parker, to write the accompanying "blurbs"—the head notes preceding each. We also invited another of our UNT grad students, William Grove-Fanning, to take on the task of writing the definitions that appear in the glossary. We reviewed and edited the blurbs and the glossary. We would like to thank both Parker and Grove-Fanning for their excellent work.

The final tasks for the EICs, as July 2008 drew to a close, was to complete the Introduction and also the Foreword and the Afterword. As with most of the academic editorial tasks for this work, we tackled these jobs cooperatively. We consulted, we exchanged drafts, we cut, we pasted, we edited, and we agonized. Each of our own personal proclivities and inclinations were tempered by those of the other, to achieve what we hope is a useful, probative, balanced and, not least, inspiring Introduction.

Because the articles in the main body of an encyclopedia appear alphabetically, the user of an encyclopedia has only the guidance that the editors provide at the end of each to see how that article might be related to other articles in the encyclopedia. To augment this method of grouping, the editors have also provided a thematic or topical outline in the front matter, in which the titles of articles are grouped according to theme or topic. Most of these topics are self-explanatory and need no further explanation here in the Foreword.

However, the several categories of biography cry out for clarification. As an identifiable subject matter, environmental ethics and philosophy came into existence in the 1970s. Thus we have biographies of "self-identifying environmental philosophers"—those who do or would if pressed—call themselves "environmental philosophers." Not all self-identifying environmental philosophers have a biographical sketch devoted to them and their work. In addition to making a substantial and influential contribution to the field, we decided to limit the category to those whose body of work is complete or nearly so—in practice, those who are either deceased or have entered the seventh decade of their lives. Richard Sylvan, for example, who wrote the first philosophical paper on environmental ethics, died in 1996. Arne Naess—founder of the Deep-Ecology school of environmental philosophy—is still living, but has entered his tenth decade. Val Plumwood died in 2008, but, as a person having entered her seventh decade, already had a biographical sketch devoted to her and her work. (And, we might add in passing, she had submitted an article for publication in this encyclopedia only a few weeks before her death.) Robert Frodeman, for example, does not have a biography devoted to him and his work, despite its substance and significance, because, as a younger scholar, his contribution to the field is far from complete.

One of the first things the newly minted environmental philosophers did in the 1970s and 1980s was to identify their "precursors"—people who contributed to environmental ethics and philosophy before environmental ethics and philosophy were recognizable as such. The holy trinity consists of Henry David Thoreau, John Muir, and Aldo Leopold, but

they were by no means the only precursors. Some of the "notable environmentalists," such as Chico Mendes and Ken Saro-Wiwa, exerted their influence less through thought than through action. Others, like Eugene P. Odum (an ecologist), Edward O. Wilson (a biologist), and Gary Snyder (a poet) are certainly thinkers as well as doers, but their contributions parallel and cross-fertilize those of environmental philosophers. The "historical figures" are the thinkers of the more distant past who have attracted much attention from environmental philosophers: Francis Bacon and René Descartes are routinely vilified by environmental philosophers; while St. Francis of Assisi is routinely lionized; and Baruch Spinoza's worthiness to be regarded as a distant precursor has been hotly contested.

We would like to express our deepest appreciation and gratitude to Jason Everett, first and foremost, and the rest of the in-house editorial staff at Cengage Gale, including Ken Wachsberger who helped review the main body manuscript and managed processing of the back matter. We are keenly aware, looking back on the whole process, that this work would not exist were it not for their skills and diligence. We would like to thank Dale Jamieson for reviewing a draft table of contents and offering helpful criticisms and suggestions. Also, we would like to thank another of our UNT graduate students, who is now a doctoral student of philosophy at the University of Colorado, Erin Moore, who provided us with administrative assistance at the beginning of this project and later filled several breaches by writing a couple of articles, which, for one reason or another, were left unwritten by other authors—in addition to those she originally volunteered to write. A special thanks goes to our home institution, the University of North Texas, which has supported this project from the beginning through to completion, both financially and through release time. Our Dean of Arts and Sciences, Warren Burggren, has been stalwart in support of this project, which has been crucial to its timely completion. And last but not least, we would like to thank all the authors who contributed to this work. It is their work as much as it is ours, the editors, both in-house and academic.

J. Baird Callicott and Robert Frodeman

Introduction

In 1988 *Time* magazine's "Man of the Year" was not a man—or even a human—at all. It was the Earth itself. This Earth—simultaneously resilient and fragile, beautiful and functional, a pale blue dot floating in the inky blackness of space—has been for millennia the taken-for-granted background of all human activities. It has served as storehouse and refuse bin. It has been pushed and prodded, shaped and reshaped, sometimes beyond recognition (see the "Mining: III. Mountaintop Removal" entry). And now, it seems, humanity may be facing a day of reckoning. If the present reality were a disaster movie, its title might be *The Earth Strikes Back.*

In December 2006 the project team for the *Encyclopedia of Environmental Ethics and Philosophy* met in Farmington Hills, Michigan. Our task that day was to explain why this undertaking was worth the lives of so many trees. Our answer was that students, teachers, professors, professionals, and the public need a source that provides succinct accounts of the core values and issues surrounding humanity's relationship to the natural world. Given the importance of today's environmental challenges, a synoptic account of environmental attitudes and values is crucial.

Given the magnitude of our environmental problems, philosophy has become practical again. The development of environmental philosophy—which originated in the 1970s—was inspired by the widespread perception of an "environmental *crisis*." The manhandling of nature turned the attention of a small group of philosophers to questions concerning human obligations to (or for) nature—that is, to environmental *ethics*. The earliest work in environmental philosophy is narrowly located in the area of environmental ethics, and the bulk of it still is. The field reflects mostly the Anglo-American philosophical approach, which draws on the legacy of ethical theory inherited from modern European and North American philosophy as refined in various ways by British, Australian, and American academic (or professional) philosophers. (See the Afterword for a more detailed account.)

As the field has matured, it has attracted thinkers with a wider range of perspectives and interests. For example, feminist environmental philosophers (ecofeminists) expanded the field to a focus on epistemology, critiquing knowledge and truth claims made by those vested with power and authority. Continental philosophers entering the field focused attention on ontology with (to mention only one instance) a critique of the previously taken-for-granted Cartesian notion of an isolated immaterial self inhabiting an alien material body. To what degree are we truly distinct from nature? Analytically trained philosophers of science are now

taking an interest in ecology and conservation biology, fields closely allied with environmental ethics. And politically oriented thinkers have raised questions of justice vis-à-vis nature, especially as regards the distribution of environmental burdens and benefits across populations.

After a period of adolescence, environmental philosophy is bursting through conventional disciplinary boundaries—a trend that has placed it increasingly at odds with the academic-philosophy establishment. This encyclopedia, intended for an audience spanning both academia and the larger public, is one reflection of this development. In what follows we characterize the fields of philosophy and ethics from the point of view of concern with the natural environment. We then turn to the question of how environmental ethics and philosophy is transforming the discipline of philosophy and the world itself as the twenty-first century unfolds.

PHILOSOPHY

For most of its history, philosophy was far from an academic exercise and was deeply involved in thinking about nature. Philosophy was born independently in several isolated parts of the world during the "Axial Age," a period of world history roughly five or six hundred years before the common era (BCE). Confucius in China, Siddhartha Gautama (the Buddha) in India, and Socrates in Greece all lived at about the same time and all reflected a profound, even revolutionary change in human consciousness.

Prior to the Axial Age, myth was the main human mode of thought about the world. Mythic thought is well adapted to an oral means of communication. The linguistic form that myth takes is poetry, which both enhances its aesthetic appeal and assists in memorization. The meter and rhyme of poetry discipline memory; if the meter is out of sync or if it fails to rhyme, the rhapsode and his audience alike are alerted to an error in a myth's transmission. Myth also takes the form of narrative—a story line, which also aids memory—and thus necessarily involves action and actors faced with moral choices.

To us modern sophisticates, the great myths of the past appear quaint and fantastic, so straining credulity that we can scarcely imagine how people took them seriously. In the Greek myth of creation (or procreation), for example, a male sky god, Ouranos, impregnates a female earth goddess, Gaia, who gives birth to all the forms, features, and forces of the natural world—mountains, seas, winds, and so forth—and even to things that we would regard as psychological states, such as love (Eros).

In an age in which human consciousness has long been conditioned by literacy, such tales seem ridiculous, but they reflect the fact that for most of history, humans felt located within a cosmos. The myths themselves were a fabulous expression of a profound intuition—that humans live in a richly layered and alive universe full of meanings and portents and that their decisions and actions fit within the greater story of nature. This worldview was quite different from the post-Enlightenment picture of the world as consisting of purposeless atoms in motion, devoid of moral meaning. Aristotle represents atoms (in which he himself did not believe), quite revealingly, by analogy with letters. Letters are the meaningless elements of meaningful written words. Atoms are the meaningless elements of "meaningful" natural entities. (And yes, the atomic theory of matter itself was a product of ancient Greek natural philosophy.)

The invention of writing in many forms over many centuries created new means of storing information, freeing the human mind to do things other than maintaining and reproducing the precious oral traditions that constituted the cultural heritages of humanity. The Greek alphabet was the first to introduce symbols for vowels; it thus enabled written Greek to perfectly mirror spoken Greek. The linguistic form of literacy is prose; hence the structure of literate thought becomes less of a story line and more logically ordered.

The logical structure of thought is, like the written form it takes, quasi-spatial—a type of conceptual architecture having foundations and multiple but ordered and systematic

connections among its parts. Narratives remained, but they were more and more submitted to increasingly rigorous logical analysis. As ancient Greek philosophy progressed, logic emerged more clearly in the thought of Parmenides and Zeno and, with Aristotle, became a matter for systematic reflection and formal expression in, for example, the syllogism.

Literacy, especially the Greek alphabetic form of literacy, makes the independent status of abstract ideas both more possible and plausible. For now a word—the same word—can be both heard and seen, embodied in both sound and ink. By itself, the word is neither an audible sound nor a visible figure. It transcends both these forms of material embodiment; it flies from the world, an immaterial, abstract entity. Plato seems to have been so impressed by the novelty of the abstract idea that he idealized abstractions with his Theory of Ideas or Forms.

Moreover, literacy intensifies individuality. Oral communication—as the word *communication* suggests— necessarily involves a community; and myth is the common cognitive property of a community. In a state of orality, one's personal identity is thus merged with one's community. But one can read and write alone; the written text directly addresses the mind of the reader. One's personal identity is thus dissociated from that of the community, and it, too, is disembodied. Thought is no longer necessarily ours but can become mine or yours, personally. The prospect of personal death thus soon emerged as a leading philosophical problem, especially in both India and Greece. In India the problem was solved by meditatively dissolving one's individual being into universal Being. In Greece some thought (Plato among them) that the solution to that problem might lie in the prospect of the existence of a disembodied (or heavenly) world to which the disembodied individual self might repair upon the death of its bodily vehicle.

After its birth in the Axial Age, philosophy developed differently in China, India, and Greece. In China, consistent with the traditional Chinese veneration of ancestors, new thinking had to be tied securely to the thinking of the founder. In China, therefore, there is a long tradition of Confucianism, which survives down to the present in a form that is faithful to and would be recognizable by the Master himself. In contrast, although Socrates is a venerated figure, there is no comparable Socratism in the European and North American cultural tradition descended from the ancient Greeks. In India, consistent with the traditional Indian practices of yoga and meditation, philosophy was more intimately bound up with religious belief and practice than in it was in Greece. Siddhartha Gautama became the Buddha, the founder of a still-vital world religion.

It is important to emphasize that the first philosophy in the European tradition—the tradition in which environmental ethics first emerged—was "natural philosophy." That is, the first European philosophers asked and boldly answered questions about nature such as the following: (1) Of what is the world composed? The first answer was water; among the last was atoms. (2) What principles or laws govern its behavior? The logos, Heraclitus declared, which unites the ideational and natural world. (3) What forces move it? The worldly impulses of love and strife, according to Empedocles, and mind, according to Anaxagoras.

The first Greek philosophers who focused their thinking on nature were especially concerned with understanding the relation between the microcosm (things human) and the macrocosm (the larger natural universe). These first philosophers speculated that all things arose from a single, living, self-organizing, intelligent, and divine natural substance—variously identified as water or air—and that into it they will eventually return. Greek philosophy was founded on the assumption that there was an intelligible order to the universe and that this order expressed the purpose inherent in all things. The main concern of natural philosophy was less with what today we call *nature* (rocks, animals, ecosystems), but with the *natural*: the way things are implicated in the κοσμοσ the beautiful order and the way things are supposed to be.

Heraclitus, among the first philosophers in the European tradition—and the one most frequently invoked by contemporary environmental philosophers as a distant precursor—

certainly embedded his thinking in the natural world. His most famous dictum—that you cannot step into the same river twice—points up the temporal nature of all things. Indeed, the thought of almost all the pre-Socratics (as they are usually called) was suffused with nature: the four elements of Empedocles were earth, air, fire, and water rather than abstract and theoretical entities (such as Democritus's tiny, invisible atoms). Even though the atomic theory of matter is of ancient Greek origin, the Greek philosophic tradition, including the philosophies of Plato and Aristotle, portrayed a meaningful, living, and divine cosmos in which the human social and personal microcosms were embedded and which they reflected.

Writing is a form of technology, and so it is somewhat paradoxical that an essentially material invention made possible immaterial or abstract thought and an individual, private, and disembodied self. The birth of Greek philosophy, however, did not mark the abandonment of interest in the natural world characteristic of the mythic mode of thought—the first philosophers were primarily interested in the nature of the cosmos. With Socrates, however, philosophy made a decisive turn away from cosmology and the link between the natural world and human affairs. In Plato's *Phaedrus*—and Plato is our main source of knowledge about the philosophy of Socrates—Socrates famously claimed that his concern was only with the world of men and that nature had nothing to teach him. Moreover, as Greek philosophy progressed and Christianity appeared, distrust of the body grew, with an increasing focus on a mentalist view of life that turned away from human embeddedness in the natural world.

Reviving ancient Greek atomism, seventeenth-century natural philosophers—Bacon, Descartes, Galileo, Newton—described a natural world devoid of purpose: only efficient or mechanical rather than final causes existed. It took a while for this message to take hold: Natural theology still flourished through the eighteenth century, in the form of the argument from design. For William Paley, then the most notable proponent of that argument, the natural world exhibited an order that could only be explained by referring to a creative, purposive intelligence.

With F. W. J. Schelling's death in 1854, natural philosophy dissolved into science. Philosophers no longer sought the purpose of human life within the processes of the natural world. From then on, the scientific method provided our only rational access to the world, with the great traditions of natural philosophy and theology relegated to the shadows of history. The scientific method revealed only a physical world driven by blind causes. In 1859 Darwin's theory of natural selection delivered the final blow to teleological accounts of nature—nature explained in terms of either its inherent purposiveness or divine design—by offering a nonteleological explanation of biological adaptations. In his 1871 book, *The Descent of Man*, Darwin explained all things human by the same theory. By placing human beings firmly within a directionless natural order, Darwin left us as purposeless, in relationship to the cosmos as the merest molecule.

ETHICS

A turn from philosophy in general to ethics in particular invites a comparison of the European tradition with others that sprang from the Axial Age. Unlike other philosophic traditions, such as Buddhism, which emphasized the importance of not harming any sentient creatures, Greek and subsequent European and North American ethical thinking has traditionally operated within a human context. It was not until the twentieth century that thinkers such as Aldo Leopold explicitly sought to enlarge the moral community beyond the human.

In ordinary discourse, the term *ethics* often refers to a code of conduct or a set of rules that is supposed to govern or guide behavior. The Ten Commandments is a familiar example. Thus, readers who consult a work titled *Encyclopedia of Environmental Ethics and Philosophy* might well expect to find—at least somewhere therein—a code of environmental conduct that might look something like this:

1. Thou shalt not litter.
2. Thou shalt not pollute thy air and water.
3. Thou shalt not burn incandescent light bulbs.
4. Thou shalt not drive a Hummer.
5. Thou shalt not waste resources.
6. Thou shalt recycle.
7. Thou shalt eat organic foods.
8. Thou shalt reduce thy consumption.
9. Thou shalt xeriscape thy lawn.
10. Thou shalt install solar-energy panels on thy roof.

As treated, however, in the long history of philosophy—going back more than 2,500 years—ethics has not been particularly concerned with formulating codes of conduct. That is the task of "moralists" or, when enacted as laws, of legislators. Rather, ethics has been preoccupied with three other more general and abstract tasks.

First, one task of ethical reflection is to identify that single overarching principle—or those very few general principles—that lie behind the codified laundry lists of ethical dos and don'ts. For example, John Stuart Mill argued that lying behind our inherited code of conduct, the rules by which we govern our behavior (such as thou shalt not steal, thou shalt not commit adultery, and the like), is the "principle of utility," or the general-happiness principle. These rules guide human behavior in such a way that, on the whole and on average, following them will achieve the greatest happiness of the greatest number (of human beings): that is, the greatest utility.

Second, philosophers have sought to expose the *foundations* of ethics. Why, for example, should the principle of utility—human happiness—be a goal of human action? In sharp contrast to Mill, Immanuel Kant thought that it should not. In his estimation, reason lies at the foundations of ethics and is better suited to determine human duties. Reason, rather than happiness, is the ground of human freedom, human autonomy, and ultimately human dignity.

Third, philosophers have sought to discover the origin of ethics. Does ethics arise when groups of competing, hostile individuals agree to refrain from doing various harmful things to one another—such as killing one another and stealing from one another—that serve no one's ultimate advantage? According to the social-contract theorists, such enlightened self-interest is the origin of ethics, which humans create to protect themselves from one another. Or is ethics a natural outgrowth of family and community life, where natural bonds of affection are enlarged and codified as communitarian theorists argue?

As noted above, ethical systems in European and North American culture have expressed only a limited concern for the natural world. True, for thinkers over the 2,500 years, *nature* has signified a natural order that is simultaneously metaphysical and moral: Both individual human beings and human society are viewed as microcosms to be modeled upon the macrocosm of natural processes. Humankind has sought principles for how to live—that is, an ethic—and ethics would find its basis in an understanding of the basic purpose of the universe. This last concern fell within the domain of metaphysics. Aristotle, Plato's successor in the tradition of European philosophy, called the questions of metaphysics "first philosophy." He held that, although ethics was the fruit of philosophical reflection on practical wisdom, the principles that grounded our ethics must be sought among the cosmic "causes"—especially the final cause, which pertains to the ultimate end, goal, or purpose.

Although there has been a deep-seated ethical naturalism in European philosophy—no less than in Chinese Daoism—there was little or no consideration of what we would call

environmental ethics in that tradition until the mid-twentieth century. Nature itself, especially at the cosmic scale, seemed beyond the reach of humans' ability to affect for good or for ill. Although guidance may have been sought from an understanding of the macrocosmos, ethics was confined to the microcosmos of human affairs. The actual physical world of plants, animals, and ecosystems was relentlessly exploited. The same was true throughout the non-European world as well. For example, although Chinese philosophy, especially Daoism, promoted attitudes that were apparently more ecologically sensitive, China was ecologically ravaged and its resources exploited to the maximum degree possible for a preindustrial society. And with the rise of scientific materialism as a global worldview, philosophical commitments to an ethics grounded in nature gradually declined the world over.

Even before the final death throes of cosmos-grounded ethics and natural theology, European philosophers were seeking a noncosmological basis for ethics: Kant in the faculty of reason, Mill and Jeremy Bentham (the founder of utilitarianism) in pleasure and pain. For all their differences, what united these eighteenth- and nineteenth-century ethical theories was the sense that there was no point in looking to nature for a normative principle. Nature modeled nothing except chance and necessity. Physics and ethics, the material universe and the good life, lost their connection. One important trend in contemporary environmental ethics and philosophy is to reunite them—if not physics and ethics (and some have seen ethical implications in quantum physics), then ecology and ethics. The very first paper on environmental ethics by an American philosopher—Holmes Rolston III—was titled "Is There an Ecological Ethic?" In a subsequent paper his title asked, "Can and Ought We to Follow Nature?"

The loss of nature as a normative principle has prompted the development of proceduralist approaches to ethics. Once we deny the possibility of identifying a common good somehow rooted in nature, all that remains are rules and procedures. Justice becomes redefined as whatever comes about when one faithfully follows a set of rules. Contemporary ethics often means engaging in the proper process rather than attaining insight into the ultimate good and cultivating virtue. From a purely procedural-ethics perspective, the question of what constitutes the good life is now a private issue—private by default, because the question is no longer believed to be subject to rational debate and resolution.

By the twentieth century, then, the modern, relativistic, proceduralist, and pleasure-oriented stance toward ethics had become the received viewpoint both inside and outside the university. But although ethics became, on the common view, both subjective and relativistic, it also retained its hold on the cultural imagination. Call it a performative contradiction, but people remain insistent, even zealous, about protecting and defending their rights, even when no agreement was thought to be attainable about what rights are or why humans, uniquely, have them. This fact made it inevitable that environmental philosophy would be cast in terms of environmental ethics, even if environmental concerns regularly strain the bounds of ethics. What about animal rights? That is a reasonable and meaningful question to ponder, even if, on reflection, one concludes that animals cannot have rights. One environmental historian, however, was led to wonder, "Do rocks have rights?" It is hard to make sense of that question, much less imagine how it could be possible that they do. The silliness of that question marks the limits of environmental ethics and poses the need for environmental philosophy to go beyond ethics into the terra incognita of environmental metaphysics, epistemology, aesthetics, and other domains of philosophical inquiry.

In today's prevailing worldview, the physical world is nothing but brute matter and blind energy devoid of purpose, a world that science can in principle fully describe. In the positivist spirit of late twentieth century, metaphysics in the grand manner, aesthetics, and theology had become antiquated categories, expressions of dogmatism and subjectivity that had lost their raison d'etre. In the 1960s, when environmental issues caught the attention of the public, these concerns were naturally expressed in the two languages most likely to get a hearing: science, which defined the real, and ethics, which addressed questions of rights and obligations. John Passmore summarized the state of affairs within environmental philosophy

in the title of his book (one of the first book-length treatments of environmental ethics), *Man's Responsibility For Nature* (1974). Passmore argued that humans could not have any responsibility to the aimless material aggregation that is nature; their only responsibility was to guard against nature becoming the medium of injustice to other humans, say through the prodigal use of natural resources and wanton disposal of waste.

In opposition to Passmore's anthropocentrism, the main quest of environmental ethicists since 1980—the holy grail, so to speak, of the field—has been to find a plausible and defensible theory of intrinsic value located somehow in nature. On the hypothesis that nature has intrinsic value—which, it must be said, has been developed in many and varied ways—natural objects either have a value independent of human valuers or at least are valued for their own sakes rather than for their usefulness, their instrumental value.

ENVIRONMENTAL ETHICS AND PHILOSOPHY

An excellent historical and systematic review of environmental ethics and philosophy is found in the entry of this encyclopedia titled "Environmental Philosophy: V. Contemporary Environmental Philosophy" by Andrew Brennan. Here we have tried to locate environmental ethics and philosophy in the history and future of European and North American philosophy, the philosophical tradition from which it first emerged.

European and North American philosophy took an unprecedented and, we believe, anomalous turn at the beginning of the twentieth century. The major division of ancient Greek philosophy was that between natural philosophy and moral philosophy. After the long Christian-dominated medieval interregnum, the ancient Greek philosophical texts were rediscovered during the Renaissance, and the early modern philosophers of the seventeenth century picked up where the ancient Greeks left off. But after a century or so of development, philosophy evolved into modern science: Bacon and Descartes renounced final causes, and scientific investigations began to ramify into astronomy, physics, and chemistry.

In the late nineteenth century many of the concerns of ancient moral philosophy were budding off from the mother discipline in the form of the modern social sciences: sociology, psychology, economics, anthropology, and political science. Also at this time the U.S. college was superseded by the research university, which was dedicated to the production of specialized new knowledge. Scholarly expertise mushroomed as scholars of all types became specialists. The traditional role of the philosopher as inspired generalist seeking a view of the whole was increasingly marginal to the brave new educational enterprise.

Some philosophers protested this state of affairs; in 1905 William James complained of the "plaster-grey temperament of our bald-headed young Ph.D.s boring each other in seminaries, and writing those direful reports of the literature in the 'Philosophical Review.'" Others, however, sought to identify their own region of specialization—their own "regional ontology." Anglo-American (that is, Australian, British, and U.S.) philosophers found their own turf to stake out—the analysis of language—and, aping science, cultivated a "rigorous" science-like methodology based on logic. Why language? Philosophy, historically, especially after Kant, was concerned with the conceptual structures of the human mind. But concepts are immaterial things if they are things at all and the mind was philosophically lampooned as the "ghost in the machine." The syntactical and especially the semantic structure of language, however, embodies immaterial conceptual structures and thus gives philosophy something more material that it can analyze empirically in a science-like manner.

Although Anglo-American logical positivism, the prototype of what eventually came to be called "analytic philosophy," celebrated—to the point of adulation—science, the scientific method, and "positive" scientific knowledge, continental philosophers (i.e., those whose work evolved from thinkers from the European continent, such as G. W. F. Hegel, Friedrich Nietzsche, and Wilhelm Dilthey) offered up a wholesale critique of science and a radical alternative to it: phenomenology. Modern science posits as ultimately real a fundamental set

of entities—such as subatomic particles like electrons and photons—that we do not directly experience and, indeed, cannot even sensorially imagine. In addition to fabricating reality out of a skein of abstractions, science regards all events as causally determined, whereas human consciousness seems intentional and free. In contrast, phenomenology sought to provide a detailed description of the world that we directly experience and an exploration of "intentionality" or consciousness.

As twentieth-century philosophy developed, the discipline—in both its analytic and continental manifestations—became ever more arcane and self-absorbed. To make matters worse, the two camps became seriously estranged. Phenomenologists saw analytic philosophers as suffering from physics envy, whereas analytic philosophers dismissed continental philosophers as philosophical charlatans devoid of rigor. The natural and social sciences, meanwhile, went about their business with spectacular success, as measured by the level of funding they received, the number of the members of various scientific societies, and their usefulness to the advance of various technologies. What united the two camps of philosophers was the curiously dogmatic and unexamined assumption of specialization and expertise—that philosophers, like scientists, should specialize, drawing themselves ever more tightly into smaller and smaller communities of adepts who spoke a language impenetrable to outsiders.

Thus conditions were set when academic environmental ethics came on the scene in the 1970s: it was first ignored, and then dismissed as not "real philosophy" by both the analytic establishment and the more marginalized community of continental philosophers. The field seemed too interdisciplinary and too closely allied to real-world problems. Moreover, because it was closely allied to ecology rather than physics, analytic philosophers dismissed it, whereas continental philosophers recoiled from it as too scientific, a fellow traveler of "naturalism," guilty of a blind commitment to the methodological canons of the hard sciences. Thus, by the powers that arbitrated late twentieth century philosophy, environmental philosophy was no philosophy at all.

But the field would not go away, in part because it was engaged with something relevant and useful outside the walls of academia. Increasingly, natural-resource managers, ecologists, conservation biologists and professionals in both the theoretical and applied environmental sciences took an interest in the values aspects of environmental problems. There was, moreover, a growing demand by students for environmental ethics courses on college campuses. And the few but gradually growing number of professional philosophers who were attracted to the field realized that environmental ethics and philosophy returned philosophy to its traditional role of synthesizing as well as analyzing—philosophy conceived not as handmaiden and emulator of the sciences, not as quixotic challenger of the sciences, but, once more, as queen of the sciences.

As many of the entries in this encyclopedia attest, Lynn White Jr.'s article "The Historical Roots of Our Ecologic Crisis," published in *Science* in 1967, stimulated the development of environmental ethics and philosophy by academic philosophers. In that essay White laid the blame for the environmental crisis at the doorstep of Christianity, with its belief that "man" is created in the image of God, given dominion over the rest of creation, and commanded to subdue it. Christianity was the dominant worldview in Europe when both science and technology began to take their eventual form, and modern, science-enhanced technology is the proximate cause of the environmental crisis.

That is indeed the lurid text of that essay. But there is a deeper subtext. A constant refrain in "Historical Roots" is that what humans *do* in and to the natural environment depends on what they *think* about it. So in order to change what they do in and to the natural environment, they must first change what they think about it. More science and more technology will not solve the environmental crisis, White averred (indeed, more of the same will only make matters worse, in his view) unless we "rethink our axioms," that is, our most

fundamental beliefs concerning the nature of nature, human nature, and the relationship between humans and nature. And whose job is it to do that? Philosophers.

White thus implicitly—and, we daresay, unwittingly—set the agenda for a future environmental philosophy. The first item on the agenda is to criticize the evidently erroneous ideas that we have inherited from our past intellectual tradition about these matters. Why are they evidently erroneous? Because having guided our behavior toward the environment by what we think we know about nature and who we are in relationship to nature, we have encountered some unexpected and untoward consequences, which are more than just "side effects." These untoward surprises are collectively called the environmental crisis. It is as if nature were talking back to us and informing us that we have mistaken her for something she is not—something like a machine with which we can tinker and reengineer. White began the critical phase of this agenda with his critique of the Judeo-Christian worldview; but, as this essay amply illustrates, Christianity is by no means the only legacy of ideas originating in Europe. We must critically revisit atomism, Platonism, hedonism, and Cartesian dualism in the new light of the environmental crisis. The second item on the agenda of a future environmental philosophy, as White implicitly set it forth, is speculative: we must somehow reconceive nature, human nature, and the proper relationship between humans and nature. One way we might do that, White suggested, was to look into non-European traditions of thought for insight into these perennial themes in all human thought. That stimulated the emergence of comparative environmental philosophy. However, as White also indicated, turning for guidance to non-European traditions of thought is by no means the only way, or perhaps even the best way, to rethink our axioms.

Environmental ethics and philosophy could thus liberate philosophy from the narrowness and overspecialization into which it had fallen during the twentieth century. The environmental crisis gives philosophers an opportunity once more to ask and to try to answer the big, perennial questions that, until the twentieth century, philosophers of all the past ages and in all traditions tackled. We do not, let us hasten to say, imagine that all future ethics and philosophy will be environmental ethics and philosophy. Rather, environmental ethics and philosophy are the harbingers of the more general shape that philosophy is likely to take in the future. All future philosophy, like environmental philosophy of the present, will probably look outward toward other disciplines—rather than inward toward its own—as a vital component of interdisciplinary problem solving. In addition to environmental ethics and philosophy, biomedical ethics has been pioneering this new interdisciplinary focus, though with less radical a departure from traditional moral paradigms. Also, some philosophers in the analytic tradition have been working at the interface of philosophy of language and linguistics, philosophy of mind and neuropsychology.

INSTITUTIONAL TRANSFORMATION

The most daunting and vital challenge humankind faces today is coping with global climate change. As that challenge grows more acute and urgent with each passing day, the need for interdisciplinary approaches to knowledge will also become more acute and urgent. As Lynn White so clearly pointed out, the response to such a formidable threat cannot be exclusively scientific and technological. How can human problems be solved without employing the resources of the humanities and especially those of philosophy? For who but philosophers can undertake the task of rethinking our axioms, our most basic ideas about the nature of nature, human nature, and the proper relationship between humans and the natural environment?

One of the consequences of the inbred nature of philosophic research is that the question of the institutional status of philosophy has not been considered philosophical enough to warrant being the subject of articles, conferences, and curricular and institutional reform. For most of the past century the discipline has ignored the philosophic dimensions of the institutional setting and structure of philosophy. Why is it uncritically assumed that the proper, indeed the only real role for philosophers (environmental or not) is to write arcane philosophy papers for other philosophers? Isn't philosophy too important to simply

be left to . . . well, philosophers, cloistered academicians? Future historians may come to see the environmental crisis as the occasion for philosophers to once again do philosophy in the grand manner of the rich and marvelous two and a half millennial tradition of European philosophy—a philosophy once again abroad in the world, willing to get its shoes muddy and its hands dirty.

Environmental philosophy and ethics have exploded in a wealth of critical and creative theorizing—not only ethical theory but also, more recently, theoretical aesthetics, metaphysics, epistemology, social and political philosophy, and nearly every other domain in the European tradition from which it first emerged. Now, some think that environmental philosophers have overindulged themselves in an orgy of theory at the expense of having an impact outside the environmental-philosophy community and closely related academic fields, such as ecological restoration, conservation biology, and ecological economics. Especially the "environmental pragmatists" have vigorously registered the complaint that environmental philosophers have been too preoccupied with theory and need to become more relevant.

Bryan Norton, one of the associate editors of this encyclopedia, is well known for advocating a policy-oriented approach; he recommends thinking about environmental ethics as a force in public policy first and examining philosophical questions in passing. Norton, it is worth noting, is located in a school of public policy rather than in a department of philosophy. Norton also distinguishes between applied and practical philosophy—the former applies theoretical principles to problems, whereas the latter begins with real cases and seeks to insinuate philosophic insights into these cases in a spirit of amelioration and compromise. In a similar vein, in 1994 Donald Van de Veer and Christine Pierce published the textbook *The Environmental Ethics and Policy Book: Philosophy, Ecology, Economics.*

But none of this seems to have moved the needle. The reason is that even the environmental pragmatists are still trying to make better or different arguments rather than focusing on the institutional situation of and disciplinary limitations of environmental philosophy. It is one thing to call for relevance and engagement; it is quite another to roll up one's sleeves, get to work, and get on with the job.

The contested future of environmental philosophy—theoretical, applied, or practical, to employ Norton's taxonomy—turns on something other than more metatheoretical debates among environmental philosophers. Instead we might, for instance, raise logistical questions: should philosophers be housed (or housed exclusively) in philosophy departments, or should they be scattered across campus? Some already are. In addition to Norton's location in a school of public policy, the environmental philosopher Dale Jamieson is the director of environmental studies at New York University, with a joint appointment in the NYU Law School; he has only the most circumspect involvement with the NYU philosophy department, one of the most narrowly focused and specialized in the United States. The environmental philosopher Michael P. Nelson is located in the Lyman Briggs College of science at Michigan State University, with a joint appointment in philosophy; and Paul Thompson, also one of the associate editors of this encyclopedia, has a joint appointment in the Michigan State philosophy department and the MSU Department of Agricultural Economics in the College of Agriculture and Natural Resources. (If space permitted, this list could easily be lengthened.) We might also ask whether or to what degree environmental philosophers can find employment as philosophers, beyond academia. We might even wonder whether philosophy should be regarded as a discipline in the same sense that other fields are. Most expansively, we might ask what public roles philosophy can take in these philosophically dynamic and unsettled times.

Above all, environmental philosophy should continue explicitly to challenge the current, failing, and curiously ahistorical notion of philosophy that has dominated the academy during the past 100 years. The history of philosophy is calibrated in centuries: the sixth, fifth, and fourth centuries BCE; the seventeenth, eighteenth, and nineteenth centuries CE; and the

twentieth century has now passed into history as well. Surely it is strange that the same people who pay homage to our philosophical ancestors—Socrates, Descartes, Leibniz, Nietzsche, Dewey—fail to recognize that if a young version of any of these thinkers showed up for a job interview today he or she would be dismissed out of hand. None of these immortal philosophers in the European and North American tradition were well-trained specialists in the contemporary academic sense. None of them spent all their time reading and writing for a philosophical audience. And we think it is quite unlikely that they would unquestioningly adapt to the times and start reading and writing for the *Philosophical Quarterly* or *The Journal of Philosophy*.

There are some signs that this insular view of philosophy is finally being challenged. At our own institutional home, the Department of Philosophy and Religion Studies at the University of North Texas (UNT), we are gaining a reputation for a new, "UNT model" of a philosophy department. The difference is not limited to our focus on environmental ethics and philosophy. The entire department participates in the "dedisciplining" of philosophy—for instance, by hiring and tenuring an ecologist (with an M.A. in philosophy) within the department, by giving greater credit toward tenure and promotion for publishing *outside* rather than within the confines of recognized philosophy forums, and by projects like UNT's field station in environmental philosophy at Cape Horn, Chile.

Even the logistics of our department challenge the twentieth-century model of philosophy as a discipline among disciplines, with a well-defined subject matter, a rigorous methodology acquired through training (as opposed to education), carried on in a jargon-laden discourse unintelligible to outsiders. We are housed in the UNT Environmental Education Science and Technology building, and our offices are scattered among those of our fellow denizens, mainly geographers and biologists; and many in our department are active members of UNT's Institute of Applied Sciences. This interdisciplinary housing arrangement has not been just cosmetic. It has enormously affected the intellectual lives of almost everyone in the building, prompting philosophers to get interested in the sponsored research projects of the environmental scientists, whose research projects are in turn enriched by the contributions of the environmental philosophers, who are inspired to propose sponsored research projects of their own, enriched by collaboration with the environmental scientists.

We believe that the efforts at UNT portend a view of twenty-first century philosophy as an interdisciplinary and transdisciplinary activity rather than one among other disciplines. These are possibilities that we hope will find welcoming soil in other locations: philosophy gone wild, or perhaps better said, gone feral. *The Encyclopedia of Environmental Ethics and Philosophy* reflects this enlarged vision of the subject it treats. Although the rich, nearly forty-year history of theoretical environmental ethics and philosophy is well represented here, we have also included articles on environmental policy and law; case-study articles on important events, such as the Chernobyl nuclear accident; articles on activist movements, such as EarthFirst! and the German Green Party; articles on geophysical phenomena such as rivers, forests, and mountains; biographies of doers such as César Chávez as well as thinkers such as Holmes Rolston III; and much more, as the Thematic Outline systematically reveals. In the main body of this work the reader will find the full spectrum of what environmental ethics and philosophy was, what it is, and what, we believe, it will become.

Robert Frodeman and J. Baird Callicott

Afterword: General Types of Ethical Theory

A new development in physics, such as Albert Einstein's Special Theory of Relativity, must have some continuity with the existing state of physics that it advances and transforms; otherwise, it could not even be recognized as physics. Similarly, a new development in ethics, such as environmental ethics, must have some continuity with the existing state of ethics to be recognizable as ethics. Because environmental ethicists have advanced and transformed the existing state of ethics, we thought it would be helpful to summarize the stock of ethical theories on which environmental ethicists have built. There are a limited number of types of ethical theory that have emerged in moral philosophy over the two and a half millennia of its history. Here we review the most important. And we illustrate how they have lately been advanced and transformed by environmental philosophers.

THE THEORY OF DIVINE ORIGIN

Antedating moral philosophy was the age-old belief that ethics are of divine origin. In the Hebrew Bible there is the dramatic portrayal of Moses going up on Mount Sinai to receive from God the Ten Commandments, etched onto stone tablets. In Hesiod's *Theogony*, which functioned among the Greeks as Genesis and Exodus functioned among the Israelites, one finds an equally dramatic portrait of the triumph of Zeus and his ordination of Justice as the governing principle of mortals and immortals alike. If God or Zeus is the source of ethics, such a divinity is also the source of moral truth and authority. While one might question an ethic wrought by humans, one can hardly question a god-given ethic. And if ethics have a divine origin, they also are sanctioned by divine authority punishing transgressors. The notion that the origin of ethics is divine is a perennial theory espoused in various permutations by ancient, medieval, and modern philosophers of various religious persuasions. But contrary to the belief of the many people whose main source of moral guidance is religious scripture, a divine origin is by no means a necessary condition of a robust foundation for ethics.

As we indicated in the Introduction, Lynn White, in "The Historical Roots of Our Ecologic Crisis," blamed Christianity for the environmental crisis. He claimed that Western civilization has been premised on the idea that humankind was created in the image of God, given dominion over the creation, and commanded to subdue it. The influence of this worldview over two thousand years culminated in modern technological civilization, which, along with many wonderful things, has also brought about our current environmental crisis.

This historical analysis provoked those with strong Christian commitments and equally strong environmental concerns to develop an alternative interpretation of the biblical texts, the first two chapters of Genesis, that were the basis of White's allegations. The result was a Judeo-Christian environmental ethic of stewardship. After each day of creation, God declared his work to be "good," which can be interpreted to mean that the creation has what environmental philosophers call "intrinsic value." For humans, being created in the image of God implies unique responsibilities—first among them, to care for the creation—as well as unique privileges. Further, to have dominion over the creation is not license to destroy it, but responsibility to manage it as a steward employed by a property owner, who, in the case of the creation, is God. The stewardship interpretation of the first chapter of Genesis is confirmed in the second, where it is written that Adam, the first man, was created to "dress and keep" the Garden of Eden, which could be interpreted to refer to the whole of nature freshly created. Islam also includes Genesis among its sacred texts, so this scripture-based environmental ethic is as applicable in the context of that religious tradition as it is in the context of Judaism and Christianity.

RULES VERSUS VIRTUES

Modern Westerners are inclined to think of ethics in terms of sets of rules, or codes of conduct. The ancient Greeks, on the other hand, were inclined to think of ethics in terms of virtues, or qualities of character. Though Western civilization largely descended from Greek origins, most contemporary Westerners are inclined to think of ethics more in terms of rule obeying than in terms of acting virtuously. The reason for this is that between the ancient Greek origins of Western civilization and the present, the West was long dominated by a religious tradition of Middle Eastern origin, the Judeo-Christian tradition.

Judaism is a religion of laws, the Ten Commandments being only the most prominent. And Christianity, erected on a Judaic foundation, inherited and perpetuated a legalistic conception of ethics—a Golden *Rule*, for example. For the ancient Greeks, a good person is one who manifests virtue. In the Christian-influenced West, a good person is one who follows the moral rules, the Ten Commandments, say. While the Greeks recognized many virtues, they too had a short list of important ones, later called "the cardinal virtues" —prominently among them: justice, courage, temperance, wisdom, generosity, and piety.

SOCIAL-CONTRACT THEORY

In the history of Western moral philosophy, the first, and still viable, theory of ethics was the social-contract theory of the origin and nature of ethics. This theory of the origin of ethics is equally a theory of the origins of formal governments and political states. Thus the social-contract theory is as much a mainstay of political philosophy as it is of ethics. This is reflected in one of the great debates surrounding Plato's magnum opus, the *Republic*.

At the beginning of the second book of the *Republic*, Socrates' interlocutor, Glaucon, summarizes the social-contract theory as it was then variously articulated by the so-called sophists—among them Thrasymachus, with whom Socrates had jousted in the first book of that great work. According to Glaucon's summary, the social contract is a mutual agreement among mutually hostile egoists to practice the personal virtue of justice as a burdensome and onerous means to an end—protection from the depredations of others—not as a good in itself. And Glaucon begs Socrates to offer a plausible alternative to that widely circulating and variously expressed theory of the origin of justice. So the bone of contention in the great debate among Plato scholars about the purport of the *Republic* is this: Some argue that the central theme of the *Republic*, as its name would suggest, is political philosophy and only secondarily ethics. Others contend that Plato's description of the ideal state is only his analogical way of describing the ideal condition of the soul: virtue, especially the virtue of justice, writ large in the body politic. The *Republic*, in other words, is primarily an ethical treatise and only secondarily an exercise in political philosophy.

However that debate may be resolved, the social-contract theory of the origin and nature of ethics (and of states) was variously promulgated: most notably by Protagoras (a contemporary of Socrates) among ancient Greek philosophers of the fifth century BCE, by Thomas Hobbes among early-modern philosophers of the seventeenth century, and by John Rawls among late-modern philosophers of the twentieth century. It thus nicely illustrates how the philosophical treatment of ethics transcends apparently incommensurable popular conceptions of ethics, in this case, a Judeo-Christian legalistic conception and a Greco-Roman aretaic (or virtue) conception. That the social-contract theory could explain equally well the origin and nature of justice (in both the personal and political sense of the word) and the other cardinal *virtues* as it could the *moral rules* forbidding murder and theft testifies to its powers of generality and comprehensibility. But the social-contract theory of the origin and nature of ethics is by no means unique in this regard. All moral philosophies worthy of the name should have this capacity.

According to the social-contract theory, ethics arise when mutually antagonistic individuals agree to refrain from doing various harmful things to one another—such as killing one another and stealing from one another—which come to no one's ultimate advantage. According to the social-contract theory, the nature of ethics is enlightened self-interest. As with most historical theories of ethics, the social-contract theory in its ancient, early-modern, and late-modern iterations is anthropocentric—only human individuals were thought to be eligible parties to a social contract. If domestic animals, however, were not enslaved and domesticated by force, but voluntarily associated with humans—as some accounts of domestication indicate—then such animals and the humans they associated with had forged something analogous to a social contract. Thus has Bernard Rollin adapted the social-contract theory to nonanthropocentric animal ethics.

Animal ethics can be grounded especially well by social-contract theory in the hypothetical version of it developed by John Rawls in the twentieth century. Rawls dispenses altogether with the notion of an actual state of nature prior to the social contract, in which fully human individuals were supposed by ancient Greek sophists and, in a more circumspect way, by Hobbes to have lived as solitaries, each at war with every other. Instead, Rawls asks us to imagine an "original position" behind a "veil of ignorance," which prevents one from knowing anything about one's eventual lot in life: one's race, gender, sexual orientation, religion, intelligence, and other natural capacities. Nor does one have any prior knowledge of one's preferences or tastes, even of one's conception of the good. Rawls's version of the social-contract theory is thus an excellent illustration of what we noted in the Introduction: that ethics in the twentieth century tended to be bled dry of substance and reduced to procedural form. As long as the circumstances of rule making are guaranteed to be unbiased, that is all that is required for justice as fairness. Under such circumstances, we can well imagine that the rules such individuals would create for themselves would prohibit discrimination based on race, gender, sexual orientation, religion, and various kinds of disability. Now add ignorance of one's species to the list of things that the veil of ignorance conceals, and we can also well imagine that the rules would also prohibit discrimination based on species. Going beyond animal ethics, a contemporary French environmental philosopher, Michel Serres, has even proposed a *contrat naturel*, or natural contract, analogous to the social contract—that is, a contract between humans and a personified Nature.

PLATO'S THEORY OF JUSTICE AS HARMONY

From the point of view of the social-contract theory, ethics, though grounded robustly, are created by convention; they are human artifacts, not divine artifacts. Plato discerned three weaknesses in this stance. First, ethics and egoism—the basic assumption of social-contract theory that people are concerned only with their own interests and are indifferent to the interests of others—work against one another. One has grudgingly to give fair consideration to the interests of others in exchange for their fair consideration of one's own interests. Second, because ethics are represented as only an indirect means to achieving the ultimate

goal of maximizing one's own self-interest, one might best maximize one's own self-interest by appearing to be ethical—and thus enjoying all the benefits of a member of society in good standing—while secretly committing murder, theft, and other crimes to advance one's own ends. This is the moral of the story of Gyges in Plato's *Republic*. In the divine-origin theory, however, you can run, but you cannot hide; that is, you cannot escape detection and fearsome retribution by Zeus or God. But if morality is not divinely sanctioned, people can get away with murder, as we say. Third, Plato thought that the social-contract theory misrepresents human beings as hyperindividualistic, that is, as egoists, originally living as mutually belligerent solitaries in a state of nature. Rather, Plato thought, human beings are quintessentially social beings *naturally* living in societies or communities.

Plato believed, however, that the divine-origin theory of ethics was no longer persuasive by his time. Formerly, to the oral-mythic mind, Zeus was not only the author and enforcer of ethics, but also the cause of various natural phenomena—such as lightning and thunder, rain and snow—which, over the course of the previous two centuries, the natural philosophers had begun to explain more convincingly as phenomena that had natural, not supernatural, causes. Widespread skepticism about Zeus's existence thus made the divine-origin theory of ethics no longer viable.

So Plato devised an alternative to both the divine-artifact and human-artifact theories of the origin and nature of ethics: Justice is the natural condition of both the soul and the body politic (society), just as health is the natural condition of the physical body. Injustice, Plato observes, creates faction, hatred, enmity, and conflict in society, while justice creates unity, friendship, peace, and harmony. Injustice creates the same condition in the psyche, fracturing the soul into warring parts and inducing pangs of conscience, remorse, and guilt. Plato does not altogether challenge the presupposition that the supreme good is maximizing one's own self interest. Rather, he makes being virtuous the very essence of self-interest—it enables a life of inner personal and outer social unity, friendship, peace, and harmony. Thus, Plato identifies the supreme human good in three formally similar and *natural* manifestations: first and foremost, virtuous qualities of character (the good of the personal soul), physical health and well-being (the good of the personal body), and a just and well-organized society (the good of the body politic). These in turn "participate" in the cosmic Form of the Good, the general principle of order and harmony in the universe.

Plato's influence on environmental ethics has been both subtle and diffuse. For example, J. Baird Callicott (who began his philosophical career as a scholar of ancient Greek philosophy) has argued that the human economy is a proper part of the economy of nature, and thus that the human economy should mold itself to the same form as the economy of nature. The economy of nature is organized on the basis of a solar energy budget and the biogeochemical cycling of materials—such as carbon, nitrogen, and other elements—through the earth's ecosystem. The human economy, on the other hand, supplements its solar-energy budget with nonrenewable energy from fossil fuels; and rather than assiduously cycling materials, it causes most of them to flow linearly from sources, such as mines, to sinks, such as landfills. Thus, the human economy is out of phase with—that is, not in harmony with—the economy of nature. Practical projects as various as Wes Jackson's attempt to create an agriculturally viable "perennial polyculture," based on the form of prairie ecosystems, and "industrial ecology," in which the waste of one industry (such as spent fry oil in the fast-food industry) becomes the raw material for another (the biodiesel industry), are attempts to harmonize the human economy with the economy of nature.

ARISTOTLE'S VIRTUE ETHICS

Aristotle, who succeeded Plato in the historical dialectic of ideas in Western philosophy, thought that the supreme human good was *eudaimonia*, often inaptly translated as *happiness*. But *daimōn* in Greek means *spirit* (and is the word from which the English word *demon* is derived, although the Greek word has no pejorative connotation). And *eu-* in Greek is a prefix meaning *well* (still functioning that way in English in such words as *euphoria*, *eulogy*,

and the like). So all human action aims, Aristotle thought, at a well spirit, at a good condition of the soul. But what is this condition, more precisely? And how can it be realized?

We can get a clue, Aristotle suggests, by examining more limited human functions. What is a good musician, a good doctor, a good carpenter? Simply to realize well the nature of those professional functions. A good doctor and a bad doctor are both doctors, but the former doctors well and the latter doctors poorly. Similarly, a good human and a bad human are both human beings, but the former realizes human nature well and the latter does so poorly. And what is human nature? Aristotle gave us the classic definition: *Anthropos* (humankind) is the rational animal. Hence, to be a good human is to live the animal life—having passions and desires and experiencing their pleasurable satisfaction or painful frustration, activities that we share with all other animals—governed by reason, a capacity that is uniquely human.

One fundamental attribute of reason is the ability to weigh and measure, to find the mean or ratio (the root Latin word of the English word *rational*) between extremes. Our animal desires and passions run to extremes. Animals often sate their hunger until they are gorged and express their rage to the point of violence. And as animals, we are variously inclined to gluttony and abstemiousness, debauchery and celibacy, fury and diffidence, rashness and terror, and many similar extremes of desire and passion. However, the good *rational* animal will find the ratio, the mean, between the extremes of excess (too much) and defect (too little). From this analysis, Aristotle derives the cardinal virtues commonly recognized among his contemporaries: Temperance is the mean between eating and drinking too little (abstemiousness and teetotalism) and too much (gluttony and inebriation); courage is the mean between cowardice and rashness; generosity is the mean between stinginess and prodigality; and so on. Thus, a functionally good human being is a morally good human being, from an Aristotelian point of view, as well as a happy human being.

Just as Christianity has its Golden Rule, so Aristotle's classic ethic has its Golden Mean: the rationally determined intermediate state between excess and defect. Virtue ethics—as the ethical tradition inherited from the ancient Greeks and given classical philosophical expression by Aristotle is now called—was vigorously revived in the twentieth century, most notably by Alistair McIntyre, and was popularized by William (Bill) Bennett, who has a Ph.D. in philosophy and served as secretary of education and then drug czar in the George H. W. Bush Administration. Virtue ethics has also been adopted as one approach to environmental ethics, as detailed by the entry of that title in this encyclopedia.

HEDONISM AND UTILITARIANISM

In the *Nichomachean Ethics*, Aristotle devotes much critical discussion to the hedonistic theory of ethics, a theory promulgated by Greek philosophers as early as the fifth century BCE. It is most commonly associated with Epicurus, Aristotle's younger contemporary, who was born in the fourth century BCE and lived into the third. The Greek word for pleasure was *hēdonē*, and hedonism is the theory that the good or end of all human action is pleasure and, just as important, freedom from pleasure's contrariety, pain.

Of course, in ordinary English, a hedonist is someone who pursues the former with no regard for assiduously avoiding the latter. But Epicurus and his followers carefully examined various kinds of pleasure *and* their various attendant pains, if any, and recommended eschewing those pleasures inherently linked to pains—such as the way the pleasures of inebriation are inherently linked to the pains of a hangover or the way the pleasures of tobacco smoking are linked to the pains of lung cancer and heart disease. Moreover, they discriminated among the qualities of different kinds of pleasures, commending not only those that are "purer" (unassociated with attendant pains), but also those that are "higher," namely, the pleasures of the spirit or soul (such as those of listening to music or poetry or engaging in philosophical discussion), in contrast to those of the body (such as those associated with eating, drinking, and fornicating).

Utilitarianism is the modern descendent of ancient hedonism. According to Jeremy Bentham, founder of the modern utilitarian school, the goal of human action is happiness, and happiness, he states, consists of a greater amount of pleasure over pain. Bentham developed a crude "hedonic calculus" intended to quantify pleasures and pains in order to make a rational choice among alternative courses of action so that one might choose the alternative that would result in the greatest quantity of pleasure and the least of pain. Bentham democratically refused qualitatively to discriminate among "higher" and "lower" pleasures, instead making a case for preferring the aesthetic, intellectual, and spiritual pleasures strictly on the basis of their net quantity. John Stuart Mill, his successor in the tradition, pointedly differed in this regard. While ancient hedonism emphasized personal pleasure and pain, modern utilitarianism emphasized collective happiness or "aggregate utility"—the greatest happiness *of the greatest number*.

As clearly demonstrated by the entry herein on cost-benefit analysis, utilitarianism is the ethical theory on which contemporary economics is based. As utilitarianism developed in twentieth-century economics, its hedonistic foundations were abandoned in favor of the concept of "preference satisfaction." The goal of human action is to maximize welfare (not necessarily happiness) and welfare consists in satisfying human preferences (not necessarily in achieving a greater amount of pleasure over pain).

Utilitarianism has had a central role in the development of animal ethics. Because animals too can experience pleasure and pain, the utilitarian principle of equal consideration of equal interests requires, according to Peter Singer, that we give equal consideration to the interest that all animals—not just human animals—have in enjoying pleasure and, more especially, in living free of pain.

KANTIAN DEONTOLOGY

The principal modern philosophical antagonist to the utilitarians is Immanual Kant, whose moral philosophy has no antecedent in ancient Greek ethical theory. The utilitarians determine the moral value of an action on the basis of its consequences. If it produces utility, it is good; if it produces disutility, it is bad. Kant thought that consequences were irrelevant to whether an action is good or bad, right or wrong. He would agree, in other words, with the popular moral adage, "Do the right thing, and let the chips fall where they may"—the chips here being the morally irrelevant consequences of the right thing.

But if not by reference to consequences of actions, how do we determine what is the right thing to do? Kant's answer is that a moral action is one in accord with universal law. This is captured in the popular moral question often asked when contemplating doing an ethically questionable action: "What if everyone acted that way?" If the answer is that one would not want everyone else to act that way, then neither should one act that way oneself. According to Kant, one has a duty to act only in ways that one can universalize—that is, that one can will that others act in the same way as oneself.

Because of his stress on the moral importance of duty, Kant's ethic is technically labeled *deontology*, from the Greek word for duty *deon*. The duty to act in a way that can be universalized rests on a fundamental principle of reason: self consistency. Kant's example is promise making. Suppose that we are contemplating making a promise that we have no intention of keeping. Then we ask ourselves, What if everyone always made promises with no intention of keeping them? Then, ironically, no one could make a promise, because no promise would ever be believed, and so promise making would cease to be possible. When universalized, falsely promising self-destructs. So also with stealing. If everyone always stole everything then there would no longer be any private property, and so no one could steal anything (an alleged condition of the state of nature, made vivid by Hobbes). In every transgression of duty, we find a "contradiction of the will": We at once will that everyone act in a certain way while we make an exception for ourselves.

An idea of central importance to environmental philosophy is traceable to Kant's ethics: the concept of intrinsic value. Kant believed that reason conferred intrinsic value on rational

beings, or, more technically and precisely, that intrinsic value supervenes on rationality. Because rational beings possess intrinsic value, they deserve to be treated as ends in themselves, according to Kant, not as means only to the ends of others. Human beings routinely treat nonhuman organisms as mere means, as "natural resources." Some environmental philosophers think that one way to expand Kant's "kingdom of ends"—so that it would include some nonhuman organisms—is to find some property other than reason on which intrinsic value might supervene. Tom Regan has argued that this property ought to be robust consciousness, and that all "subjects of a life"—that is, all beings that have a subjective, conscious life, such as the "higher" animals—should have intrinsic value. Paul W. Taylor has argued that this property ought to be having interests or a good of one's own. Then all "teleological centers of life" —in effect, all organisms—would have intrinsic value.

THE THEORY OF MORAL SENTIMENTS

Kantianism and utilitarianism have dominated ethics in modern philosophy and have been the dominant schools of thought informing the ethical thinking of laypersons and policy makers, who try to achieve aggregate utility while protecting individuals' rights (resting on their intrinsic value). As noted, a third tradition, social-contract theory, has been only a little less influential in modern times, mainly among libertarians, free-marketers, and property-rights zealots. A fourth tradition in modern moral philosophy has been less widely influential, but deserves mention here: the theory of moral sentiments advanced by David Hume and Adam Smith in the eighteenth century.

As we have seen, most traditional Western moral philosophy involves reason in some centrally important role. In social-contract theory, reason illuminates the path to enlightened self-interest and the need to make peace with one's rivals. In Aristotle's virtue ethics, reason is part of the essence of the human species and the faculty that steers us toward the Golden Mean. In utilitarianism, reason calculates aggregate utility and enables rational choice. For Kant, reason is the source of the moral law and the ground of the intrinsic value of rational beings.

Hume, in the spirit of a contrarian, declared that reason is never a motive to action—neither right actions nor wrong actions—and both is and ought to be the slave of the passions. The difference between moral and immoral actions has nothing directly to do with reason, according to Hume. Rather, moral actions are motivated by other-oriented sentiments, such as sympathy and benevolence, which are just as much a part of the human psychological constitution as self-oriented sentiments, such as greed and lust—the only ones recognized by the social-contract theorists.

Reason, according to Hume, does have an important supporting role to play in the drama of ethical behavior. It discerns the often complex relations of cause and effect and the proper objects of our various other-oriented moral sentiments. Along these lines, Aldo Leopold, for example, devotes much of *A Sand County Almanac* to informing readers of the existence of a "biotic community," which he thinks should be a proper object of our moral sentiments of affection, respect, loyalty, and sociability.

EMOTIVISM

A degenerate form of Humean ethics, called emotivism, was prominent in twentieth-century analytic philosophy. The logical positivists declared that only empirical statements are meaningful. Ethical statements such as "Murder is wrong and bad!" are merely emotive ejaculations expressing the feeling of repugnance that the declarer experienced in contemplating murder. Among the many untoward consequences of this theory of ethics is moral relativism. If someone else were sincerely to say "Murder is good and right!" this person too would only express a feeling—in this case a feeling of pleasure upon contemplating murder.

However, because these expressions of feelings correspond to nothing in the real world, neither declamation regarding murder can be true or false, according to the positivists. Murder is neither right nor wrong, neither good nor bad. Moreover, all putatively assertive

ethical statements are actually just expressions of *personal* feelings, contradictions between which cannot be intellectually adjudicated and resolved any more than conflicts among children about which color is the prettiest. Emotivism has powerfully contributed to a phenomenon, noted in the Introduction, characterizing much twentieth-century ethical thought: the subjectivization and privatization of the good and the associated reduction of ethics to a procedural form.

Hume himself, in contrast, thought that the moral sentiments were a normal aspect of universal human nature. Just as all human beings normally have five fingers on each hand, so all human beings normally have the same set of moral sentiments. Thus while the statement "Murder is wrong and bad!" may be unverifiable by reference to some state of the physical world, it can be verified by reference to the normal state of human psychology. And just as, owing to accidents of birth or physical trauma, some people do not have the physically normal number of digits, so, owing to similar causes, some people do not have the psychologically normal set of human feelings. They are morally abnormal. Those who are morally abnormal to a grotesque degree, such as serial killers, are often tellingly and properly referred to as "monsters."

Thus, from a Humean perspective, moral norms are rooted in human psychology, just as medical norms are rooted in human anatomy and physiology. A temperature of 98.6 degrees Fahrenheit is the human physiological norm—deviation from which is cause for medical remediation. A strong aversion to murder is the human psychological norm—deviation from which is cause for social remediation. Yet Hume's theory of ethics does allow for some limited cultural relativism. The moral sentiments are both natural and universal, but they are often channeled differently in different cultural contexts.

Hume's theory of ethics also allows for moral education. Leaders of the American Civil Rights movement, such as Martin Luther King Jr., addressed the familial sentiments of their fellow Americans by insisting that racial differences are literally only skin deep, and that we humans are all really "brothers and sisters under the skin," members of one human "family." Similarly, Leopold, as just mentioned, tries to inform our moral sentiments by accessibly expressing information provided by the science of ecology. The most important piece of information forthcoming from ecology, Leopold thought, is that in addition to our many human-community memberships, we humans are also members of a biotic community.

EVOLUTIONARY ETHICS

Hume's theory of moral sentiments formed the basis of Charles Darwin's account of the origin and development of ethics in *The Descent of Man*. Reason-based ethical theories are suspect from an evolutionary point of view. The social-contract theory nicely illustrates why. As noted, in Hobbes's putative state of nature, fully human individuals are imagined to live in a condition of war, each one against every other. Because in such a condition, life is "solitary, poor, nasty, brutish, and short" (to quote Hobbes), it dawns on them that it would make sense to call a meeting and hammer out some rules, the mutual observance of which would make life a lot better for all, and to appoint a sovereign to enforce the contract they all agree to. But how could reason or even speech evolve in the absence of well-formed and well-integrated cooperative societies? The evolution of reason depends on the prior evolution of society, but the social-contract theory assumes that the emergence of society depends on reason, which is the source of self-interested enlightenment. Yet proto human societies could not exist without ethics. As Darwin notes, "No tribe could hold together if murder, robbery, treachery, etc., were common." Therefore, reason cannot be a sin qua non of ethics. Rather, as Hume thought, ethics must rest on something far more primitive, namely, the moral sentiments, such as affection, sympathy, and benevolence.

Darwin's theory of the evolution of ethics has been developed not in the late-modern philosophy of the twentieth century, but in twentieth- and twenty-first-century biology—first in sociobiology and later in evolutionary psychology. It has also been of great importance to environmental ethics. Aldo Leopold was the first person extensively and

systematically to outline an environmental ethic. Because he was more conversant with Darwin's biological account than with the standard philosophical accounts of ethics, he based his land ethic on Darwin's evolutionary account of the origin and development of ethics in *The Descent of Man*. And because Darwin's account rests on Hume's theory of the moral sentiments, the foundations of Leopold's land ethic are traceable to Hume.

CODA

All secular environmental ethics so far devised have built on one or another of the historical moral philosophies reviewed here. Religiously specific environmental ethics have been based on the tenets of various religious traditions—not only of Judaism and Christianity, but also of Confucianism, Daoism, Buddhism, Hinduism, Jainism, and Islam. The articles in this encyclopedia focused on religiously specific environmental ethics provide the background necessary to understand them. We thought that it would be helpful here to provide the background necessary to understand the various articles detailing secular theories of environmental ethics, which assume some familiarity on the part of the reader with the perennial types of ethical theories in Western moral philosophy and thought.

Thematic Outline

The following classification of articles arranged thematically gives an overview of the variety of entries and the breadth of subjects treated in the encyclopedia. Along with the index and the alphabetic arrangement of the encyclopedia, the thematic outline should aid in the location of topics. It is our hope that it will do more, that it will direct the reader to articles that may not have been the object of a search, that it will facilitate a kind of browsing that invites the reader to discover new articles, new topics, related, perhaps tangentially, to those originally sought.

A

ABBEY, EDWARD

1927–1989

Edward Abbey was born in Indiana, Pennsylvania, on January 29, 1927, and died in Tucson, Arizona. A talented author described as the Thoreau of the desert Southwest (Fadiman 1968, McMurtry 1975, Cahalan 2001), in essays and novels Abbey extolled individualism and decried the effects of the destruction of wilderness on human liberty.

In the spirit of self-invention, Abbey cultivated the image of a rough-hewn redneck (Abbey 1991), a persona that belied a sophisticate who listened to Sibelius and Shostakovich and playfully referenced Socrates, Shakespeare, Schopenhauer, and Sartre in his writings.

Abbey was not an environmentalist in the conventional sense (Berry 1990). He rolled a tire into the Grand Canyon (Abbey 1988a), rhapsodized about the virtues of littering highways with beer cans (Abbey 1977), and claimed that he killed a rabbit with a rock (Abbey 1988a, Cahalan 2001). He was not an environmental philosopher, although he earned a bachelor's degree in English and philosophy and a master's degree in philosophy. He initially resisted the path of academe (Abbey 1990a) but eventually became a tenured professor of English at the University of Arizona (Cahalan 2001).

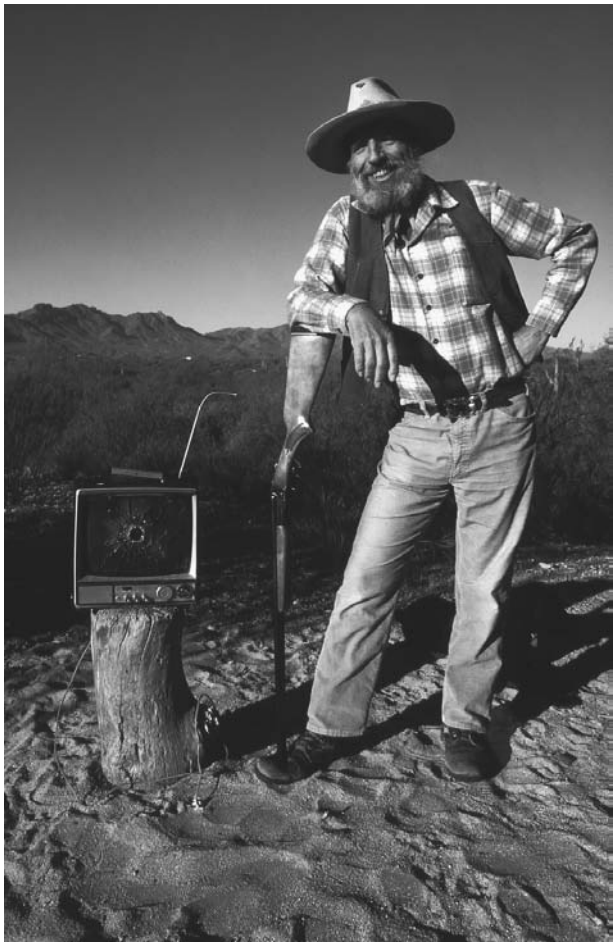
Although Abbey never produced a recondite analysis of the axiology and metaphysics of nonhuman nature, his work has important implications for environmental ethics (Rothenberg 1998). In his master's thesis in philosophy he argued that although resistance to domination is morally justified, violence against people is not (Abbey 1959). Abbey reworked this tenet decades later within the framework of environmental activism: Safeguarding wilderness from industrial defilement through sabotage of machinery is permissible as long as no injury results (Abbey 1990b).

Sabotage may be considered radical, but Abbey displayed traditional American libertarianism. According to Abbey, any form of repression—governmental bureaucracy or corporate hegemony—must be thwarted. In the western United States such authoritarianism is symbolized by rising dams, wending roads, and metastasizing suburbia (Abbey 1988b), making the means of their production legitimate targets for ''ecological sabotage.''

Existentialism—the idea that each individual must create life-directing meaning in the absence of objective ethical norms—is also a prominent theme throughout Abbey's work. Human potential cannot be achieved without the freedom to pursue possibilities, and in this activity people are on their own; no transcendent being helps them in the struggle (Abbey 1988a).

In Abbey's view, self-actualization is of the highest importance for ethics. Wilderness, with its gifts of wonder, surprise, solitude, and danger, is the ideal stage on which to act out the unfinished script each person has been handed. In wilderness lurks danger (Abbey 1987). Danger hovers at the limits of possibility. Exploration of these limits—death or exultation—is freedom. Freedom is the summum bonum of human existence (Abbey 1985).

The failure of industrial civilization lies in its inability to recognize the multidimensional noneconomic values of untrammeled land—aesthetic, ecological, and spiritual—that are essential to human well-being. Abbey



Edward Abbey. *Shown here near Tucson, Arizona in 1986, Abbey was not a typical environmentalist. Through his writings, Abbey espoused his libertarian beliefs about the threat of industrial tourism for the Wilderness.* **PHOTO BY TERRENCE MOORE. COURTESY OF TERRENCE MOORE PHOTOGRAPHY.**

at times seems misanthropic (Abbey 1988a), yet careful exegesis reveals a robust humanism.

Abbey's rant against "industrial tourism" (Abbey 1988a) can be analyzed in several ways. An environmentalist interpretation emphasizes the denigration of wilderness. A Marxian interpretation emphasizes the reification of wilderness travel into commodities purchased at visitor centers and shopping malls. An existentialist interpretation emphasizes the inauthenticity of sanitized experience: glossy pamphlets, scenic drives, paved nature walks, handrail-circumscribed overlooks, panoramic movies shown in air-conditioned and insect-free auditoriums.

Although all three interpretations are present in Abbey's work, the existentialist viewpoint looms largest: People are the real losers to industrial tourism (Abbey 1988a). The fundamental ontology of human being remains hidden amid the cacophony of civilization and is discernible only in the context of wildness.

By most measures Abbey lived wildly: drinking liberally, coveting numerous women, living from paycheck to paycheck, traveling incessantly. By his own admission, he diverged from Thoreau's fastidious New England sensibilities (Abbey 1982). Nonetheless, a comparison of the two authors is instructive. Both loved to meditate on the relevance of wilderness for the human condition. Both have been categorized as nature writers but are best characterized as prescient social commentators whose critiques have implications for environmental policy.

Abbey was an existentialist with environmentalist proclivities. It is not clear whether for him nonhuman nature has intrinsic value independently of human cognition. It is clear that nonhuman nature has extrinsic value for the authenticity of human experience it enables. Wilderness delimits ranges of possibilities; it is up to each individual to discover those limits. Wilderness experience allows people to glimpse their inner humanity.

ADAPTIVE MANAGEMENT

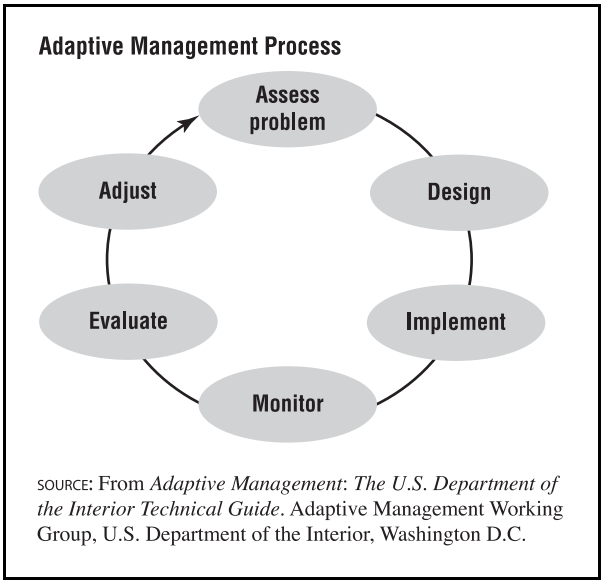
Adaptive management, also called collaborative adaptive management (CAM), has deep roots in the environmental professions reaching back at least to Aldo Leopold's emphasis on community, ecology, and prudence. CAM reflects a shift in worldview from arrogance, control, and technocracy to humility, learning, and collaboration. It accepts that ecological and social systems are so complex and dynamic that our knowledge of them will always be partial. It expects to be surprised by an unpredictable future. It views every management action as an opportunity to learn. And it helps to refine visions of a desired future as humans collaboratively adapt and reformulate management goals in response to experience.

In principle, CAM is as simple as it is powerful. Experts work collaboratively with stakeholders to define desired future conditions and identify the management actions most likely to produce those conditions. Each of these management actions provides an opportunity to learn how ecological systems function and respond to human intervention. The management actions are carefully monitored as they are implemented and progress toward agreed-upon goals, yielding feedback that leads to adjustments in both goals and management. Failures lead to a reevaluation of both the means and the ends. Scientific understanding advances through comparisons of changes in socioenvironmental conditions with predictions that were made using the best available science. CAM, therefore, provides a platform for scientific and social learning that gradually but deliberately builds the capacity to manage resilient, thriving, and sustainable biocultural systems.

CONTEXT AND HISTORY

Contemporary ecology integrates the thinking of chaos and systems theories that gained prominence in the later half of the twentieth century. Ecologists now accept the idea that natural disturbance and change are normal in most ecological systems and that many disturbance-driven changes are unpredictable (e.g., by fire, hurricane, flood, and disease). Ecological systems are organized so that changes in smaller units occur within constraints determined by the larger units in which the smaller units are nested. Changes in smaller units can sometimes induce changes in the larger, and some of these changes can be nonlinear, abrupt, and dramatic because whole systems "flip" to a new state, perhaps irreversibly, when enough change in the smaller levels accumulate to affect functions at larger levels. A celebrated example is the change from grass savannas to brushy fields in the southwest United States. This shift alarmed Aldo Leopold, who contended that this abrupt ecological revolution was caused by suppression of the region's fire regime and the introduction of domestic livestock. Contemporary ecology acknowledges that humans likely will never possess sufficient understanding and technical capacity to control the biocultural system that is constantly evolving in response to both natural and cultural disturbances and evolving human desires.

CAM has also evolved in response to the failures of rational comprehensive environmental planning, a style of decision making that dominated the twentieth-century, positivist, Progressive-Era policies of the United States. Public agencies assumed public interests were best served if decisions were made by scientists and technicians using objective methods that avoided the biases of parochial interests and political power. Rational comprehensive planning further assumed that solutions that would serve the public interest could be found if sufficient resources were available for expert analysis of problems.



SOURCE: From *Adaptive Management*: *The U.S. Department of the Interior Technical Guide*. Adaptive Management Working Group, U.S. Department of the Interior, Washington D.C.

What Is Adaptive Management? *Adaptive management focuses on learning and adapting, through partnerships of managers, scientists, and other stakeholders who learn together how to create and maintain sustainable ecosystems.* **CENGAGE LEARNING, GALE.**

Rational planning failed, in part, because environmental planning problems are not just complex, they are what planning analysts Rittel and Webber call "wicked" problems. Wicked problems are not only difficult to define, there exist no right or wrong solutions for them, only better or worse solutions because they involve competing goals, divergent values, little scientific agreement on cause-effect relationships, imperfect information, and inequitable distribution of political power in implementing and influencing planning. Furthermore, rational planning, with its reliance on experts, excludes full and informed citizen participation in decision making. The "tell us what you want, and leave it to us to find the optimal solution" public involvement strategy bred contempt and conflict between planners and their constituents. This approach to public involvement could not adequately deal with deep-seated conflicts among stakeholders. Planners were forced to resolve conflicts using their expert judgment, which often left competing interests dissatisfied and with little recourse but to work outside the planning process through litigation and political intervention, blocking plans and stopping action. A classic failure of rational planning occurred when national forest planning and endangered species habitat conservation efforts stalled when confronting the wicked problem of balancing jobs, economy, spotted owls, and old growth timber in the Pacific Northwest.

The rational planning approach offered few solutions to these wicked problems other than to collect new information and to conduct additional analysis in the never-ending search for an optimal solution that would generate enough credibility to resolve conflicts and overcome political opposition. The result was often analysis paralysis. Agencies became consumed by planning, leaving managers uninformed by a shared vision, but still forced into action as daily crises demanded responses.

Multiple ways of knowing—for example, scientific, professional, spiritual, experiential, local, and global—are not just possible but can be equal to each other in their power and utility at solving environmental planning problems; knowledge is not the exclusive domain of science experts and professional planners. Public-involvement strategies respect pluralism and accept that preferences and perceptions change through involvement as plans evolve in the light of new information and experiences. Snapshot public hearings and socioeconomic surveys neither sufficiently engage participants nor permit learning and change to occur. Planning involves learning, and learning means change.

LEARNING

Social learning is perhaps the most important outcome of CAM. Building on the adage that it is easier to create a future than to predict it, CAM provides a powerful opportunity for stakeholders to learn about cultural and ecological systems, respect and influence one another's values, and collaboratively craft scenarios and motivate actions that lead society toward a sustainable future.

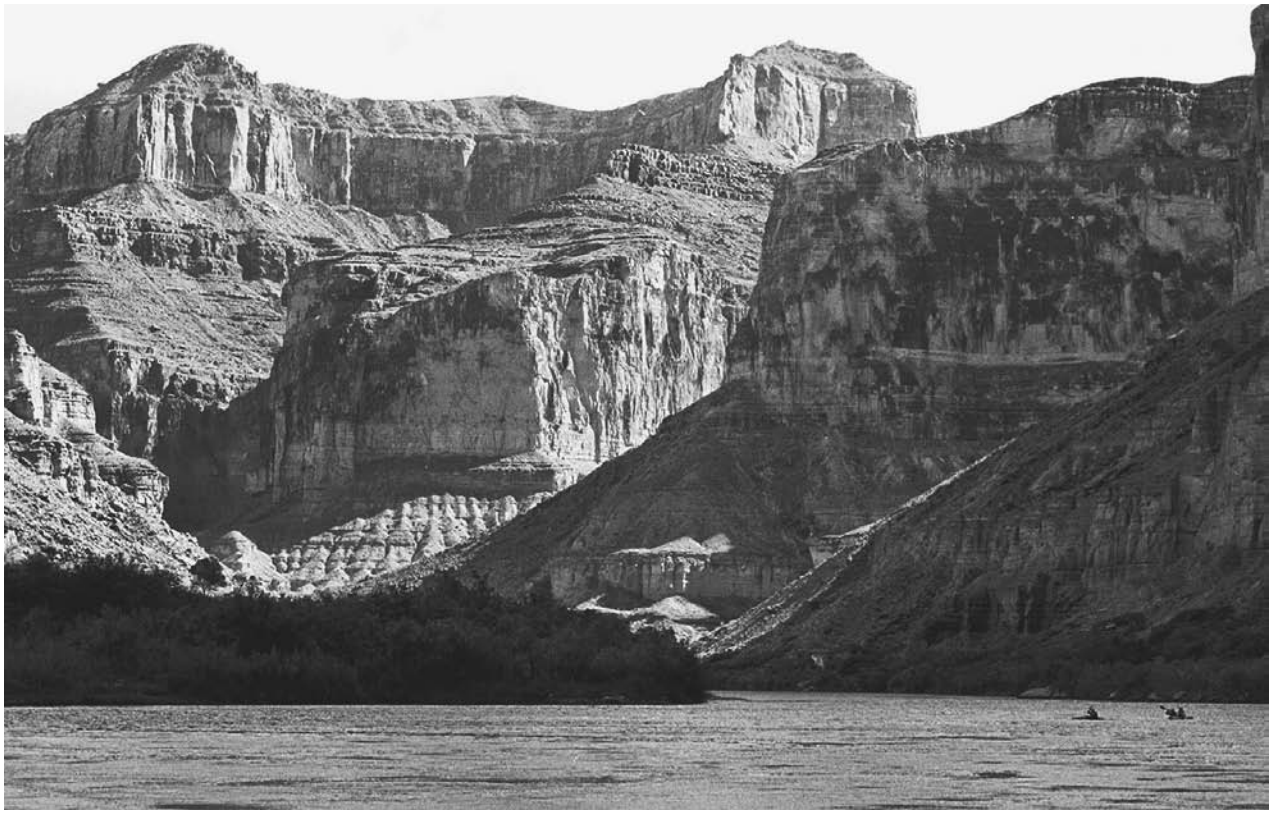
CAM is as much about managing learning as it is about managing the environment. Learning occurs at two levels. Mundane but essential learning results from the success and failure of management actions. Each intervention is an experiment that improves understanding of the biocultural systems being managed and refines the management techniques used to manipulate these systems.

Social learning, the second level of learning enabled by CAM, occurs by engaging and motivating society in the task of sustainability. The planning process situates people in the unfolding trajectory of history, giving them roles, defining settings, and giving direction. It thereby motivates and engages people in creating that future. By articulating desired future conditions, people identify and refine their values. As the plans become realized, people learn about whether their values and hopes were appropriate. With a view toward the future and achieving the good life, people can understand the changes and sacrifices being asked of them today.

Planning goals are hypotheses about values that are just as refutable as hypotheses about ecological functions and management techniques. Stakeholders invested in a planning effort can, and often should, change their goals in response to what they learn. For example, a community may seek to maximize wealth and freedom through real estate development. After years of pursuing this goal, residents may become frustrated by traffic congestion, fossil fuel dependence, and the loss of local foods, open space, and ecosystem services. Another goal might emerge, one that concentrates real estate development into pedestrian-oriented clusters containing shopping and employment opportunities and connected to other clusters by mass transit and surrounded by working farms and forests that, in addition to providing food and fiber, offer scenery, solace, and biodiversity.

Adaptive management can facilitate such social learning. It is forward-looking, believing that truth lies in the future, as the outcome of countless experiments that reveal which conditions are desirable and resilient and thus sustainable. It forces us to engage the future. It attempts to balance visions of the good life, practices of earning and living, and the environmental capacity to sustain these visions and practices.

The social learning agenda of CAM requires protracted engagement among community members rather than infrequent information exchanges between decision makers and affected publics. Public hearings, opinion surveys, and other episodic, one-way public-participation



Adaptive Management Techniques in the Grand Canyon. *Colorado River kayakers, lower right, glide through the Grand Canyon National Park, in Arizona. The construction and operation of Glen Canyon Dam fundamentally altered the Colorado River ecosystem. The Glen Canyon Dam Adaptive Management Program was established to provide for long-term research and monitoring of resources.* **AP IMAGES.**

procedures that solicit public input (or worse, announce and defend decisions) fail to help society grow in its understanding and expectations of environmental stewardship. A longer-term and more collaborative commitment is required so that stakeholders learn from one another and find ways in which to match their private interests and share common goals. Collaboration through participation builds tolerance and respect among participants, as well as ecological literacy. It also helps build trust and support for managers and planners, making possible informed and deliberate action instead of paralysis and polarization.

CHALLENGES

CAM, like any management process, requires investing significant resources. Planners must be trained and employed to nurture collaborative relationships among vested stakeholders with diverse backgrounds and values. They must encourage a common language and develop and share knowledge relevant to the social and environmental dimensions of the management problem. They must build trust among parties by encouraging evidence of commitment and understanding. Both managers and participants may need to be replaced if they become overtaxed by this process, potentially negating established trust, learning, and momentum.

CAM requires full participation by managers and scientists, but both may be reluctant to offer it. Scientists may lack the incentives to invest the time needed to monitor ecological change, which can often take years to effect, and to develop valid tests of management prescriptions if results are slower to emerge and more mundane than those in other ecological-research opportunities that might offer faster publication of results and thus quicker professional advancement. Managers are understandably cautious about losing control to a stakeholder-driven process and worry about reducing efficiencies as management prescriptions get modified to address scientific requirements of hypothesis testing, which seeks to minimize confounding factors and alternative explanations. Managers also face real budgetary limitations and feel heavy political pressure to deliver goods and services to constituents who may not appreciate the purpose and process of CAM. Moreover, it is difficult for managers

and scientists to secure and maintain the resources essential for monitoring and learning because these resources are scarce and are often quickly redirected to the next crisis. Absent a mechanism to ensure that experiments are carried through, they can be abandoned or altered in ways that forego learning opportunities and waste the investments of time and money that went into designing an adaptive management process.

CAM has also been criticized as compromising conservation goals because too much emphasis gets placed on stakeholder participation, development, and equity. CAM occurs locally, and it respects the nuances and idiosyncrasies of local conditions, which include ecological as well as social systems. Thus, efforts to conserve flora, fauna, and ecosystem services get balanced against local community and economic-development needs. Local interests need not dominate the process, but they typically are significant.

A major premise of CAM is that democratic control over environmental management and development will produce greater justice and sustainability. This may be true in principle; in practice, the degree of justice and sustainability achieved depends upon who participates and has power to influence the goals set by CAM. Centering CAM locally does not ensure democratic control. CAM could fall into the "local trap" and empower stakeholders who benefit from social oppression and environmental exploitation. Individuals and organizations can strategically attempt to manipulate collaborative efforts in ways that do not serve the public good or any conservation goal.

CAM also may fail because institutional barriers and inertia resist the adaptations CAM reveals and recommends. CAM encourages the acknowledgment of failure and the flexibility to adapt—two things institutions and professionals do not do well. Organizations and individuals who benefit from the status quo lack an incentive to respond to feedback that calls for alternative practices to remediate previous errors. Professional identities and agency budgets may be threatened by admitting failure or discontinuing established practices. Institutional change—change in goals and practices—is critical to the success of adaptive management, and that may not be possible without considerable political will and power. This challenge is particularly problematic for federal and state agencies that lack a legal mandate to employ adaptive management strategies. Many agencies with responsibilities for environmental planning are constrained by the National Environmental Policy Act and related legislation, which is grounded in the principles of now-obsolete equilibrium ecology (the old "balance-of-nature" and rational management precepts that CAM rejects).

CONCLUSION

CAM is a humble, experimental, and deliberative method of management and learning that attempts to grope toward sustainability under variable and unpredictable circumstances. In theory, CAM seems noble and straightforward. It encourages managers, scientists, local experts, and other stakeholders to negotiate an outcome that is acceptable to all parties. It requires crafting a management plan using the best available information. The plan gets implemented with the expectation that it will fail in two important ways: First, it will fail to produce the intended outcomes because the complexity of the biocultural system thwarts efforts at understanding and prediction, and because there are usually insufficient resources to perfectly control and implement even the best-laid plans. Second, the plan will fail because society will reevaluate its goals and refine its vision of a desired future. Because failure is anticipated, CAM develops and deploys monitoring strategies that track progress toward desired conditions. Tracking progress offers lessons in how to manipulate the biocultural system, encouraging flexibility in management techniques, the clarification of goals, and the adaptation of expectations to experience. Implementing CAM presents considerable challenges that require vigilance, political power, and perhaps new legislation.

AFRICA, NORTHWEST

Northwest Africa consists of ecological regions that range from Mediterranean forests, woodlands, and shrubs between the Mediterranean Sea and the Atlas Mountains to the conifers and mixed forests of the Atlas Mountains, the juniper steppe of the High Atlas, seasonally flooded halophytic (salt-adapted) plant communities in saline depressions, northern Saharan steppe and woodlands, and the Atlantic coastal and Sahara deserts. The plants and animals found between the Mediterranean and the Atlas Mountains are similar to those in much of the Mediterranean basin, including commercially grown olives, grapes, citrus fruits, and dates. Libya, Algeria, and Morocco grow wheat and barley, whereas Tunisia has more beef and dairy production. Major halophytic communities include Tunisia's greatest salt lakes Chott el Fedjedji, Chott el Djerid, and Chott el Gharasa and Algeria's Chott Melghir. Salt lakes are dry pans for much of the year but may hold a meter or more of water during the winter rains. They lie in a region of past volcanic activity, and although they once may have been inlets of the Mediterranean Sea, it is likely that human activities have contributed to their high salinity levels.

The northern Sahara steppe and woodlands form an ecological transition zone between the better-watered Mediterranean region to the north and the hyperarid Sahara to the south. The Atlantic coastal desert consists of a narrow strip of land in Morocco-occupied Western Sahara and extends southward into Mauritania, where the cool Canary Current provides enough moisture through fog to support a variety of shrubs, lichen, and succulents. Libya experiences more sandstorms and dust storms than its neighbors do and is home to scorching, hot, dry, sand-laden winds known as *ghibli* that can raise the temperature within hours to 40 or 50 degrees Celsius and last for days. Natural hazards in Morocco include earthquakes throughout its geologically unstable mountainous region and periodic drought. Severe earthquakes affect Algeria's mountains; other hazards include mudslides and flooding during the rainy season.

ARABLE LAND AND WATER SUPPLIES

The proportion of arable land in the region ranges from 1 to 3 percent in Libya and Algeria, respectively, to 17 to 19 percent in Tunisia and Morocco. Accordingly, Libya and Algeria have permanent crops on less than 0.5 percent of their land, and their economies rely heavily on petroleum reserves.

Libya has attempted to increase its proportion of arable land through the largest water development project in the world, the Great Man-Made River, which taps vast freshwater aquifers in rock strata beneath the Sahara. Libya hopes to use the project to showcase its engineering prowess, achieve food self-sufficiency in part through improved livestock production, and offer its coastal citizens inexpensive, high-quality fresh water relative to what had been available through its desalinization plants. The massive project was conceived in the late 1960s, and feasibility studies were undertaken in the 1970s. Work started in the 1980s, and the first phase of the project, including a 1,200-kilometer pipeline, was completed in 1991. The network of pipes (some as much as four meters wide), pumps, wells, and other infrastructure is expected to reach completion, including 3,500 to 4,000 kilometers of pipeline and two aqueducts stretching 1,000 kilometers, around 2030. Water is expected to flow through the 2050s, possibly to 2100, but skeptics wonder whether Libya plans to use the large pipes for military purposes such as storing chemical weapons, whether the removal of such large volumes of underground water will shift the course of the Nile toward Libya, whether Libya is tapping aquifers to which Egypt or Tunisia may have claims, and what compensation may go to those whose homes stand in the path of the giant project. Among Libyans the project has widespread support and is a source of pride for its sheer size, with popular media describing it as the Eighth Wonder of the World for its size and the fiscal restraint demonstrated by the project's investment-based and largely locally derived funding such as taxes on luxury goods, as opposed to amassing debt in the form of World Bank loans. Libya's longtime leader, Colonel Muammar al-Qaddafi, points to the project as evidence that Libya is a peaceful nation seeking development, not a terror state as it is portrayed in the West. Economic sanctions from the West have slowed progress on the Great Man-Made River, but Libyans are determined to achieve food self-sufficiency and technological proficiency despite those impediments.

Algeria struggles to provide adequate supplies of potable water to its citizens. Water supplies in Algeria, Morocco, and Tunisia are contaminated by the dumping of raw sewage. Regional environmental issues include desertification and soil erosion from overgrazing, farming in marginal areas, and vegetation destruction and/or deforestation. In Tunisia threats to health are posed by ineffective disposal of toxic and hazardous wastes. The coastal waters off Morocco and Algeria are polluted with raw sewage, fertilizer runoff, wastes from petroleum refining, and other industrial effluents. Algeria's rivers are similarly polluted. The Mediterranean is also a major oil transportation route into which up to a million tons of crude oil are discharged annually through accidental spills, illegal tank cleaning, and inadequate harbor facilities. Pollution of coastal waters has implications for tourism and Moroccan fish exports. With reference to other resources, Tunisia, unlike Libya, is heavily invested in extractive industries

The Great Man-Made River, in Southern Libya. *The son of Libyan leader Moamer Kadhafi Saif al-Islam, center, attends a ceremony to mark the arrival of water from the Great Man-Made River. The river is a huge network of pipes that supplies water from under the Sahara desert to various cities throughout Libya. The percent of arable land in Libya is between one and three percent, and the hope is that this project will increase self-sufficiency and availability of higher-quality freshwater in the country.* **MAHMUD TURKIA/ AFP/GETTY IMAGES.**

and, with Morocco and Algeria, has reserves of iron ore, lead, and zinc, whereas Tunisia and Morocco mine salt and Morocco and Algeria extract phosphates.

HISTORY AND RELIGION

Culturally, much of the population in Northwest Africa shares a French colonial history and an Arab and Islamic identity. The Berbers are the region's most significant non-Arab population. During the colonial period traditional use and cultivation of the land were assailed and suppressed by the colonizers; for instance, French scientists' and administrators' environmental narratives focused on indigenous people's destruction of the natural world through rampant deforestation and desertification. Pastoralists and farmers who used fire for land management were portrayed as destroyers of formerly lush green Northwest African lands. The French suppressed the practice of clearing land with fire and restricted the movement of pastoralists. The need for environmental control was used as a rationale for imperial expansion and served as a means of a social control; sedentary populations could be taxed. However, the scientific basis of French colonial environmental narratives was questionable (Davis 2007) and at odds with local perceptions of human-environment relations.

In the Islamic worldview shared by the majority of people in Libya, Morocco, Tunisia, and Algeria, the natural world as presented and described in the Islamic holy book, the *Qur'an,* is a living, holistic, orderly, and perfect world populated by angels, spirits, humans, and animals. Practitioners of Islam share many beliefs with Christianity and Judaism with regard to attitudes toward the natural world. Each of these monotheistic religions espouses a worldview in which humans are portrayed as God's stewards of the natural world. An important aspect of the Islamic worldview is *Tauhid* (also transliterated as *Tawhid* or *Tawheed*), or the oneness of God. *Tauhid* is the point of origin of a theological doctrine of ecology in

which all things, even those not seen, are God's signs (*aya* or *ayat*) and act as witnesses to God's existence. All things in the universe are from God and manifestations of God.

Islamic law, or *Sharia,* provides a framework through which Muslims can set limits on and establish guidelines for behavior to avoid ecological crises. Humans should behave toward the natural world as just rulers behave toward their subjects. People have the power to dominate nature, but in dominating it they are misusing God's trust in humans as intelligent and able to care for divine bounty. The anticipated depletion of Libya's aquifers caused by the Great Man-Made River project might be viewed as humans expressing their dominion over rather than stewardship of the natural world and could make the project controversial rather than a source of Arab Islamic pride.

ENVIRONMENTALISM

Environmentalism is not a strong movement in the predominantly Muslim countries of Northwest Africa or in much of the broader Islamic community, although Muslims in Western countries are beginning to form green groups such as the London Islamic Network for the Environment (LINE). Fazlun Khalid is the founder and director of the Islamic Foundation for Ecology and Environmental Sciences (IFEES) based in the United Kingdom. He has written widely on the Islamic approach to environmental protection (Khalid 1999) and hosted environmental ethics workshops, but Islamic environmental ethics and environmental law remain in their infancy. The Iranian environmental philosopher Seyyed Hossein Nasr pointed out that many Muslims believe that their countries should focus on development and at a later date consider the environment; they view environmentalism as form of European and North American control intended to keep Muslims from realizing their economic potential.

Environmental activism in Northwest Africa is fragmented, often limited to protests by small groups or individual protests such as Najib Bachiri's opposition to Morocco's megaresort Mediterranea, which may threaten turtles, ducks, lizards, and trees, and Algerian environmental activists' protest of a road linking Tunisia, Algeria, and Morocco that may reduce biodiversity in wetlands. Governments allow the dumping of waste into the Mediterranean and other environmental abuses in part because few citizens voice opposition in those authoritarian states. Progress and development often come before environmental considerations. Government-supported conservation efforts include eleven and fourteen national parks in Algeria and Morocco, respectively, and seven national parks each in Libya and Tunisia. Tunisia's parks protect several endangered species, including the Barbary hyena, the Barbary leopard, Cuvier's gazelle and the slender-horned gazelle, the Mediterranean monk seal, the oryx, and the Moroccan dorcas gazelle. Northwest African countries frequently are thwarted in the development of sustainable marine fisheries by fishing boats from Spain, Japan, Korea, and other countries that operate illegally in their waters. In Morocco the public and private sectors are working to reduce the country's reliance on oil and increase the use of renewable energy sources.

Morocco, Algeria, and Tunisia, often with Libya and Mauritania and sometimes with Western Sahara and Chad, are considered part of the Maghreb, and Algeria, Libya, Mauritania, Morocco, and Tunisia formed the Arab Maghreb Union in 1989. The economic union has had limited success in setting environmental policy because of disputes between Algeria and Morocco over the sovereignty of Western Sahara. Economic priorities have slowed environmental initiatives throughout the region, although several Northwest African countries are working with the World Conservation Union (IUCN) and the Food and Agriculture Organization (FAO) to protect medicinal plants, promote ecotourism, and enhance community involvement, especially among women, in conservation projects. The FAO also works to curb locust swarms in West Africa, which can spread to Northwest Africa, contributing to reduced harvests and ultimately famine. Fair trade, recycling, and other environmental issues that have been gaining interest in Southwest Asia (the Middle East) have not made notable inroads into Northwest African societies. Although Northwest African countries have started to host conferences on biodiversity and sustainable tourism, even relatively westernized universities such as Al Akhawayn in Morocco offer little in the way of environmental studies. Some courses include the study of resource use, but the focus is on development, not the environment.

Academic courses in the United States in which Northwest Africa is studied generally place it in the context of regional studies. These programs, often geared toward training students for the foreign service and other forms of employment, focus on understanding the culture, history, politics, English-language literature, and economic development of Northwest African countries but rarely center on the physical environment, biodiversity, or conservation.

FUTURE CONCERNS

In the future, meeting people's freshwater needs will remain a shared concern for Northwest African countries, as will curbing the activities of Islamic groups associated with terrorism and furthering socioeconomic development. Both the rate of development and the degree to which these issues have been addressed have varied in the region. Morocco's rural population struggles to gain access to clean water, Algeria and Libya have curbed the politicized Islam of the 1990s and encouraged Western investment, and Tunisia's considerable post-mid-1990s economic success has enabled

the implementation of national-level environmental programs. Economic improvement probably will be necessary in Algeria, Libya, and Morocco before their governments pay more attention to long-term environmental planning, including national environmental action plans and university-level environmental studies programs.

AFRICA, SUB-SAHARAN

Sub-Saharan Africa covers a landmass larger than North America and includes over a dozen nations and hundreds of cultural groups. African worldviews are neither wholly monotheistic nor completely anthropocentric. They involve environmentally friendly beliefs and laws that have encouraged or enforced limits to the exploitation of biological resources. The worldview of most indigenous African communities promotes a unitary conception of reality. In that cosmology human beings are seen as a distinct but completely embedded part of nature. Human existence is integral and is part of the flow of the universe. Balance is seen as the ideal relationship between humans and the natural environment.

The expansion of modern education and of religions such as Christianity and Islam has threatened the existence of African belief systems. The colonial legacy, the introduction of a money economy with a capitalist mode of production, the global economic system, the expansion of transnational corporations and the commercialization and privatization of knowledge, state control of natural resources, and the appropriation of sacred lands by governments favor Western knowledge and civilization over the indigenous variety. The expansion of HIV/AIDS, poverty, climate change, and injustice have exacerbated the threat to the existence and development of indigenous environmental ethics.

ENVIRONMENTAL IMPACTS OF THE COLONIAL PERIOD

The Portuguese and later other Europeans who arrived on the west coast of Central Africa after 1400 tried to control African natural and human resources. They participated in a slave trade for plantations and mines in the Americas. Intermittent drought and food shortages contributed to the engagement of southwest central Africa with the Atlantic slave trade. According to Joseph Miller (1982), periodic drought and famine increased slave raiding in southwest central Africa and increased the death rates of people enslaved during times of ecological crisis.

An industrializing Europe further penetrated equatorial Africa in the nineteenth century to satisfy its demand for African raw materials to produce textiles, steel, and other products. Some Africans in the Congo River basin participated in that international trade by trading manioc, palm oil, wine, slaves, and ivory for firearms, beads, and cloth. Western Africa also participated in that trade. International resource exploitation led to the decline of forests and wild animals. Also, the trans-Saharan slave and ivory trade in the northern savanna led to the creation of large trading posts and thus the introduction of new diseases, including smallpox, syphilis, and measles.

Some European colonizers believed that Africans were devoid of reason and did not qualify as human beings. Although they represented their mission in terms of civilizing Africans, they saw Africans as a servant class in their own colonized countries. However, European colonization caused the underdevelopment of the continent in many ways.

Colonial powers introduced formal conservation during the late nineteenth and early twentieth centuries without paying attention to the dynamics of indigenous farming and livestock management practices. Colonial authorities reserved land for national parks, forest reserves, and hunting reserves and thus restructured land-use traditions. European game laws and the tradition of hunting preserves were used as wildlife protection laws and the bases of national parks. Hunting reserves primarily served the interests of European sport hunters, with little regard for the subsistence needs of local people. Many colonial governments considered indigenous Africans degraders of the environment and restricted their access to natural resources such as woodlands and forests. In addition, they set aside

Trapping a Giraffe, South Africa. *In many parts of Africa, the relocation of wildlife has replaced natural migration as human development has closed the ancient paths African animals normally follow. Predators, antelope, giraffe and even elephants are captured and moved for commercial or scientific reasons.* **ADRIAN BAILEY/AURORA/GETTY IMAGES.**

land for the protection of endangered species and habitats, following the conservation ethic of the North. Peasant farmers and nomads were forced to overuse resources because of restrictions on their movement and the concentration of people and animals around new high-capacity water sources. Moreover, colonial forestry and agriculture officers forced local people to grow exotic species for export to Europe and the United States, using cultivation methods inappropriate to local ecosystems. Monocultural cash crops often displaced indigenous crops.

African peasant farmers and pastoralists resisted those policies and abandoned foreign conservation measures immediately after the end of colonialism. However, the conservation policies of some postcolonial African governments were similar to those of the colonial powers as they continued growing cash crops, mining, logging, and other activities of the colonial era. The great majority of Africans active in conservation were trained in traditional Western methods of wildlife management and have hindered the growth of an indigenous conservation ethic by promoting European management systems. Thus, the policies of postcolonial African governments have not reduced the destruction of forests and wildlife.

However, some colonial policies have had a positive influence on conservation initiatives. In the first decade of the twenty-first century the South African and Zimbabwean governments used wildlife reserves established by British colonial governments and settler states as sites for wildlife preservation and tourism.

ENVIRONMENTAL PROBLEMS AND CONTROVERSIES IN AFRICA

Deforestation Large-scale clearing of forests, the burning of biomass, and charcoal burning have led to the depletion of forests in Africa and have contributed to global climate change. Seventy-six percent of the African population relies on solid fuels, and only 24 percent has access to electricity. Africa is experiencing the gradual extinction of hundreds of species of plants and animals because of the destruction of forests and other habitats. However, several studies have found that the density of trees is increasing in parts of the West African savanna despite annual burning.

Soil Erosion, Drought, and Desertification The decline of intercropping, overcultivation, lack of fallowing, overgrazing, deforestation, the use of chemical fertilizers, and poor irrigation practices have caused soil erosion in Africa. Some studies have shown that El Niño–Southern Oscillation (ENSO) has had a negative impact on climate in Africa. The ENSO phenomenon and the temperature of the Indian Ocean affect the climate of eastern and southern Africa, whereas the conditions in the Atlantic Ocean affect that of West Africa.

Vegetation productivity and desertification in sub-Saharan Africa may be influenced by global climate variability attributable to the North Atlantic oscillation (NAO) as well as to ENSO. According to Gufu Oba and his co-authors, "[f]ully 75% of the interannual variation in the area covered by the Sahara Desert was accounted for by the combined effects of NAO and ENSO" (Oba, Post, and Stenseth 2001, p. 343), with most of the variance caused by NAO. Continuous climatic variability in the North Atlantic may explain the expansion and contraction of the Sahara. Atmospheric pressure variability related to NAO appears to affect aridity and atmospheric export of dust from the Sahara directly and to influence the spatial dynamics of the Sahara through variation in the 200-millimeter rainfall isocline. Natural climatic fluctuation may be largely responsible for vegetation dynamics in sub-Saharan Africa. Much of the interannual variability in vegetation productivity in the Sahelian zone and southern Africa is the outcome of the combined effects of NAO and ENSO, implying that both may be useful for monitoring the effects of global climate change in sub-Saharan Africa.

Drought is a recurrent feature in most parts of southern Africa, with five major episodes since 1980. The entire sub-Saharan region was affected during the 1982–1985 drought.

Desertification increases with each drought cycle. Environmental insecurity in the African drylands led to famines and food shortages in the 1970s and 1980s that resulted in mass starvation, death, and disease and the exodus of millions of environmental refugees.

Mediterranean Africa, the Sudano-Sahelian region, and the Kalahari-Namib region in southern Africa are at the highest risk of desertification; thus, desertification has affected one-third of the continent. The direct causes of desertification include human-related activities such as deforestation, cultivation, rangeland grazing, and inappropriate use of irrigation technology, which can result in soil salinization; the indirect causes include population pressure, poverty, landlessness, history (colonialism and the erosion of traditional systems of pastoral resource management), the new global economic order (declining commodity prices and unfavorable trade terms), and inequitable distribution of resources (Smith and Koala 2003, Darkoh 2003a). However, global climate patterns are responsible for desertification more than is local farming.

Water Pollution and Sanitation Africa has experienced increasing scarcity of clean water because of long spells of drought and water pollution caused by industry, agricultural chemicals and fertilizers, and raw sewage. This persistent shortage of clean water will be aggravated by climate change. The regional report by Working Group II of the Intergovernmental Panel on Climate Change (IPCC) predicted that because of continued increases in greenhouse gases, 75 to 250 million people in Africa will be at risk of increased water shortage with a one-degree-Centigrade rise in global temperature by the 2020s, 350 to 600 million people with a two-degree climb by the 2050s, and up to 1.8 billion people if global temperature rises by three degrees, which could happen by around 2080 (Boko, Niang, Nyong et al. 2007). According to United Nations Environmental Program (UNEP), as of 1999, "14 countries in Africa are subject to water stress or water scarcity" and a "further 11 countries will join them in the next 25 years" (quoted in New Economic Foundation 2005, p. 13). The decline of rainfall will lead to the deterioration of water as sewage and industrial effluents are more concentrated and become a breeding ground for water-borne diseases. Africa increasingly will experience climate- or water-related diseases, both vector- and water-borne, such as cholera, typhoid, diarrhea, dysentery, yellow fever, river blindness, bilharzia, malaria, and tuberculosis, according to the regional report by Working Group II of IPCC. It is estimated that an additional 80 million people will be at risk from malaria epidemics in the twenty-first century. Although large parts of the western Sahel and much of southern and central Africa will become unsuitable for malaria, the highlands of Ethiopia, Kenya, Rwanda, and Burundi may become highly suitable for malaria mosquitoes by the 2080s. Malaria is also likely to rise in Zimbabwe, the highland areas of Angola, and Somalia.

HIV/AIDS HIV/AIDS is the single most important threat not only to the health-care system but also to development and environmental protection in Africa. It can accelerate environmental degradation by decimating the most productive members of a society. The expansion of HIV/AIDS has discouraged some people from making long-term investments in or conserving their natural resources; they spend their funds on AIDS patients rather than on conservation and wildlife preservation. African economies that have been crippled by poverty, debt, and unfair trade policies are being compromised by the epidemic.

Poverty Rural poverty has aggravated environmental degradation. Much of sub-Saharan Africa not only has failed to become part of the global economy but has become

Haboob Dust Cloud Advances Over Khartoum, Sudan, 2007. *The gigantic dust cloud known as "haboob" is a seasonal type of monsoon, which can reach a height of 3000 feet. Global climate change is an environmental issue of particular concern in the sub-saharan Africa region, due to its likely influence on vegetation productivity and desertification.* **STR/AFP/GETTY IMAGES.**

poorer than it was in the late twentieth century. Poverty in the South is structurally rooted in the prevalent North-South relationship. However, rural poverty is not the major cause of environmental degradation but its effect. Although people are aware of the consequences of their actions, lacking alternatives for subsistence, they are unable to stop degrading their land.

Environmental deterioration has exacerbated the paucity of resources and forced people to adopt survival strategies that are harmful to the environment. Rapid population growth, inadequate food production, inappropriate land tenure systems, poor access to social services, ill-defined or nonexistent property rights, poor marketing systems and price incentives for farmers, inadequate safety nets in times of stress or disaster, lack of participation in decision making, and global environmental trends such as climate change have forced Africans to put more pressure on the land. This has led to increasing encroachment on marginal lands, forests, and other natural resources, which has resulted in further environmental degradation.

The relationship between poverty and environment is complex. In some cases environmental degradation increases poverty by reducing the stock of natural capital and increasing economic vulnerability. In other cases poverty increases risk aversion, leads to ill health, and reduces the capacity to invest. Moreover, protecting the environment may reduce or increase poverty, just as reducing poverty may help or hurt the environment. Although there is a poverty–environmental degradation spiral in some instances, in other cases another cause increases both poverty and environmental degradation.

Migration Environmental refugees are people who have been forced to leave their homelands temporarily or permanently because of environmental disruption (natural and/or triggered by people) that has had a negative impact on their lives (El-Hinnawi 1985, Myers 2005). Environmental degradation and competition for natural resources have caused massive internal and external migration and put new pressures on host countries in different parts of Africa.

Population Growth Some writers consider population growth one of the major causes of environmental degradation. However, some studies have shown that in certain cases population growth has had a positive impact on the environment (Boserup 1965, Fairhead and Leach 1996, Tiffen, Mortimore, and Gichuki 1994). Although population growth could be a factor in environmental degradation in the region, it is not the major cause.

Conflict and Civil War Many countries in Africa frequently experience civil wars and other forms of social unrest. Civil war has led to transboundary migration, immigration, deforestation, and other environmental problems. The lawlessness associated with war has led to the poaching of protected animals and uncontrolled harvesting of bush meat, in some cases threatening species with extinction. There have been conflicts over river basin resources in African drylands. For instance, there were conflicts between Senegal and Mauritania in the 1980s over the utilization of resources in the Senegal basin, between Niger and Nigeria over the two dams on the Lamido and Maggiya rivers, and between Nigeria and Cameroon over the Ladoo Dam on the Benue River.

GLOBALIZATION AND GLOBAL CAPITALISM IN THE CONTEMPORARY PERIOD

Colonization facilitated the proliferation of private companies in the late nineteenth and early twentieth centuries. Those companies exploited forests, wild animals, diamonds, gold, and cash crops in different parts of the continent. The environmental challenges to African natural resources continue to accelerate as a result of world trade liberalization, the expansion of transnational corporations, and global capitalism. The World Bank, the International Monetary Fund (IMF), and individual Western aid donors have promoted structural adjustment programs under which states do not regulate the activities of transnational corporations or guarantee social and environmental protection for their citizens.

Many studies have shown that international trade and Western corporations have contributed to the escalation of conflicts and the exploitation of environmental resources in Africa. The strategic importance of Congo-Kinshasa geographically and economically attracted the attention of countries such as the United States, France, and Belgium and transnational corporations such as Executive Outcomes and American Minerals Fields Inc. (AMFI) (Nzongola-Ntalaja 1999, Yengo 2002). Those external forces aggravated the exploitation of natural resources and industrial pollution in Congo and other countries.

Experiences in Sierra Leone, Angola, Nigeria, and other countries show that there have been strong ties between state officials, rulers, and warlords and foreign commercial interests and investors. African governments often side with international capital intent on the exploitation of local resources. For instance, multinational oil companies and the Nigerian government have been exploiting the people of the Niger Delta (particularly the Ogoni people) by destroying their environment and undermining local economic activities (Ibeh 2003, Steyn 2004).

Industrialized countries have transported and dumped toxic and hazardous wastes in many African countries, including Egypt and western African countries such as Nigeria, Equatorial Guinea, the Republic of Benin, and Guinea Bissau (Dimah 2001). The governments of some countries have let their lands be used as dumping sites to get income and aid from industrialized countries.

INDIGENOUS ENVIRONMENTAL ETHICS IN SUB-SAHARAN AFRICA

Limited by preconceived notions, European travelers, missionaries, colonial powers, colonial anthropologists, and some Western philosophers portrayed the African people and their beliefs and practices as barbaric or uncivilized, irrational, unscientific, and prelogical. They considered Africans as devoid of morality, religion, and political philosophy. The lack of documentation before modern times and the variety of peoples in Africa hindered an appreciation of African ethical teachings.

African peoples have had their own religions and moral principles for as long as any other peoples. Belief in a God and an afterlife existed among Africans long before the arrival of European Christian missionaries and Muslims. Although each community has its own religious beliefs, several doctrines, practices, and rituals are prevalent, justifying the concept of a generic African worldview. These commonalities include a belief in the existence of a supreme being, the return of the human soul to God after death, and the absence of eschatological statements such as those found in Christianity and Islam regarding divine judgement, heaven and hell, the segregation of bad from good souls, bodily resurrection, and the hope of a joyful life in heaven or paradise.

African worldviews embody both anthropocentric and nonanthropocentric attitudes toward the environment. Africans protect their environment for utilitarian reasons; that is, the African worldview is characterized by an ethical anthropocentrism that distinguishes humans from the environment while fostering a cooperative relationship. Rural people, whether pastoral or agricultural, have acquired experience as a result of working the land from childhood and have developed sustainable modes of environmental management and exploitation. They have developed detailed knowledge of the celestial sphere, the earth, the weather, animals, vegetation, water, soil, crops,

insects, and the environmental and nutritional requirements of people and animals. They have preserved the biodiversity of the continent for millennia and have succeeded in mitigating environmental degradation through traditional conservation practices and in coping with climatic and environmental changes.

The bonds between the environment and the people are considered not only material but spiritual and moral. Many African peoples envision a kinship relationship between themselves and the natural world. They have developed an organic conception of nature that promotes an ecological interdependency among human, plant, and animal life. Nature is an integral part of their day-to-day existence. In many sub-Saharan countries environmental knowledge relies on the relationships between both humans and nature and the visible world and the invisible world. Accordingly, in the traditional African worldview the visible and the invisible dimensions of the world are inseparable. Africans in traditional cultures adopted a sense of self extended in time to include all their ancestors, the unborn, the entire community, and all of nature. Reality includes not only what is observable or what makes cognitive sense but also the invisible, the emotional, the sentimental, and the magical.

The pan-African worldview emphasizes the dynamic unity and interdependence of all things. Examples from different parts of sub-Saharan Africa illustrate this fact. The Oromo of Ethiopia, the San of south-central Africa, the Nso' of the grassy highlands of Bamenda in Cameroon, and other groups recognize the coexistence of nature and the rest of creation. The Oromo, the largest ethnic group in Ethiopia, believe that *Waaqa* (God), *Lafa* (Earth), and all other created things are interconnected. *Waaqa* is the creator of all things. *Ayyaana* (spirit) is a manifestation of the one *Waaqa*. The spirits act as intermediaries between human beings and *Waaqa.* The Oromo regard *Waaqa* as the father and Earth as the caring mother of all. Human beings are not above other creatures and cannot despoil them as they wish. They are part of the natural world and are given a special place in the diversity of the cosmos; they are endowed with intelligence that enables them to understand cosmic events. Thus, *Waaqa* expects them to care for other creatures and all of creation by acting in harmony with the cosmic whole. The relationship between *Waaqa* and other things is governed by *saffuu* or *ceeraa fokko*. *Saffuu* is a moral concept that serves as the ethical basis for regulating practices to ensure a high standard of conduct appropriate to different situations. *Saffuu* is a mediating category between different things (Kelbessa 2002, 2005). Human and nonhuman beings have their own place and role in the Oromo worldview, and this should be observed and respected by human beings. Thus, the Oromo conception of *saffuu* reflects a deep respect and balance between various things. The Oromo do not consider justice, integrity, and respect as human virtues applicable only to human beings but extend them to nonhuman species and the earth.

Oromo environmental ethics is based partly on *Gadaa*, a democratic egalitarian system that includes leaders who conduct the government (political, economic, social, judicial, legislative, ritual, and military affairs) of Oromo society for nonrenewable eight-year terms. It is the *Gumi* or *Ch'affe* (the national assembly, the assembled multitude) that is responsible for making and revising environmental and other laws, and the power of *Gumi* is above the power of the *Gadaa* and the *Qalluu* ritual leaders (Legesse 1973, 2000).

Unlike the Western concept of a person as rational, autonomous, individual, and separate from others, the traditional African notion of personhood is relational, communitarian, and extended. In Africa systems of ethics, relational views of the self and world, and visions of the common good are expressed through cultural concepts such as *ubuntu,* a word common to several Bantu languages. *Ubuntu* signifies that a person is a person only through another person. It enables human beings to acknowledge and appreciate unity in their humanity despite differences. According to Mogobe B. Ramose, *ubuntu* is the foundation of African philosophy: "[t]he be-ing of an African in the universe is inseparably anchored upon *ubuntu.* Similarly, the African tree of knowledge stems from *ubuntu* with which it is connected indivisibly. *Ubuntu* then is the wellspring flowing with African ontology and epistemology" (2002, p. 40). Ramose stressed that *ubuntu* is related to both human beings and the universe. This is expressed by the prefix *ubu-*, which contains being as enfolded, whereas the stem–*ntu* means its unfolding by means of an incessant continual concrete manifestation through particular forms and modes of being. Thus, the concept indicates that "the human individual is inextricably linked to the all-encompassing" physical and metaphysical universe and also to the "human universe in the sense of community" (Ramose 2002, p. 65).

Many Africans believe that land is not something that people own; rather, it belongs to God (Omari 1990). Humans are not the masters of the universe but the friends of other beings, although they are at the center of the universe (Mbiti 1996). Thus, in traditional African worldviews the earth is not a property or commodity to dispose of as people wish (Millar 1999). For most Africans, the Earth is the true source of life and commands reverence and respect (Ramose 2004), although the concept of private property is not unheard of in sub-Saharan Africa.

SPIRITUAL AGENCIES AND THE NATURAL WORLD

Many people in sub-Saharan Africa believe in spirits (Parrinder 1962, Zahan 2000, Kelbessa 2001, Kimmerle 2006). Although spirits are considered intermediaries between the human and divine realms, they also are believed to dwell in nature. Mountains, trees, animals, and human beings have their own spirits. Some spirits are connected with natural phenomena such as wind, rain, thunder, and lightning or elements on which human life depends, such as the earth, rivers, the sea, and the sun. Some people in West Africa regard the spirits in nature as nature gods and respect the natural things in which they dwell.

In some sub-Saharan countries trees, animals, and natural phenomena are thought to have intrinsic worth and attract respect. Trees around religious centers are considered sacred. The Oromo, for instance, recognize some trees as sacred on the basis of essentially spiritual values. The East African Bantu of highland Kenya do not fell giant trees because they believe spirits find safe abodes in those trees. Some Oromo clans and individuals have been so inspired by nature that they have named their clans and children after trees. The Fon of Benin believe that men and women descended from the branches of an iroko tree.

Many African societies have preserved wild animals through totemism and other religious beliefs. Totemism is the practice of using a natural species or class of objects as the symbol of a group. Totems can be animals, plants, or geographical features. Many lineages have their own totems. Totem animals have special cultural value and associations. Members of each totemic group are required to abstain from harming, killing, and eating their totem. The respect is mutual, and the totem is expected to revere the clan.

Some ethnic groups, such as the Shilluk of the Sudan (El-Mahi 1994) and the Oromo, have firm restrictions on hunting wild animals. The Oromo do not consider animals as mere resources that can be exploited at any time without exception. They are expected to respect the rights of animals given to them by the creator. Wild animals as species have the right to exist whether they are useful or not. The Oromo kill wild animals selectively to avoid depletion of breeding stocks and also believe that domestic animals should be treated humanely.

Both indigenous and imported religions have influenced environmental ethics in Africa. Some writers attribute belief in a divine origin to morality. They assert that there can be no morality without religion. Some indicate that Africans are religious in all things. For these writers there is no clear-cut distinction between the religious and secular spheres in Africa. They maintain that all Africans believe that humans receive their moral nature from God and that any event may be influenced by gods, ancestors, and spirits.

However, religion is not the only source of moral laws in Africa. Although they believe that there are divine laws, the Oromo think that laws are predominantly a product of human deliberation rather than a gift from God or heroic ancestors. In his analysis of the Akan conception of morality in Ghana, Kwasi Wiredu (1983) argued that the basis of morality in Akan society is rational reflection on human welfare. Belief in God is more a personal affair than a societal requirement. Accordingly, the rules of good conduct would be in place even if there were no belief in God.

ENVIRONMENTAL ETHICS IN SUB-SAHARAN AFRICAN UNIVERSITIES

Environmental ethics has become part of the philosophy curriculum in some African universities. It is taught in Stellenbosch University in South Africa, Nairobi and Kenyata universities in Kenya, Addis Ababa University in Ethiopia, Makerere University in Uganda, and Lomé and Kara universities in Togo. Stellenbosch University established the Unit of Environmental Ethics in 1992 as part of the Centre for Applied Ethics. In Tanzania environmental ethics is taught as a topic in courses in environmental science. Environmental philosophy is taught in the University of Lagos in Nigeria and the University of South Africa. UNISA also teaches biomedical ethics. The Cape Peninsula University of Technology offers a course in the philosophy and ethics of environmental management in its Environmental Management Program in South Africa. The universities of Yaounde 1 in Cameroon and Ibadan in Nigeria offer a postgraduate program in bioethics. Environmental ethics is an elective course in Ibadan.

AFRICAN-AMERICAN ENVIRONMENTAL ETHICS

Environmental activism in African-American communities dates back to the Progressive era. Generally local in focus, it is traditionally aimed at such issues as access to green space, combating pollution, and protecting public health—concerns that continue to inform the environmental justice movement today. Indeed, African-American environmental ethics shares much common ground with the environmental justice movement; both are centrally concerned with the connection between justice and environmental stewardship. However, African-American environmental ethics extends beyond the distributive issues at the heart of the environmental justice movement; it is rooted in a broader intellectual tradition that addresses the political, economic, and cultural dimensions of humans' relationship with the land.

Some scholars would argue that this broader intellectual tradition is essentially African rather than Western. Lawrence Levine in *Black Culture and Black Consciousness* (1977) forwards the claim that African-American culture is strongly shaped by the traditional African sensibilities carried by slaves and their descendants. That African worldview, he contends, taught African Americans to see humans as part of a natural order rather than spiritually distinct from the natural world. This Afrocentric thesis could have great significance for contemporary African-American environmental ethics, but its implications have yet to receive sustained attention from scholars.

It is easier to document the effect of slavery itself, which made the relationship between social justice and environmental stewardship a key axis of African-American environmental ethics. More precisely, African-American theorists have focused on the social conditions necessary for individuals to develop an ethical relationship to the natural world, and how those social conditions have been eroded by racial injustice. For example, Frederick Douglass's 1873 speech to the Tennessee Colored Agricultural and Mechanical Association explores the effects of slavery on agriculture stewardship (concisely summing up the abolitionists' environmental critique of slave agriculture): Under slavery, he argues, those who worked the land had little incentive to improve the soil. Moreover, slavery fostered anger, hatred toward land, and a general indifference to rights that led slaves to mistreat farm animals. Good stewardship, under Douglass's view, requires that those who tend the land develop an attitude of affection and generosity toward the world, which grows out of a confidence that good care will be valued and repaid. That attitude, he contends, is hard to maintain under oppressive labor conditions.

This insight informs later environmental critiques of racial oppression, such as W. E. B. Du Bois's analysis of the post-Emancipation peonage system in *Souls of Black Folk* (1903) and the effects of racial segregation on urban neighborhoods in *The Philadelphia Negro* (1899). Both racially oppressive systems, Du Bois contends, reduce the victims' capacity and incentives to maintain the land or housing stock. As a result, African Americans suffer more acutely from a range of environmental problems, from soil erosion and exhaustion in rural areas to public health threats and reduced access to green space in urban environments.

Du Bois, Booker T. Washington, George Washington Carver, and Alain Locke were among the early African-American intellectuals concerned with the environmental problems facing their communities, and more broadly with how human communities can interact creatively, productively, and meaningfully with natural world. They typically adopted an anthropocentric perspective, beginning from the assumption that humans must exert some control over the natural world in order to make the landscape suitable for good human lives. However, they were also keenly sensitive to the fact that "mastering" nature involves mastering other humans. Thus they did not imagine a legitimate "dominion" relationship as an exercise of naked power. Carver, for example, encouraged scientists to create new strains of plants and animals, but he saw them as "copartners" with God in this work of creation. For Carver, humans' right to control the natural world was contained by a moral and spiritual framework in which nature has independent value as God's creation. For Du Bois, too, nature was not merely a material resource to be exploited. His writings on gardening and other aspects of

Activist in front of a Closed Incinerator. *Aaron Mair, a New York-based activist, poses in downtown Albany with a now closed incinerator smokestack in the background. African-American environmental ethics extends beyond the distributive issues at the heart of the environmental justice movement; it is rooted in a broader intellectual tradition that addresses the political, economic, and cultural dimensions of humans' relationship with the land.* **AP IMAGES.**

homemaking suggest that our relationship to nature is an integral part of our aesthetic and spiritual life. Interacting with nature should not be blind mastery but a creative response, attentive equally to the aesthetic, spiritual, moral, and economic dimensions of the landscape.

Creativity in fact became a central concept in African-American environmental thought during the early twentieth century, reflecting the influence of Romanticism and pragmatism on African-American intellectual life generally. Drawing on these intellectual currents, African-American theorists built on the earlier critiques of slavery to develop a broader perspective on the connection between social justice and environmental stewardship: One of the chief harms of racial oppression, they argued, is that by destroying the foundations of community and social life, it undermines its victims' capacity to interact creatively with the natural world—to give it meaning by expressing their values and perspectives in the landscape. For example, philosopher Alain Locke in the 1925 collection *The New Negro* argues that the challenge of modern, urban African Americans is to create out of their common condition a common consciousness, by giving their physical world meaning through the creative articulation of its materials. Racial oppression, Locke contends, undermines African Americans' ability to express their common ideals through creative expression. As a result, they experience their environment as a jungle, a wilderness without form or meaning.

This thesis is most compellingly developed by Richard Wright in his 1940 novel *Native Son,* which describes the sense of alienation and meaninglessness that haunts black inhabitants of an urban ghetto. The "white city" Wright describes physically embodies white Americans' perspectives and values; the black inhabitants of the city, unable to express their own understandings and values in their environment, are imprisoned in an urban wilderness they cannot make sense of or navigate safely. This vision of captivity in a degraded and degrading urban environment persists in African-American thought and plays a central role in the environmental justice movement.

If the city is a wilderness in need of regeneration through creative articulation of its materials by its black inhabitants, what of the traditional wilderness? Du Bois offers an incisive comment on the wilderness preservation movement in his essay, "Of Beauty and Death," from the 1920 collection *Darkwater*: When asked by his friends why he doesn't seek relief from racial oppression by escaping to wild and beautiful places like Acadia (one of the first national parks), he answers, "Did you ever see a 'Jim Crow' waiting room?" (p. 229). Segregation and racism have limited African Americans' opportunities to enjoy the American wilderness. Thus Du Bois, like most African-American theorists, does not conceptualize wilderness as a place of unmediated contact with nature; on the contrary, contact with nature is always mediated by social structures and practices.

But this is not to suggest that the concept of wilderness plays no role in African-American environmental thought. For African-American writers, the concept of wilderness is usually associated with Africa rather than the American West. Throughout the nineteenth century, black leaders such as Martin Delany, Edward Blyden, and Alexander Crummell urged black Americans to colonize the African wilderness. They described this project not as a return to the innocence of a primeval garden but as an attempt to regenerate a landscape degraded by centuries of oppression—and in the process to reclaim African Americans' own heritage and identity. It was a communal project, an expression of group solidarity rather than rugged individualism. For African-American theorists, a historical connection to the group's aboriginal wilderness, preserved in the group's collective memory, could serve as a source of inspiration, identity, and sense of obligation to the land. This concept of wilderness as a source of cultural creativity, a fatherland to which the artist must return (at least in memory) in order to unlock her own creative power, remains an important part of the black intellectual heritage.

In sum, the African-American tradition of environmental thought offers a distinctive perspective on environmental problems and the relationship between humans and the natural world. We can see its influence in the rhetoric of the environmental justice movement: Sociologist Robert Bullard's seminal work, *Dumping in Dixie* (2000), echoes Douglass in claiming that there is a direct link between exploitation of the land and the exploitation

of people, and that environmental activism must include efforts to rectify race relations. Indeed, environmental activism itself can be a means of liberating and empowering the oppressed. As activist Carl Anthony explains in his essay "Reflections on the Purposes and Meanings of African American Environmental History," "The knowledge of the earth, and of our place in its long evolution, can give us a sense of identity and belonging that can act as a corrective to the hubris and pride that have been weapons of our oppressors" (2006, p. 203). This tradition thus links environmental stewardship, social justice, and political activism in its conceptualization of our "common struggle": to create a "fitting home for humans" in a land cursed by injustice (Anthony 2006, p. 209).

AGRARIANISM

Agrarianism is a nonsystematic philosophy that claims variously that a sense of nurturing stewardship, deep understandings of place and labor, virtuous character developed through rooted communities, and even a spiritual relationship to nature and cosmos are normatively significant features of the practice of nonindustrialized agriculture, and perhaps even unique to agriculture. In positive terms, agrarianism maintains that farming is a virtuous human activity that provides for a special vantage point on the natural environment and the well-being of both individuals and communities. Agrarianism is a general temperament more than a fully theoretical perspective, although some agrarian writers attempt to synthesize a number of important themes. The nonsystematic character of agrarianism may be an inherent by-product of both its emphasis on historical and local experience and the fact that agrarian views are often appendages to other philosophical claims. One thing all versions of agrarianism share, however, is a conception of the land as much more than a material resource.

Only a few contemporary works attempt to develop a philosophically rigorous understanding of agrarianism (the essential philosophical survey is Montmarquet 1989; see also Thompson 1994 for an agrarian ethics; and the essays in Thompson and Hilde 2000 for a study of the relation between agrarianism and the American philosophical tradition of pragmatism). Agrarian literature, however, is broad and varied and agrarian themes often only implicit. This literature extends from the ancient Greeks and Romans (e.g., Hesiod, Xenophon, Aristotle, Cato the Elder, and Virgil) through the modern philosophers and writers (e.g., John Locke, David Hume, Georges-Louis Leclerc de Buffon, Benjamin Franklin, Thomas Jefferson, François Quesnay, Jean-Jacques Rousseau, and J. Hector St. John de Crèvecoeur), and twentieth-century groups (the Country Life Movement, and the Vanderbilt agrarians), to contemporary writers such as Wendell Berry and Barbara Kingsolver. Themes running through these works include the nobility of farming, the nature of labor and property rights, yeomanry and the family farm, political and economic rebellion, pastoralism, democratic community, nationalism and exceptionalism, the "spirit of the soil," and the relation between scientific progress and tradition.

Agriculture itself is the primordial organized technological relationship between human beings and the natural environment. Through this relationship, human beings eventually transcended wild nature and came to exert some control over their own fate as a species and ultimately over their environment. Furthermore, agriculture literally rooted people to particular places and societies. Over human history, agricultural practice developed deep

cultural roots at the intersection of human labor and wild nature. The land and the activity of farming became a fund of cultural metaphors, spirituality, basic political concepts, ethical and social norms and values, and aesthetic appreciation, as much as a source of food. Agrarians view the history of working on the land in particular places as an evolving, experimental understanding of nature and natural processes and cycles as well as a locus of human values, traditions, and community. Since the Industrial Revolution, agrarians have often extolled the virtues of a rich culture of small farming and bemoaned its gradual erosion by modern forms of agricultural production. In a modern age in which the primordial agricultural exit from the hunter-gatherer life in wild nature is often presumed to be a fully ontological distinction (culture/nature), agrarianism has come to represent a philosophical attitude that is critical of the cultural and environmental losses sustained by industrial economic progress and its valuation of the natural environment as purely instrumental. It is thus easy to see why agrarianism is sometimes a form of romanticism, perhaps culminating in the antimodernism of the Vanderbilt agrarians' *I'll Take My Stand* collection (Ransom et al. 1930). Cultural agrarianism is in many ways based on at least implicit recognition of loss of the practical life and social bonds of agrarian community and stewardship. Today, agrarianism retains its critique of industrial production and resource use, but this critique has gained greater variety and urgency in a context of widespread environmental, social, and health problems. Three agrarian themes are of particular, although not exclusive, interest for contemporary environmental thought: virtuous character, community, and environmental stewardship.

CHARACTER AND VIRTUE

Much of the earliest agrarian works emphasized the development of masculine virtues through working on the land, a theme continued in the work of Victor Davis Hanson (1995). Xenophon's version of Socrates and the Roman statesman Cato believed the farmer made for a good soldier, partially because of the physical prowess of the farmer, but partially also because the farmer would seek most ardently to defend his own land from invaders. Later agrarian writers emphasized an analogy between the farmer and God's work as the original husbandryman, suggesting a spiritual, if not divine, relation between arduous work and the land in which abundant harvests reveal God's blessings (see Miller 1956; see also Charles Taliaferro's chapter in Thompson and Hilde 2000). Henry David Thoreau extolled the "poetic farmer" who united both material labor and a respect for spiritual nature. Thoreau maintained, however, that virtues had to be cultivated and nurtured as much as the famous bean field of *Walden*. For Wendell Berry, the farmer explicitly takes on the role of the naturalist.

In *Notes on the State of Virginia*, Thomas Jefferson maintained that "corruption of morals in the mass of cultivators is a phenomenon of which no age or nation has furnished an example." Agrarians commonly suggest that certain individual character traits result from the practice of farming. These traits include discipline, self-reliance, prudence, industriousness, patience, humility, and cooperativeness, and are elevated to the status of virtues. As such, the heart of agrarianism as an ethics may be viewed as a virtue ethics, focusing on the habits of character that produce virtuous persons.

Agrarian virtues, however, have often been intertwined with received notions of class divisions and exploitation, with some exalting the aristocratic nobility of the propertied farmer (see Montmarquet 1989). Furthermore, emphasis on personal virtues gained through farming often overlooks historical problems of severe poverty, lack of education, and unjust social roles in agricultural life. New agrarians such as Eric Freyfogle thus raise the challenge of articulating a contemporary agrarianism that can nurture important individual virtues while encouraging agrarian families, healthy communities, and economies not based on unfair social arrangements (2001). The development of virtues in individuals is, of course, a function of the health of contexts in which they may flourish. Today, a composite vision of the values and virtues of the environmental steward and the social importance of rebuilding communities motivates many new developments of post-industrial farming.

COMMUNITY

Agriculture, in contrast with commercial trade, is a practice that is necessarily bound to specific places. Traditional agrarianism has centered on the economic, social, and political dimensions of small farms, often revolving around conceptions of property ownership. Locke's labor theory of value contributed a core concept to this version of agrarianism: The adaptation of the land through labor created new forms of value and was the very source of private property. The Physiocrats of the eighteenth century, especially Quesnay, took this further and argued that only agriculture produced new value not already located in nature for the taking (through mining, for example), nor possible in commerce. Berry makes a similar distinction: that agriculture is *reproductive*, not merely *productive* (1977). For Quesnay, the fertile soil generated new wealth, while the broader economy only circulated it (see Montmarquet 2000, pp. 46–50). The Physiocrats focused on how to maximize and manage such wealth. Rhetoric about the magical nature of fertile soil, however, has two facets: The unique land has been a powerful source of cultural symbols and national

identity, but it can also become a predominant feature in nationalistic and racist elements of political culture.

There are other articulations of agrarian communitarianism not centered solely on the creation and management of property. Jefferson commented on the economy of agricultural life and small land ownership as a means of securing greater democratic community and equality in the early United States (Jefferson 1984). A. Whitney Griswold likewise focuses on farming's importance to democracy (Griswold 1948).

The most influential contemporary agrarian, Berry develops a rich critique of modern society, environmental devastation, the dissolution of community through the "predation" of modern economic ideology and "internal disaffection," and the concomitant loss of virtues associated with small farming. Earlier echoes of this loss are found in Oliver Goldsmith's 1770 poem (and evocative image), *The Deserted Village*. Berry writes that, "food is a cultural product; it cannot be produced by technology alone" (1977, p. 43). The basic community for Berry is the family and farm neighbors, a community that survives through the production and reproduction of not only food but the historical continuity of shared practices and narratives. The healthy community resides at the intersection of virtuous beings and good environmental stewardship.

AGRARIAN ENVIRONMENTAL STEWARDSHIP

People must eat. Making use of the land through agriculture is thus a basic necessity. Agrarians seek to harmonize human productive practices on the land. They lean away from environmental concerns about the intrinsic or instrumental value of nature or ecocentrism and anthropocentrism. Agriculture is a necessary practice involving the human use of land and resources. Whether through the lens of self-interest or appreciation of a parcel of land's intrinsic properties, the farmer must understand the long-term effects of any given practice on the land for the sake of both the farmer's livelihood and the health of the land. Means and ends are intertwined in environmentalist agrarianism.

Aldo Leopold maintained that management of healthy land is a function of preserving the integrity, stability, and beauty of the ecosystem (1949). To "think like a mountain," in Leopold's evocative phrase, is to recognize the land as an interconnected biotic community in which the balance of an ecosystem can be broken by unreflective human activity that considers the environment only in terms of short-term scales of economic production rather than the long-term scales of ecosystem health and reproduction.

A similar holistic sense of the land runs throughout Berry's agrarian writings. Berry and Wes Jackson (1985) articulate the idea that small farms are ultimately more sustainable in environmental and communitarian terms. Both have emphasized what they consider the destructive effects of specialization in agricultural and social sciences in which an ecosystemic and interdependent understanding of nature and community is replaced by isolated scientific languages. There are, of course, better or worse farm techniques. Overuse of pesticides, monocultural planting, and tilling practices that deteriorate the soil have costs that outweigh any benefits. Proper environmental stewardship explores new techniques of farming consistent with the well-being of the land. Only a holistic understanding of the land, however, can improve knowledge of its management.

THE FUTURE OF AGRARIANISM

As long as agriculture is practiced, agrarianism will likely survive in some form, even if solely as an idealized critical stance on modern food production practices. Most people today are very distant in space and understanding from the sources of their food. Furthermore, food production systems no longer depend exclusively on even the heavily industrialized large farm. It is conceivable today that all food could eventually be produced in biotechnology laboratories. The future of agrarianism depends on society choosing at least sometimes not to develop and implement technologies based solely on considerations of productivity or efficiency or free markets.

This future looks unlikely at present but has intellectual resources in agrarian thought. Agrarian values appear today in a number of different practices: community-supported organic agriculture, urban gardens to individual efforts, "return to the land," the reappearance of "heirloom" varieties of fruit and vegetables, sophisticated restoration projects such as Jackson's Land Institute in Salina, Kansas, and social and political thought that focuses on the moral significance of the small community.

Even if the economic and material conditions for the family farm and agrarian thought to flourish are disappearing, agrarianism may yet make its greatest contribution to environmental thought indirectly. As Paul Thompson writes, "a virtuous community produces virtuous citizens vicariously, even when it does not actually exist. Its moral importance extends far beyond its borders in space and time" (in Lockeretz 1997, p. 27). Whence derive agrarian virtues today? They derive from an idealized, critical example of the farmer as the environmental steward, understanding the limiting resistance of nature to human endeavor, working with the reproductive cycles and longer time-scales of natural processes, and living interdependently with ecosystems as well as the endeavors of other people. This ideal farmer thinks like a mountain.

AGRICULTURAL ETHICS

Agricultural ethics is concerned with the values and moral issues involved in food production and farming practices. It explores a wide range of issues, including the proper use of land, the value of rural life, the impact of agriculture on the environment, the sustainability of agricultural systems, the well-being of farmers, the welfare of farm animals, the improvement of crops, and the safety and integrity of the food supply. By the turn of the twenty-first century this range of issues had taken on added urgency because of advanced technological manipulations such as genetic engineering of plants and animals and animal cloning.

THE DEVELOPMENT OF AGRICULTURAL ETHICS AS A SUBFIELD OF PHILOSOPHY

Although agricultural ethics did not become a distinct academic discipline until the 1980s, its concerns extend back as far as ancient works such as the *Oeconomicus* of Xenophon and the Bible, with its attention to the stewardship of the earth's resources. The virtues of rural life figure prominently in the works of prominent European and American intellectuals of the eighteenth and nineteenth centuries such as Leo Tolstoy, Thomas Jefferson, and Ralph Waldo Emerson. Scholars trace the contemporary debate on agricultural values to the pioneering works of twentieth-century agricultural scientists, novelists, and intellectuals such as Liberty Hyde Bailey, Richard M. Weaver, Wendell Berry, Louis Bromfield, and Glenn Johnson.

The growing interest in the ethical aspects of agriculture led to the introduction of courses, curricula, and programs in agricultural ethics in a number of U.S. universities and research centers during 1980s and the 1990s. Subsequently, topics in agricultural ethics were incorporated into the curriculum of life-sciences programs across United States and Europe. The evolution of agricultural ethics into a full-fledged academic discipline in the field of philosophy is linked to the contributions of international scholars such as Ben Mepham of the United Kingdom; Bernard Rollin, Paul Thompson, Jeffrey Burkhardt, and Gary Comstock of the United States; Michiel Korthals of the Netherlands; and Peter Sandøe of Denmark.

Agricultural ethics is a growing interdisciplinary area within applied ethics. It draws scholars from diverse backgrounds such as philosophy, sociology, political science, agronomy, animal science, ecology, biotechnology, and science and technology studies. The discipline has developed specialized periodicals such as the *Agriculture and Human Values* and the *Journal of Agricultural and Environmental Values* along with growing professional societies such as the Agriculture, Food and Human

Values Society (AFHVS) and the European Society of Agricultural and Food Ethics (EurSAFE).

AGRICULTURE, ENVIRONMENTAL PHILOSOPHY, AND ETHICS

Agriculture is one of the oldest and most fundamental ways in which human beings interact with the environment. It involves the cultivation of land, crops, and animals for food production; these activities cause profound and irreversible changes in humans' natural surroundings and often lead to the destruction of ecosystems. Therein lies the apparent conflict between agriculture and environmental concern: The need to produce more food to meet the demands of an increasing human population requires the expansion of farmland and the modification of crops and animals to better meet human needs. Farmland growth means less land for wild plants and animals. Modifying crops and animals often decreases genetic diversity, thereby resulting in a lower quality of life for the animals. Intensive farming expends large amounts of energy, erodes the soil, and pollutes the waters with eroded sediments, fertilizers, and pesticides containing toxic chemicals. Agricultural practices have therefore come under scrutiny by those concerned with environmental ethics and the preservation of nature.

Modern agricultural practices are responsible for numerous environmental crises worldwide—deforestation, desertification, destruction of wetlands, the salinization and siltation of rivers—and for such industrial disasters as the release of toxic gas in Bhopal, India, and the drying of Aral Sea. On a general philosophical level agriculture and environmental concerns seem counterposed: Whereas the former is driven by human-centered concerns (providing sufficient quantity and variety of food for human consumption, securing the livelihood of farmers, and preserving the rural way of life), the latter emphasize the well-being of the natural environment, nonhuman animals, ecosystems, and nature as a whole. In some respects the goals of agriculture and environmentalism overlap because the success of agriculture depends on the functional integrity and stability of earth's biosphere. Hence striking a balance between human needs and ecosystem health is a shared goal of both environmentalism and agriculture.

CONTROVERSIES IN AGRICULTURAL ETHICS

Agricultural practices are complex, and their parts are interrelated, so they cannot be understood or debated in isolation. In tackling complex problems, agricultural ethics draws on three distinct sources: (1) the classical ethical theories of utilitarianism, deontology (the theory or study of moral obligation), virtue ethics, and contractarianism; (2) the newly emergent subfields of ethics such as environmental ethics, animal and research ethics, food ethics, and biotechnology ethics; and (3) the ethical tools developed expressly for application to agricultural ethics, such as the ethical matrix devised by Mepham (2000) to guide ethical evaluation in agriculture by considering its major components: the biota (flora and fauna), producers, consumers, and the treated organisms. Three representative issues in the ethics of agriculture—the family farm, farm-animal welfare, and genetically modified foods—exemplify the complexity of agricultural practices and the moral and theoretical issues they raise.

The Family Farm Some of the most persistent debates in agricultural ethics and policy concern the preservation and value of the family farm. Traditionally the small family-run farm has been the central unit of rural life and agricultural production. This unit has undergone a precipitous decline because of the combined impacts of industrialization and agriculture (Burkhardt 2000, Zimdahl 2006). Some liken the disappearance of the family farm to the waning of other technically superseded forms of production and livelihood such as blacksmithing; in this view the consolidation of farms into large corporate entities is a byproduct of an inexorable march of economic, social, and technological forces. From this perspective there is no ethical obligation to protect or preserve the family farm because of its supposed lack of economic efficiency. This narrowly economic view of the endangered family farm is rejected by a school of agricultural ethicists called agrarians, who argue that family farms have important socioeconomic, cultural, political and/or moral value that is irreducible. Because of those considerations, they argue, there is a moral obligation to protect and preserve small artisan farms.

Agrarianism is divisible into two distinct types: populist and traditionalist. Each offers a distinct vision of the significance of the family farm and a corresponding set of arguments for its protection (Thompson at al. 1994). Agrarian populism—as articulated by Thomas Jefferson and, in the twentieth century, by Harold Breimeyer and Jim Hightower—stresses the importance of the family farm to the social and political well-being of society. Jefferson praised the value of the farmer as a citizen whose ties to the land guarantee social stability because his or her private interest is linked to the prosperity of society. Breimeyer argues that small farms are viable and important social institutions because they guarantee the right of poorer and less educated people to self-employment and economic independence, thereby contributing to individual freedom and political liberty. Hightower views the small farmer as an independent entrepreneur whose interests must be protected by the government as a matter of social justice. The agrarian traditionalism

articulated by Wendell Berry emphasizes the intrinsic value of the small farm and the agrarian way of life. Berry offers virtue-based arguments in defense of the family farm. He argues that farming develops a sense of unity with nature, shared community values, loyalty and responsibility within the family, and care and concern for the land. These qualities, he holds, are valuable for their own sake: They give a holistic meaning to life and act as an antidote to the alienation inherent in specialized activities such as intensive farming and manufacturing. For agrarian traditionalists, then, the family farm becomes "a metaphor for the good life, ethically conceived, rather than a profession or an occupation" (Burkhardt 2000, p. 13).

Traditionalist arguments about the intrinsic value of the family farm, with their ethical imperatives to preserve and sustain it as a way of life, provide a yardstick for evaluating moral issues in agriculture such as social justice, the impact of industrialization and biotechnology on agricultural practices, the environmental effects of agriculture, and responsibilities to the future generations (Burkhardt 2000). Champions of family farming argue that it fosters a concern for the land and a willingness to forgo short-term gains in order to preserve the land for future generations. This approach stands in contrast to industrialized agriculture, with its emphasis on productive efficiency; its intensive use of energy, water, and synthetic chemicals; and its contribution to erosion, the depletion soil fertility, and other adverse environmental effects. Because of those problems, the family farm has gained additional support from environmentalists, who see in that way of life an example of a sustainable relationship with the land that respects the needs of the environment and the interests of future generations.

Farm-Animal Welfare The development of industrialized agriculture in the twentieth century resulted in the transformation of animal agriculture from extensive, decentralized pasturing and cooping to intensive, concentrated factory farming. Whereas traditional, extensive farming relied on fewer animals that could move freely in large spaces and received individual care and attention, intensive farming involves the confinement of very large numbers of animals in very small spaces and barren environments, with the emphasis on economic efficiency, low cost, and high productivity. The care and handling of animals is highly mechanized and entrusted to a small number of unskilled workers. The change from extensive to intensive farming has transformed the human-animal relations, adversely affecting both animals and the environment. The introduction of cloning and genetic engineering has added more fuel to the fires of controversy surrounding industrial agriculture.

Confinement operations often restrict animals to isolated, small stalls or cages, making it impossible for them to move, turn around, scratch, or stretch their legs. In addition to physical discomfort, this enclosure leads to psychological and social deprivation that results in aggressive and self-destructive behavior patterns (e.g., bar biting in sows, tail biting in pigs, feather pecking in hens) and production diseases (e.g., liver abscesses in cattle) that foster the widespread use of antibiotics and vaccines. Branding and castration without anesthesia, dehorning and tail-docking of cattle, the confinement of sows into very small stalls, debeaking, toe trimming, forced molting of hens, and hormone injections are other ethically controversial practices associated with factory farming (Rollin 1995a).

In traditional extensive (as opposed to intensive) farming, there is an overlap in the interests of human and beast: The well-being of the farmer depends on the productivity and health of fewer animals, each of which has a high monetary value. This circumstance encourages humane husbandry that provides animals with a stress-free environment; adequate food, water, and shelter, and individual medical care as needed. In contrast, the structure and goals of industrial farming create a conflict between the interests of the farmer and the good of the animals. Intensive farming is an economy of scale. In the drive for profit maximization and efficiency, the care of animals is transferred to machines or low-paid workers without adequate knowledge and experience. Rollin (2006) notes that, from a purely economic point of view, it may be more efficient to kill a sick animal or let it suffer rather than spend time, money, and labor on veterinary care. Factory-farm animals, he argues, are objectified and treated as things whose only value is in the profit derived from satisfying humans' food needs. This cold economic calculus contrasts sharply with the humane techniques and goals of traditional husbandry and farming. As Roger Scruton (1996) observes, a major casualty of industrialized farming is the quality of the relation between the farmer and his animals.

Factory farming uses large amounts of natural resources (fossil fuel, water) and generates huge amounts of solid and liquid animal waste that contaminates the soil and groundwater, and gaseous waste that pollutes the air and contributes to global climate change and acid rain. Two proposed solutions to the environmental toll of intensive farming are organic livestock farming and the genetic modification of animals to reduce their environmental impact. Each alternative, however, generates further dilemmas. Organic livestock production is a form of extensive farming. It improves animal welfare but cannot eliminate the animal-waste problem; moreover, because it is less productive, organic farming cannot satisfy the nutritional needs of a growing world population. From

an environmental perspective, the genetic modification of farm animals may be a better solution, but it raises concerns about the welfare and integrity of the animals and about human safety.

Which of the competing interests—human, animal, or environmental—ought to take priority? Can the amount of animal suffering in industrial farming be morally justified by appeals to human needs and interests? Can these seemingly conflicting interests be harmonized for the benefit of all? The need to answer such pressing questions led to the development of farm-animal ethics as a subfield of agricultural ethics. Farm-animal ethics emerged as a response to the growing public awareness of the suffering of farm animals in the 1970s and 1980s, the expansion of the scope of traditional ethics to include nonhuman entities such as animals (most notably in the works of Peter Singer, Tom Regan, and S. R. L. Clark) and the environment (most notably in the writings of Aldo Leopold and Holmes Rolston III). The recognition of animals as subjects of moral standing led to greater recognition of the suffering of farm animals and to efforts to formulate an ethic of livestock production, most notably in the works of Bernard Rollin (1995) in the United States and Peter Sandøe (1999) and Michiel Korthals (2004) in Europe.

There are five distinct ethical approaches to the issue of reconciling the welfare of farm animals with the needs of humans and the protection of the environment (Korthals 2004). The most radical among them is the abolitionist approach based on Regan's animal rights view. In this view animals have intrinsic value because they are subjects of a life. Regan argues against the use of animals as mere means to human ends. He rejects commercial agriculture, animal experimentation, and hunting as irredeemably immoral. He leaves it unclear, however, what should be done with the already domesticated animals that depend on humans for their existence.

The animal-integrity approach is grounded in Holmes Rolston's view of species integrity, which appeals to the genetic integrity of animals as a basis for moral evaluation. It prohibits any manipulations or destruction of the genetic code of animals, thus condemning genetic engineering and certain kinds of breeding. This view, however, does not address welfare issues from the perspective of the individual animal. Rolston also ascribes intrinsic value to entire ecosystems. He criticizes the animal-liberation view and allows for animal agriculture as long as it does not encroach upon the environment. Rolston, however, fails to specify the criteria for defining an ecosystem and offers little help in resolving dilemmas raised by animal agriculture.

The animal-welfare view is perhaps the most influential and widely accepted approach to farm-animal ethics. It has been advanced by Rollin and Sandøe (1999), whose leading concern is the welfare of the individual animal. In this view humans have a moral obligation to maintain and promote the welfare of farm animals by taking into consideration their needs and subjective experiences and their ability to express their natural patterns of behavior. These philosophers call for improving the living conditions of farm animals and for "conservation of welfare" (Rollin, 1995b). They hold that animal agriculture and biotechnology (e.g., genetic engineering and cloning) are morally acceptable as long as they do not undermine animal welfare.

Korthals has proposed a pragmatist approach to animal welfare. Drawing on the ideas of the American pragmatist John Dewey, Korthals complements Rollin's welfare view with considerations of the environmental and social aspects of animal care. Korthals calls for "differentiated treatment of animals, such that their specific function is considered, with proper partitions as it were being placed between farm animals, semi-wild animals, and pets" (Korthals 2004, p. 93). Korthals recommends broader and tighter regulations of animal welfare and further research into optimal farming techniques and possible limits on meat consumption.

In response to the growing concerns about the welfare of farm animals, governments and professional organizations across Europe and the United States have enacted regulations to change farming practices, prevent animal cruelty, and improve the welfare of farm animals. Most prominent among them are the Brambell Commission of 1965, the Five Freedoms formulated by the Farm Animal Welfare Council in 1979 in the U.K., the Swedish law of 1988 abolishing confinement operations, a series of European Conventions for the Protection of Animals issued by the Council of Europe and ratified by the member states, and the European Union (EU) legislation on farm animal welfare.

Genetically Modified Foods The introduction of genetically modified (GM) foods has triggered heated debates over issues of safety and environmental impact. GM foods are derived from microbes, plants, or animals produced through genetic engineering. The process involves the artificial manipulation of the genes of an organism or the transfer of foreign genes into its DNA. The resultant GM foods contain genes that do not exist in nature and have new qualities that are unlikely to develop otherwise. The main goal of GM foods is to alleviate world hunger and make agriculture more economically efficient and/or environmentally friendly by achieving improved crop and animal yields; increased resistance to pests, diseases, and herbicides, thereby reducing the use of chemicals; and improved nutrition, shelf life, and palatability of food (Mepham 2000).

The crops that are most commonly subject to genetic modification are soybeans, canola, corn, cotton, tomatoes, and rape seeds, and the traits most commonly introduced are herbicide and pesticide resistance. The world's largest producer of engineered crops is the United States, where more than 80 percent of soybeans and cotton are genetically modified and more than 70 percent of all foods on the market are GM foods. The amount of land used for modified crops has also been growing rapidly worldwide (ISAAA Brief 37-2007).

The production and sale of GM foods raise an array of ethical questions with far-reaching moral, social, and policy implications: Are GM foods safe? What will be their effect on environment? How might GM foods affect farmers in the local and global economy? What are the responsibilities of food manufacturers, distributors, consumers and society regarding GM foods?

Thompson divides the various moral issues raised by GM foods into substantive and procedural concerns. The substantive concerns are based on moral, religious, cultural or philosophical beliefs held by individuals or groups. The procedural concerns pertain to the policies and mechanisms for making food choices in society. On the procedural level there is a growing consensus among ethicists that, in a democratic society, substantive concerns regarding GM foods ought to be taken seriously in policy making and food practices regardless of their scientific merit if the substantive beliefs are based on reasonable cultural, religious, or moral beliefs. Respect for substantive belief is grounded in the principle of consumer sovereignty, according to which individuals should be able to make food choices based on their own beliefs and values (Thompson 1997). In this view consumers must be informed about the origin of their food to exercise their choice, but there are divergent views as to the best way to deliver the information. Some believe that the best way to facilitate consumer choice is by mandatory labeling of GM foods, which is the policy of EU. Others claim that it is better to label non-GM foods because this would be more practical and will provide equivalent information. Yet others argue that there is no moral obligation requiring producers to label GM foods, and some question the efficiency of food labels in enhancing personal autonomy.

The substantive arguments for and against GM foods can be divided into extrinsic and intrinsic concerns (Comstock 2000). Extrinsic concerns focus on the effects of GM foods, especially their safety and environmental and social impacts. Intrinsic concerns, which are grounded in principles of respect and duty, question the very process by which GM foods are produced. Those who argue against GM foods on extrinsic grounds note that their safety has not been sufficiently established. These critics point to potential allergens in GM foods, the possibility that newly created proteins may be toxic, and the risks of increased antibiotic resistance (Hopkins 2001). They also charge that GM foods pose environmental risks, such as contamination of conventional crops, the spawning of superweeds, and wiping out of innocent species such as the Monarch butterfly (Brown 2001). The proponents of GM foods counter that they are safe because they undergo rigorous testing and that no adverse health effects have been reported. The proponents claim that there is no significant difference between conventional food and GM food and that mandatory labeling is therefore unneeded. Supporters of GM foods also point to their potential in alleviating world hunger, reducing pesticide use, and promoting environmentally friendly farming.

The extrinsic objections to GM foods are contingent rather than principled. Such objections can be met by perfecting the technology for GM foods, enforcing strict safety regulations, and conclusively demonstrating that their benefits outweigh the risks. The more challenging task is to judge the moral status of GM foods without appealing to unsettled empirical claims. Would there be anything morally objectionable about GM foods even if they were proved to be safe and beneficial? Such questions lead to the intrinsic issues surrounding GM foods. Most intrinsic objections invoke the unnaturalness of GM foods; they are viewed as a sign of human arrogance and disrespect for nature. Other intrinsic critics claim that the technology is morally objectionable because it violates species boundaries and integrity. Apologists for GM foods claim that all such objections are based on religious, not scientific, principles and thus have no place in public policy. The intrinsic critics counter that the processes of Darwinian evolution have produced a wide array of species, each with its own integrity and specific boundaries. Other critics claim that GM foods represent a threat to the integrity of traditional ways of life and farming (Pascalev 2003). The policy debates about GM foods reflect broader ethical and philosophical differences about the role of technology in society, individual and social tolerance for risk, the value of nature, and the meaning of food.

CONCLUSION

Despite its young age, agricultural ethics has established itself as an important area of ethical inquiry that draws the attention of academics, policy makers, farmers and concerned citizens alike and serves as an exemplar of modern interdisciplinary discourse. It has successfully identified pressing moral issues in the practices of food production and has developed the level of awareness and the conceptual and theoretical tools for formulating ethically sound solutions to the problems it identifies. It is

safe to predict that in the years to come, agricultural ethics will enjoy even greater attention and impact on policy making and agricultural practices due to the growing import of agriculture in light of climate change and continued population growth. The rapid development of biotechnology and the need for ongoing ethical assessment of its applications will also contribute to the growing relevance of agricultural ethics to human practice. Concerns about world hunger, the impact of agriculture on nature and on the interests of future generations, developing environmentally friendly agricultural practices, the place of organic farming and alternative production modes will be among the issues of the day. The main challenge for agricultural ethics and its main contribution would be to find solutions that are practical while also withstanding philosophical scrutiny, and to build a broad consensus around them among all stakeholders.

AGRICULTURE

Agricultural practices have a major impact on the natural environment. How these practices should best be carried out is a major concern of environmental ethics and of agricultural ethics. The word *agriculture,* like *medicine,* refers to a group of technologies or techniques that humans have developed for sustaining life. An agricultural system consists of a cultivated environment and a group of socially and economically related production units, or farms. Agricultural systems encompass diverse methods of cultivation and socioeconomic organization. One common feature of successful agricultures is the continuous renewal of their constituent elements. Thus, soils are renewed through natural events or human practices that restore the physical structure (or tilth) and nutrients critical to plant and microbial life. Plants and animals are renewed in giving rise to progeny and in maintaining a diverse gene pool that allows for flexible responses to variations in weather and climate. Human institutions are also renewed so that, in classic agricultural systems, many generations of farmers engage in stable social and exchange relationships.

THE EVOLUTION OF AGRICULTURAL TECHNIQUES

One of the first stable agricultural systems was swidden or "slash-and-burn" agriculture. In this system cultivators cut down and burn trees and other foliage, producing a very rich but temporary soil for cultivation of plants. These patches can be cultivated for three to five years before they must be abandoned to the forest to allow for renewal of soils, which may take more than fifteen years. Although sustainable when human populations are low,

Paddy Fields near Yangshou, China. *A farmer in China utilizes an old-fashioned plow, pulled by an ox, in China's Guangxi province. Modern agricultural practices, such as biotechnology, raise many ethical concerns, especially concerning the environment.* **PETER PARKS/AFP/GETTY IMAGES.**

swidden agriculture is not suitable for expanding populations, which require faster soil-recovery periods. Hence slash-and-burn farming is unsustainable in most parts of the contemporary world.

Swidden systems were succeeded in most parts of the world by systems that restore fertility—either by frequent flooding, as in the Nile Valley of Egypt, or by combining various forms of animal production with cultivation of crops. Systems that emerged in Europe approximately 1,000 years ago used a cycle whereby crops such as wheat or barley would be cultivated in a rotation with long periods when fields would be left fallow so that animals could graze on grasses that were planted following the main food crop. Fallow periods often exceeded eighteen months, meaning that the rotation took a number of years to complete. Beginning in the 1500s this system was gradually replaced with the production of forage crops such as hay and oats, and manual redistribution of animal wastes to recover soil fertility. Only then did farming begin to resemble the annual cycle of cropping in stable fields with which we associate the word *agriculture* today.

AGRICULTURE, SCIENCE, AND EDUCATION

The conversion to forage crops and the elimination of fallow periods coincided with the growth of European science. In England, especially, the idea of science was widely associated with agricultural reformers such as Jethro Tull (1674–1741) and Arthur Young (1741–1820). By the nineteenth century the German chemist Justus von Leibig (1803–1873) was laying the foundations for yet another agricultural revolution: the use of synthetic fertilizers and scientifically developed plant and animal varieties. Cyrus McCormick (1809–1884) was perfecting a horse-drawn mechanical harvester. In the twentieth century these technologies became commonplace, along with steam, gasoline, and diesel-powered tractors and mechanized equipment.

Viewed from a governmental or scientific perspective, agriculture encompasses a wide array of renewable-resource production activities, including fisheries or aquaculture, forest management, and the production of managed outdoor recreational areas such as golf courses. Most national governments have a ministry or department of agriculture that is also responsible for these additional activities. Agricultural colleges (in the United States, land-grant colleges) also include departments and programs for wildlife and fisheries management, recreation and parks, and forestry. Their research, development, and extension agenda emphasizes increasing "production efficiency." Agricultural science has helped to reduce the number of farmers in the United States from 85 percent of the population to less than 5 percent while increasing the output of agricultural goods produced. This success caused the land grants to replace traditional

clientele (farmers) with new clientele. Many have changed their names from "The College of Agriculture" to "The College of Natural Resources and Life Sciences" to include concerns such as food and environmental safety, human health and nutrition, and conservation of resources.

Linkages between agricultural colleges and medical-research colleges have strengthened. Many agricultural disciplines now conduct research sponsored by the National Institutes of Health. These linkages also have ethical implications. For example, the notion of health presupposed by medical research remains unexamined, as does the notion of agriculture. The questions "What is agriculture?" and "What is health?" are important topics of investigation for bioethics, and the meaning of the term *ecosystem health* is an important issue for environmental ethics.

Critical reflection on agricultural practices in the United States came to the public's attention through books by Rachel Carson (1962), Jim Hightower (1979), and Wendell Berry (1977). These authors challenged the vision of agriculture promoted by public-sector science. Carson questioned the environmental impact of chemical farming. Hightower raised questions about the clientele of the land-grant complex that promoted this type of farming. Berry viewed modern agriculture as symptomatic of the fragmentation of modern culture, a trend that he believes is creating irresponsible specialists who are ignorant about the impact of their activities because they do not live where they work. These works have stimulated a growing body of "critical" and "ethical" literature questioning standard assumptions underlying "scientific agriculture" or "agribusiness" and the costs and benefits of agricultural research and farming practices for humans and the natural environment.

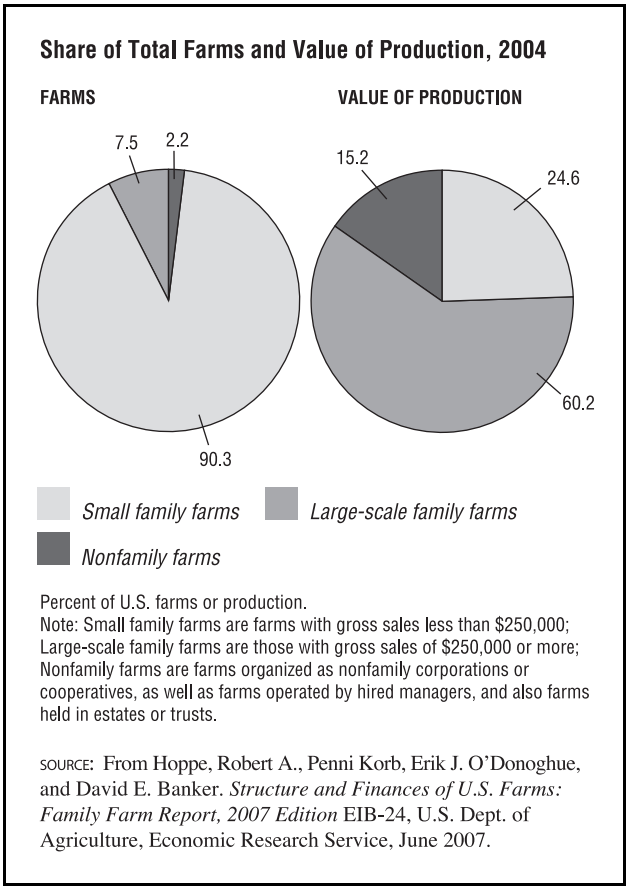

Figure 1. CENGAGE LEARNING, GALE.

THE MEANINGS OF AGRICULTURE

Ethical questions about the appropriate use of agricultural technologies are about the responsible use of power. Do technologies benefit their users and justify their costs? Are they efficient? Critics of the instrumental notion of agricultural technology raise other issues. What is the assumed end that agricultural technologies are designed to serve? Critics argue that there are other considerations besides increased productive efficiency, such as food quality, the way in which the costs and benefits of the production system are distributed among the population, and the impact of the system on the nonhuman environment. Regarding agriculture merely as a morally neutral instrument ignores other values. A more fundamental criticism focuses on the metaphysical status of the practice of agriculture.

Through the intensive management of natural systems, humans "re-create" nature, an idea that seems questionable. But only the more modern version of management by domination may be misguided. The idea of "man's dominion over nature" is symptomatic of patriarchy, which dominates the nonhuman environment, women, and other groups. But not all agricultural systems are equally dominating. Different conceptions of agriculture thus reflect different metaphysical or religious conceptions of the human condition and the human relationship to "creation," or nature. For Wendell Berry (1977) agriculture signifies the margin between wilderness and civilization—between nature and the products of human labor. The separation of agricultural production from other activities marks our loss of a sense of the natural and the ways in which human activities have changed it. Agriculture can be viewed as an experiment in the creation of new forms of the natural. Berry does not see scientific agriculture in this way because it does not perform experiments in creating new forms of nature and does not measure them against old forms. It merely seeks an increase in the human power to change nature.

Opposition to a "productionistic" conception of agriculture can be linked to an agrarian tradition that

values farming as a way of life and sees in it social and personal values that transcend its products (Montmarquet 1989). If agriculture allows farmers to have more fulfilling lives or to be more dependable citizens, if it creates the basis for more stable communities or allows its practitioners to experience a cooperative relationship with the natural world, as in organic farming, then technologies should be developed to help secure these practices, and government policies should increase the opportunities to engage in them. This is a different issue from whether the opportunity to benefit economically or nutritionally from agriculture is distributed equitably.

In addition to encompassing issues of who farms and how, agriculture now includes the industries that produce farming inputs (fertilizers, pesticides, farm machinery) and those that process and market farm commodities. It also includes policymaking, administration, government, research, and education. This expanded notion of agriculture broadens the area of agricultural ethics to include practices involved in business, science and technology, professions, the environment, and policy making.

THE QUESTION OF EQUITY: WHOM SHOULD AGRICULTURE SERVE AND HOW?

Who are the beneficiaries of conventional agriculture? Are its costs and benefits distributed equitably? Benefits in agriculture include access to goods produced on farms (food and fiber), the revenues derived from agricultural activities, and other, less tangible advantages such as status, pleasure, and virtue. Costs include loss of opportunities to practice agriculture or to have access to farm products, loss of nonagricultural resources (e.g., potable water), loss of wildlife habitat and other important features of the natural environment, and the unethical treatment of farm animals.

Carson's criticism of "chemical farming" is that it is harmful to the environment, a criticism acknowledged by the National Research Council's (NRC) report on alternative agriculture (NRC 1989). Industrial agriculture can have serious negative impacts on and beyond the sites of production. The scientific research agenda that supports these practices has not adequately included a study of these impacts and how to avoid them (Busch and Lacy 1983, NRC 1989). Negative effects include loss of soil fertility; contamination of ground waters by pesticides (these endanger wildlife and make the water unfit for human consumption) and by high levels of nitrates from fertilizer runoffs; excessive tapping of groundwater; destruction of wildlife habitats; and loss of genetic diversity. Agriculture is the largest source of nonpoint water pollution (NRC 1989.) Pesticides pose threats to on-farm safety, consumer safety, and wildlife (NRC 1989). Highly managed agricultural systems reduce genetic diversity and increase ecological vulnerability. Industrial agriculture has social costs that are external to the production system and that are borne unwillingly by those who pay for them (externalities) or who will pay for them later (future generations).

Hightower's criticism is that the research clientele of public-sector science has been highly capitalized producers. Access to conventional agriculture has been systematically denied to farmers with low access to capital, nonprogressive farmers, African Americans and other oppressed ethnic groups, and women. These groups have been excluded because U.S. policies have promoted productionism, encouraging producers to adopt expensive technologies that favor capital-rich early adopters. Others must either adopt or quit, creating "the treadmill effect" (Cochrane 1979). Producers who are more risk-averse or who do not have access to capital are thus at a strong disadvantage. Neither women nor African Americans have had access to capital to the degree that white males have. Women have also been excluded from farming and from the agricultural professions because of male biases against female participation in these fields. (In many third world countries, European and North American development agents ignore women, who constitute the majority of subsistence producers in many regions.) Those so excluded lose access to the goods they once produced for themselves or to the income needed to purchase goods produced by others. Many of the costs and benefits of industrial agriculture are not distributed equitably.

Public-sector research and development have contributed to these inequities by promoting capital-intensive technologies (Perkins 1982). These technologies have other costs: to consumers, to farm labor displaced by machinery (Friedland and Barton 1975), to the general public, to other producers who cannot stay on the treadmill, and to future generations. These technologies include farm machinery, inputs like soil amendments and pesticides, irrigation equipment, and new life forms. Nevertheless, public-sector agricultural science has begun to explore alternatives to the system that is used as a model for agricultural development around the globe because of the growing realization that transferring conventional technologies to low-resource producers does not enhance production. There is also an increasing awareness that older forms of agricultural knowledge can foster practices that are more sustainable ecologically. The exploration and critical evaluation of alternative models for agriculture is part of a growing body of literature on the concept of sustainable agricultural development.

SUSTAINABLE AGRICULTURAL DEVELOPMENT

Agricultural practices become unsustainable when they fail to meet the demands placed on them. Conventional agriculture has stretched the productivity of farming by importing materials from other locales and by introducing management techniques that substitute for in situ biological relationships. These practices require the use of nonrenewable resources, the supply of which has become inadequate to meet an increasing demand. Scarce resources include soil and water, petro-based chemicals (pesticides and fertilizers), and soil amendments (phosphate). Inadequate technologies include petroleum-dependent machinery, chemical pesticides, and monocropping. Genetic diversity—a potential resource for new plant varieties—is being threatened as well (NRC 1989)

The loss of topsoil through erosion is a major problem in many parts of the world (NRC 1989, Worster 1985). Hyams (1976) traces the rise and fall of civilizations to the need to shift production sites because of soil erosion. Jackson (1980) suggests as a remedy the adoption of perennial crops that do not depend on soil tillage, a primary cause of soil erosion. Jackson's recommendation is part of a wider movement to adopt more ecologically friendly practices.

Conventional agriculture's effect on water quality is another serious impediment to sustainability. Soil deposition, nutrient loading, and contamination by pesticides are major sources of water pollution. The excessive use of irrigation technology, which causes the serious depletion of aquifers in many areas, and the expanding competition for urban water sources raise doubts about the sustainability of current practices.

Contamination of water by pesticides poses threats to wildlife and humans. Pesticide use can be harmful to farmworkers. Residues pose risks to the safety of food (NCR 1989). Pesticide technology is rapidly becoming ineffective; insects develop resistance faster than new pesticides can be developed (Metcalf 1987). The use of antibiotics in animal feed is another concern. The emergence of antibiotic-resistant strains of bacteria caused by the use of antibiotics in animal feed may be a source of meat contamination (NRC 1989).

Many of the unsustainable features of conventional agriculture were introduced as replacements in systems

Harvesting Corn, Springfield, Illinois. *Industrial agriculture is a controversial practice in terms of environmental ethics. Critics of U.S. agricultural practices argue that such practices produce more harm than good; for example, by releasing chemicals and pesticides into the ecosystem, destroying wild habitats, and reducing genetic diversity. Some believe that the solution is to turn to more sustainable agricultural systems, such as the use of biotechnology.* **AP IMAGES.**

that had become underutilized. The replacement of one system with another is sometimes referred to as a "revolution" (e.g., the "green revolution") (Danbom 1979, Richards 1985, Pretty 1991, Merchant 1989) and sometimes as "development." The notion of "agricultural development" has its roots in the rationalization of European territorial expansion from the late fifteenth century to the end of World War I. Many regions of the world were considered underutilized. These regions became the source of raw materials for manufacturing and the location of new markets for European products. Many indigenous production systems were converted to plantation agriculture by colonizers. The imposed systems—mixes of the indigenous and the exogenous—soon became unsustainable and were replaced with more "progressive" forms of farming (Merchant 1989). After many of these European colonies achieved independence after World War II, "development" became synonymous with nation building, the creation of urban industrial centers, producing cheap food for urbanites, and promoting marketable export goods to bring in needed capital. "Agricultural development" meant increasing productive efficiency. The assumption was that such development would foster rural development—rural producers would benefit, presumably, through increased incomes and a higher standard of living, or through opportunities in urban labor markets. Frequently the opposite occurred. The more productive systems that displaced the older ones were unsustainable and inequitable, thus producing a demand for more sustainable agricultural systems worldwide.

Sustainability means different things to different people (Douglass 1984, Lockridge 1988). Advocates of sustainability propose greater use of biotechnology to break dependence on pesticides and nonorganic fertilizers, readoption (with some modern adaptations) of agricultural techniques from earlier local systems (Warren 1991), adoption of organic or reclamation production techniques, the development of systems that accord greater recognition to the environmental and social characteristics of the regions where production takes place (Sale 1985, Altieri 1987, Harwood 1992), and the return to more decentralized production systems that are based on local, independent producers who keep capital in their rural communities (Strange 1988). The use of biotechnology to correct the failures of conventional agriculture has received the greatest amount of attention and research funding.

BIOTECHNOLOGY

Biotechnology is the term most often applied to the development of new life forms through sophisticated biochemical techniques. Biotechnology has been hailed by many as a major advance that will help develop sustainable agricultural systems; its use in agriculture includes the development of "improved" plant and animal strains, biological controls for pests, and biochemicals that stimulate plant and animal growth and productivity. Safety and equity questions have arisen about all of these techniques.

Plant improvement is a prominent example of biotechnology. Hybridization is not a new process, but its successful application to seed corn in the 1930s by Henry Wallace (Kirkendall 1987) led to increased corn yields and marked the beginning of research efforts to develop other high-yielding grain varieties. The justification for developing and disseminating these new plants was the alleviation of hunger. A geometrically increasing world population requires that yields from farming continue to increase (Borlaug 1986, Perkins 1990). This technology, however, has had only limited success in preventing malnutrition. Capital-intensive, it favors highly capitalized farmers and drives poorer farmers out of production, diminishing their opportunities for producing or purchasing food. Some hybrid varieties that replace more traditional varieties are more vulnerable to adverse growing conditions, more costly to produce (farmers cannot produce their own seeds), and more reliant on other purchased inputs.

Proponents of biotechnology—especially the techniques of genetic modification that have evolved since the 1990s—claim that it can produce new life forms that can tolerate many of the adverse conditions that other developed varieties cannot because traits from hearty local weed plants can now be introduced into unrelated crop species. Through recombinant DNA genetic engineering, plants can be "designed" to resist pests, to use nutrients more efficiently, or to produce their own nutrients, thus eliminating much of the need to depend on other inputs such as fertilizers or pesticides. Genetic engineering can also be used to develop microorganisms that can produce biologically useful materials such as animal growth hormones.

Although biotechnology may hold great promise for sustainable agriculture, it has generated controversies about the health consequences of many of its products. Bovine growth hormone (bGH) has been the target of health and safety concerns, for example. Many of the new life forms will be patented by their developers. If they replace more traditional nonpatented varieties, farmers' dependence on the patent-holding seed producers will increase.

The environmental consequences of genetic manipulation are unknown (Weaver and Morris 2005). Many critics fear a host of unanticipated risks to both wild and tame ecosystems from the spread of genetically modified organisms that were generated in a laboratory. Finding suitable traits to introduce into crop plants may mean the

mining of the genetic resources of third world countries (Silva 1988). Moreover, biotechnology may just substitute inputs, not eliminate them. For example, herbicide resistance has been genetically engineered into tobacco. Although this technology allows the use of herbicides to replace tillage, it would require the purchase of a product whose environmental impact is largely unknown.

Critics of biotechnology see this approach as not very different from the conventional fix of high-tech global agriculture (Burkhardt 1992), an approach that often does not take into account the physical and social systems in which agriculture operates. As agricultural-development research becomes more interdisciplinary and includes a wider range of social science and humanities perspectives, there is a growing agreement that considerations of economic, social, and environmental justice should inform development models. Given the diversity of social and biological systems throughout the world, no single model of sustainable development can satisfy all these criteria. Considering the conflicting demands that will be placed on agriculture in the next century, some critics now argue, in Harwood's words, that the "key to success will be the recognition and structuring of appropriate patterns of diversity. No single pattern is acceptable. No one type can meet the diverse social, economic, and resources-availability conditions of even a single country" (1992). Included in the social resources of many regions are traditional knowledge systems that do not rely on purchased inputs and rely on more sustainable techniques of cultivation.

Research to aid smaller producers through "farmer participation" is in vogue. There remain some fundamental conflicts between environmental interests and agricultural-development interests, even if the concept of ecological agriculture becomes the dominant one. Incursions into pristine ecological systems on a global scale are likely to persist even in the face of widespread efforts to preserve wilderness areas because it is impossible to demarcate impenetrable boundaries between these areas and systems of cultivation. The interactions at the margins will inevitably modify wilderness areas.

The conflicts between environmental concerns and agricultural development have started to become an important focus for those seeking recognition of the need for equitable access to food and opportunities and the need to preserve precious global environmental resources. There is a clearer recognition of the role that the social sciences and the humanities must play in this research. Indeed, agriculture needs a greater integration not only with nonhuman nature but also with other areas of human concern that it has previously neglected—especially health and nutrition. (Engel and Engel 1990, Clancy 1992).

ALTERNATIVE TECHNOLOGY

"Mechanization and regimentation … dominate every aspect of our existence," Lewis Mumford wrote in *Technics and Civilization* (1934, p. 4). During the protest movements of the late 1960s, large numbers of academics, artists and musicians, and political activists took up the call for more democratic and environmentally responsible forms of technology. Civil rights advocates, anti-war protesters, back-to-the-landers, feminists, and adherents of the counter-culture had diverse concerns, but many criticized an increasingly technologized society threatening ecological systems while operating at a scale difficult for most people to understand or influence (Ellul 1964, Roszak 1969, McRobie 1981). Although scarcely a threat to what was then called the military-industrial complex, the opposition did lead to increased interest in organic foods, toxics reductions, pollution prevention, alternative energy, and other facets of the contemporary environmental movement.

ORIGINS OF THE CONCEPT OF ALTERNATIVE TECHNOLOGY

The concept of alternative technology was popularized in the 1970s by E. F. Schumacher's *Small Is Beautiful* (1973), which advocated meaningful work, local agriculture, human-scale manufacturing, and renewable energy. Murray Bookchin (1971), David Dickson (1974), Amory Lovins (1977), and others helped develop the general idea of fitting technologies to people, ecosystems, and cultures—instead of the other way around. Alternative technologies such as improved charcoal cook stoves that conserve wood and protect habitat while reducing women's labor have been considered especially important for less affluent societies. But questions about how to shape technologies wisely are of universal relevance, and some political philosophers of technology envision an affluent "alternative modernity" with non-toxic chemicals and other public-regarding technologies (Winner 1986; Feenberg 1995; Woodhouse and Breyman 2005). The terms *appropriate* and *intermediate* sometimes are used as synonyms for alternative technology. "*Appropriate" technology* is the most widely used term, despite the fact that no technology can be equally appropriate in every respect given inevitable tradeoffs trade-offs among ease of use, effectiveness, environmental sustainability, aesthetics, price, and durability. Moreover, the suitability of any artifact or system varies among different users, cultures, and eras (Winner 1980, Bhalla 1996). Some technologists who focused on non-Western cultures adopted the term "*intermediate*" to indicate technologies complex enough to require engineering expertise but operating closer to traditional than to high-tech ways of life. Examples include more efficient plows, sanitary latrines, biogas generators, and rolling devices to ease the task of carrying water (Smithsonian Institution 2007). In contrast, "alternative" technologies such as wind power and fuel cells are visualized as competing with mainstream technologies in affluent settings. Although the nuances matter for some purposes, for brevity we henceforth refer to the entire endeavor simply as "AT."

COMPLEXITY OF THE ISSUE

AT as a philosophical perspective and everyday practice is more complex than initially appears. It is not clear that alternative technologists can identify technologies that unambiguously promote their goals, or point to alternative

Indian Village Girl Uses a Mobile Phone. *Indian nongovernmental organizations and other groups have distributed mobile phones to a select number of villages. The owners of the phone charge other villagers for making calls. Programs like this can be seen as forms of alternative technology, and as increasing the global telecommunications market.*

technologies in wide use that are incompatible with dominant political and economic regimes (Winner 1980). For example, the "Village Phone" program operated through India's Grameen Bank provides small loans to women to initiate community cell phone service; the women gain much needed income and improved social status, while villagers obtain otherwise inaccessible communication at an affordable rate price (Aminuzzaman, Baldersheim, and Jamil 2003). Does this qualify as an alternative technology, or is it mostly an extension of the global telecommunications market? The same question can be asked about video recorders used by indigenous groups to revive or protect their traditional cultures: However laudable the effort in some respects, are not such technological transfers also a form of cultural intrusion?

Perhaps even more of a conundrum is a proposed cassava plant genetically modified to resist the mosaic virus that can destroy much of a crop on which several hundred million people in sub-Saharan Africa depend for a substantial fraction of their calories. The Cassava Plus plant is also designed to have bioavailable zinc and iron, high-quality protein, vitamins A and E, as well as improved post-harvest storage (Danforth Foundation 2007). Moreover, little cultural disruption would result from planting and growing Cassava Plus. Does that make it "appropriate," or are the benefits overwhelmed by the fact that the genetically modified seeds would be based on an environmentally controversial technology commercialized primarily by U.S. multinational corporations?

CRITICISMS OF ALTERNATIVE TECHNOLOGY

Along with the interpretive complexities are outright criticisms of AT. Denying the need for it altogether are market ideologues who assume that businesses already produce the technology that customers "demand." Others "wonder if Appropriate Technology is a way to discourage the Third World from industrializing and becoming competitors" (Hazeltine and Bull 1999, p. 11); they see it as hypocritical for the affluent to decide whether the poor should be allowed to emulate "advanced" technologies. With nearly three billion Chinese, southeast Asians, and Indians avidly pursuing consumer culture, the AT movement could be construed as dead except perhaps in Africa (Anderson et al., 1999; Gustavsson 2007).

A slightly more sanguine view would be that low-tech AT innovation (e.g., inexpensive water filtration and storage) and higher-tech AT innovation (e.g., bioplastics from corn) are becoming part of mainstream innovation, "a manifestation of an increasing tendency towards diversity and pluralism.... AT will occupy an increasing number of ecological niches in the global technological system ... where it is adapted to its environment" (Brooks 1980, p. 55). Although it has some validity, that interpretation comes close to depicting innovation as a more or less automatic process in which buyers, sellers, and technical experts proceed straightforwardly to "improve" technological artifacts and systems. Omitted is the key lesson of AT theory and practice: Technologies are inherently political in the broad sense of that term because each artifact or service is oriented toward certain social and environmental objectives and away from others. Hence, designing or redesigning a technology thoughtfully would require a deliberate choice among possible objectives such as whether to use corn for ethanol fuel, even if the result is to increase food prices or build high densities in newly constructed residential areas to facilitate mass transit, even if home buyers prefer suburban sprawl. Because the capacity to discuss such tensions and make thoughtful choices is not built into the contemporary innovation system, most technologists (and their bosses and customers) at least implicitly work against the ideals of the alternative technologists.

WAYS TO IMPLEMENT ALTERNATIVE TECHNOLOGY

What would it take to choose more deliberately among possible social futures as designers, entrepreneurs, customers, government officials, and citizens negotiate alternative technological paths? One common prescription among experts on technology policy is to bring more diverse stakeholders into the decision-making process so that no

small group of insiders can run away with the process (Sclove 1995). To ensure that technoscientists consider the public implications of their work before becoming irrevocably committed to a trajectory, there should be early, "real-time" rather than after-the-fact technology assessment (Guston and Sarewitz 2002). Getting public values onto the negotiating table (Bozeman and Sarewitz 2005) through these and other political innovations would help bring technological innovation into better alignment with democratic principles and practices.

Regardless of whether one champions low or high technology, then, the AT tradition offers a lesson for wise shaping of technological innovation. Rather than relying on the hope that business executives, their technical employees, and their customers will make private decisions that work well for public purposes, an obvious alternative is to institute governance mechanisms to promote deliberate choice concerning public facets of innovation. Among many other options would be the following:

1. Act in a precautionary way to safeguard public values, for example by requiring premanufacture testing and authorization of innovations potentially harmful to environment and health (as governments do for pharmaceuticals).
2. For epochal technologies such as human cloning and androids, create new international deliberation and regulatory mechanisms as a public counterbalance to technologists' enthusiasms, entrepreneurs' quest for sales, and nation-state government officials' desires to beat the international competition.
3. Create a global taxation system designed to shift purchasing power toward those who lack the resources to maintain local ecosystems, use sustainable agricultural practices, and obtain safe sanitation and clean drinking water.
4. Create a chemical trust fund to tax persistent toxic chemicals, using the proceeds to subsidize the trillion-dollar process of moving toward a benign-by-design chemical industry.
5. Institute tort liability penalties and white collar criminal laws to prosecute individual executives and technologists, not just corporations, when technologies turn out to be unacceptably damaging.

Even those who accept the basic spirit of alternative technology obviously will disagree about which, if any, of these or other practices merit experimentation and a gradual phasing in.

QUESTIONS FOR THE FUTURE

Although it has contributed in the near term to simple, affordable technologies for less-affluent people and cultures, the AT movement has placed on the longer-term human agenda the possibility of shaping technologies to serve more thoughtfully deliberated purposes. Questions with enduring import for technological civilization include the following:

1. How can future technologies enhance the quality of work life, counteracting the twentieth-century tendency to privilege machines, hierarchical organizations, and affluent consumers?
2. How can technologies be shaped so that their users experience a balance among task accomplishment, price, physical effort, personal satisfaction, family, community life, and protection of the environment?
3. How can each technological activity be structured so that it does not undermine other valuable activities (for example, television and computer gaming have encouraged many children to spend less time playing outdoors)?
4. What changes in social norms, laws, and monetary incentives can help assure that one person's or group's technology does not interfere unduly with other people's rights and liberties?

Although no one can conclusively answer these and other fundamental questions about technological shaping, the fact that the questions are even arising is due in part to the AT movement. It no longer is unthinkable to ask about alternative technological trajectories that could be more appropriate environmentally and socially than those now prevailing.

ANARCHISM

The word *anarchism* derives from the ancient Greek term *anarchos,* meaning "without ruler." Anarchism is a political philosophy that views the ideal society as noncoercive, nonauthoritarian, and nonhierarchical, lacking the existence of a compulsory government or state. Anarchists advocate libertarian political strategies for advancing toward those goals.

Anarchism assumes a variety of forms: individualist, mutualist, collectivist, and syndicalist. These variants of anarchism express diverse views on issues such as the proper or necessary roles of violence, the free market, technology, property, organized labor, and religion and spirituality. Ecological or green anarchism finds close connections between the idea or practice of controlling the natural world and the social domination of humans by one another; it commonly challenges reformist, narrowly anthropocentric ideas and institutions, including those of mainstream environmentalism. Ecoanarchism envisions a harmonious relationship between humans and nature, fostered by nonpolluting ecological technologies and human-scale practices. With its emphasis on community, ecoanarchism stresses the importance of small-scale, local human interactions, voluntarism, decentralism, and direct political action. Like most anarchist philosophies, it combines utopian aspirations with prescriptions for political and social practice.

HISTORY AND KEY FIGURES

Anarchism has a long history rooted in opposition to government, especially to what it considers to be illegitimate or oppressive forms of political authority. Anarchist luminaries have come from a wide variety of fields: revolutionary activists such as Michel Bakunin (1814–1876) (who battled Marx and Marxists) and Emma Goldman (1869–1940) (feminist and defender of free love), writers and novelists such as Leo Tolstoy (1828–1910) and Oscar Wilde (1854–1900), and academics such as Noam Chomsky (1928–). Anarchists have combated what they perceive as unjust social and political power and have sought to establish counterinstitutions, subcultures, and communities that are egalitarian, libertarian, and/or ecologically sensitive.

Daoism is among the most ancient philosophical forebears of anarchism. It arose in southern China in the sixth century B.C.E. and anticipates several themes of later anarchist thought, especially ecoanarchism. Daoists believe in following the Dao, the true way of nature as opposed to the artificial rules and conventions of human society, which can generate social conflict and personal tensions. Lao-tzu (flourished in the sixth century B.C.E.), the reputed author of the *Tao De Ching*, perceived a harmony and organic wholeness in the natural world—

sometimes represented by the symbol of the yin and yang—that suggested the possibility of a peaceful, nondomineering relationship with the social and cosmic order. Rejecting traditional philosophical dichotomies and legal and political structures, Daoists endeavor to follow the natural flow of the social and physical worlds—like water running gently to the sea—and to practice *wu-wei* (literally "nonaction"), a nonforcing, flexible way of life.

Some forms of Buddhism like Zen echo Daoism in their deep love of nature and their strong opposition to coercive power. Such themes clearly influenced the thought and practice of the Indian political and spiritual leader Mohandas Gandhi (1869–1948), who practiced and taught the Hindu concepts of *ahimsa* (nonviolence and nonharm) and *satyagraha* (passive resistance or truth-force) in helping to liberate India from colonial rule.

The French geographer Élisée Reclus (1830–1905) was one of the first anarchists to advocate a holistic view of the environment; he espoused a form of nature mysticism that embraced ethical vegetarianism. In Germany Gustav Landauer (1870–1919) also advanced a pantheist variant of nonviolent ethical anarchism. The Russian geographer, field naturalist, and revolutionary Peter Kropotkin (1842–1921) emerged as one of the most significant anarchist theorists by linking a lasting vision of the natural world with a new political framework for human society. Kropotkin stressed the mutualistic, altruistic, and cooperative aspects of animal and human communities and argued that mutual aid—not just ruthless struggle and competition—is a vital aspect of evolutionary change, a point later supported by many biologists. He tried to provide a naturalistic foundation for ethics by showing that humans can derive moral ideas and social ideals from the patterns of the natural world. By vocally criticizing capitalism and the state as unjust, outlining a garden model for agriculture, proposing the medieval commune as a normative exemplar for culture, and using the sciences of biology and ethology for social analysis, Kropotkin creatively united evolutionary and revolutionary orientations into a coherent environmental worldview.

Henry David Thoreau (1817–1862), the American writer, naturalist, and transcendentalist, has exercised a profound and enduring influence on environmental thought. Thoreau was an individualistic anarchist who celebrated nature and was deeply skeptical of the government, especially insofar as it imposed slavery and waged war. "I heartily accept the motto,—'That government is best which governs least,'" he wrote, adding, "I also believe 'That government is best which governs not at all'" (1937, p. 635). Through his experiences living and writing at Walden Pond and his journeys into the wilderness, Thoreau found in the complex workings of the natural world inspiration for an environmental ethic that involves compassion for animals, respect for the wild, a commitment to place, and the virtue of living simply, self-sufficiently, and sustainably.

Strongly influenced by Kropotkin, the American Murray Bookchin (1921–2006) explicitly wed anarchist philosophy with environmental concerns in developing Social Ecology into an important school of thought. In essays like "Ecology and Revolutionary Thought" and books such as *Toward an Ecological Society* and *Ecology of Freedom*, Bookchin held that ecological problems originate in the social sphere, especially in hierarchical political systems. Social Ecology articulates a developmental view of nature and extols the merits of ecological communities and what Bookchin called "libertarian muncipalism" as alternatives to the nation-state. Toward the end of his life, however, Bookchin grew increasingly critical of anarchists and anarchism, describing himself as a communalist instead. Other prominent American writers and thinkers whose ideas fit broadly within the ecoanarchist tradition include the historian and urban planner Lewis Mumford, the poet Gary Snyder, the political theorist John Clark, the ecopsychologist Theodore Roszak, the historian Peter Marshall, the writer Edward Abbey, and the technological critic David Watson.

ANARCHISM AND ENVIRONMENTAL THOUGHT

Kirkpatrick Sale once remarked, "What better understanding of the liberatory possibilities of humankind could the ecologist get than from the anarchist; what better understanding of the liberatory character of the natural world could the anarchist get from the ecologist?" (1985, p. 23). This comment underscores the convictions of many green anarchists, who find in nature a model, a measure, or a mentor for their political practice and thought. Ecological anarchism has close ties not only with Social Ecology but also with bioregionalism, a perspective built around the notion of "life places" that serve as alternatives to established political territories. Bioregionalists stress the importance of geographical areas that provide natural local frameworks for human communities. Bioregions are defined by their biota and topography—including soil, climate, and watersheds—instead of by human conventions; they can be divided into ecoregions, georegions, and morphoregions that nest in one another like Chinese boxes. According to its proponents, bioregional awareness encourages a respect for the earth and its inhabitants and offers an environmental, economic, and political paradigm of local self-sufficiency and mutual aid that resonates with, draws upon, and expands the basic tenets of ecological anarchism.

Also associated with such forms of ecocommunalism is ecomonasticism, a perennial environmental current that calls for individuals and groups to secede, disengage, or withdraw from unsustainable institutions and cultural practices. This outlook has antecedents in intentional communities, utopian experiments, and monastic orders in which members attempt to cultivate ways of life that are ecologically friendly, nonauthoritarian, and nonconformist.

Another significant variant of ecoanarchism is anarchoprimitivism, a viewpoint kindred in some ways to Deep Ecology. This current has issued an ecological and political critique of the very origins and historical development of civilization itself, including what it claims to be the deleterious effects of technology, agriculture, domestication, population growth, science, industry, and the division of labor. Anarchoprimitivists hold that with the rapid rise of civilization over the last 10,000 years, humans have disembedded themselves from the ecological web of life and have thereby surrendered leisure time, social equality, and physical health while falling prey to a destructive relation to the land, organized violence, new and dangerous diseases, the subjugation of women, and meaningless or repetitive work. One such theorist, John Zerzan, traces some of these changes to the advent of symbolic language, numbers and agriculture. Anarchoprimitivists such as Paul Shepard look toward hunter-gatherer societies and tribal groupings for more balanced relations with the environment and for more livable "future primitive" models of community, advocating "re-wilding" the earth along with the active use of simple tools as opposed to the passive utilization of complex or opaque technological systems, which, he argues, sacrifice resources, time, and important human values.

Many, though not all, ecoanarchists support vegetarianism and animal rights or animal liberation. Some work with direct-action groups like Earth First!, the Animal Liberation Front, or Earth Liberation Front in order to promote environmental goals through property destruction, creative protest, theft, or other illegal activities when these efforts are deemed necessary or beneficial.

Critics of ecological anarchism have noted its penchant for utopian or romantic views of nature, politics, or human nature; its opposition to all forms of the nation-state, an institution that some environmentalists deem necessary to address large-scale, complex, international ecological problems; and its emphasis on voluntaristic solutions or decentralist forms of organization, which critics judge to be ineffective or unworkable. Ecoanarchists counter such critiques by arguing that the urgency of ecological and political crises necessitate radical ethical and social changes in order to adequately mitigate or vanquish the sources of these predicaments.

Anarchism clearly exerted an early influence on the nascent environmental movement. In the very radicality of its analyses and ideals, it poses a bracing challenge to any misplaced complacency about the depth and gravity of the contemporary environmental crisis and the extent of the measures needed to address it.

ANIMAL CLONING

Since Ian Wilmut and his colleagues presented the Dorset ewe Dolly to the world in 1997, the notion of cloning has captured the public imagination and provoked discussions about the ethical implications of the technology. Initially, the most prominent concern was whether the technology could be applied to humans as well. Later,

there was a growing focus on possible applications of the technology to animals and their ethical implications. Thus, the initial worries that animal cloning would lead to human cloning are less widespread in 2008. To some extent those worries have been replaced by the view that the two applications of the technology can be separated and that the possibilities of animal cloning can be explored without its leading to reproductive human cloning. In the beginning, the hopes regarding the potential applications of animal cloning were high. In 2008, more than ten years after Dolly, those hopes have given way to a more nuanced understanding of the difficulties in mastering the technology and applying it in different areas.

THE SCIENCE

In nature there are many examples of cloning, understood as the production of organisms that are genetically almost the same (like identical twins) or that procreate by cloning (like potatoes). Cloning can also be achieved by splitting the early embryo into separate cells, which will each develop into a whole individual. What is usually discussed when referring to cloning is somatic-cell nuclear transfer. In this process the nucleus of a cell from an adult individual is inserted into an oocyte that has had its original genetic material removed. The oocyte is then manipulated into behaving as if it had been fertilized by a sperm cell and thus begins to divide. The key point is that the genome in the new organism is almost the same as that of the original adult animal.

There is much discussion about the degree to which a clone can be said to be a genetic copy of the "parent" animal. In total, 99.9 percent of the genetic material in the cloned egg originates from the cell of the animal being cloned. But the last 0.1 percent of the clone's deoxyribonucleic acid (DNA) comes from the mitochondrial DNA of the unfertilized egg cell (i.e., the cell into which the nucleus is inserted). This is unavoidable, but it raises serious questions about the possibility of creating a genetic copy. It is not that 0.1 percent of the DNA is a lot, but rather that even the limited knowledge we have about the function of mitochondrial DNA suggests that it plays an important role both in the formation of the early embryo and in influencing which genes in the organism will be activated.

In addition, it is as yet only poorly understood what role the various nongenetic influences in the Petri dish, the womb, and the postnatal environment play in the organism's development. These epigenetic factors and the mitochondrial DNA might explain the low success rates and welfare problems associated with cloning. These problems also raise questions about a range of applications often presented as benefits of the technology, especially when it comes to using cloning as a tool within the agricultural-breeding industry (Vajta and Gjerris 2006).

APPLICATIONS

The emerging picture is that in the foreseeable future cloning will likely play its greatest role in basic research and medicine. Here it can serve as a source of information about fetal development, cell biology, epigenetics, and the like. Furthermore, in biomedical research, cloning can help produce genetically modified disease models to further our understanding of human diseases. For example, researchers may genetically modify pigs to resemble humans with Alzheimer's disease or mice to have diabetes. Animals can also be engineered to produce in their milk, blood, or eggs valuable medical substances such as human proteins, so-called bioreactors.

Also suggested are more exotic applications, for instance, using cloning to save endangered species, such as giant pandas and tigers, or to re-create extinct species, such as the gaur or the mammoth. None of the attempts made in these areas have shown any promising results, and even if the technology becomes developed enough to be used in these contexts, such development will most likely come only in very specific and limited areas. The idea of cloning pets has also been explored, but its economic feasibility has yet to be proven.

Between these extremes lies the possible use of cloning technology in the agricultural sector. At first cloning technology was welcomed as a new and exciting tool to use in animal breeding (Di Berardino 2001), but as the limitations of the technology became apparent, the possible usefulness of cloning in agriculture has been drawn into question. The main idea would be to clone elite breeding animals to use in breeding schemes. This would allow spreading useful genes more quickly, but breeders have questioned the value of this tool (Gjerris and Sandøe 2007).

In many instances, cloning will prove useful as an enabling technology together with genetic modification of animals. Genetically modifying animals is very difficult, and the possibility of cloning cells that have been successfully modified, or even grown animals that have the acquired characteristics, is perhaps the area where cloning will be most useful in the years to come.

ETHICAL CONCERNS

Basically, the ethical concerns regarding animal cloning can be divided into two large subsets: risks to humans and risks to animals. With regard to humans, concerns center on three aspects: risks to human health, socioeconomic risks, and risks to the fundamental relationship between humans and animals.

In the area of risks to human health, the question is whether products from cloned animals or their progeny could have adverse and unwanted effects on humans and/or the environment. The research so far shows that this is not the case (U.S. Food and Drug Administration 2008, European Food Safety Agency 2008). The socioeconomic concerns relate especially to agricultural applications of animal cloning and typically focus on the risk that animal cloning could further trends within agriculture toward fewer players in the market, greater specialization, and a deeper divide between rich and poor countries. Finally, there are concerns that our increasing utilization of animals will reduce our ability to relate to them as anything other than providers for human needs. We will thereby lose a sense of kinship and responsibility toward other living beings—features deemed essential to the development of a sound human psyche (Gjerris and Sandøe 2007).

The ethical concerns regarding risks to animals can be divided into two aspects: risks to animal welfare and risks to animal integrity and naturalness. The low success rates tell a story of huge welfare problems related to the technology. Many animals are stillborn or born with health defects. Two things should be noted, though. First, the animal-welfare problems related to cloning are not special to cloning. They are the same as experienced with other reproductive technologies. It is just that they occur more often in cloning. Second, most of the problems seem to be related to the first generation of animals. Once cloned animals have reached a certain age, they seem to develop like conventional animals. Similarly, the welfare problems do not occur in animals sexually bred from cloned animals (Vajta and Gjerris 2006). Still, the welfare problems in cloning are serious enough that the ethical advisory committee for the European Union has suggested that animal cloning is justified only in research and medical applications (European Group on Ethics in Science and New Technologies to the European Commission 2008).

Some people experience the technology as unnatural and as violating the integrity of the animals. This concern does not relate specially to cloning but rather is closely connected to more general concerns about animal biotechnology and human use of animals. Basically, this concern relates to the dignity of animals and can be interpreted as a longing for a less exploitive relationship between humans and animals (Gjerris and Sandøe 2007).

ANIMAL ETHICS

Animal ethics is a field of study within environmental philosophy. Animals often have been classified as beings of nature, and in contemporary terminology they form an integral part of concepts central to environmental philosophy, such as ecosystems, biodiversity, species, and environments. However, the link between animal ethics and environmental philosophy is complex: Animal ethics concentrates on individual animals and their value, whereas environmental philosophy traditionally has had more comprehensive (soils, waters, and plants as well as animals) and holistic (species, not specimens; biotic communities; ecosystems) concerns. Many animal ethicists, by contrast, maintain that animals should not be valued only as members of species or communities.

HISTORICAL BACKGROUND

Philosophical discussion of the moral status of animals has a long history. Many ancient Greeks, including Pythagoras and Plutarch, were vegetarians on primarily ethical grounds, and many later philosophers, such as Michel de Montaigne, Jean-Jacques Rousseau, and John Stuart Mill, contemplated the normative dimensions of the human-animal relationship. In the nineteenth century Henry Salt published a thesis on that topic in which he defended moral vegetarianism. In addition, serious discussion of the moral status of animals and the normative elements of the human-animal relationship long existed on the margins of philosophy.

The discussion about animals became more central and direct in the 1970s, when animal ethics in its contemporary form took shape. The general interest in animal issues can be traced to various factors, such as growing concern for the environment and the ensuing criticism of anthropocentric values, along with new trends in political and moral thinking that underlined nonviolence together with equality and the rights of all human beings regardless of race, sex, religion, or other incidental characteristics. Because the cultural climate was filled with criticism of inherited values and with advocacy of tolerance and equality, it is not surprising that the moral status of animals was reinvestigated. If the human-centered worldview had produced an environmental crisis and if all equal human interests should be given equal consideration regardless of their holders' differences, perhaps the equal interests of animals should be given equal consideration rather than being ignored. Perhaps species might be as irrelevant as a moral criterion as sex or race. Further, as more people moved to cities distant from agriculture and animal production, questions about the moral status of animals became less uncomfortable, as a growing number of people no longer gained livelihood from animal husbandry.

A work often cited as a groundbreaker in animal ethics is *Animal Liberation* by Peter Singer. Published in 1975, it combined detailed descriptions of animal production and experimentation with moral analyses. On a practical level it had an impact on the popularity of vegetarianism and animal advocacy. On a theoretical level it provoked more philosophical investigation into the moral status of animals. Tom Regan published *The Case for Animal Rights* in 1983, and the next year saw the publication of *Animals and Why They Matter* by Mary Midgley. The moral status of nonhuman animals and the normative nature of the human-animal relationship have become mainstream topics in academic philosophy. Not only philosophers working specifically within animal ethics but also philosophers in other fields of philosophy, such as Martha Nussbaum (2004), Alasdair MacIntyre, and Jacques Derrida (2004), have looked into animal ethics. Some philosophers—Singer is the most notable example—with a background in animal ethics have become prominent contributors to philosophical discussion of other, more mainstream ethical issues, such as world hunger and health care.

Animal Experimentation. *Animal ethics is a relatively new topic relating to environmental philosophy, and is concerned with the moral status of animals, among other things. Issues such as the use of animals in research (like the lab rat shown here), education, for food production, and as companions have all been hotly debated.* © IMAGEBROKER/ALAMY

GENERAL TRENDS

Animal ethics can be divided into three categories: the analytical school, the postmodern school, and the pragmatic school. Members of the analytical school investigate the relevant issues by reference to the familiar ethical theories and methods of modern Western philosophy. Standard moral theories such as utilitarianism, deontology (rights theory), social-contract ethics, and virtue ethics have been applied to the animal issue to see if they could be extended to include nonhuman animals. The familiar commitments of modern Western moral philosophy to neutrality, universality, and consistency are honored. Neutrality requires suspending a bias favoring fellow humans, universality requires that morality remain the same in all contexts, and consistency requires giving equal consideration to similar interests. The most common approach is to take a moral theory and apply it to other animals, often simultaneously amending the theory to make it more comprehensive. Tom Regan, for example, amended Immanuel Kant's deontology, substituting a robust subjective or conscious life for Kant's rationality criterion for moral rights. Just as theoretical backgrounds in the analytical school differ greatly, so do various

theories in animal ethics. Perhaps the most common example is the conflict between orthodox utilitarianism, championed by Peter Singer, and modified Kantian deontology, championed by Tom Regan, as forms of animal ethics.

The majority of philosophical approaches to animal ethics are of the analytical school. Philosophers who have used this approach include Peter Singer, Tom Regan, Mark Rowlands, Dale Jamieson, Bernard Rollin, Stephen Clark, Paola Cavalieri, Evelyn Pluhar, James Rachels, Steve Sapontzis, and David DeGrazia.

The postmodern school approaches animal ethics by reference to Continental and poststructural philosophy. In many ways this school is the opposite of the analytical school in that its proponents view neutrality, universality, and consistency with suspicion. The divide is meta-ethical in nature and can be traced back to the general divide that emerged in twentieth-century philosophy between Anglo-American philosophy and Continental philosophy. Postmodernists think that neutrality and objectivity are impossible to achieve because humans are inextricably embedded in their specific epistemologies and perspectives. It also is maintained that values are not universal but socially constructed. In practice this means that emphasis should be placed on explorations of various human perspectives; those explorations include how gender, ethnic identities, biologies, bodily situatedness, and contexts affect values and understandings of animals. For instance, attention has been focused on reevaluating human identity from the animal perspective. Instead of concentrating on how humans view animals, emphasis is placed on how animals may view humans and the possible normative implications of such interspecific points of view. Also, postmodernists maintain that instead of reason and logic, emphasis should be placed on emotions such as awe, care, feelings of being bound, and other affective and intuitive responses.

The postmodern school is highly diverse, and not all its proponents share all of these characteristics. Philosophers who have used this approach include Gilles Deleuze and Jacques Derrida. More specific to animal ethics, philosophers who use the postmodern and continental approaches include Cary Wolfe, David Wood, Matthew Calarco, Giorgio Agamben, and Ralph R. Acampora. Some ecofeminist approaches to animal ethics are similar in eschewing rationality, neutrality, universality, and consistency and embracing emotion, difference, context, and partiality. The most notable postmodern-leaning ecofeminists who have contributed to animal ethics include Val Plumwood (1993), Carol Adams (1990), Marti Kheel, Josephine Donovan (1990), and Greta Gaard; Vandana Shiva and Karen Warren also have touched on the animal issue. Many philosophers who have contributed to animal ethics deploy the insights and methods of both the analytical and postmodern schools by taking part in both, combining the two (e.g., taking an analytical approach to postmodern works), or developing entirely new approaches. Those philosophers include Mary Midgley (1984), Clare Palmer (2001), and Steve Best.

Despite the meta-ethical differences, the analytical and postmodern schools share many basic premises and conclusions. In regard to shared premises, both resist anthropocentric assumptions and thus seek to explore the value of nonhuman animals from a viewpoint that is not biased toward human beings. In practice this means that the value of nonhuman animals is not derived from instrumentality; the value of a pig, for example, is not derived from bacon. Although humans are tied to the human viewpoint in an epistemological sense (all human valuing originates in the human perspective), they do not have to be tied to a human viewpoint in a moral sense (privileging humans over all other beings). The origin and content of values need to be separated. Although human sensibilities create aesthetic values, it is not true that only humans are of aesthetic value, that only humans are beautiful. Analogously, although human ethical sensibilities create moral value, it is not necessarily true that only humans are of moral value. It is important to acknowledge that other-than-human beings are also valuing beings aesthetically and possibly morally. Therefore, avoiding anthropocentrism is not a logical impossibility, as some have claimed.

Another shared premise is the rejection of dualism. Historically the human-animal dichotomy was one of many forms of dualism. In Plumwood's (1991) analysis, privilege, difference, and homogeneity are fundamental to dualism. One of the two terms of the dualism is privileged and regarded as superior to the other: Classically, men were supposed to be superior to women and whites were supposed to be superior to people of color. The two terms of the dualism are marked by mutually exclusive difference, and those of the other category are regarded as being all the same (white people in the South used to say of blacks, "They all look alike to me"). In the classical human-animal dualism, humans are defined by culture, rationality, and morality and animals are defined by biology, emotion, and instinct.

The classical human-animal dualism, however, is plagued with problems. Proponents of animal ethics often draw from cognitive ethology to point out that many capacities traditionally thought of as exclusive to humans are found among other animals. Many animals, animal ethicists argue, can form beliefs and even abstract concepts, behave intentionally, have consciousness in the phenomenal sense (are capable of experience), and even have social and physical forms of self-understanding.

This problematizes dualistic notions because it posits that animals are not merely instinctual but also cognitive beings. Humans are biological creatures and one species among other animals. People do not exist outside nature and do not have special value because they somehow have stepped outside animality. Many animal ethicists refer to the theory of evolution and its insistence that humans are not at the top of a biological ladder but are a part of an evolutionary tree and an ecological web within which no species is objectively more valuable than another. To remind their readers of this fact, animal ethicists use terms such as *nonhuman animals* or *other animals.*

Another shared element is an emphasis on the animal itself. It is the moral status of and the norms concerning animals, independent of human beings, that are of interest. Animals are not passive objects and a tabula rasa on which humans can write different conceptions but active beings with their own independent abilities and interests. A common conclusion is that the capacity to experience (consciousness in the phenomenal sense) is the basis for individual or inherent value both in humans and in other animals. The value of other animals implies that many current practices, from animal production to hunting and animal experimentation, are morally problematic.

The pragmatic school concentrates on specific practical issues such as particular aspects of animal experimentation or agriculture. The work often is carried out by nonphilosophers such as veterinarians, biologists, and others interested in specific moral problems that arise in conventional interactions between humans and animals. The theoretical input of this school is small, and its relevance in philosophy is minor in comparison to the other two schools. Whereas the analytical and postmodern schools have come to similar conclusions about animals, the pragmatic school often is guided by a different set of principles. For instance, whereas most analytical and postmodern animal ethicists consider meat production morally unjustifiable, those working in the practical sector may ignore that conclusion and investigate specific criteria for the acceptability of various methods of production and slaughter. Often the philosophical reflection among pragmatic animal ethicists is comparatively limited because their interest lies in the details of specific practices rather than the overall moral nature of those practices. A typical example of the pragmatic school can be found in interdisciplinary approaches to welfare studies in which, for instance, agronomists seek to construct ethical guidelines to matters such as dairy farming by taking into account specific welfare issues brought to light by ethologists. The development of the pragmatic school is one of the key challenges for the future of animal ethics. From the point of view of the pragmatic school, analytic and continental animal ethicists do animals a disservice if they simply dismiss animal agriculture because for the foreseeable future animal agriculture will continue despite the condemnation of animal ethicists. In the meantime paying more heed to present practical issues concerning animals could greatly improve their lot and doing so might encourage more philosophical rigor within the pragmatic school. The case typifies the conflict between an animal rights/liberation stance and an animal welfare stance, both of which have their merits, but the first one has thus far been theoretically stronger.

In academia animal ethics also is discussed in disciplines other than philosophy. The analytical and postmodern approaches have coexisted with works in cultural studies that have attempted to locate normative understandings of animals in historical and contemporary cultural perspectives and create critical theories that would question anthropocentric views of animals. Authors who have worked within cultural studies, often with an emphasis on philosophy, biology, and women's studies, include Donna Haraway (2003), Lynda Birke, Joan Dunayer (2004), Eileen Crist (1999), and Barbara Noske. Themes relevant to animal ethics also have been explored outside academia, with one example being the work of the novelist J. M. Coetzee.

THE WORKS OF SINGER, REGAN, AND ADAMS

The most influential or at least the most widely discussed works in animal ethics are those of Peter Singer, Tom Regan, and Carol Adams.

Peter Singer Peter Singer is a utilitarian theorist who has applied that standard moral paradigm to animals. Singer's work is a version of preference utilitarianism, named for its emphasis on the satisfaction of interests.

Singer takes as his starting point two claims central to utilitarianism: maximization of aggregate utility and equality. Under the first principle people should favor the action that produces the greatest utility, which in Singer's framework means the greatest satisfaction of the interests of all those affected by that action. Under the second principle people should consider similar interests equally irrespective of gender, race, class, intelligence quotient, and species. Traditionally, utilitarianism has maintained that gender, race, class, and cognitive abilities are morally irrelevant. Singer adds to the argument the idea that species should be among the peculiarities considered irrelevant to moral decision making. People should not overlook the interests of animals just because of their species; that would be a naked prejudice—speciesism—that is analogous to racism. Furthermore, limited intellectual capacities or a complete lack of those capacities should not be used as a reason for excluding the interests of animals from equal consideration. The fundamental

ANIMAL EXPERIMENTATION

Animal experimentation is one of the most controversial areas of animal use. Politically, it gained attention at the dawn of the contemporary animal welfare movement as the United Kingdom in the nineteenth century witnessed heated debates about the justification of what was called vivisection. The trend continues in the beginning of the twenty-first century, and the animal rights movement has launched many campaigns against pharmaceutical industries and universities that take part in animal research. Experimentation has been a common point of debate in philosophy and more specifically in animal ethics. For instance the book often cited as the groundbreaking work in animal ethics, *Animal Liberation* (1975) by Peter Singer, draws examples from the animal experimentation industry.

The emphasis placed on experimentation is understandable for three reasons. First, experimentation can cause severe harm and suffering to the animals involved. Vivisection refers to the practice of cutting open live animals and reminds people of the suffering that took place before anesthesia was developed. In the contemporary context suffering is arguably still commonplace in areas such as toxicology (testing of chemicals such as medicines, household cleaners, cosmetics, and pesticides for their toxic effects), cancer research (in which cancers are induced artificially in animals by means of genetic modification or chemical stimulation), neurological research (in which brain damage may be inflicted on animals by mechanical or chemical means), and bone and joint research (in which fractures and other injuries are induced to the bones, or animals are made ill with conditions such as arthritis). Second, experimentation is a constantly evolving industry and thus merits ongoing moral discussion. It includes possibilities that test the human imagination, ranging from genetic modification, cloning, and the creation of animal bioreactors to the creation of hybrids between species. Third, experimentation is more complicated from a moral point of view than, for instance, meat eating. It can be argued that meat eating, if done purely for reasons of taste or custom, is difficult to justify; however, because experimentation may save human lives, its moral nature is more complex.

There are three basic criticisms of animal experimentation. The argument from marginal cases rests on comparison. The claim is that in the name of consistency, people cannot kill nonhuman animals for the benefit of humans as long as they do not condone using humans of similar or less mental ability in experiments. The argument from benefit concentrates on the possible benefits of experimentation. It is argued that because meta-analyses of experimentation show that the benefits are statistically very small, experimentation cannot be justified. The cost-benefit analyses go against experimentation: It is wrong to cause actual harm for a hypothetical benefit. This argument often is accompanied by claims according to which experimentation is scientifically problematic (animals are not strong models for human physiology) and politically misguided (experiments are concentrated on common Western ailments that in most cases could be prevented by changes in lifestyle and are motivated by the economic gains of the pharmaceutical industries). The argument from value rests on the value of animals regardless of any comparison or benefit. People cannot use a being of individual value as an instrument to benefit another, and this makes animal experimentation morally unjustified.

Critics have argued that even if one accepts all these claims, it still is possible to imagine extreme circumstances in which people would sacrifice a small number of animals to benefit a large group of people. However, it has been maintained that this argument from extreme cases does not justify experimentation as an everyday practice. First, in a lifeboat situation in which it is necessary to choose whether to throw overboard a human or an animal, many people would choose to save the human. However, altering the choice to concern an elderly person and a child or a person similar to oneself and a person very different from oneself points out that it is difficult to draw general moral principles from such preferences. Extreme situations may say little about general principles and the justification of everyday practices; they only describe difficult choices made in extreme circumstances. It also has been argued that as opposed to thinking of ethics as a matter of conflict between two sets of beings (humans and animals), it would be better to concentrate on taking both into account. One would not use other human beings in a similar situation because of their individual value: They are included in the moral sphere and are thus exempt from being used as instruments. The argument here is that perhaps also animals should be included in the moral sphere.

utilitarian principle of equality requires that the interests of animals be taken into account equally with the interests of humans.

This makes Singer's argument radical in the contemporary moral climate. A self-consistent utilitarian cannot overlook the interests of other animals when making moral decisions, and in fact those interests must be taken account of to the same degrees as the interests of human beings. What matters in relation to the moral status of both animals and humans is whether a being has interests; no other factors are relevant. Cognitive abilities may have a bearing, but only when they are tied directly to interests. Thus, the interests of rabbits do not have to be taken into account in discussing freedom of religion, for rabbits do not have cognitive abilities that would give them an interest in participating in that freedom. Similarly, cognitive abilities may heighten or lessen interests, such as the interest not to feel pain or be killed. However, when it comes to interests of equal measure had by both humans and animals, a consistent utilitarianism requires that they be taken equally into account.

Singer presents a clear, consistent approach to animal ethics. If one accepts utilitarianism as the most persuasive moral theory, it is difficult to avoid his conclusion. However, those conclusions, though theoretically straightforward, are radical in practice. A consistent utilitarian would have to denounce most practices involving animals in European and North American societies, such as meat eating, hunting, fur farming, and animal experimentation.

Singer has been criticized for overlooking the difference between passive (objective) and active (subjective) interests. R. G. Frey (1980) maintained that inanimate objects such as tractors also may have interests in the passive sense (it is in their interest to be oiled). It is not passive interests but active interests that are morally relevant, and if an animal lacks cognitive abilities that enable it to formulate active interests, its interests do not have to be taken into account in moral choices.

Singer has responded to this criticism by maintaining that both active and passive interests are relevant and by arguing that inanimate objects do not have interests in anything more than a metaphorical sense. The basis of having morally relevant interests is the capacity to experience. Only when a being experiences the satisfaction or dissatisfaction of its interests do those interests become morally significant; whether the interests are passive or active does not matter. Thus, a cow does not have to conceptualize or be introspective about its interest to avoid pain; all that matters is that it will or will not experience the satisfaction of that interest. People take into account the interests of humans even if the human whose interests they are cannot conceptualize them (and thus have them in an active sense), and the same thing applies to animals. Further, in many cases passive interests have more moral significance than active interests. For instance, an addict may have an active interest in shooting heroin and a passive interest in remaining healthy. In this case the satisfaction of the passive interest generates more utility. Thus, there is little reason to exclude the interests of animals from the moral sphere merely because many of their interests are passive, for many of the most important human interests are passive.

It has been claimed that some of the conclusions drawn by Singer do not by necessity apply within utilitarianism. Experiments on animals that lead to greater aggregate utility would appear morally justifiable, at least in some cases. Singer has responded with a version of the argument from marginal cases: If people believe it wrong to use, as subjects of painful medical experiments, human beings with similar or less mental ability than that of the animal subjects of those experiments, they also should believe that it is equally wrong to use the animal subjects in those experiments. If, more particularly, people believe that it is wrong to kill ten mentally unable humans to find cures for ten thousand mentally able humans, they should believe that it is just as wrong to kill ten dogs to achieve that goal. Here Singer appears to emphasize equality—the principle that people should take equal interests equally into account—more than aggregate utility. However, the conundrum of sacrificing a few for the benefit of many is a problem often cited in relation to utilitarianism per se apart from its extension to animals. Deontologists seize on the intuitive repugnance of deliberately sacrificing a few for the benefit of many as evidence that utilitarianism must be supplemented by the acknowledgment that individuals have rights or intrinsic value that protects them against being used as instruments for others.

Utilitarianism also may be inadequate in another way. If an animal has no comprehension of the future or the possibility of its own death, it may lack the interest to live, and that would make its painless killing a morally neutral act. Singer has maintained that because animal production usually leads to at least some suffering (and, as he emphasizes, often severe suffering), such a situation would be merely hypothetical; that is, animal production cannot be justified by claiming that animals have no active interest to remain alive because in practice it ignores other interests that such animals have. Another possible rejoinder is that even if a cow does not have an active interest in continuing to live, it does have a passive interest in doing so and thus cannot be killed justifiably. Hence, even if a cow cannot conceptualize an interest in remaining alive, it is in its interest to remain alive because remaining alive is the prerequisite for the fulfillment of all of a cow's other interests.

THE GREAT APE PROJECT

The Great Ape Project (GAP) is an attempt to extend fundamental protections enjoyed by humans to individuals of four nonhuman species (gorillas, bonobos, orangutans, and chimpanzees) and their habitats. This concept originated with the philosophers Peter Singer and Paola Cavalieri in the early 1990s. In 1993 Cavalieri and Singer published *The Great Ape Project: Equality beyond Humanity*, a collection of thirty-one essays by prominent scientists, philosophers, educators, and activists. The editors stated in the Preface, "We seek an extension of equality that will embrace not only our own species, but also the species that are our closest relatives and that most resemble us in their capacities and their ways of living" (p. 1). The founders' vision of a "community of equals" thus included humans and the other four great-ape species.

As set out in the organization's foundational document, "The Declaration on Great Apes," GAP seeks to offer three specific protections to these closest biological cousins: protection of life, protection of liberty, and freedom from torture. Reasoning that individuals who have these fundamental protections are entitled to "equal respect and concern," GAP advocates that these nonhuman animals be protected by such social mechanisms as legal and moral rights.

GAP's materials emphasize that modern scientific findings about the nonhuman great apes establish that they are complex beings with unique personalities, demonstrable intelligence of several kinds, communication abilities that exceed those of virtually all other animals, profound social needs, and true emotions that humans can easily recognize. According to GAP, these features of the nonhuman great apes clearly justify extending fundamental protections beyond the human species to not only the individual animals but also their native habitats.

In general, GAP's reasoning follows two different paths. One path focuses on the cognitive and other psychological complexities of nonhuman great apes as individuals and as members of families and societies. These features in and of themselves are sufficient to merit fundamental protections for these animals. A second path of reasoning is that since these animals are demonstrably complex and since some humans with lesser abilities are protected, it is only fair to protect the nonhuman great apes as well.

GAP's ideas have been advanced by national organizations in numerous countries, including Australia, Brazil, Britain, Canada, France, Germany, Italy, Portugal, and the United States. The furthest penetration into public policy has come in three countries: New Zealand, where the national GAP group successfully advocated legally enshrining basic protections for nonhuman great apes in 1999; Spain, where in 2006 the national organization succeeded in scheduling Parliament-level votes on adoption of GAP's basic premises as national policy; and the Balearic Islands, where the government in 2007 officially adopted GAP's recommendations as national policy. Other countries, including Austria and Britain, have enacted GAP-inspired legislation or administrative bans on experiments on nonhuman great apes.

GAP's theme of "equality beyond the species line" has also appeared in philosophical discussions, the recently emerged field of animal law, and other scholarly discussions and publications in various areas of human and animal studies. Some universities have even adopted GAP's central ideas as an educational theme for interdisciplinary courses.

Criticisms of GAP's ideas have varied. Some have suggested that the emphasis on cognition is a covert way of affirming a human paradigm for measuring moral worth (individuals similar to humans may qualify, while dissimilar individuals, no matter how complex in their own right, do not). Some have argued that GAP relies on an overstated view of nonhuman ape minds. Another criticism sometimes heard is based on the fear that extending fundamental protections to some nonhumans risks sliding down a slippery slope and extending rights to all animals.

However, as in the case of painful experiments on animal subjects, this consideration leads to another. If people should cease raising cows for slaughter and consumption, only a few cows would be raised as museum pieces that illustrate a bygone period in human civilization. If being alive is a prerequisite for the fulfillment of

all of a cow's other interests, the many interests of the many cows that thus would not exist would fail to be satisfied and thus diminish aggregate utility, at least of the bovine variety. Therefore, if animal production satisfied the interests of animals more than it dissatisfied those interests, a utilitarian might have to agree with it. Singer holds that contemporary farming practices lead to a greater dissatisfaction than satisfaction of interests and therefore argues for moral vegetarianism. However, if the situation were to change, a strict utilitarian would have to reconsider the case. Such considerations again point toward the problems that emerge when all the emphasis is on aggregated satisfaction of interests and the value and rights of individuals are sidelined. Although Singer provides a valuable take on ethics concerning animals, it can be argued that more attention needs to be placed on the individual.

Tom Regan Tom Regan has taken an entirely different theoretical approach to animal ethics. He espouses deontology, or a duty-oriented ethical theory, and especially rights theory. Whereas utilitarianism emphasizes the consequences of actions, deontology emphasizes the conformity of actions to the practical law of universalization and the logical law of noncontradiction. For example, if everyone always lied—if lying were practiced universally—no one would believe anything anyone said, and thus it would be impossible to lie effectively. It is possible to lie only if telling the truth is the norm, the rule, the moral law. Because universal lying is self-contradictory and one's actions should pass the test of universalization, from a deontological point of view it is wrong to lie regardless of the consequences. A particular lie may lead to felicitous consequences but still be morally unsound; certain acts are wrong in principle regardless of their outcomes.

Deontology, which largely derives from the moral philosophy of Kant, also emphasizes the inherent value of individual moral patients. Whereas utilitarianism underlines utility, deontology underlines the value of the individual regardless of utility. What is inherently valuable is the individual being, not the satisfaction of its preferences. Regan explicitly endorses rights theory as opposed to utilitarianism because only rights theory takes the individual directly into account.

Regan starts by maintaining that certain types of beings have inherent value, which is distinguished from instrumental value. According to Kant, every person is an end in himself or herself as opposed to a means to another person's ends. That inherent value is categorical and hence equal: All beings that have it have it to an equal degree. A person's inherent value is the foundation of his or her moral rights. Those with inherent value should be treated with respect for their rights, which are universal, equal, and self-sufficient. Therefore, rights exist regardless of the context, are equal for all beings that have inherent value, and are not dependent on the vagaries of politics; they may or may not be recognized politically, but they are neither created nor destroyed by political fiat. Regan further characterizes rights as justified claims that are made on moral agents. Thus, one cannot have a right against a flood, but one can have a right against a prospective murderer; one can, however, have a right against an agent who causes a harmful flood. Regan argues that the value of an individual is independent of gender, race, intellectual ability, or social class. He also places a great deal of emphasis on moral principles such as the respect principle, according to which beings of inherent value are to be treated respectfully.

Up to this point Regan endorses the familiar modern understanding of human rights: All people universally have the same value and basic rights regardless of gender, race, culture, social class, or intelligence. However, like Singer, he makes a radical claim: Species must, if people are to be consistent, also be irrelevant. Therefore, some animals may have the same basic value and rights as humans. Again, the consequences are clear: Animal production and experimentation and other practices that instrumentalize animals should be stopped. Kant made rationality the criterion for inherent value and thus rights, but here again the argument from marginal cases may be deployed. Not all humans are rational: The marginal cases include prerational infants, subrational mentally disabled persons, and postrational senile persons. By Kant's criterion they have no inherent value and thus no rights and therefore may be treated just as people treat other animals: experimented on in medical research, hunted for sport, made into dog food. Because such treatment of the marginal cases would be intuitively repugnant, the criterion for inherent worth and thus for having rights must be made more inclusive so that it includes those cases.

The criterion for inherent value that Regan proposes is being a subject of a life. That subjectivity, according to Regan, consists of the ability to have beliefs, emotions, intentionality, and lasting psychophysical identity and memory, among other things. However, the fundamental criterion that Regan uses is the capacity to experience. Whereas for Kant only moral agents can be moral patients, Regan is careful to emphasize that the class of moral agents is only a subset of the class of moral patients. As the argument from marginal cases shows, people commonly give equal value and rights to human beings who are not moral agents; by parity of reasoning, therefore, animal subjects of a life cannot be excluded on the basis of their assumed lack of agency. In relation to rights he also maintains that moral patients do not have to be able to make a claim; it is enough that they have a

Concentrated Animal Feeding Operation (CAFO), Midwestern U.S. *Hundreds of chickens are seen at a large-scale egg producing facility in the midwest known as a CAFO. These are massive, sprawling facilities where hundreds of thousands of animals are housed, often releasing enormous amounts of liquid sewage into the local water tables and even infecting drinking water. Such facilities have been criticized by environmental groups like the Sierra Club.* **DANIEL PEPPER/GETTY IMAGES.**

claim. Hence, the moral agents toward whom the claim is directed have the responsibility to ensure that that right is respected regardless of one's capacity to insist upon that right.

Against Regan, Carl Cohen (Cohen and Regan 2001) has argued that being a moral agent is necessary for a being to have inherent value and rights. He emphasizes active liberty rights: Rights are liberties to do something, with an example being the right to vote. Such rights, it is argued, presuppose agency; thus, nonhuman animals, or at least nonhuman animals incapable of agency, are excluded. However, this criticism does not pay enough attention to passive rights such as the right to life, which one does not necessarily act upon intentionally and which primarily rest on corresponding duties that fall on others. Like marginal cases, animals seem to be capable of having passive rights and also could have active rights understood in a broad sense, for instance, the right to follow species-specific traits. Moreover, Regan advocates a correspondence theory between duties and rights: Any right had by one can be translated into a corresponding duty falling on others. Therefore, animals do not have to be able either to assert their rights intentionally or to act upon them; it is enough that people as moral agents recognize their duty to respect those rights.

Another criticism concerns the enforcement of rights by humans among other animals. It has been argued that if some animals have a right to life, that right must be protected not only from violation by moral agents but from any violation. Thus, people must prevent predators from attacking prey. Regan has replied that because predators are not moral agents, they can assume no duties and thus cannot violate the corresponding rights of their prey. Critics have responded by pointing out that the issue may concern those in a position to help rather than the predators themselves: As people would have a duty to help those who are drowning, they may have a duty to help those who are attacked by moral agents (whether animals, small children, deranged people, etc.). Thus, one could argue that animal rights means that people

should prevent predators from attacking their subjects-of-a-life prey by, for example, rounding them up, incarcerating them comfortably in large enclosures, and feeding them soy products until they die a natural death. Some animal rights proponents have argued that this view overlooks the rights of the predators: People cannot prevent predation, for to do so would go against the rights of predators. Small children and deranged serial killers do not have a right to kill, whereas predators, whose survival depends on killing, are in a different position. Moreover, it has been pointed out that preventing predation would lead to ecological destruction, which would lead to large-scale violation of the welfare and rights of animals. If humans prevented predation, they would be directly responsible for an environmental catastrophe and thus guilty of violating the rights of countless animals. Perhaps most important, respecting the inherent value of animals requires respecting the inherent nature of animals; preventing the manifestation of species-specific behaviors clearly would go against any such respect.

Therefore, the animal rights view does not by necessity imply that predation should be abolished. However, it does lead to some dilemmas in the context of environmental issues. A holistic approach can be in conflict with an animal rights approach. The topic has raised a lot of debate, and animal rights proponents have tended to claim that the two approaches are compatible: An emphasis on the value of individuals does not mean that species and ecosystems have no value. The links between the two have become especially evident in the context of climate change because animal industries have been named as one of the key factors contributing to global climate change. Thus, respect for animal individuals may have environmental benefits.

Carol Adams Carol Adams has offered an ecofeminist approach to animal ethics that follows some themes from the postmodern school. She seeks to locate animals within cultural discourses and brings together the oppression of women and that of animals. By doing this she presents an animal ethics that is based on awareness of cultural history, vegetarian literature and voices, and what she terms the vegetarian body.

Her basic claim is that animals are made into ''absent referents'' in the contemporary culture. People constantly are met with cultural texts that involve the animal—most notably dead body parts (meat)—but the referent of those texts, the living animal, is absent. Adams argues that the most common referents concerning animals have nothing to do with an animal itself as a living, experiencing being. The absence of animals is emphasized by objectification (the animal body becomes pure biological matter devoid of subjectivity), fragmentation (the body is fragmented into different edible parts and into euphemisms such as *beef* and *bacon*), and consumption (the animal is valued only in terms of money and flavor). Contemporary discourses deny not only animals' intrinsic value but animal presence and by doing the latter avoid questions about the former.

Adams maintains that there is a link between different types of oppression because they tend to involve similar structures, such as violence, absent referencing, marginalization, and belittling. Not comprehending the connections leads to a type of oppressive ethics that excludes *y* instead of *x*, a fault Adams finds with mainstream feminism, which excludes animals. One way to fight oppressive ethics is to bring to light the multiple absent referents in the culture and make animals present once more. This can happen through different types of texts, whether fiction, vegetarian voices, or the vegetarian body, which refuses to eat meat and thus leaves the animal intact.

Adams takes part in the ecofeminist tradition that emphasizes emotion, narratives, shared experience, and critical theory. Rather than concentrating only on reason, the ecofeminist tradition in regard to ethics also takes emotion into account; rather than abstract theory, it should take local and personal narratives into account in which the lives of animals are acknowledged and shared experiences between species are recognized; finally, ethics should give more consideration to the impact that cultural discourses have on people's ethical understandings and, when necessary, assume a critical stance in relation to those understandings.

CRITICISM

Proanimal arguments in animal ethics have been criticized from several different viewpoints. Among those viewpoints are the human species, perfectionist capacities, emotive ties, and cultural meanings.

It often is argued that human species is a morally relevant factor. However, the argument faces difficulties because the moral relevance of a purely biological identity is unclear. Perhaps because of this, the argument tends to turn to perfectionist capacities (rationality, moral agency, etc.): Only humans have individual value, for only humans have specific perfectionist capacities. As has been pointed out here, this claim faces the challenge of the argument from marginal cases. Some have suggested that such cases some day will be normal adults or have been such adults in the past and thus have equal value. However, this claim also has various difficulties. Potentiality or past capacity cannot be used as the criterion for value at the present moment (a person will be dead some day but should not be valued or treated as a dead person at the present time). Moreover, making normal adults the source of value is prejudiced and gives

only indirect value to marginal cases. Also, there are human beings who never will be and never have been moral agents or otherwise intellectually able but who still are considered to have equal value. In general, it is important to emphasize the difference between the value of a capacity and the value of an individual. People may rate a particular capacity, such as rationality, highly, but this does not by necessity mean that rationality is the basis of the value of individuals.

In relation to emotive ties, it often is maintained that the special value of humans is based on the intrahuman tendency to have stronger attachments to other human beings. However, this argument requires more premises to justify its conclusion. If people followed this line of thought, they quickly would come to the conclusion that middle-class white women have more value if one is a middle-class white woman; value would become entirely relative to the context. In that case if one happened to have more emotive attachment to pinecones than to humans, one would be entitled to sacrifice the latter for the former. Emotions are an important part of life, but values cannot be reduced to emotions without facing issues such as bias (Westerners favoring Westerners) and relativism. Another variation of this argument maintains that each species has a biological tendency to favor its own kind and that humans therefore have special value from the human point of view. This claim also faces difficulties because one could seek to justify sexism or even racism on similar grounds. The most fundamental problem is derived from the naturalistic fallacy, which differentiates facts from values and norms: The way people factually tend to value is a different matter from how they *should* value. Thus, tendencies cannot be the sole basis of ethics.

It has been argued that the special value of humans is a basic cultural meaning—part of human language games—and requires no further justification. This argument also faces the naturalistic fallacy because the factual existence of a particular meaning is taken to be the normative justification of that meaning. One has to scrutinize existing cultural meanings from a moral point of view or there would be little room for criticizing sexism and racism. This leads to the problem of relativism: If one lived in a culture with predominantly racist meanings, according to this argument, one would have little reason to criticize its practices. On a more fundamental level proponents of the argument seem to forget that meanings change, come in the plural form, and are often in conflict with one another. It is precisely because of these aspects that people must engage in moral exploration: The change within meanings and resolution of conflicts between meanings ought to be guided partly by morality. Thus, in a time when meanings concerning animals are going through a rapid change, critical thinking in the domain of animal ethics is needed more than ever.

CONCLUSION

Animal ethics is a relatively new discipline that consists of three broad schools (analytical, postmodern, and practical). It emphasizes freedom from anthropocentric bias and wishes to investigate the value of and norms concerning animals in a direct sense by taking the animal itself as the object of study. Proanimal arguments in animal ethics have been met with some criticism, but often that criticism faces problems such as the naturalistic fallacy. It can be argued that animal ethics has presented important approaches to the study of human-animal relations and offered strong reasons to rethink the human understanding of the value of animals and current practices of using animals.

ANTARCTICA

Antarctica, the seventh continent, is anomalous, compared with the six inhabited continents. The usual concerns of environmental ethics on other continents fail without sustainable development, or ecosystems for a "land ethic," or even familiar terrestrial fauna and flora. A political Antarctic regime developed policy with a deepening ethical sensitivity over the second half of the twentieth century, remarkably exemplified in the Protocol on Environmental Protection to the Antarctic Treaty (Madrid Protocol) at the end of the twentieth century, protecting "the intrinsic value of Antarctica," though puzzles remain about how to value Antarctica.

Without inhabitants, claims of sovereignty are problematic. Antarctica is a continent for scientists and, more recently, tourists. Both focus on wild nature. Relatively lifeless, in Antarctica life is driven to extremes. Antarctica as common heritage has come to be viewed as Antarctic wilderness. An appropriate ethics for the seventh continent has proved to differ radically from that for the other six: in some ways more eccentric, in other ways more intense.

THE ANTARCTIC TREATY REGIME

Antarctica is governed by the Antarctic Treaty of 1959, entered into force in 1961. Originally there were twelve consultative parties (ATCPs); in 2008 there were twenty-eight. On the second tier are acceding states (ACSs), which support the treaty but do not vote. In total, some forty-four nations are involved. For the nations that can vote, decisions must be authorized by consensus. The last of the treaty's five goals is the "preservation and conservation of living resources in Antarctica." But the main concerns originally were military, shaped then by the Cold War: Antarctica will be used for peace; there will be no nuclear detonation or wastes dumped there; scientists are to exchange findings about Antarctica.

The treaty was followed in 1964 by the first of a series of annexes, the Agreed Measures for the Conservation of Antarctic Fauna and Flora, which entered into force later, in 1980. The Convention for the Conservation of Antarctic Seals (CCAS—pronounced C-cass), followed in 1972, entered into force in 1978, and was concerned about seals' "vulnerability … to commercial exploitation" and seeking the "protection, scientific study, and rational use of Antarctic seals." Sled dogs have

been banned in Antarctica since the mid-1990s, for fear of contaminating seals with distemper.

Since 1994, the International Whaling Commission has designated Antarctica the Southern Ocean Whale Sanctuary, banning all whaling, including scientific whaling, below forty degrees south latitude. Japan, objecting, has continued to kill hundreds of minke whales a year there, claiming scientific study but also eating the whales. In 1980, entering into force in 1982, came the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR—pronounced Cam-lar). The interest, more specifically, is fish and krill. Krill, shrimp-like animals, feeding on the phytoplankton, are the basis of the oceanic food chain in Antarctic waters. Millions of tons have been harvested for food for fish or cattle or fertilizer. CCAMLR sets quotas.

The Convention for the Regulation of Antarctic Mineral Resource Activities (CRAMRA—pronounced Cram-rah), adopted in 1988, proposed rules and procedures for regulating mineral extraction. The Convention failed to enter into force, with a surprising turn. Australia and France balked at ratifying it, and, given the consensus requirement, they had veto power. Several environmental activist groups were active in opposition. The outcome, surprisingly, was the Protocol on Environmental Protection to the Antarctic Treaty (Madrid Protocol), 1991, though not entering into force until 1998, when the United States and Japan ratified it. ''The Parties commit themselves to the comprehensive protection of the Antarctic environment and dependent associated ecosystems and hereby designate Antarctica as a natural reserve, devoted to peace and science.'' There is a ''50 year moratorium'' on mineral exploitation in the Antarctic. There are strict sections on conservation of fauna and flora and the protection of special areas. The nations seek to keep the continent as pristine as possible.

After fourteen years of further negotiation, sometimes intense, the parties in 2005 at Stockholm adopted an annex on Liability Arising from Environmental Emergencies (Johnson 2006). This annex imposes liability for mere damage to the environment, even where there is no economic loss or damage, something novel in environmental law. This annex is viewed as a first step toward further, more comprehensive agreements about liability for environmental damages in Antarctica.

TERRITORIAL CLAIMS ON THE UNINHABITED CONTINENT

Seven nations have made territorial claims—Argentina, Australia, Chile, France, New Zealand, Norway, and the United Kingdom. Notably both the United States and the Soviet Union (now Russia) have made no territorial claims. Six of the seven claims are as sectors, pie-shaped pieces widest at the coast and diminishing to a point at the Pole. The claims overlap; Britain's claims include all of Argentina's and most of Chile's. Argentina has always objected to British claims. Argentina and Chile also dispute the border between their own territories. Norway has claimed only a coastline area on which it placed huts and bases, mostly infrequently used. Though supporting the Protocol, Australia has claimed, under the United Nations Convention on the Law of the Sea, offshore rights to subsea minerals adjacent to its sector (off their 5,000 kilometer coast for 200 nautical miles).

The grounds of classical territorial claims were the colonial discovery and occupation of unoccupied lands (with Europeans typically overlooking indigenous peoples). Antarctica has been anomalously ''discovered'' (coastlines or ice sheets seen from ships, much of the interior seldom visited). Antarctica is only marginally land, 2 percent at the edges, or vertical rock cliffs, or bare, dry valleys, and then mostly in short summer. The continent is barely occupied. Argentina has sent women and children, families of military or scientific personnel, to a station on the Antarctic Peninsula to establish its territorial claim. The U.S. position has typically been that these lands are unsuitable for effective occupation. There is darkness much of the year; in Antarctic summer, there is continual light but the sun is never high in the sky.

Many dispute such territorial claims, arguing that Antarctica should be international. The Antarctic Treaty has held in abeyance all further territorial claims. Territorial claims can be ''administrative'' claims, ''spheres of influence'' or ''stewardship jurisdictions.'' One way of reading what happened with the Madrid Protocol is that the environmentalists persuaded the politicians to concede that, at least for purposes of minerals extraction, nobody owns the Antarctic. Some nations have proposed United Nations administration, but this is resisted by most of the treaty regime nations. The United Nations has enough problems on the other continents and no expertise on the seventh.

ANTARCTIC SCIENCE AND TOURISM

Antarctic politics mixes closely with Antarctic science. A Scientific Committee on Antarctic Research (SCAR), with a secretary at the Scott Polar Research Institute, Cambridge, existed even before the Antarctic Treaty, and has since continued, regularly advising the treaty parties. Antarctic science often deals with natural phenomena found in extremes: the coldest temperatures on Earth; the most unusual environments; strange diatoms, algae, lichens. Icefish, which have no hemoglobin. Life in the Dry Valleys is embedded in rocks. Such science might reveal knowledge helpful elsewhere, particularly with regard to global climate change. Antarctic scientists

Tourists Disembarking from Ship in Antarctica. *The highest population of people in Antarctica are tourists; during the 2006–2007 season, over 29,000 people visited the continent. The growing tourism industry has introduced both regulatory and environmental issues. The multi-nation Madrid Protocol of 1991 seeks to preserve the unique flora and fauna of Antarctica's ecosystems.* **ZELFA SILVA/ ANTARCTICA EXPEDITION/AFP/GETTY IMAGES.**

have been among its keenest conservationists. Science as such does not, however, produce an ethic—regarding whaling, or mineral exploitation, or territorial claims.

The largest groups of persons in Antarctica are the tourists, although they do not often actually set foot on the continent. Scheduled tourism started in 1966, and by 2000 included more than 14,000 persons per year. Almost all visit only the Peninsula by ship. Regulating tourism has proved difficult. The consultative treaty parties have attempted to address this issue off and on over twenty years but never acted. It was not clear whether or from whom tourists might need to get permission. Do they need passports? Visas?

Nothing in the Antarctic Treaty or international law requires asking permission of anybody. None of the territorial claimants requires visas to the Antarctic. Even if they did, these claims are disputed, even among the claimants, and the tourists remain mostly on their ships, there presumably under the law of the nation whose flag the ships are flying, or under the Convention on the Law of the Sea. Generally tourist companies get permission from the government of the country where the company is based, or, sometimes, the country from which most of the tourists come.

Such uncertainties might as easily avoid regulation as enforce it. U.S. nationals are the largest component of tourists (about half), but of some fifteen ships cruising there, two-thirds travel under flags of convenience. The U.S. Environmental Protection Agency has ruled that U.S. commercial operators must submit environmental documentation for review. Increasing numbers of tourists visiting Antarctica find a no man's land, no immigration officials, no customs authorities, reinforcing the idea that Antarctica is stateless.

The International Association of Antarctica Tour Operators (IAATO) released their own "code of conduct" for visitors, evidently sensitive to respect for wildlife, a do-not-interrupt-and-leave-no-trace ethic. "Antarctica, the world's last great wilderness, is particularly vulnerable to human presence. Life in Antarctica must contend with one of the harshest environments on earth, and we must take

care that our presence does not add more stress to this fragile and unique ecosystem." "Do not disturb, harass or interfere with wildlife." "Give animals right of way." At the 2007 Antarctic Treaty Consultative Meeting (ACTM) the treaty parties essentially adopted IAATO's operating strategy after sixteen years, as ATCM Resolution A (2007), though this resolution is less stringent than IAATO's bylaws and the code of conduct there.

Many argue that tourism should remain ship-based. Tourism ought never to move on land, except for transient expeditions. Project Antarctic Conservation, a research team from the Scott Polar Research Institute, was formerly monitoring Antarctica tourism (Stonehouse 2000, pp. 264–267). The Madrid Protocol indicates that any citizen of a country that has ratified the protocol should have, or be traveling with a tour operator that has, a permit based on an environmental impact assessment filed with their home Antarctic authority. The U.S. Congress and courts have held that the National Environmental Policy Act applies to Antarctica.

ANTARCTIC WILDERNESS, COMMON HERITAGE, WORLD PARK

Environmental ethics for Antarctica—so the argument is increasingly developing—is about Antarctic wilderness. Antarctica is not a political place, and it is a mistake to try to make it one. On the uninhabited continent, one should not apply criteria from other continents. We are not seeking sustainable development, a land ethic, one of people in harmony with their landscape, or protecting natural capital, or ensuring that future generations have as much opportunity for development as do we.

Subantarctic islands have noticeable human interruptions, even human habitations. But a typical square hectare of the continent has seldom, if ever, had a human set foot on it. There is science, but what the scientists are studying is wild nature. There is tourism, but the tourists take pleasure in seeing, again, wild nature. On the seas, the shores, on the Peninsula, one needs an ethic for wildlife, for penguins and seals, lichens and mosses. But fauna and flora go into a bigger, wilder picture. Antarctic wilderness features the desolate and empty. When NASA wanted to simulate the surface of Mars, they went to the Dry Valleys. The expanses of the continental interior, even after being mapped, are little more than white spaces on the map.

The ethic needs to respect where life is found, but beyond that, is more like that for canyons, mountains, rivers, or caves. One conserves Mount Everest as the highest point on Earth, although the highest thousand meters is lifeless and has no ecosystem. The lowest point on Earth, the Dead Sea, also a difficult place to live, seems less commanding. The Barwick Valley in Victoria Land is protected from nearly all visits because it is one of the most nearly sterile areas on Earth. On Antarctica there are also places designated for particular protection, Sites of Special Scientific Interest (SSSIs) and Specially Protected Areas (SPAs), the latter isolated even from scientific activities. In 2002, such areas were grouped together as Antarctic Specially Protected Areas (ASPAs).

Humans ought to conserve the geysers in Yellowstone National Park, though we usually do not think that we have duties directly to non-living natural phenomena (geysers, waterfalls, cliffs, clouds), so much as to people who enjoy them. There are no duties directly to glaciers or icebergs. But Antarctic places, some of them at least, have site integrity; something makes them special, notable. Mount Erebus in Antarctica is majestic. We respect the Delicate Arch in Utah, the crystals in Mammoth Cave in Kentucky, unusual achievements in nature. Once we move past respect for life, environmental ethics needs some further account of where the values lie that command our respect.

Perhaps the ethic will be mostly directed to life in Antarctica. This will be as much toward life in extremes as toward any biodiversity hotspots, as might be the case elsewhere. On the Subantarctic islands, fauna and flora can be abundant. But on the Southern continent itself one is first struck by the barrenness of the land and ice contrasted with the teeming waters of the Southern Ocean. What wildlife there is is really marine life that uses the coastal edges for nesting or resting, typically not for feeding.

There are no native land animals, not at least as characterize other continents. Antarctica's native terrestrial animals are all invertebrates, mostly arthropods, such as mites, lice, springtails, and midges, many of which are parasites of seals and birds. Much is microscopic: protozoans, rotifers, nematodes, tardigrades, bacteria. The largest animal that really dwells on the land is a wingless midge (*Belgica antarctica*), only two to six millimeters long, which spends all but two months of its two-year life cycle encased in ice and mostly frozen. Animal welfare or rights ethics will be needed mostly only in the waters, for the whales and seals. Although there is life in the nooks and crannies of the continent, there are almost no higher flora, two species on the Peninsula (a grass, *Deschampsia antarctica,* and a pearlwort, *Colobanthus quitensis*), and none south of the Antarctic circle. Mostly the flora is lichens, 350 species, 100 species of mosses, and hundreds of species of algae.

An ecosystemic ethic will find rather simple ecosystems in terms of food-webs, stratification of organisms, mineral cycling, and primary productivity. There is rather little predation, but some: a mite eating a nematode worm. Food chains are short. Decomposition and nutrient turnover are slow. The terrestrial/ice system is

not productive enough to support higher animals. Such ecosystems are fragile, easily stressed, disturbed by introduced exotics or wastes, and slow to recover from human interruptions. That means that scientists and tourists will need to take extra care.

Some argue that the most plausible answer is to go back to people. The best model is that of World Park Antarctica. This is not Yellowstone or Yosemite; this would have to be an atypical park, but maybe the "park" idea is moving in the right direction. Since 1972, the World Conservation Union (IUCN) has advocated designating Antarctica some kind of World Park, as have the Antarctic and Southern Ocean Coalition, Greenpeace, the Jacques Cousteau Society, and other non-governmental organizations. The World Wilderness Congress in 1987 called for a World Park. A wilderness park will involve the idea that people do not remain and that the landscape displays primarily the processes of spontaneous nature, but it does connect up with people, who must visit for Antarctica to be a park. Antarctica does have surprising aesthetic value.

ENVIRONMENTAL ETHICS AT EXTREMES

In Antarctic wilderness, people get let in on nature's show, whether icebergs or penguins, and that happens with particular intensity on this uninhabited continent, a continent of extremes. Another way to think of this is that environmental ethics, like the life there, is also driven to extremes. The further south one goes, the more life disappears; even lichens and algae cannot survive. On land and in ice, life at its edges challenges the ultimate limits—down in rocks in the Dry Valleys, with microbial colonies 200,000 years old (a hundred times older than a redwood tree), on a landscape where no rain has fallen in two million years, and it is now too dry to retain snow. "Endolithic life," as the biologists term it, is algae, bacteria, and fungi inhabiting the spaces between grains in rocks. There are microbes at the South Pole. There is life in the deep freshwater lakes, perhaps even in Lake Vostok, under two miles of ice and not exposed to the atmosphere for a million years, since before *Homo sapiens* appeared on Earth. Recent research has found that forms of both plant and animal life there have survived glacial cycles over millions of years.

Respect for life is not gone; rather, respect goes to extremes with these achievements. The really exciting science here is about nature irrelevant for people—microbes at the Pole or hemoglobin-less fish. Such science might bring us a deeper respect for life, more resolution to leave no human imprint. This life is "untrammeled by man"; that is fact of the matter. Problematic though the transition from *is* to *ought* is, scientists, policymakers, and environmental ethicists have been forming a consensus that in Antarctica humans ought to let life already at the limits continue untrammeled. The wonder of life at the limits of possibility commands our respect.

Here is nature revealed in the wildest: the southernmost penguin colonies, the densest feathers, penguins that live on ice and need never touch land. We respect remote oceanic islands or desert canyons, with odd forms of life, or little life at all. Life pushing into those extremes does deserve human respect when we encounter it, and demands more vigilance, lest we disturb it. Antarctica is a "wonderland."

GLOBAL ANTARCTICA

Antarctica is at once unique and global, combining both particular and universal dimensions. Antarctica will not solve the population problem; it holds no answers to global warming (although this may be monitored there), or to the loss of biodiversity, escalating consumerism, or sustainable development. But this stateless continent could be a pace setter for an ethic of the common heritage of humankind, rather slowly developing on the other continents, with some 170 nation states. Typically the nations presently in control in Antarctica have denied that the common heritage principle applies here, but this denial seems increasingly implausible with the resolution not to develop the continent.

The protocol states: "The development of a comprehensive regime for the protection of the Antarctic environment and dependent and associated ecosystems is in the interest of mankind as a whole." One way of reading that is that this continent belongs to nobody because it belongs to everybody. But other interpreters wish to turn that idea on its head and take "belonging to nobody" to mean more precisely what it says: no humans, individually, nationally, or internationally, own this place. Human ownership is not the relevant category. The Madrid Protocol seeks to protect "the intrinsic value of Antarctica, including its wilderness and aesthetic values." It is impressive to have a consensus of several dozen nations resolved to protect what they call the intrinsic value of Antarctica. In Antarctica, in the protocol, the nations have reached a transcultural, even a global ethic. If this is still a pragmatic ethic, Antarctica for science, tourists, and future generations, this pragmatism has convictions about Antarctic nature independently of the human presence.

Antarctica is particularly challenging because here is the one continent on the home planet that is not, cannot, and ought not be our home.

ANTHROPOCENTRISM

Literally defined as "human-centeredness," anthropocentrism is for many environmental philosophers the ethical attitude the field was created to overcome. The critique of anthropocentric assumptions and moral judgments and their supplementation with nonanthropocentric (i.e., biocentric or ecocentric) commitments have driven much environmental ethical theorizing since the academic founding of the field in the 1970s. The critique of anthropocentrism, however, is not seen as a purely intellectual task by environmental philosophers. Most theorists identify the militantly and exclusively anthropocentric worldview as the root cause of environmental problems such as species extinction, the loss of natural areas and wilderness, and the general decline of environmental quality. As a consequence, the rejection of anthropocentrism has become the hallmark of environmental ethics since the 1980s, although not all environmental philosophers believe that an exclusively anthropocentric orientation necessarily leads to the destruction of wild species and ecosystems. For these dissenting voices in the field, a sufficiently reformed and enlightened anthropocentrism not only is capable of motivating a strong, effective environmental ethic, it is defensible as a superior approach to moral, ontological, and policy questions. With global climate change eclipsing all other environmental concerns, anthropocentrism became ascendant in environmental ethics early in the twenty-first century.

Philosophically, anthropocentrism may be understood in ethical, ontological, and epistemological terms. As an ethical view anthropocentrism refers to the explicitly stated or implied claim that only human beings have intrinsic value; all other natural beings and things have only instrumental value, and human interests thus always trump the interests of nonhumans and the environment. This is an evaluative and priority judgment that many nonanthropocentric philosophers believe reflects an arbitrary bias. As an ontological view, anthropocentrism refers to the position, sometimes identified as Aristotelian or Thomistic, in which humans are seen as the center of the universe or the ends of creation. Typically, environmental philosophers conflate the ontological and ethical positions in their critiques as well as in their positive nonanthropocentric proposals even though, as Tim Hayward (1998) pointed out, ethical anthropocentrism does not necessarily entail ontological anthropocentrism and vice versa. Indeed, most secular anthropocentric environmental philosophers, such as Bryan Norton and Andrew Light, are not ontological anthropocentrists, publicly accepting an evolutionary account of human origins in which *Homo sapiens* is not regarded as an ontologically privileged species. However, many self-identifying Christian, Jewish, and Islamic anthropocentric environmental philosophers are both ontological and ethical anthropocentists, grounding the latter type of anthropocentrism in the former. As an

epistemological view, anthropocentrism is tautological: All human values are human values, including the intrinsic value that ethical nonanthropocentrists ascribe to nature. Thus, no ethical nonanthropocentrist can be a self-consistent nonanthropocentrist, although this truism often is overlooked or denied in the heat of the anthropocentrism -nonanthropocentrism debate.

Terminologically, anthropocentrism sometimes is confused with related words that crop up in discussions about the human-nature relationship, especially the terms *anthropomorphism* and *anthropogenic*. The first term refers to the practice of ascribing uniquely human attributes to nonhuman beings or entities (e.g., the human traits given to the animal characters in the Disney film *Bambi* and in Kenneth Grahame's book *The Wind in the Willows*). The second term simply means "human-caused" rather than produced by natural forces, as in anthropogenic climate change.

Anthropocentrism as it is commonly understood in environmental ethics and philosophy refers to the view in which nonhuman nature is valued primarily for its satisfaction of human preferences and/or contribution to broader human values and interests. Another way to put this is that in the anthropocentric worldview, individual plants and animals, populations, biotic communities, and ecosystems are accorded only instrumental, not intrinsic, value; Eugene Hargrove (1992) and Ben Minteer (2001) have given alternative readings.

ENVIRONMENTAL ETHICS AS ANTIANTHROPOCENTRISM

One of the most significant influences on the rise of the antianthropocentric agenda in environmental ethics has been the 1967 essay "The Historical Roots of Our Ecologic Crisis" by the historian Lynn White, Jr., in the magazine *Science*. White's article proved controversial mostly because of its harsh assessment of the environmental ethic embedded in the Judeo-Christian tradition. According to White, the creation account in Genesis placed humans in a superior ontological position: Man was created separately from the rest of Creation, and he alone was given "dominion" over the creatures of the earth and commanded to "subdue" them and the earth. White's "despotic" reading of Genesis therefore emphasized the divine sanction of human control and mastery over nature. Furthermore, his provocative remark that except for Zoroastrianism Christianity is "the most anthropocentric religion the world has ever seen" (White 1967, p. 1205) drove home the point that the human-centered outlook of the dominant Western religion was ultimately responsible for overpopulation, species loss, air and water pollution, and other environmental ills. Such dilemmas were ultimately the product of deep cultural and religious beliefs about the proper place of humans on the earth, White concluded, and only a rethinking of the "axioms" of Western culture (i.e., an interrogation and rejection of ontological anthropocentrism) would enable humans to adopt a more harmonious relationship with the natural world.

White's argument, especially his identification of anthropocentrism as the cause of the ecological crisis, had a strong influence on the work of environmental ethicists in the subsequent decades. Indeed, nonanthropocentric environmental philosophers have focused most of their attention since the appearance of White's paper on discrediting both ontological and ethical anthropocentrism as a philosophical attitude toward nature and constructing an alternative worldview and ethical system that would recognize the intrinsic as well as the instrumental value of nature (Rolston 1975, 1986, 1988, 1994; Taylor 1986; Callicott 1989, 1999; Katz 1997). Many in the field presumably would agree with the nonanthropocentric philosopher J. Baird Callicott, who observed that White's essay is the "seminal paper in environmental ethics" and that after its publication in the late 1960s the "agenda for a future environmental philosophy thus was set" (Callicott 1999, p. 31).

The antianthropocentric (and prononanthropocentric) movement in academic environmental ethics received an early boost in 1973 when Richard Routley (later Sylvan) published the first essay on environmental ethics by an academic philosopher, "Is There a Need for a New, an Environmental Ethic?" in 1973. Just as White attacked primarily ontological anthropocentrism, Routley attacked primarily ethical anthropocentrism. Routley presented his well-known "last man" thought experiment, which became a kind of ethical litmus test separating ethical anthropocentrists from nonanthropcentrists. It was also an exercise that, at least in Routley's and many nonanthropocentrists' view, exposed the failure of conventional anthropocentric ethical systems (e.g., utilitarianism, deontological ethics) to account for environmental harm, especially harm to nonsentient parts of the environment.

Routley claimed that according to the traditional moral principles of the European and North American philosophical tradition, the last man surviving the collapse of the world system would be committing no wrong if he set about destroying every species of animal and plant on the earth that he could. Because only humans (or the satisfaction of human preferences or the fulfillment of human interests) have intrinsic value in traditional Western ethics and no other human is left to be harmed (or have his or her preferences frustrated or interests adversely affected) by the actions of the last man, that man's destructive actions would not run afoul of conventional ethical codes. In other words, if the last

man goes about destroying all nonhuman life on the planet, Western moral philosophy provides no good reason why such wanton destruction could be deemed wrong. To Routley's mind, and similar to White's arguments about the Judeo-Christian tradition, standard Western ethical theory reflects a clear ''human chauvinism.'' Routley was thus able to answer the question posed in his essay's title: A new ethics is needed if people want to be able to condemn individuals and communities morally for driving species to extinction and despoiling natural areas. In addition to a thorough rejection of ontological anthropocentrism, a critique of ethical anthropocentrism—with its exclusive emphasis on human preferences and well-being—is called for, along with the mounting of a nonanthropocentric complement.

Although a strong strain of both ontological and ethical nonanthropocentrism took hold in environmental ethics after the early essays of White and Routley and became the dominant approach in the field in the last quarter of the twentieth century, not all environmental philosophers were convinced that a new ''nature-centered'' ethic was necessary. John Passmore's *Man's Responsibility for Nature* (1974), published a year after Routley's paper, was the first book-length treatment of environmental ethics and is significant in part for its rejection of the emerging view that traditional Western philosophical thought is adequate for the resolution of environmental problems. The established (anthropocentric) ethical tradition, Passmore claimed, with its sensitivity to the consequences of human actions and its array of moral principles directing the promotion of genuine and enduring human interests (i.e., those beyond immediate physical and material enjoyment), had far more ethical resources at its disposal than the new environmental ''mystics'' and ''primitivists'' understood or appreciated. Among other things, Passmore's early work in the field suggested that environmental ethics might not be synonymous with nonanthropocentrism.

WEAK ANTHROPOCENTRISM AND ENVIRONMENTAL PRAGMATISM

Passmore's denial of the need to inject nonanthropocentric principles into the ethical discussion of human-nature relations would gain further play in the field over the ensuing decades. In the 1980s the philosopher Bryan Norton introduced to the discussion what he termed weak anthropocentrism, a broadly humanistic project that distinguished between strong anthropocentrism and a weaker (i.e., less consumptive) variant of instrumentalism. In Norton's project human contact with nature (e.g., outdoor recreation, environmental education, ecotourism) could prompt individuals to question their own and others' ecologically irrational commitments and shape normative ideals affirming human harmony with the environment (Norton 1984). Although a strong anthropocentrist would regard the biological richness of a forest as little more than a storehouse of raw materials to be harvested and measured only in commercial terms, in Norton's view a weak anthropocentrist would value that landscape differently, recognizing its present and future beauty, cultural expressiveness, therapeutic and recreational value, and ability to inspire individuals and communities to care for and protect nature (Norton 1987).

The philosopher Eugene Hargrove (1992) also proposed a version of weak anthropocentrism, though it differed from Norton's in a critical respect. Like Norton, Hargrove acknowledged that environmental value necessarily originates from a human valuer. In effect, Hargrove brought attention to epistemological anthropocentrism and to its logical necessity. Unlike Norton's weak anthropocentrism, however, Hargrove's version included recognition of the intrinsic value of natural objects. Grounding his approach in the naturalistic traditions of nineteenth-century landscape painting and field naturalism, Hargrove wrote that people may ascribe intrinsic value to the elements of nature they judge to be beautiful or scientifically interesting—just as one might ascribe intrinsic value to a priceless work of art such as the *Mona Lisa*—even though that ascription is made from a distinctly human point of view and is intimately related to a complex suite of human values (Hargrove 1989).

The anthropocentric approach in environmental ethics received a boost with the emergence of environmental pragmatism in the mid-1990s, a philosophical movement drawing from both the substance and the spirit of classical American philosophy, particularly the work of Charles Sanders Peirce, William James, and John Dewey, who adamantly opposed the notion of intrinsic value whether ascribed to nature or to anything else (Light and Katz 1996). Ben Minteer (2001), however, has argued that Dewey did recognize a form of non-instrumental value (if not exactly intrinsic or final value) in his overall logic of moral inquiry. Pragmatists in environmental ethics for the most part retain the anthropocentric orientation of the historical American pragmatists and endorse a broad instrumentalism in which nonhuman nature is valued for its contribution to a wide range of human interests, such as those described above in Norton's work. Many environmental pragmatists argue that this reformed or liberal anthropocentrism not only is a more philosophically sound approach to environmental ethics but has greater political and policy appeal inasmuch as most people are unreflectively anthropocentric—indeed, many are unreflectively egocentric and ethnocentric—regarding the value of nature

and its direct and indirect uses, including nonconsumptive ones, exclusively in terms of human interests (Norton 1995, Minteer and Manning 1999, Light 2002).

THE DEBATE CONTINUES

Despite the growing number of anthropocentric approaches in environmental ethics and the sobering prospect of the impact on humans and human interests of global climate change, nonanthropocentrism is still the dominant philosophical position in the field. Moreover, nonanthropocentric philosophers remain committed to complementing anthropocentric arguments in ethical and policy discourse with nonanthropocentric arguments. Some seem to take an even more extreme view that anthropocentric arguments for nature preservation should be replaced altogether by nobler (as they see it) nonanthropocentric arguments. For example, Holmes Rolston III, one of the founders of academic environmental ethics, has asserted, "Both anthropocentric and anthropogenic values have to come to an end before we can be the best persons. We have to discover intrinsic natural values" (Rolston 1994, p. 166). Similarly, the philosopher Eric Katz has argued that apparently ontological anthropocentric approaches are not only philosophically suspect, they are "imperialistic" and ultimately devastating to the goals of environmental protection. "An anthropocentric worldview," Katz stated, "leads logically to the destruction of the nonhuman natural world" (Katz 1997, p. 183). J. Baird Callicott, in contrast, also a founder of the field and a staunch defender of the nonanthropocentric approach, recognizes that nonanthropocentric values are also human values—that is, he recognizes that there is no alternative to epistemological anthropocentrism—and that the intrinsic value nonanthropocentrists ascribe to nature often must compete with as well as complement the various instrumental values in nature.

In response to the extreme nonanthropocentrism of Katz, anthropocentrists argue that there is no necessary or inevitable linkage between ethical anthropocentrism and ecological destruction. Instead, they claim that it is human arrogance toward nature and a related myopic view of the effects of human actions and their consequences on a broad range of human interests and values that are the culprit, not human-centered values per se. This distinction, which in essence restates the division between strong and weak anthropocentrism, is implicit in White's "Historical Roots" essay but often is neglected by nonanthropocentric environmental ethicists who have chosen to focus on the perceived philosophical flaws of anthropocentrism as a general theory of value (Norton and Minteer 2002). Although the anthropocentric-nonanthropocentric debate continues to divide many philosophers, Norton (1991) has proposed that the most defensible forms of weak anthropocentric and nonanthropocentric arguments actually "converge" on a similar policy agenda, an argument that would seem to lower the practical stakes of the dispute, if not its philosophical import (Minteer forthcoming). Norton's convergence hypothesis, however, remains contested by nonanhropocentrists, and the debate continues.

Ben A. Minteer

ANTHROPOMORPHISM

The straightforward definition of "anthropomorphism" is the attribution of human qualities or characteristics to nonhuman entities. While correct, this definition does little to express the significance of the term to environmental ethics. Most often, anthropomorphism (personification) has served as a common literary device. For example, in William Blake's "To Autumn," autumn is portrayed as a man who is enjoined to sit, rest, and sing "the lusty song of fruits and flowers." Anthropomorphism is also strongly associated with religion and mythology, notably in the tales of the ancient Greeks, where, for example, the personification of the earth is the goddess Gaia and the renewal of spring is Persephone. Predictably, literary and religious uses of anthropomorphism impact environmental ethics, both directly and indirectly, culminating in contemporary critiques not only of anthropomorphism per se, but also of how anthropomorphism is linked with racism and sexism.

Within a religious context, anthropomorphism has had currency in both the East and West. The God of the ancient Jews was often described in physically human terms as engaging in human activities, for example, wrestling with Jacob in the book of Genesis. The God of Israel was also characterized as expressing very human emotions, such as anger and vengefulness. Sometimes called "anthropotheism," this attribution of human characteristics to divine figures has been controversial. Significantly, Islam generally forbids such images, regarding them as tantamount to idolatry.

Within Hinduism, anthropomorphism is complex. The conception of Saguna Brahman (the Absolute with qualities) suggests the existence of a supreme being with describable humanlike characteristics. According to this version of Brahman, it makes sense that Hindu gods, such as Vishnu and Shiva, and goddesses, such as Durga and Parvati, would be depicted in human form. Interestingly, much drama alludes to the notion that Hindu gods and goddesses are not to be understood as ultimately human. Durga, for example, may be presented in the form of a woman, but with eight arms. Ganeshe has the body and posture of a human, but the head of an elephant and also many arms. Krishna is often depicted as a young man, but his skin is blue. By contrast, the conception Nirguna Brahman (the Absolute without qualities) emphasizes the Absolute not as a god per se, but as ineffable ultimate reality, the ground of all being uncapturable by any words or images, human or otherwise.

Another aspect of anthropomorphism can be discerned in Hinduism's understanding of reincarnation. This familiar doctrine allows that one may be reborn in the form of various sorts of animals or even insects. It has often been suggested as an explanation for Hindu vegetarianism and injunctions against harming cows and other animals. One may be discouraged from eating animals or even harming insects on the grounds that, despite appearances, such creatures may be the actual or potential reincarnations of human beings. This reasoning is loosely anthropomorphic in the sense that spiritual potential, the human soul or atman, seems to be projected onto the animal or insect. This anthropomorphism may be merely apparent, because the Hindu perspective includes a more nuanced explanation. One is enjoined from harming animals not so much because animals are thought of as being previous or potential humans, but because humans, animals, insects, indeed all beings, are aspects of one and the same undifferentiated ultimate reality (Brahman).

Anthropomorphism has also figured in Western scientific contexts. The eighteenth-century taxonomist Carl Linnaeus, for example, relied heavily on anthropomorphic metaphors in his elaborate classification schemes for plants, overtly basing his system on human reproductive organs and the language of heterosexual intercourse. Also in the eighteenth century, Anton von Leeuwenhoek adopted the view of preformationism and insisted that the human sperm contained a fully formed human in miniature. This sort of anthropomorphism involves projecting a human form onto a substance emitted by a human being.

Within primatology, not surprisingly, anthropomorphic descriptions have been especially common and the subject of much critique, notably from feminists, who objected, for example, to the use of the word "harem" to describe a group of female gorillas (Haraway 1990). In contrast, humans are often unwilling to see human qualities in animals, a kind of opposite of anthropomorphism.

For this tendency, the primatologist Franz de Waal (2002) coined the term "anthropodenial."

Within the early environmental movement, anthropomorphism received seminal expression in the work of the twentieth-century writer Aldo Leopold. Most obvious is Leopold's penchant for referring to particular nonhuman creatures in human terms. For example, in his well-known work *A Sand County Almanac*, Leopold writes that, after a night of hunting, an owl, "in his trisyllabic commentary, plays down the story of the night's murders" (1949, p. 61). Similarly, a goose "speaks with the authority of all the far hills and sea." This strategy not only reflects Leopold's own deep kinship with such creatures, but also brings the reader into sympathetic union with nature, as Leopold's "land ethic" espouses.

At the heart of this land ethic is Leopold's conviction that nature ought to be regarded not merely as a human resource, but as an extension of our community. As Leopold expresses it, the land ethic "changes the role of *Homo sapiens* from conqueror of the land-community to plain member and citizen of it" (1949, p. 220). While less clearly anthropomorphic than the obvious references to particular animals as personlike, the idea that nature and natural creatures should be regarded as an extension of the human community may also be considered to involve projection of humanlike traits or values onto the nonhuman. Indeed, the suggestion is that other creatures are members of our community, and that we can better appreciate their value by emphasizing their similarity to us.

While Leopold's anthropomorphisms may be a clear improvement over an utter disregard for nature and over conceptions of nature in solely economic terms (as a mere resource, for example), they have hardly been regarded as wholly positive or even innocuous. In fact, it has been argued that such anthropomorphic strategies reveal the anthropocentric character of much of early environmental theorizing. Why must we frame the natural world in human terms to appreciate its worth? The lineage of this anthropocentric view can be traced to the philosophy of Kant (1963), who, for example, was careful to emphasize that nonhuman creatures ought not be mistreated, not for their own sake, but rather because of the pernicious effect that their mistreatment tended to have on human beings.

Jeremy Bentham's utilitarian theory challenges views that devalued animals because of their supposed lack of rationality. Anthropocentric, rationalistic approaches such as Kant's might be seen as negatively anthropomorphic. That is, supposedly uniquely human capacities are valued, and their lack or absence is projected onto animals. By contrast, Bentham insists on emphasizing our shared nature as animals. As he puts it, "The question is not, Can they *reason*? Nor Can they *talk*? but, Can they *suffer*?" (1948, p. 311). Thus began a line of ethical theorizing that has received its most famous contemporary expression in the work of Peter Singer.

The shift from early anthropocentric regard for the natural world to valuing nature in its own terms is part of what distinguishes the contemporary environmental movement from the early stages of environmental consciousness. Contemporary philosophical debates in environmental ethics seem to assume that obviously anthropocentric and/or anthropomorphic characterizations of nature are problematic. Yet questions about more subtle forms of anthropomorphism still abound. For example, some of the controversy about whether it is appropriate to speak of animal *rights* can be understood as a question about whether this involves inappropriate projection of human qualities associated with rights theory onto animals.

Other critics of anthropomorphism have pointed out that since human qualities also include factors such as race and gender, then to the extent that the natural world is conceived of as human, it will also be regarded in ways shaped by sexism and racism. For example, while Leopold revered so-called natural animals, those connected to the romantic and perhaps macho values associated with the wilderness, he bestowed no such regard on agricultural animals (Davis 1995). While some animals are often regarded as masculine (bears, wolves), others are considered feminine (notably cows and chickens), and all are valued according to a hierarchy that privileges male over female (Dunayer 1995). An especially influential critic in this vein is Carol J. Adams, whose book *The Sexual Politics of Meat* (1991) draws vivid comparisons between the use and literal consumption of animals to the objectification and more figurative consumption of women. In short, since prejudices enter into the equation of what particular qualities are associated with which particular humans, it is to be expected that the study of anthropomorphic tendencies in animal ethics will also involve the study of issues associated with race, sex, and other factors.

APPROPRIATE TECHNOLOGY

SEE *Alternative Technology.*

AQUIFERS

An *aquifer* consists of an underground body of permeable rock (e.g., limestone or sandstone) or unconsolidated materials (e.g., gravel or sand) from which water can be extracted. Of all the water on earth, 97.5 percent is salt water. Of the remaining 2.5 percent that is freshwater, 70 percent is contained in the Antarctic (where the ice is up to 2 miles in thickness) and the Greenland ice sheet; there is also a negligible amount at the North Pole, where the ice is only a few feet thick. Lakes, rivers, and wetlands contain only a small percentage (around 0.01 percent) of the world's freshwater. Groundwater makes up about 20 percent of the world's freshwater supply.

SOURCES AND USES OF AQUIFERS

The study of aquifers is called hydrogeology. To hold water an aquifer requires an aquitard, an impermeable layer alongside an aquifer, as well as an aquiclude, an impermeable barrier beneath the aquifer. The surface level of the saturated rock or gravel forms the aquifer's water table. The water-bearing rock then provides water to wells and/or springs in the surrounding region. Contrary to common belief, groundwater exists only rarely in underground rivers or lakes. Although varying from season to season, groundwater rates of movement range from a half inch to tens of feet per year.

Aquifers are a limited and precious natural resource that must be carefully husbanded. While it is possible for aquifers to be replenished through rainfall or deliberate recapture, aquifers recharge at different rates through differences in precipitation, storage characteristics, and use, and are generally in decline worldwide. Pumping out water at rates greater than recharge results in lower flows, poorer water quality, and higher prices. (Changes in the amount of groundwater can also affect the lubrication of geologic faults, thereby causing earthquakes.) Through overuse the well eventually runs dry. In many cases around the world societies are, in effect, mining fossil water that, once used up, will be gone until the next Ice Age.

Figure 1. CENGAGE LEARNING, GALE.

Aquifers occur at various depths all around the world. Notable aquifers occur in Australia (in the Great Artesian Basin), South America (the Guarani Aquifer, shared by a number of countries), Lebanon and Israel, North Africa (in the Atlas Mountains), and in North America. In North America the best known aquifers are the Ogallala and the Edwards aquifers.

Aquifers are crucial for a variety of human uses from industry to drinking and washing, and agriculture (by far the largest use). Many towns and cities can be reliant on aquifers for their water supply. One example of this is the Edwards Aquifer, which provides drinking water for 2 million people in Central Texas, including the city of San Antonio. While this aquifer is being adequately recharged, the aquifer is threatened by development in the recharge areas surrounding Austin and San Antonio.

A second example of fundamental societal reliance on groundwater is the Ogallala or High Plains Aquifer, a

huge (and hugely important) source of water across the Great Plains of the United States. Underlying portions of eight states (Nebraska, South Dakota, Colorado, Kansas, Wyoming, Oklahoma, Texas, and New Mexico), the Ogallala provides potable water for eight out of ten people living above the aquifer and supplies 30 percent of the groundwater used for irrigation in what is one of the most productive agricultural regions in the world (see Figure 1). Because the Ogallala recharges much more slowly than it is being depleted, the economy of the U.S. High Plains is critically dependent on a finite resource.

ETHICAL AND POLICY DIMENSIONS

Since its creation in the 1970s, the field of environmental ethics has typically sought to identify arguments that focus on the intrinsic value of the entity under consideration. Although there have been arguments within the field directed toward the intrinsic value of animals, species, ecosystems, and even rocks, no one appears to have argued that aquifers should be preserved in part or in whole because of their intrinsic value. Perhaps because they are too out of sight; they appear to be out of mind. Aquifers seem to be distinctive in that they are an entity toward which everyone takes an instrumentalist view.

Surrogates for the intrinsic value of aquifers are the endangered species that inhabit the springs they feed. The Edwards Aquifer feeds a number of springs in south-central Texas, the most notable of which are Barton Springs in Austin and San Marcos Springs in San Marcos. The Barton Springs salamander is listed as an endangered species under the Endangered Species Act of 1973. Protecting its habitat and that of other similar endemic species in the springs fed by the aquifer requires municipalities, such as Austin and San Antonio, and regional irrigation districts to cooperate in maintaining sufficient in-stream flow in these springs to avoid a prohibited "taking" of the protected species. Perhaps protecting such endemic species, while important, is also a means that conservationists, who valuing the Edwards Aquifer intrinsically, have devised for protecting the aquifer itself.

The fate of the Ogallala Aquifer is a useful case study in the environmental-ethical and policy dimensions of the use of aquifers. The sustainability of the Ogallala has been a policy issue since it became apparent in the 1970s that this aquifer was running dry. Since then ethical and policy questions have turned on issues of equity, for both current users and for future generations (i.e., sustainability).

Across the High Plains, withdrawals from the Ogallala are controlled by the "rule of capture." Under this rule individuals only need pay the cost of pumping the resource, not for the value of the water removed from the ground. This approach externalizes the social costs of pumping water, with the inevitable result of excessive exploitation of the resource. As Garret Hardin showed in his famous 1968 article on the tragedy of the commons, common pool resources are usually overused if left unregulated. In the case of the Ogallala, regulation is difficult: Although some states in the High Plains can deny new water permits if local groundwater-management districts deem it likely that new wells will be reduced, the Supreme Court in the state of Texas has ruled that "the owner of the land is the absolute owner of the soil and percolating water" (*Houston & T. C. Ry. Co. v. East*).

Questions of equity and sustainability concern the distribution of water resources both within and across generations of users. In the case of the Ogallala, the floor (or aquiclude) of the aquifer is uneven, meaning that landowners drilling into the aquifer might be able to reach water at the same time that the wells of nearby neighbors are running dry. Under such conditions conservation becomes crucial; if a high water table is maintained, water access will be preserved across the region.

On the other hand, equity across generations (or sustainability, defined by the Brundtland Commission as "meeting the needs of the present without compromising the ability of future generations to meet their own needs") turns on questions of what if any responsibility current generations have to preserve the capacity of aquifers for future generations. As in all cases of cross-generational equity, questions arise concerning possible technological innovation (e.g., novel irrigation systems or new crop varieties that might lessen water requirements) and the proper discount rate to apply to the concerns of future generations.

Robert Frodeman

ARCTIC

The Arctic is the region delimited by the Arctic Circle, at 66.6° latitude north; it marks the southernmost position of the polar day and night, where twenty-four hours of daylight and twenty-four hours of night occur once a year. It contains the North Pole and encompasses the Arctic Ocean.

CHARACTER OF THE REGION

Ecologically the Arctic is the area that extends north beyond the border between boreal forest and northern tundra; it often includes the interdependent sub-Arctic environments. In the popular imagination it is any area of the far north. Politically the Arctic comprises parts of eight nations: Norway, Sweden, Finland, Denmark, Iceland, Canada, Russia, and the United States, with the Inuit homeland of Nunavik anticipated as the ninth. The Arctic Region has a sparse human population of approximately 4 million, 10 percent of whom are indigenous.

The terrestrial ecology of the Arctic is primarily tundra, with a permanently frozen subsoil known as permafrost. The Arctic region is home to more than thirty-six kinds of mammals, including marine mammals such as the beluga and bowhead whales, and land mammals such as the polar bear and caribou. There are more than 130 bird species in the area, which is an important migratory center in the spring. Although the Arctic region has a short growing season and is treeless, it has a number of small shrubs and flowering plants, with mosses, lichens, and grasses being the most common type of vegetation. Coastal marine life abounds with fresh and sea water algae, more than a hundred phytoplankton species, copepods, amphipods, jellyfish, kelp, and various benthic invertebrates. There are more than thirty-one species of freshwater fish, including Arctic char, trout, grayling, whitefish, and sturgeon, as well as three species of salmon in their spawning stage. The largest marine fish is the Greenland shark, which averages 6.5 meters in length and weighs up to 1,980 pounds.

RESOURCE DEVELOPMENT AND THE ENVIRONMENT

There has long been intense interest in the Arctic region's large deposits of fossil fuels—oil, gas, and coal—as well as minerals such as nickel, copper, gold, uranium, tungsten, and diamonds. There are significant deposits of oil and natural gas in the Beaufort Sea and Chukchi Sea coast in the North Slope of Alaska, the Nunavut area of Canada, northwest Russia, and the Barents Sea. Oil fields in the North Slope of Alaska have produced more than 14 billion barrels of crude oil through 2002 and have averaged about 20 percent of U.S. domestic production since 1977. Coal deposits, strongly in demand in Asia, have been found in the eastern Canadian Arctic Archipelago, the Svalbard Archipelago in Norway, and near Point Lay in Alaska. The last area is thought to have nearly one-tenth of the world's sub-bituminous and bituminous coal.

The ethical issues concerning the development of such nonrenewable resources pertain mainly to two areas: (1) the utility of the resources versus the value of preservation of natural ecologies; and (2) the social justice of resource extraction, especially as it affects indigenous peoples.

By some estimates 80 percent of the world's energy supply comes from fossil fuels. With the amount of nonrenewable resources dwindling, demand growing (especially in China and India), the price of oil rising, and investments in alternative sources of energy languishing, the economic value of nonrenewable resources and the profitability of their extraction have increased. This upswing has intensified pressure for further development and exploration in the Arctic, especially as extraction technologies have advanced. Furthermore, governments in this region encourage such development because the resulting taxes and profit generate a large percentage of their revenue. Moreover, the end of the cold war and moves toward a globalized economy have fostered greater possibilities for extraction partnerships: for example, the Russian-Norwegian cooperation in off-shore natural gas development in the Barents Sea and the Russian–British Petroleum partnership in the development of the Samotlor oil field in Siberia.

These pressures for development have led to increased concerns about the fragile ecologies of the Arctic. The rapid industrialization of the Kola Peninsula in northwest Russia during the Soviet period is a good example of the effects of reckless development of the region. Because the large deposits of nickel and copper on the peninsula occur naturally in sulfur compounds, when the deposits are smelted, they cause significant sulfur dioxide pollution. The 1980s saw the emission of an estimated 937,000 tons of noxious substances that caused vegetation damage and forest dieback over a region of nearly 3,100 square miles.

Even with environmental controls in place, as they are in the North Slope of Alaska, there are significant ecological risks in the development of the region, as a 2003 report from the U.S. National Academies of Science has documented (Orians 2003). The ecological health of the tundra has been adversely affected by industrial activity, which has mushroomed from one field to a complex of fields with the accompanying network of pipelines, pads, roads, seismic exploration trails, and other elements of infrastructure. These industrial incursions have affected patterns of habitat behavior, including migrations of whales and caribou. The increasing industrialization of the eastern coastal plain will likely interfere with the reproductive success of the Central Arctic caribou herd, because the area provides insect relief during calving. In addition, the transportation of oil from

the North Slope poses the risk of spills. Not only is the 800-mile trans-Alaska pipeline vulnerable, but there are also risks from tankers plying Prince William Sound out of the Valdez terminal—as the infamous *Exxon Valdez* oil spill in 1989 showed. Feeder pipeline leaks at the North Slope facilities in 2007, arising from negligent preventive maintenance for corrosion, are reminiscent of the poor past performance of pipeline services; there are similar problems at the Samotlor fields, where oil has contaminated groundwater.

ETHICAL VALUES AND ENVIRONMENTAL DECISION MAKING

Despite any merits of *ecocentric ethical theories*, the reality of decision-making in resource management among democratically oriented countries in the Arctic is usually couched in the anthropocentric language of *cost-benefit analysis*, primarily through permitting processes, environmental impact statements, public testimony, and public-political venues, all of which fall within the mandates of environmental laws and administrative procedures. The basic algorithm of cost-benefit analysis is relatively simple: Identify all costs and benefits associated with a targeted action, convert these into a common value system (usually monetary), and determine whether benefits outweigh costs. The technique's deficiency as an ethical tool lies in its difficulty in translating incommensurable values into quantifiable money terms. Thus, although it may be easy to calculate the economic value of resources extracted from an area, it is not so easy to assess the area's other use values, such as health and recreation, and its nonuse or passive values, such as aesthetics and legacy. More sophisticated analyses attempt to address this difficulty by techniques such as contingent valuation, which elicits what people would be willing to pay for loss or degradation, or replacement valuation, where the loss of animals is calculated by what animal brokers would pay to replace or rehabilitate them in zoo environments. Studies calculating the costs of the *Exxon Valdez* spill may serve as a model.

A well-known case of the tension between use values and existence or passive values of the land is the controversy surrounding the opening of the Arctic National Wildlife Refuge (ANWR) to development. The establishment of ANWR by the Alaska National Interest Lands Conservation Act (ANILCA) in 1980 left the future development of 1.5 million acres coastal plain uncertain. The United States Geographical Survey (USGS) in 1998 estimated the presence of 4.3 to 11.8 billion barrels of recoverable oil in the region. Yet, despite pressures to develop the region and support for that development by a large majority of Alaskan citizens with a powerful legislative delegation, by 2008 most Americans continued to oppose development of the region. Interestingly, the same division is found within the Alaska Native community: Most of the Inuit support the development of ANWR, whereas the inland Gwich'in are strongly against it. The coastal Inuit are more interested in the protection of marine environments as their source of subsistence hunting and find some economic benefit to the oil development that has occurred on their lands; the Gwich'in, by contrast, depend on the Porcupine caribou herd whose calving grounds are in ANWR and so have sought strong protections for the area. Because of the guesswork concerning the amount of oil in the refuge, for some people the risks to the environment associated with development may outweigh any prospective gains.

The Chukchi Sea lease sale of 2008 is another case that illustrates the tensions between the value of resources and the value of preservation. The Department of Interior's Minerals Management Service opened 29.7 million acres to oil and gas exploration. It is anticipated that the thinning ice in the Arctic Ocean may open up shipping opportunities across the region and facilitate offshore oil exploration and extraction. This was the reason that the sale was the most successful in Alaska's history, with bids totaling $3.4 billion. The thinning ice, however, is projected to gravely affect the polar bear and ice-dependent seal populations, and the lease sale area overlaps their critical habitat. The lease sale came just days before the U.S. Fish and Wildlife Service was due to decide if the polar bear should be listed under the Endangered Species Act. Because of a delay in that decision, several environmental organizations filed suit. On May 15, 2008, the U.S. Fish and Wildlife Service finally listed the polar bear as a threatened species. Shortly after that action, the State of Alaska announced that it planned to take legal action against the agency for that listing, while environmental groups planned to take legal action despite the favorable ruling, since the U.S. Fish and Wildlife Service had no specific plan for addressing threats to the critical habitat of the polar bears.

RESOURCE EXTRACTION: ETHICS AND SOCIAL JUSTICE

There is a second problem with the ethics of cost-benefit analysis. The mere quantity of benefits versus costs does not provide a sound basis for judging issues of social justice. For example, even if the overall benefits exceed costs in a given case, there should be scrutiny of the kinds of costs and who must endure them. *Pareto-based principles* justify a distribution of benefits to some if it does not worsen the condition of others. Modified versions may permit those harms if they are compensated by those who benefit. By this criterion resource extraction that would yield large benefits to nonlocal people would be acceptable if it did not significantly harm the environment of local inhabitants or if local inhabitants were compensated

Arctic National Wildlife Refuge, Alaska. *With the dwindling supply and rising demand of fossil fuels, many are pushing for increased exploration and development in the Arctic region as a source of these materials. It has been estimated that the Arctic National Wildlife Refuge, or Area 1002, holds between 4.3 to 11.8 billion barrels of recoverable oil. However, the cost to the ecological health of the region may not be worth the economic benefit.* **AP IMAGES.**

through revenues or other means to a degree that would not leave them worse off.

A *utilitarian principle*, on the other hand, might have a different result. Gifford Pinchot (1865–1946), the first chief of the U.S. Forest Service and one of the staunchest utilitarians among conservationist thinkers, characterized utilitarianism as the greatest good to the greatest number for the longest time (Pinchot 1910). Under reasonable interpretations of the principle, it might be morally justifiable to extract resources that will benefit a large portion of a population, even if degrading the local environment for a few, so long as that benefit far outweighs the harm for the entire population.

A third issue to consider is the *difference principle* propounded by the twentieth-century philosopher John Rawls. According to this principle, social injustice and unfairness occur when the benefits and costs of some practice are inequitably distributed through a population—unless it can be shown that the inequity benefits the least advantaged in the population. If most of the costs of resource development are endured by the indigenous, least-advantaged population in a region but the benefits accrue to privileged nonlocals, then such a policy violates Rawls's basic principle of justice (1971).

Pragmatic ethics suggests that public discourse tends to result in normatively correct outcomes so long as the institutions and practices that constitute it are open, inclusive, and fair. When confronted with the reality of effects from pollution over the years, public norms in democratic societies have drifted toward advocacy of more protections for the environment. On this view what matters most, then, is not the use of an ethical formula for decision making but ensuring open, fair, and inclusive deliberative practices among stakeholders. Australia and British Columbia have attempted to apply this model, emphasizing consensus-based practices among businesses, scientists, government managers, and native groups. These processes aim at affording greater control over natural resources to local communities and giving increased attention to indigenous ecological knowledge and realistically sustainable practices.

Traditionally viewed as a remote hinterland, sparsely populated by indigenous peoples who have often been subjected to racist disdain, the Arctic has been vulnerable to exploitation and colonization: for example—the development of Kola Peninsula and the amazing story of Edward Teller's attempt to experiment with hydrogen bombs in blasting a cold-water port near Point Hope, Alaska. Later development projects by national and international

extraction companies have shown greater ethical cognizance of the dignity and interests of indigenous peoples. There are growing expectations that governments, and national and international extraction companies, will ensure proper ethical treatment of indigenous peoples. The history of the development of the North Slope in Alaska illustrates how some of these ethical concerns have been addressed. With the discovery of oil in this region in 1968 came the realization that a pipeline would be needed to transport the oil to an accessible port. Because the proposed pipeline route would traverse native-owned lands, the Alaska Native Claims Settlement Act (ANSCA), was proposed and passed in 1971. Although still considered controversial, ANSCA granted aboriginal Alaskans title to 44 million acres of public lands of their choice and conferred a $962,000,000 cash settlement in exchange for a waiver of existing land claims. ANSCA also established twelve regional native corporations to manage the lands. Since then the native corporations have become significant economic and political forces in the state and have, ironically, been responsible for the development of some ecologically sensitive lands in a way that has undermined subsistence hunting among some native shareholders.

ENVIRONMENTAL ISSUES AND CLIMATE CHANGE

Pollution from mineral extraction and fossil fuel emissions has long been a matter of serious concern; there is increasing alarm over the contribution of those activities to climate change. If, as the evidence suggests, fossil fuels contribute to global climate change through the greenhouse-gas effect, then the costs of resource extraction are considerable, particularly because their use weakens incentives for developing alternative energy sources. Nowhere on the globe are the effects of climate change more palpable than in the Arctic. Obvious signs include air temperatures that have risen at twice the global average and rapidly melting, retreating glaciers. The Greenland Ice Sheet, the second-largest such formation in the world at 1 million square miles, has melted at a rate of 17 percent from 1972 to 2002. The catalogue of environmental impacts on the Arctic are quite large: the effects of thinning ice on the habitats of polar bears and other species; changes in vegetation patterns that will disrupt food sources for animals; the drying of freshwater lakes; an increase in invasive species; increased insect impacts on vegetation; greater likelihood of forest fires; and the acidification of ocean waters, which will significantly affect plankton life in the sea. Changes in weather patterns have increased storm activity along the coast, affecting human coastal communities such as Shishmaref, located on a barrier island on the Chukchi Sea in Alaska. Because of erosion from sea storms and melting permafrost, the village must be relocated. The melting of the permafrost will compromise road infrastructure and building stability. Ultraviolet radiation from the thinning ozone will interfere with photosynthesis processes and affect the health of vegetation.

Changes in climate in the Arctic will have repercussions beyond that region, including an increase in global air and ocean temperatures because of the loss of sunlight-reflective ice and snow. As the permafrost melts, the release of methane gas will increase the amount of greenhouse gases in the atmosphere. Rising ocean levels from glacial melt will threaten coastal communities around the world and will affect temperatures globally.

Climate change in the arctic raises two interconnected issues of *intergenerational justice*. Assuming anthropogenic causes of global climate change, one issue concerns how much responsibility the current generation should accept for the existing state of the environment, given the cumulative actions of previous generations. Assuming we accept some of that responsibility—and there are feasible ways to lessen the effects of global climate change—a second issue concerns what it is we owe future generations in that respect (see Beckerman and Pasik 2001; Page 2006). A 2007 study by the Intergovernmental Panel on Climate Change provided evidence that there are anthropogenic causes of global climate change and that there are feasible ways to improve the state of the environment (IPCC 2007). Thus, a resolution to these ethical issues of intergenerational justice is needed and has a special urgency for the arctic, the region of the world most glaringly affected by global climate change.

James Jakób Liszka

ASIAN PHILOSOPHY

Asian philosophy, like Western philosophy, includes a great deal in terms of both method and content. Through the centuries Asian philosophers have defended an immense variety of theses, including almost any position—metaphysical, epistemological, or ethical—with which Western readers will be familiar. Asian philosophical traditions can be divided into two very broad categories: those originating in India and those originating in China. This distinction is not merely geographical: Indic traditions are, on the whole, very different from Chinese traditions, and for this reason are treated separately below. These two categories are, in turn, conventionally subdivided on the basis of religion, the Indic philosophical traditions being classified as Brahmanical-Hindu, Jain, or Buddhist, and the Chinese philosophical traditions as Confucian or Daoist.

As these subdivisions indicate, Asian philosophy is closely related to Asian religion. This is not to endorse the popular notion that the former is essentially mystical and nonrational. Rather, it is to suggest that in Asia, philosophy has usually been thought to have a soteriological function. That is, within Asia, philosophy has been regarded not merely as an intellectual pursuit, but also as an activity essential to attaining the proper ends of human life.

SAMSARA

For many Indic philosophical traditions, the ultimate end of human life is to realize *moksha* (for Buddhists, nirvana)—an awakening from the ignorance and craving that mark ordinary existence. From a cosmic perspective, the aim is to escape from samsara, the realm in which sentient (experiencing) beings undergo a recurring cycle of rebirth from one form to another. This cycle is said to be driven by the law of karma, according to which one's past actions, morally good or morally bad, affect the form of one's rebirth. Good karma is thought to make for a favorable rebirth; bad karma for a less desirable rebirth.

This view of the world might, in some respects, appear to be ecological, or green. For one thing, the spiritual predicament of human beings is portrayed as being in certain fundamental respects like that of nonhuman animals: neither I nor my dog has attained *moksha*, and so we are both caught up in samsara. For another, since any individual has been reborn countless times in countless forms, any particular human has undoubtedly been reborn many times as an animal. The opposite holds true for animals as well. My dog would not once have been me, to be sure, but she could have been my parent, mate, or child in some former life. On this basis the Mahayana Buddhist *Lankavatara-sutra* endorses vegetarianism, for how, it is asked, could one consider eating a being that had once been one's mother?

If in these respects Indic cosmology might seem attractively green, in others it might seem thoroughly anthropocentric and quite at odds with the concerns of modern environmental thinkers. For one thing, the cosmic order (*Dharma*) is conceived of as a strict hierarchy. Just as, according to traditional Brahman-Hindu conceptions of caste, it is better to be reborn as a Brahman (priest) than as a Sudra (servant), so rebirth as a human is considered superior to rebirth as an animal. For another, samsara itself is not portrayed as a pleasant place. On the contrary, it is a realm of desire, frustration, and anxiety (*duhkha*), a bad

dream from which the wise individual will seek to awaken. What is more, in Indic traditions such as Samkhya and Advaita Vedanta, this awakening is achieved in a way that would make contemporary environmental thinkers blanch, namely, by distinguishing one's true self (*purusha*, *atman*) from the mundane, empirical world.

On the basis of these observations, some writers have concluded that Indic philosophy is world-negating and so inherently at odds with the efforts of environmentalists. Such assessments must be balanced, however, against other aspects of Indic thought. Here some writers emphasize the world-sacralizing aspects of Indic thought, as present in the panentheism (all-in-God system of belief) of Ramanuja (1017–1137), for example (see Mumme 1998). Others contend that to achieve *moksha* is not to escape the world, but merely to free oneself from the craving and ignorance that bind one to the cycle of rebirth. Indeed, in many Indic texts—the Buddhist *Theragatha* verses, for instance—contemplation of the natural world is recommended as an exemplary practice for those seeking to cultivate such nonattachment.

SELFLESSNESS AND NONVIOLENCE

In Indic traditions, the primary vices, those dispositions of character that bind one to the cycle of rebirth, are craving and ignorance. The unawakened accept worldly appearances and so are led to crave worldly things. Hence they condemn themselves to the suffering of continuing rebirths.

Indic thinkers tend to focus on one manifestation of this ignorance: the inveterate tendency to identify a part of the world as one's self. This delusion is the primary component of the self-centered anxiety characteristic of unawakened existence. Accordingly, to be liberated from samsara is to become selfless. This selflessness need not translate into a moral concern for others. The hero of the *Bhagavad Gita*, for example, manages to reconcile one kind of selflessness with his duty, as a warrior, to slaughter his own kinsmen. Nonetheless, selflessness, in combination with other virtues, is often considered an integral part of such moral concern.

Especially important here is ahimsa (nonviolence), a virtue thought to bear, not just upon interhuman relations, but also upon the treatment of all sentient beings. A commitment to ahimsa is evident in much Indic thought: in the Buddha's objections to the ancient Brahmanical practice of sacrificing animals; in the famous edicts issued by Aśoka, the environmentally conscious king of the third century BCE; in the *Upanishads*, the *Laws of Manu*, and the epic poem *Mahabharata*; and, in the twentieth century, in Mahatma Gandhi's advocacy of vegetarianism and Ernst Friedrich Schumacher's "Buddhist economics." For Jains in particular, the imperative not to harm any living thing, even plants, is sacrosanct. Even when accidentally caused, such harm is regarded as morally wrong and as a source of bad karma.

It must be stressed that justice is not the model here, and the rhetoric of animal rights is inappropriate. References to ahimsa often seem to appeal instead to an empathic sense of kinship with nonhuman beings. All sentient beings, it is said, are like us in desiring an end to suffering, and we should therefore treat them as fellow sufferers, rather than as enemies or resources. Such views are particularly important in Buddhist traditions—in accounts of compassion, for instance, or of *maitri*, the wish that all sentient beings, human and nonhuman, be content.

FORMING ONE BODY WITH HEAVEN AND EARTH

To understand Chinese philosophical traditions, it is important at the outset to note that the idea of a creator-god is alien to such traditions, as is the notion of a God's-eye perspective from which the world may be regarded with flawless objectivity. Instead, Chinese thinkers tend to regard the world as an inhabited realm, imbued with living meaning and significance. In line with this broad conception, the soteriological thrust of Chinese philosophy is to determine how best to inhabit the world. And the general answer to this question is that one should live in harmony with the Way (*Dao*) of things.

What, then, did Chinese thinkers have to say about the natural world? The classical Confucian sages, including Confucius (551–479 BCE), had little to say, being more concerned with human self-development and politics. More of interest can be found in the writings of Neo-Confucian thinkers, such as Wang Yangming (1472–1529), who sought to use the rather fragmentary remarks of Confucius and other classical thinkers as the basis for a systematic philosophical system. A central theme of Neo-Confucian thinkers is metaphysical holism. For them, the cosmos is a dynamic, organismic whole, unified by *qi*, a psychophysical element generated in the cosmic struggle between two all-embracing principles: yin (symbolizing passivity, darkness, coolness, wetness, etc.) and yang (symbolizing activity, brightness, heat, dryness, etc.).

The concepts of *qi* and *yin-yang* indicate a commonality between humanity and nature, one so intimate that a *yin-yang* imbalance in a person's mind could, it was said, reverberate, by a *qi*-mediated cosmic resonance, in the natural world. This provided the metaphysical basis for the many tales of wicked rulers inadvertently triggering natural disasters, and also for Chinese geomancy (*fengshui*) and beliefs in the miraculous powers of animal parts.

Chinese conceptions of the unity of humans and nature also find expression in the key Chinese idea that living a good life involves assuming an appropriate relation

to the cosmos as a whole. Thus Wang Yangming maintains that to cultivate the key virtue of humaneness (*jen*) is at once to develop fellow feeling for animals and even plants. Similarly, if rather more grandly, Mencius (c. 371–c. 289 BCE) claims that the superior person, free from material desires, cultivates a "flood-like" *qi* within himself, and so fills the space between Heaven and Earth. Heaven and Earth are obscure concepts and cannot be explained here. Suffice it to say that for Mencius the ideal of human existence is to effect a kind of unity between oneself and the rest of the cosmos, to "form one body with Heaven and Earth." Modern scholars have looked to such ideas to develop a specifically Confucian model of environmental concern (see, for example, many of the essays in Tucker and Berthrong 1998). Such are the green, or environmental, tendencies in Confucian philosophy.

NATURAL HARMONIES

These tendencies are even more pronounced in another major tradition of Chinese thought: Daoism. Like Confucians, Daoists emphasize the practical benefits of living one's life in harmony with the Way, but whereas classical Confucians tended to conceive of the Way on the model of a strict social hierarchy, Daoists regard it as spontaneous, free, and inherently opposed to any sort of regimentation. Hence the hidebound Confucian sage is popularly (if somewhat unfairly) contrasted with the freewheeling Daoist, the former at home in the civil service, the latter at home on some mist-enshrouded crag, removed, both literally and metaphorically, from the straitjacket of social convention.

The exact nature of the Way is hard to describe (impossible, according to the opening line of the *Daodejing*). Provisionally, it may be conceived of as a mysterious force that is the source of all things and yet intimately related to them, not transcendent and Godlike. It is said to be flexible and malleable, like water, making its way by taking the path of least resistance. In the *Daodejing*, one in tune with the Way is said to go with the flow, his action being "nonaction" (*wuwei*)—selfless, malleable, unforced, and so on. This is the action of the woodcarver working with the grain of the wood or of the gardener sensitively responding to the turning of the seasons. Such a person is said to be unburdened by material concerns and so able selflessly to appreciate things, to "let them be," as Martin Heidegger, a twentieth-century admirer of Daoism, put it.

Such claims remind one of Buddhist ideals, and indeed there are similarities between the two traditions. Nonetheless, Indic and Chinese traditions remained, in many respects, quite different—so different, in fact, that Chinese Buddhism, which took root in the first centuries of the Common Era, grew in ways that arguably would have been unthinkable in an Indic context.

One of the main differences between Indic and Chinese Buddhist philosophy concern the spiritual significance of the natural world. As we saw, Indian Buddhist teachings tended to portray the natural world as the realm of *duhkha*; it might provide a fitting object for meditation, but it had little value in itself. Chinese Buddhists, by contrast, have traditionally regarded nature in a more positive light. This was due in part to the influence of Daoist and Neo-Daoist thought and in part to the East Asian attraction to (and adaptation of) certain Buddhist teachings. So in time the claim of the Indian *Mahaparinirvana-sutra* that all sentient beings have the potential to realize nirvana was transformed into the more radical teaching that even mountains, rivers, and streams are manifestations of the Buddha nature (see LaFleur 1989). Likewise, if, as the great Indian philosopher Nagarjuna (150 CE–c. 250) claimed, there is not a hair's breadth between samsara and nirvana, then, Chinese thinkers noted, there is no need to seek awakening in some other realm. As Zen teachers say, whatever one seeks is here in this world.

These ideas fostered a climate in which nature could be regarded as aesthetically valuable. To be sure, the green credentials of East Asian thought have often been exaggerated, and it is true that nature as revealed through East Asian art tends to be insufficiently wild for the tastes of Western environmental thinkers. However, there can be no doubting the power and importance of nature motifs in the *haiku* poetry of Bashō (Matsuo Munefusa, 1644–1694) or the ink and wash landscapes of Sesshū (1420–1506).

CONTEMPORARY WORK

Deep ecologists and other radical environmental thinkers have lauded the virtues of such Asian philosophical traditions as Advaita Vedanta, Daoism, and Zen. And their work has been joined by a deluge of books from environmentally minded apologists for Asian religions. There is no shortage of books extolling the green credentials of Buddhism, Daoism, and (more rarely) Confucianism and Hinduism.

Some of this work is well argued and compelling, but much, unfortunately, is of poor quality. All too often one comes across claims to the effect that a particular Asian tradition (Daoism, say) endorses some form of metaphysical holism (typically, the notion that all things are interconnected), and that it should therefore be regarded as a precursor of modern environmental thought. Such arguments should be treated with caution. On the one hand, they tend to rest on untenable interpretations of the tradition in question, interpretations that reflect little more than the author's own philosophical commitments and peculiarly romantic conception of Eastern thought. On the other hand, they tend to presume that the possession of certain features automatically

qualifies a particular view as green or environmental. Why, for instance, should seeing everything as interconnected necessarily engender environmental concern? And what, moreover, is meant by "environmental concern"? A concern for the welfare of individual sentient beings? For species? For the environment as a whole? Clarification is needed, but rarely provided.

The best writers in the field, by contrast, presume neither that Asian philosophical traditions are environmentally friendly, nor that they are not. Instead, they seek to foster dialogue: to learn from Asian philosophical traditions, but also to engage critically with them. In such work there is much of value for philosophers and environmental thinkers alike.

ATMOSPHERE

Along with earth, fire, and water, the ancient Greeks considered air one of the four elementary substances in the universe. It is known that air, or, more accurately, the Earth's atmosphere, is not an element but a mixture of gases that has changed in chemical composition over time in a way that has made human beings and other forms of life dependent on it for their existence. Scientific knowledge of the atmosphere helps inform environmental ethicists in their analyses of the moral consequences of human activities that cause global climate change, acid precipitation, and depletion of the ozone layer.

HISTORY OF THE ATMOSPHERE

Over the course of the approximately 4.6 billion years of the history of the Earth the chemical composition of the atmosphere has changed as a result of both planetary geology and the evolution of life. During its initial formation the atmosphere consisted primarily of helium (He) and hydrogen (H). Later in the development of the Earth extensive volcanic activity released gases such as water vapor (H_2O), carbon dioxide (CO_2), carbon monoxide (CO), sulfur dioxide (SO_2), ammonia (NH_3), chlorine (Cl), and hydrogen into the atmosphere. At that time, there was no free oxygen (O_2) in the atmosphere and thus no life as it is known today.

Beginning over three billion years ago, cyanobacteria (blue-green algae) evolved; that led to changes in the Earth's atmosphere because the bacteria were able to use the relatively high levels of carbon dioxide and water in the early atmosphere in the presence of sunlight to manufacture glucose (sugar), which they used for their metabolic needs. As a by-product (or pollutant), oxygen was released into the atmosphere, and over time its increasing levels enabled the evolution of organisms that used oxygen to break down glucose and provide for their energy needs. Consequently, the increasing levels of oxygen were critical to the evolution of oxygen-breathing life.

To understand how human actions change the atmosphere and affect environmental and human well-being, it is necessary to know something about the current chemical composition and layers of the atmosphere. The atmosphere consists of nitrogen (N_2) (78 percent), oxygen (21 percent), water vapor (0.0–4 percent), carbon dioxide (0.0003 percent), methane (CH_4) (trace levels), sulfur dioxide (trace

levels), ozone (O_3) (trace levels), nitrogen oxides (NO and NO_2) (trace levels), and other gases that are present in trace levels. Atmospheric layers consist of the troposphere (up to about 18 kilometers [km] from the surface of the Earth), which is where the weather experienced on the planetary surface takes place; the stratosphere (about 18–38 km); the mesosphere (about 38–80 km); and the thermosphere (about 80–120 km). Within the stratosphere at an altitude of about 20 to 50 km is an ozone layer. The concentrations of the various chemicals vary with the different atmospheric layers.

EFFECTS OF HUMAN ACTIONS

With respect to human actions on the atmosphere that affect environmental and human well-being, it is the changes in the chemicals other than nitrogen and oxygen that are the most important, as can be seen in the following three examples.

Largely as a result of human activities such as the combustion of fossil fuels and, secondarily, changes in land use, humans are changing the global climate system. These activities result in emissions of carbon dioxide, methane, nitrous oxides, and other gases into the atmosphere that alter the balance of heat stored in the Earth-atmosphere system. Most visible sunlight passes through the atmosphere without being absorbed by it and hence warms the surface of the Earth. The surface emits infrared radiation (heat energy) back to the atmosphere, some of which is absorbed by those gases and some of which is reradiated into space. The balance between incoming solar radiation and outgoing infrared radiation is a primary factor in the Earth-atmosphere temperature. The gases that absorb heat energy in the atmosphere that has been reradiated from the planetary surface are known as greenhouse gases because their buildup in the atmosphere causes a warming of the Earth-atmosphere system, similar to the way the glass roof of a greenhouse admits light and traps heat. In turn, human-induced warming from activities that emit greenhouse gases causes adverse impacts on natural resources and processes on which humans depend and on human health and welfare.

Examples include changes in temperature, precipitation, the distribution and productivity of agricultural crops and forestry products, increased flooding, the distribution and productivity of fisheries, rising sea levels, species extinction, and the incidence of human diseases.

Some chemicals from human activities decrease the amount of ozone in the stratosphere, primarily over the Antarctic but increasingly over the Arctic as well (the "ozone hole"). The most common examples of ozone-depleting chemicals are the chlorofluorocarbons that were used in refrigeration systems and air conditioners, the production of plastic foams, and the manufacture of solvents for cleaning electronic components. One of the major problems caused by stratospheric ozone depletion results from the fact that this ozone absorbs ultraviolet light from space and therefore helps protect humans and other forms of life from skin cancer induced by ultraviolet light.

Chemicals such as sulfur and nitrogen oxides released into the atmosphere can be converted by chemical reactions into sulfuric (H_2SO_4) and nitric acids (HNO_3), respectively. By far, most of the elevated atmospheric levels of sulfur and nitrogen oxides are the result of human activities such as the combustion of oil, coal, and gas. Environmental problems caused by releases of sulfur and nitrogen oxides include a lowering of pH (increased acidity) in some aquatic ecosystems, which affects the reproduction and survival of fish and other aquatic organisms, as well as causing releases of toxic metals into water that otherwise would be chemically bound to soil particles and hence can accumulate to toxic levels in organisms. Human health problems caused by releases of sulfur and nitrogen oxides result primarily from the fact that the oxides form small particles that are transported long distances by wind and, when inhaled into deep lung tissue, cause increased illness and premature death from heart and lung disorders such as asthma and bronchitis.

Human activities that cause global climate change, stratospheric ozone depletion, and releases of sulfur and nitrogen oxides create ethical problems for several reasons. Relevant to any discussion of atmospheric changes caused by human activities is the fact that developed nations historically and currently emit the vast majority of chemicals causing such changes. For example, with about 5 percent of the world's population, the United States emits about one-fourth of the annual emissions of greenhouse gases, although that proportion is dropping as other nations industrialize. Many impacts will not be uniform across the Earth; regions in high latitudes are projected to incur disproportionate impacts. Further, poor nations and individuals that are the least responsible for emissions of the chemicals that have adverse impacts are less able to adapt to those impacts. Finally, global climate change will affect future generations to a greater degree than the present generation.

AUDUBON SOCIETY

Sometimes referred to as the "gray lady" of the conservation movement, the National Audubon Society is one of the oldest and most influential environmental organizations in the United States. Founded in 1905 by a group of citizen-activists intent on preventing the killing of birds, the society has since expanded its mission to include the conservation and restoration of natural ecosystems. Although its members have not always agreed on how best to achieve that mission, its programs have usually reflected a broad consensus that nature has aesthetic, cultural, and scientific value to humans as well as some form of intrinsic value.

The early Audubon movement emerged when a network of scientists, hunters, homemakers, businessmen, and government employees became concerned about the declining populations of birds in the last decades of the nineteenth century. Although bird losses were the result of many factors—including habitat destruction, sport hunting, subsistence hunting, and egg collecting—early bird protectionists channeled most of their energy into eliminating market hunting, which was both the principal cause of bird deaths and the easiest to address. Market hunters shot birds to sell to restaurants, hotels, and wholesalers as food and to sell to the fashion

George Grinnell. *George Bird Grinnell (1849–1938), an American naturalist, founded the Audubon Society in 1886, after the famous painter of birds, John James Audubon. Within a year the society had approximately 39,000 members.*

industry as ornaments for women's hats. (The plumes of herons and egrets were especially valued as decorations.)

Scientists were among the first to take up the cause, forming the American Ornithologists' Union (AOU) in 1883 and quickly creating a bird protection committee. In 1886 the naturalist and writer George Bird Grinnell (1849–1938) founded an auxiliary to this committee for the general public, and he called this new group the Audubon Society, naming it after the American ornithologist John James Audubon (1785–1851), whose anthropomorphic bird paintings helped viewers see individual birds as worthy of respect. Although Grinnell's society folded in 1888, its closing was a portent of future success—Grinnell was unable to keep up with the nearly 50,000 requests for membership he received in less than three years.

In 1896 the Audubon movement was revived by Harriet Hemenway (1858–1960), a prominent Bostonian, and her cousin Minna Hall (1851–1941), who founded the Massachusetts Audubon Society to deter their fellow socialites from wearing plumes. Their concerns were quickly taken up by upper-class women in other states, who formed their own societies in collaboration with male ornithologists and sportsmen. By 1905, by which time thirty-six state Audubon societies had formed, the groups had joined together to become the National Association of Audubon Societies, and in 1940 this association became the National Audubon Society. (For complicated reasons, many state Audubon societies remain unaffiliated with the national organization, including those in Massachusetts, New Hampshire, Rhode Island, Connecticut, Maine, New Jersey, and Washington, D.C.)

Early advocates of reform pursued a dual strategy of legislation and education that proved remarkably effective. On the legislative front Audubon members lobbied for passage by the states of a "Model Law" drafted by the AOU that forbade the shooting of nongame birds. They also pushed for federal legislation that made such prohibitions uniform throughout the nation, a goal they achieved in part with the passage of the Lacey Act of 1900 and in full with the Migratory Bird Treaty Act of 1918. Although these legislative successes were largely the work of men, Audubon women were at the forefront of the movement's educational efforts, publishing pamphlets, developing slide lectures, sponsoring contests, creating circulating libraries, and organizing junior Audubon clubs. Women also provided much of the content for *Bird-Lore* (which later became *Audubon*), the bimonthly magazine begun by the ornithologist Frank M. Chapman (1864–1945).

Another major component of Audubon's efforts was the preservation of habitats, which, the society recognized, were critical to the protection of birds themselves. After President Theodore Roosevelt established Pelican Island, a four-acre island near Vero Beach, Florida, as the first federal wildlife refuge in 1903, Audubon leaders paid the salaries of the refuge's first wardens. Two years later, when Guy Bradley, an Audubon warden on patrol in the Everglades, was murdered by a plume hunter, the need for such refuges became even more apparent. The society eventually created its own network of sanctuaries and community-based nature centers, beginning with the Paul J. Rainey Sanctuary in Louisiana and the Theodore Roosevelt Sanctuary on Long Island, both established in the 1920s. In addition, beginning in 1930s, Audubon began to fund research into particular species, including the ivory-billed woodpecker, the California condor, the roseate spoonbill, and the whooping crane.

After World War II the society experienced a period of rapid growth that was due in part to the transformation of *Audubon* into a glossy bimonthly under its editor, Les Line. Membership grew by some 300,000 in the late 1960s and early 1970s, and the society's mission

expanded as well. It helped to create the Environmental Defense Fund in 1967, enact a ban on DDT in 1972, and halt a plan to build the world's largest international jetport in the middle of the Florida Everglades. It also moved into television with *The World of Audubon* series and returned to children's programming with *Audubon Adventures.* As it continued to expand, the society became involved in most of the major environmental campaigns of the late twentieth century, including helping to save the California condor, lobbying for the preservation of the Arctic National Wildlife Refuge, and publicizing the plight of the northern spotted owl.

Audubon's growth has not been without controversy, particularly during the 1990s, when the society began to distance itself from its traditional focus on birds and their habitats and devote more of its energy to human concerns. Like the Sierra Club and other large environmental organizations, Audubon has also been criticized for taking corporate donations, neglecting issues of environmental justice, and centralizing programming at the expense of chapter involvement. After a period of upheaval, however, in 2001 the society revised its strategic plan to sharpen its focus on birds, reinvest in its grassroots structure, and recommit itself to education and advocacy. In 2008 the society had some 500,000 members in more than 500 chapters around the United States.

AUSTRALIA AND NEW ZEALAND

Environmental philosophy (EP) made a vigorous debut in Australasia in the early 1970s, when it began to emerge as environmental ethics in Europe and the United States. Initially the debates turned on value theory and on what came to be known as the deep/shallow divide: Does ethical concern pertain to nonhumans or humans? These alternatives have often been assumed—mistakenly—to be mutually exclusive rather than intersecting.

ATTRACTION AND EMERGENCE

Australian environmental philosophers have contributed in major ways on both the deep and shallow sides of this argument. Richard Routley, from the Australian National University (ANU), initiated the deep or radical side at the World Congress of Philosophy in Bulgaria in 1973, challenging European and North American traditions that accorded purely instrumental status to nonhumans. Arne Naess's "Deep Ecology" and Richard Routley's "Deep Green Theory" emerged as major brand names for this kind of "deep" position in the 1970s (Routley 1973).

In his 1974 classic, *Man's Responsibility for Nature,* John Passmore (also from the ANU), a leading historian of philosophy, argued in favor of the European–North American tradition, which he identified with rationality and science. In his view the primary moral community is confined to humans, with other species' welfare necessarily consigned to secondary, derived status at best. Passmore believed that a position considering only human interests could deal adequately with the environmental crisis; if instrumentalism, albeit in a more refined version, is all that is required, he considered it neither necessary nor desirable to challenge that tradition.

Instrumentalism was just what the radical social movements of that era questioned. If nonhumans, including rocks and trees, were of intrinsic value, directly and in their own right, then "human chauvinism" was no better than other forms of discrimination based on race of gender. Others, such as Don Mannison (1980), William Grey (1993), and Janna Thompson (1990), agreed with Passmore, finding metaphysical fault with the concept of intrinsic value and defending instrumentalism.

The concept and terminology of intrinsic value conflicted with the popular idea that values are entirely subjective and hence, many invalidly concluded, instrumental. Richard Routley and Val Routley (1979, 1980) and Plumwood (1991) argued that the idea that all value must be instrumental was logically incoherent and involved an infinite regress, because every instrumental position must assume a "base class" with noninstrumental (intrinsic or initial) value as the direct bearer of value. If every value position assumes a base class, the analysis and viability of intrinsic value itself cannot be the main issue.

The real problem turns on the assumption that the primary "base class," however analyzed, is limited to the human. Routley and Routley (1979, 1980) showed that the common argument for the assumption that the "base

class'' for ethical concern coincided with the human—that humans could consider only human interests—is a fallacy based on extending to species interest the same kinds of fallacious arguments traditionally advanced for the inevitability of egoism. There is no logical barrier to moving beyond human exclusivity and exceptionalism to the direct ethical consideration of nonhumans and their needs in sharing the earth. What really needs discussion is the ethical character and conception of the human and nonhuman (or ''nature'') as the contrast has been traditionally drawn.

A growing band of Australian and New Zealand philosophers argued against the instrumental tradition and for an expansion of ethics to a larger ethical community that includes at least some nonhumans (most notably, Eliot 1985, 1989; Eckersley 1992, 1998; Fox 1990; Johnson 1991; and Singer 1974). But they had diverse views about the extent and nature of that community. Peter Singer, in *Animal Liberation* (1974), argued for extending the ethical community to animals as sentient beings—an easy extension for utilitarianism, with its emphasis on pleasure and pain as the key variables. Singer's concept of ''speciesism'' drew a parallel to racism and sexism. But other antispeciesists (Routley and Routley 1980) found this approach too limiting for an environmental ethic, objecting that focusing ethical attention on just those nonhumans most resembling the human (e.g., in consciousness) implicitly concedes and extends the ethically privileged status of humans. Singer's utilitarianism makes sentience the basis for an absolute ethical positioning of all species within a hierarchy, based on humanoid consciousness norms. Consciousness is seen in singular and cut-off terms, in a way that discounts the great variety of forms of sentience and mind—hence Singer's repeated assertions that trees have no form of sentience or awareness and thus warrant no ethical concern. A position that regards forests and rivers as devoid of primary value is of limited help for environmental issues, except for those few that are reducible to human or animal welfare.

Other philosophers who rejected instrumentalism (e.g., Plumwood 1993, 2002) aimed not for a Singerian *extension* based on human norms but for an ethical *expansion* that recognizes a much larger, less humanized earth community, with an ethic of respect, reciprocity, and attention that rests on foundations that extend beyond sentience or even life. Consciousness is just one among many relevant differences among species, differences that are largely incommensurable with respect to value and not hierarchically ordered by degree of resemblance to the human.

DEEP SUSTAINABILITY: BEYOND THE DEEP/SHALLOW ARGUMENT

Deep Ecologists themselves were not without their own internal dissensions and critiques. Mathews (1991), Fox (1990), and Naess (1973) eschewed ethics as uninteresting and unviable, emphasizing instead concepts of identification and realization. Deep Ecologists saw anthropocentrism as a major problem, and, with the concept of ''ecocentrism,'' advanced an alternative ideal (Eckersley 1992) that was not, however, well elucidated or thought through. Critiques of hegemonic (or dominating) centrisms—for example, egocentrism, eurocentrism, androcentrism, and ethnocentrism—supply useful lessons for the critique of anthropocentrism (Plumwood 1996), but it is unclear how ecocentrism should situate itself as an ideal within or in opposition to these patterns of domination.

For ''deep'' pioneers of EP during the 1970s, the main issue was not human and biospheric sustainability but rather nonhuman biodiversity loss. Everything else, including concern with human sustainability, was considered ''shallow.'' Of course, the role of humans in the mass extinctions and ecological outrages must be high on agendas for ''the examined life.'' From the perspective of later ecological politics, however, the conventional deep/shallow dichotomy of early EP looks like a false choice. Human and nonhuman concerns are not exclusive; it seems essential to consider both in a deeper, more philosophical way that questions connections and basic assumptions.

A broader analysis of human-centeredness shows how the human and nonhuman problems are linked. Human-centeredness (analyzed in Plumwood 1993, 1996, and 2002) is a complex syndrome that includes the hyperseparation of humans as an exceptional, supreme species and the reduction of nonhumans to their usefulness to humans. Countering such traditions that deny human continuity with, immersion in, and radical dependency on the nonhuman world involves *both* situating nonhuman life ethically *and* situating human life ecologically—the concern of sustainability. Traditions of human hyperseparation and exceptionalism present problems for both sustainability and ethics, because they do not conduce to an understanding of how nature supports human life. Exceptionalist delusions of being ecologically invulnerable, beyond animality and ''outside nature,'' result in ''human communities [that] have lost any sense of their ecological foundations'' (Dryzek 1997).

''Deep'' analyses that challenge human-centeredness are relevant to the issue of human sustainability; they stress the limitations of human beings, regarding them as constrained both ethically and ecologically by the needs of the larger biospheric community. Humans' deep ethical failures toward other species and their ''shallow'' prudential failures of sustainability are not opposed considerations but are closely linked.

RECENT ECOPHILOSOPHY: CONTRACTION AND CONVERGENCE

The prestige of EP and the extent of the issues it addresses have both expanded considerably since the germinal years of the 1970s. EP now encompasses such areas as political philosophy, ethics (including social-justice ethics), the history of philosophy, moral epistemology, and metaphysics. Australasian philosophy has contributed notably in all these areas since the 1970s. Nevertheless, Australian environmental philosophy no longer holds the premier place it held globally in the 1970s and 1980s among new nonscience disciplines. It has faced neglect or hostility from conventional Australian philosophy and has lost disciplinary attention and priority. In the humanities its important projects of cultural critique have been picked up by emerging disciplinary stars: ecopolitics; ecoanthropology; and, in literature, ecocriticism.

Nevertheless, important EP contributions continue to emerge from Australasia, especially in moral epistemology, metaphysics, the philosophy of mind, and political philosophy (Eckerseley 1992, 1995; Dryzek 1997; Gare 1995; and Mathews 1991). The focus on sustainability entails the need to view humans as limited and responsible beings in the biosphere, and challenges the modernist reduction of the world that underlies the framework of excessive commodity consumption. Since the mid-1990s work in moral epistemology, philosophy of mind, and metaphysics has begun to converge with indigenous philosophy and ecoanthropology. Australian indigenous philosophy posits a meaningful, mindful, communicative land, and relations with it are at the center, not the margins of life. Indigenous concepts of place and time direct attention away from the future-directed, human-exceptionalist progress narratives of European and North American thought and toward origins and ancestors, human and nonhuman. This philosophical orientation opposes the reductive, materialist philosophy of mind that has dominated European and North American philosophy and science since the Enlightenment.

Plumwood (1993, 1998, and 2002) argues against reductive materialism and for an ecological, animist concept of materiality that legitimates a richly intentional description of the world of the sort found in indigenous thought. Plumwood (1993) has distinguished between weak and strong forms of panpsychism, where the strong (deist) form assumed a humanlike, singularistic consciousness permeating the world, and the weak or animist form saw a world of multiple, dispersed intentionalities (traditionally the mark of the mental) expressing great diversity in forms and kinds of mind.

Freya Mathews (2003, 2005) also challenges this reductionism, which treats the world as an inert backdrop to the human presence rather than as a communicative presence in its own right. Mathews (2005) links the environmental crisis to a metaphysical crisis, exploring the disasters of the reductionist worldview in situated reflections on self and world, land and place. From a Spinozist position Mathews rejects materialism and embraces panpsychism as an expanded concept of mind that applies to the nonhuman world. Mathews distinguishes encounter from knowledge, viewing the former as a dialogical project that calls for response from the latter and that requires recognition of the interior or subjective dimension of matter; on this view, rationalist knowledge is materialist, reductive, instrumental, and oriented to prediction and control.

In contrast, Plumwood (1993, 2002) situates her thought within a reformed materialist tradition, dismissing traditional spirit/mind concepts as freighted with dualistic baggage. She distinguishes an ecological, animist materialism that recognizes creative, intentional matter from a reductive materialism that minimizes material creativity and denies narrative agency and intentional description to the nonhuman world. For Plumwood (1993, 2002) understanding the logic of dualism or binary opposition makes another materialism visible. Reductionism involves a reversal that assumes an original dichotomy between spirit and matter in which the "higher" side, the driver (mind, spirit, deity) is eradicated and the "lower" side, the driven (body, materiality) is affirmed instead—without, however, the fuller rethinking of materiality required for a proper resolution of the original binary antinomy. To the extent that the materialism of modernity involves negating agency and narrative, it is not a bold new beginning, as it claims, but is haunted by its lost former half. For an ecological, intentional, animist materialism, the material world is always already full of mindful nonhuman agents and narratives. For Plumwood, as for Mathews, the task of human rationality is not the instrumental one of reduction but the dialogical one of recognition and communication.

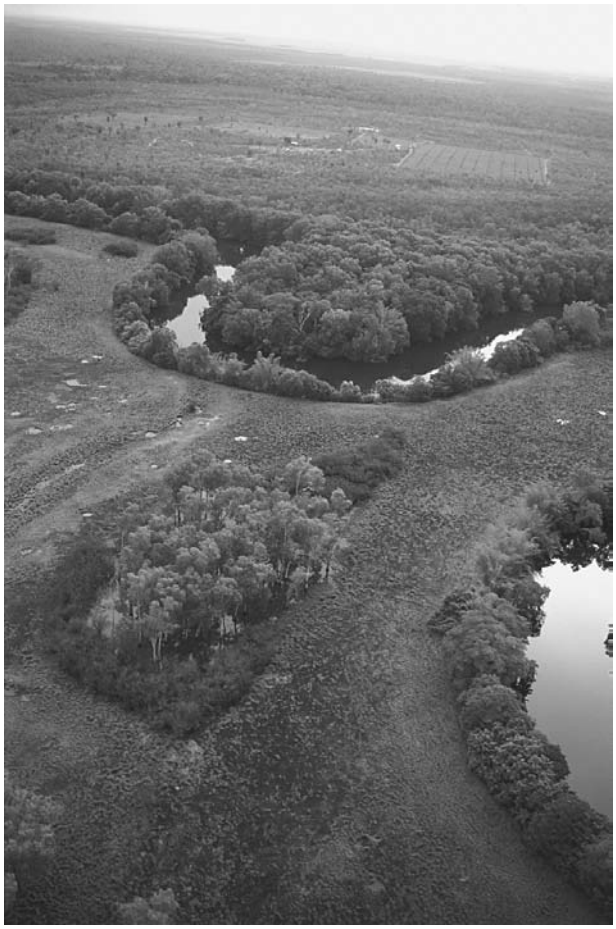
AUSTRALIAN ABORIGINES

Human beings have inhabited the continent of Australia for at least forty thousand years and perhaps for as long as sixty thousand. Anglo-Celtic settlers began arriving at the start of the nineteenth century, and since that time the population of newcomers has diversified and expanded greatly. Colonization entailed dispossession for most Aboriginal Australians, but there are many indigenous people who continue to live on or near their homelands and still hold to the ecocosmology of their forebears as well as, wherever possible, working with it in their country. Knowledge of Aboriginal environmental philosophy is the product of dialogue between indigenous people and settlers. The essence of indigenous philosophy is captured in the phrase "taking care of country." Care of country is an ecocosmology that encompasses ethics, philosophy, religion, a way of life, a set of practices, and a system of ecological knowledge.

Australia is the driest inhabited continent. Throughout the ice ages and during the warmer periods between them, in the face of the rising and falling of sea levels and increasing aridity and wind, people remained. There were no ice caps to force people away, and during the driest periods people remained even in the inland deserts. The contemporary climate is one of the most unpredictable in the world. Aboriginal Australians lived by hunting and gathering; this was a continent of foragers.

ABORIGINAL LIFE WAYS AND TECHNOLOGY

Australian Aboriginal people were nomadic, traveling regularly through their territory (known as country), following the water, the maturation of plants, and the movement of animals. Their material technology was kept to a minimum, with an emphasis on multipurpose tools. The *coolamon*, for example, is a large, shallow, oval wooden bowl. It was and is used as a baby cradle, for carrying food and other items, for winnowing and sorting



Finniss River and Paperbark Trees. *Bends in the Finniss River are the track of the Rainbow Serpent, one of the major Dreamings in this area. The habitat mosaic so evident in this photo is in part the result of Indigenous fire ecology. Country in the foreground is Aboriginal Freehold; in the distance is Settler Freehold with its grids for industrial agriculture.* **© SHARON D'AMICO/D'AMICO PHOTOGRAPHY LLC.**

seeds, and in food preparation. It is symbolic of women and figures in creation stories and songs, and in ceremonies. Populations were kept in balance with the resources of country. The major technology for living in those demanding habitats was knowledge. Carried in the mind, performed in ritual, and taught in song, story, design, and sacred objects, knowledge was the major means by which people achieved their long-term ecological, intellectual, emotional, and spiritual adaptation to country.

TOTEMISM: THE POETICS OF CONNECTIVITY

The term *Dreaming* has several referents. It includes the original creators and their actions, and the Law they established, including ecological organization, human groups, languages, territories, songs, rituals and totemic (multi-species) groups. Creation takes place both in the past and in the present. W. E. H. Stanner (1979, p. 24) coined the term *everywhen* in relation to the temporal aspect of Dreaming. Creation stories vary across the continent, but in general they concern the travels and actions of the Dreamings who walked the earth, making the places, countries, living beings, and cultures and ecosystems. All across the land the Dreamings made a world of form and difference. Countries, languages, peoples, species, cultures, landforms, plant communities, and sources of fresh water were all organized by Dreamings.

Dreamings created countries that are the homes for human groups, distinctive plant and animal communities, and the landforms that sustain their lives. A country is small enough to be known intimately and large enough to support its people. It is separate from other countries and is never subservient to another country. Countries are connected to one another through numerous relationships; none is isolated. Dreamings were the ancestors of kin groups that include both human and nonhuman descendants. For example, the kangaroo Dreaming ancestor founded groups of kin (clans) made up of kangaroo people and kangaroos, and the emu Dreaming ancestor founded emu groups of kin. People's primary responsibilities are to their country and their human and nonhuman kin.

Aboriginal Australian ecological poetics are sensuous and are embedded in specific localized knowledge. People say that their country calls them to action: They know the messages; they listen, smell, see, understand, and respond. Many people have an encyclopedic knowledge of the plants and animals of their country, the habitat requirements of the plants, the food and other habitat requirements of the animals, ways to interpret the animal and other tracks and traces of life in the land, and the symbiotic communities that enable many forms of life to flourish over time.

The care and nurturing of ecosystems express two major propositions about the flourishing of life in this created world. The first is that a country and its living beings take care of one another. This proposition asserts that relationships of care are reciprocal. To take care of one's country is to take care of the conditions by which that country can continue to provide sustenance for living things, including the people who belong to and care for the place.

The second proposition, which follows directly from the first, is that those who destroy their country ultimately destroy themselves. Attentiveness to the needs of living things pervades this ethic of care. The foods, habits, breeding requirements, behavior, and signs of stress of other living things are known, observed, and

responded to. For example, hunters look inside a dead animal to see what the animal has been eating, for this is a significant sign of the well-being of both individuals and species in the country, and people adjust their hunting accordingly.

Ecological knowledge is coded into iconography, song, and story; a great deal of myth and ritual articulates ecological knowledge for a particular country. The conventional Western division between practical action and religious action breaks down in practices of care. One of the best documented examples of the convergence of practical and religious action is the Dreaming track demarcating the travels of the red kangaroo in central Australia. This track traverses some of the most forbidding desert country in the world, and the sacred sites coincide with favored areas for kangaroos. The Dreaming sites are protected by numerous restrictions on human activity, and kangaroos also are protected at those sites. These are places to which kangaroos retreat during periods of stress where they are safe from human predation and from which they expand outward again during periods of abundance (Newsome 1980). Such ties combine ecological refugia with restrictions on human hunting, thus preventing overhunting.

FIRESTICK ECOLOGY

During much of the nineteenth and twentieth centuries, when European peoples were colonizing and settling Australia, the predominant view was that Aboriginal people were parasites on nature. For several decades that view was put forward explicitly by A. P. Elkin (1954, p. 15), one of the most respected and widely read anthropologists of the day. That view has been overturned. The evidence shows that Aboriginal people were active participants within the ecological systems that were their homes. Research into how Aboriginal people care for country, including fire ecology, dates from the 1960s (Jones 1969). Looking at the continent as a whole, it is evident that Aboriginal people's fire ecology is responsible for the open grasslands that covered much of the continent, the preservation of specific stands of fire-sensitive vegetation such as acacia and cypress and remnant rain forests, and the maintenance of a mosaic of microecological niches that enable a wide diversity of life-forms to flourish. Burning, along with a variety of other methods, is responsible for the protection of refuges, including breeding sanctuaries, and the preservation of permanent sources of water in arid environments. In addition, Aboriginal people's actions are directly responsible for the distribution of many plants and probably for the distribution of some fauna, such as freshwater crayfish.

Research into Aboriginal life is in an early stage; it has been assimilated unevenly and sometimes crudely. Not long ago there was debate about whether Aboriginal people actually engaged in firestick ecology; today it generally is accepted that they consciously managed large portions of the continent through the use of fire. Indeed, some of their principles have been incorporated into Anglo-Australian land management. Scholars continue to discuss the exact purposes that Aboriginal people have in mind when they are caring for country, but on the evidence of Aboriginal people, one of the most frequently expressed motives for burning is to "make things good for everybody" (April Bright, quoted in Rose 2002, p. 51).

All over Australia, when Aboriginal people speak English, they describe their burning practices as "cleaning up the country." There is a well-defined aesthetic:

Setting Fire to the Land. *Margaret Daiyi, White Eagle Clan (Rak Mak Mak) Elder, is lighting a fire to take care of an area of paperbark (*melaleuca sp*). As the smoke rose the firebirds came circling around looking for the animals and insects that would run from the fire; following the fire, the small swamp continued to hum with the life of insects and lizards, and with the undergrowth cleaned up, the herbivores could travel easily into the area and were enticed by the new green growth.*

Country that has been burned looks cared for and clean. According to April Bright, whose home country is in the floodplains of tropical Australia, "If we don't burn our country every year, we are not looking after our country." Not all country in Australia requires burning every year, but the underlying logic is widespread: "It is part of our responsibility in looking after our country. If you don't look after country, country won't look after you . . . The country tells you when and where to burn. To carry out this task you must know your country. You wouldn't, you just would not attempt to burn someone else's country" (Bright, quoted in Rose 2002, p. 51).

The timing of fires varied across the continent, depending on local factors, including terrains, vulnerable species, weather patterns, and patterns of regrowth. In light of the diversity of ecological niches, from the temperate rain forests of the southeast to the arid deserts of the interior and the monsoon savannas and floodplains of the north, the outstanding fact of Aboriginal firestick ecology is that everywhere people attempted to sustain a similar landscape pattern. The desired pattern was a mosaic of vegetation in various stages of recovery from fires, a reduction of combustible material that could fuel wildfires, and, where possible, sufficient stands of tall vegetation for hunters to hide behind. In ecological terms, Aboriginal burning produced habitat diversity with numerous edge zones and thus sustained conditions that were extremely favorable to biodiversity.

PHILOSOPHY

In 1999 the Aboriginal philosopher Mary Graham wrote about the "Philosophical Underpinnings of Aboriginal Worldviews." She identified two basic precepts that are both simple and complex: "The Land is the law" and "You are not alone in the world."

These two precepts can be understood as an indigenous ethic of connectivity. The second precept situates humans as participants in a larger living system. The first requires humanity to recognize and submit to the law of the living world.

Graham uses the term *land*—much as did Aldo Leopold—in a way that includes water, plants, animals, indeed the whole of what people tend to call the natural world. Her precepts are not human-centric. She explained her ideas more deeply, writing: "The two most important kinds of relationships in life are, firstly, those between land and people and, secondly, those amongst people themselves, the second being contingent upon the first. . . . [A]ll meaning comes from the land" (Graham 1999, p. 106).

Many of the mental, emotional, and spiritual values of home country are expressed in reference to flora and fauna that are of localized distribution, are common enough to sustain life, and have become synonymous with love, memory, longing, and hope. The daily practices of nurturance, sharing, and kinship, along with songs, designs, rituals, and connections with Dreamings and more immediate ancestors, all speak to an emotional and spiritual domain called home.

As the global climate system shifts into greater levels of uncertainty and as human beings in the developed world struggle to find an ethic of connectivity and accountability, Aboriginal philosophy refers to important truths. The archaeological record in Australia shows long periods of human stability sustained against an environmental history of change and exceptional uncertainty. Aboriginal languages do not have a term equivalent to *sustainability*, but Dreaming comes close in one respect. Dreaming creation was meant to endure, and lives lived according to the precepts Graham discussed promote abiding values and flourishing ecosystems.

The late David Burrumarra, a senior figure in Arnhem Land (north Australia), attempted to bring Aboriginal ecocosmology into Anglo-Australian thinking. In a paper titled "The Totemic Embrace" he sought to impress on all people, not only Aboriginal people, the idea that they must live for the totem, not just make a living from it. To live for others in the knowledge that that kind of life becomes a life that nurtures both self and others constitutes the heart of Aboriginal ecocosmology.

AUTOMOBILES

Since their invention in the late nineteenth century, automobiles have come to play a pivotal role in the everyday lives of people and have gone on to shape nations and their economies. In 2000 one in nine of the world's 6.1 billion people owned an automobile, and this statistic is growing annually. Until the first decade of the twenty-first century, automobiles have been perceived as a largely benevolent and positive influence on society, bringing independence, convenience, and speed to those who owned and used them. As such they became a sign of economic growth in the societies where they prevailed.

Most people see automobile use not as a matter of good or bad, but as an indispensable aspect of everyday life. However, the environmental, social, and economic costs of automobile use have become more obvious and acute since the 1960s, and the moral problems relating to their use need to be considered on the individual and collective levels.

Hybrid Automobile in Japan, 2007. *As automobile use continues to increase, along with knowledge of its detrimental effects on the environment, manufacturers are looking for ways to reduce negative impact. On a test course in Tokyo, individuals can drive a prototype of a Toyota Motor plug-in hybrid, which runs on chargeable batteries.* **TORU YAMANAKA/AFP/GETTY IMAGES.**

ENVIRONMENTAL IMPACTS

Automobiles cause environmental problems from their manufacture, use, and disposal. The construction of automobiles requires large amounts of raw materials, including metal, glass, plastic, and rubber, and their actual assembly involves large-scale energy use, with considerable pollution as a byproduct.

During use, automobiles consume oil, and this stimulates demand for oil drilling, extraction, refining, and transportation. The geographical distribution of oil gives rise to international disputes over territory and access. Questions over the future availability of oil could escalate such tensions. Peak oil, the point at which half of all the oil that has ever existed in the world has been extracted (the most accessible half), is thought to have occurred between 2000 and 2008. As oil becomes scarcer, prices will rise, and more intense international political skirmishes are likely to follow. This raises significant ethical issues as well as practical problems for an oil-based global economy.

Once in use, automobiles produce over 1,000 pollutants, including carbon monoxide, sulfur oxides, nitrogen oxides, and particulates, all of which damage the local environment and people's health. Asthma, bronchitis, and cancer are the main diseases associated with these types of pollution.

The issue of climate change and the contribution of transportation to greenhouse gases, particularly carbon dioxide, have come to dominate discussions about transport-related pollution. Since light-duty vehicles account for half the global transport sector's emissions of carbon dioxide, automobile use is clearly an important factor in this worldwide problem. Even at the end of their lives, automobiles continue to pollute, with each discarded vehicle containing an estimated 6 quarts of oil, 3 quarts of fuel, 5 quarts of cooling fluid, and 3 quarts of sulfuric acid.

In Los Angeles, over two-thirds of land space is primarily for automobile use. American suburbia exemplifies the interdependence of urban development and automobile ownership, and represents a way of life that promotes and depends on universal car ownership. Even this pro-automobile infrastructure struggles to cope, and traffic congestion in the United States is estimated to cost $60 billion a year.

Although the landscapes of European countries are less dominated by the automobile, the years since 1995 have seen many road-expansion schemes being targeted by environmental protesters, with land take, habitat destruction, traffic growth, noise, and air and water pollution being the key concerns. John Pucher and colleagues (2007) describe motorization rates in China and India as skyrocketing, with a fivefold increase in private-car ownership in China between 1991 and 2003 and a doubling during the same period in India. This growth has been matched by parallel increases in traffic-related deaths and injuries, as well as in noise and air pollution. Since these ownership figures still represent a rate of only 10 and 7 cars per 1,000 population respectively (compared to 745 per 1,000 in the United States and between 500 and 650 per 1,000 in European countries), the potential for further growth is huge, and the threat to the global environment immense.

DEATHS AND INJURIES

Each year 1.2 million people die, and 50 million people are injured, in road accidents. Moreover, 500 million people

are either directly or indirectly affected by road accidents at an annual global cost of $500 billion. The inequity of the distribution of these deaths and injuries is also an issue. Around 90 percent of these deaths are in developing countries, and most deaths and injuries are inflicted on pedestrians, cyclists, poor people, and children (Grayling et al. 2002). Automobile use, it would seem, can no longer be regarded as a benign aspect of society and must be seen as an activity that causes damage and destruction in many different ways across the globe. Because of the number of negative externalities and their inequitable distribution and impact, automobile use likely cannot continue to be regarded as a private matter.

As public awareness of these environmental and social impacts has grown, more debates on the ethics of automobile use have emerged. Many of these center on the tradeoff between private gain and public harm, perhaps most famously expressed by Garrett Hardin in his classic paper "The Tragedy of the Commons" (1968). Using the concept of Anglo-Saxon grazing commons, he argued that social welfare cannot be maximized by individuals looking after their own interests, because it is not possible for individuals to maximize their own interests without reference to the actions of others. Individuals freely pursuing their own interests will inevitably act in competition with each other, and the total effect of everyone's actions is that social welfare is reduced rather than maintained or enhanced. On the basis of this effect, Hardin made the case for social controls over the use of resources belonging to the commons.

The issue of personal freedom is at the core of many of these arguments, particularly since private-car use is typically seen as a symbol of this freedom. Julia Meaton and David Morrice (2001) used John Stuart Mill's theory of freedom to explore the ethics of private-automobile use. On the basis of Mill's distinction between self harm (activities that harm only oneself and therefore are not subject to societal control) and other harm (activities that harm other people and therefore are subject to societal control), they argued that a ban on private-car use is morally justified, although they concede that this is likely to be impractical.

Other ethical discussions center on the issue of choice. In a discussion on the case against the sport utility vehicle (SUV), Steve Vanderheiden (2006) argues that people can be held morally responsible for the negative consequences of their acts only if those acts are voluntary, informed, and avoidable. This adds to the confusion, since it is possible to argue that in an automobile-dominated society it is necessary to have a car and hence that the choice to own a car is neither voluntary nor avoidable, yet on the other side of the ledger it is difficult to argue that people are unaware of the ills associated with that behavior.

Religious leaders have become involved in the debate. In the United States the Evangelical Environmental Movement Network focused on the growing movement against special purpose vehicles and framed the choice of transport as a moral issue best resolved by asking, "What would Jesus drive?"—although that arguably might be better phrased as "Would Jesus drive?" In 2007 the Pope confirmed the issue of motoring as a moral issue and penned ten commandments for motorists, though these dicta focused on societal rather than environmental issues.

While widely differing opinions exist on the rights and wrongs of automobile use and on the responsibilities of governments and individuals, there is a growing consensus that more responsible behavior is a moral and environmental imperative. Examples of good individual behaviors include driving less, using public transport and nonmotorized forms of transport, and sharing cars. When automobiles are used, models with lower environmental impacts should be favored, and drivers should drive so as to be socially and environmentally responsible. Governments should institute policies that encourage such choices.

B

BACON, FRANCIS
1561–1626

Francis Bacon was born in London on January 22, 1561, and died of bronchitis on April 9, 1626. He attended Trinity College, Cambridge University, from 1573 to 1575—only two years, because of poor health. He was a lawyer, philosopher, statesman, essayist, and above all, master of the English language.

Bacon was unquestionably the most eloquent voice of Western modernity at the birth of the age of science, technology, and a quantitative economy. Galileo Galilei (1564–1642) asserted that the "book of nature" is written in the mathematical language of circles, squares, and triangles, and René Descartes (1596–1650) sought "clear and distinct ideas" based on a Galilean mathematization of nature. Bacon, in contrast, was a thoroughgoing empiricist. He advocated practical and efficacious applications of science for the sake of what he called the "love of humanity" (*philanthropia*), rather than scientific knowledge for knowledge's sake. Though Descartes and Bacon may have differed in scientific method, Descartes's view of humans as "masters" over inert, material, and mechanistic nature converges with Bacon's notion of *philanthropia*. The anthropocentrism of these two founders of modern science and technology has governed the spirit of Western science and technology and is now a dominant theme throughout the modern world. If anywhere, it is here that the intellectual and practical roots of the environmental crisis may be found.

Bacon master-minded and spearheaded an industrial civilization grounded firmly on scientific and technological advancement. In this he was an intellectual harbinger of the making of the modern world. He lauded the modern experimental and inductive method of science, and he advocated the convergence of theory and practice, the unity of knowledge and utility, and the inseparability of knowing and making—all for the sake of *philanthropia*. To create and apply technology, there must first be a knowledge of the world, obtained by what he called "the inquisition of nature." Nature must be "tortured" to reveal her secrets. Experiment is the essence of the natural sciences, because it is the only way of discovering the secrets of nature. By increasing knowledge through experiment, humans extend their dominion over inert nature. By positing utility as the end of knowledge, Bacon laid the foundation of humans' ability to "subdue and overcome the necessities and miseries of humanity." The framework of modern technology is set forth and justified when he insists on the meeting of human knowledge and power and discovers "in the womb of nature many secrets of excellent use." As Bacon himself emphasizes, the fruits of science do not grow in books.

In *The Advancement of Learning* (2000 [1605]), Bacon scorns the idea of studying words rather than matter, for "words are but the images of matter; and except [that] they have life of reason and invention, to fall in love with them is . . . to fall in love with a picture." In regard to the "degenerate learning" of the medieval Scholastics, he felt that they had "sharp and strong wits" and "abundance of leisure" in the "cells of monasteries and colleges," but that they knew little history of nature or "no great quantity of matter," and for that reason their "cobwebs of learning" produced "no substance of profit."

The idea of *philanthropia* is central to Bacon's philosophy of natural science. His short posthumous work

The Masculine Birth of Time (*Temporis Partus Masculus*; Farrington 1964), written in 1603 with the subtitle *The Great Restoration of Man over the Universe* (*Instauratio Magna Imperii Humani in Universum*), is fascinating and revealing. Bacon's conception of *philanthropia* is what contemporary environmental philosophers call anthropocentrism, pure and simple. This conception is predicated upon masculine humanity's absolute knowledge and mastery of nature, justified in terms of the Biblical mandate. The Bible mandates that nature, with "all her children," be bound and enslaved to serve humanity, to achieve "the fructifying and begetting of good" for humanity. The inquisition of nature leads to knowledge, and knowledge to technological power in the service of *philanthropia*. *Philanthropia* results from putting into action Christian duty and charity and proceeds to the worship of God. Bacon faults intellectuals who are indifferent to "the plight of mankind" and calls them "unholy" and "unclean." He wages a holy polemic in the name of Biblical religion in "Jerusalem" against allegedly wrong-headed philosophers in "Athens," whom he believes to be unholy "talkers." His Biblical call for *philanthropia* sacralizes humans at the apex of God's creation, while it desacralizes nature as a mass of inert matter. Carolyn Merchant (1980) criticizes Bacon's philosophy, especially its brazen sexism, as well as its anthropocentrism. The ecopoet Loren Eiseley puts it judiciously: Bacon's Christianity "took God out of nature and elevated man above nature."

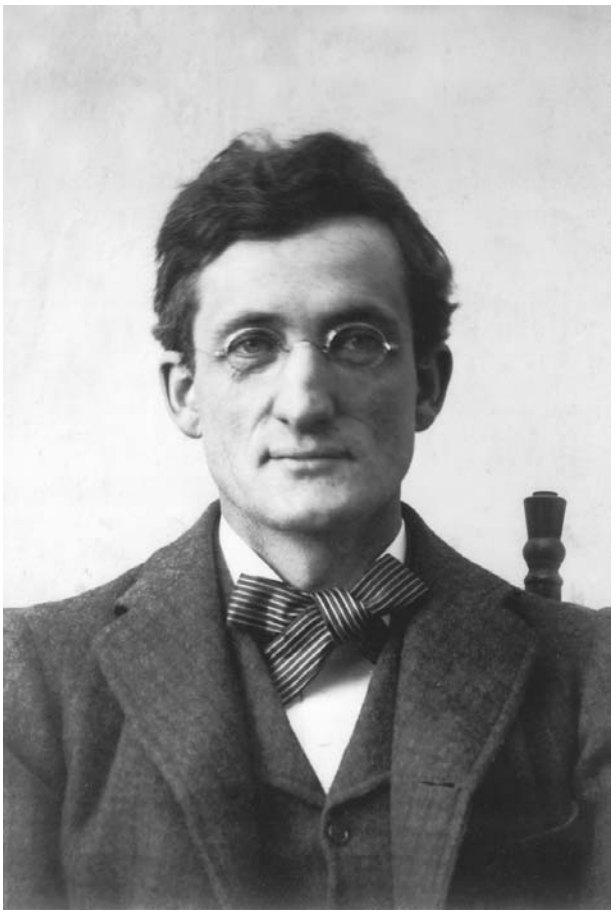
BAILEY, LIBERTY HYDE
1858–1954

An American scientist, educator, and philosopher of country life, Liberty Hyde Bailey was born in South Haven, Michigan, on March 15, 1858. In *The Holy Earth* (1980 [1915]) and other works, Bailey developed the radical implications of the theory of evolution for humanity's relationship to the planet, yielding a nonanthropocentric environmental outlook that integrated agrarian, preservationist, and conservationist thought.

A childhood spent immersed in nature and in the works of Asa Gray and Charles Darwin propelled Bailey to Michigan Agricultural College (later Michigan State University), where in 1882 he received a bachelor of science in botany. From 1883 to 1884 he served as an assistant to Asa Gray at Harvard University's herbarium. This was followed by a brief period as a professor at his alma mater.



Liberty Hyde Bailey, 1900. *Bailey is best known for his influence on environmental agrarianism and philosophy. As dean of Cornell University, Bailey worked to establish agriculture and horticulture as scientifically respectable fields.* **THE LIBRARY OF CONGRESS.**

In 1888 Bailey began a career as a professor of horticulture at Cornell University, and from 1903 to 1913 he was dean of its College of Agriculture. His most focused investigation of humanity's relationship to the planet came during his long and productive retirement years, especially in the series titled The Background Books.

Bailey's philosophy emerged from the sense of environmental crisis before and after the turn of the twentieth century. He linked species extinctions and resource depletion to outdated human attitudes of fear and antagonism toward the planet. In *The Outlook to Nature* (1905), Bailey argued for an attitude of sympathy with nature primarily because he believed it was the only condition in which one could live a happy life. The same thinking guided his philosophical leadership of the nature-study movement. Bailey's objective in *The Nature-Study Idea* (1903) was to distinguish elementary science education from nature study, which he insisted should encourage children to sympathize with their surroundings and not seek to make scientific experts of them. He thus envisioned a developmental, evolutionary approach to environmental ethics, the foundation of which was neither fear nor exaltation of nature, but rather a clear-eyed appreciation of nature's intrinsic value.

Though there are romantic elements in Bailey's writings, his absolute faith in science marks him as a distinctly modern environmental thinker. In his early years at Cornell University, Bailey labored to establish horticulture and agriculture as scientifically respectable fields of study. While he served as dean, his outlook broadened, and his field became the whole of country life. During this period Bailey's public association with Theodore Roosevelt, as the chair of the latter's 1908 Commission on Country Life and a participant in the Conservation Congresses, give the appearance of a more mainstream utilitarian conservationism. Yet Bailey's writings reveal a man with broad vision and prophetic voice focused on the meaning of scientific discovery, especially evolution, and not just on its ability to increase production and conserve resources.

Bailey's years of reflection culminated in *The Holy Earth*, his most succinct and influential work of environmental philosophy. Here his objective was to extend moral and ethical consideration to the earth itself, and he did this by first locating humankind's "habit of destruction" in a faulty understanding of dominion. Bailey believed that Darwin's theory of evolution made it possible and necessary to reinterpret dominion. His result was a radical challenge to anthropocentrism and the introduction of a new concept: "We are parts in a living sensitive creation. The theme of evolution has overturned our attitude toward this creation. The living creation is not exclusively man-centered: it is biocentric" (1980 [1915], p. 23). Bailey concluded that as conscious members of the community of life, humans have a responsibility to participate in the unfolding of life and to view all of creation, including the earth, as holy. Bailey thus charted a third way beyond the debate between preservationists and conservationists. He affirmed the intrinsic value of the planet, but counseled learning from nature how farmers and others could use the land responsibly and permanently. Ultimately, Bailey's diagnosis of humanity's destructive relationship toward the planet led him beyond the goals of conservation to the prophecy of a new worldview, or what he called the "New Hold."

Bailey's influence is most evident in environmental agrarianism, and it also extends to Aldo Leopold, who cited *The Holy Earth* in his text *Game Management* (1933). *The Holy Earth* was followed by six more books in a series titled The Background Books, where Bailey explored other facets of his outlook, including a book of poetry, *Wind and Weather* (1916), and volumes exploring social and spiritual themes, *What Is Democracy?* (1918) and *The Seven Stars* (1923).

BERRY, WENDELL
1934–

Wendell Berry (born August 5, 1934, in Henry County, Kentucky) is a principal architect of the philosophy underlying the contemporary American sustainable agriculture movement. Since the mid-1960s, he has published more than thirty books of essays, poetry, and fiction. The range, complexity, and tenor of his thought invite comparisons to Thomas Jefferson. Berry shares Jefferson's vision of an agrarian republic: a community

of laborers pursuing a modest life of virtue, seeking peace, commerce, and friendship with other nations. Both envision the decentralization of political power and economic policies that favor farmers and small-scale enterprises over large corporations; both would encourage a watchful and active citizenry to form the first guard of freedom. But the intellectual currents informing the twentieth-century environmental and peace movements also shape Berry's vision. He is, for example, a more thorough-going pacifist than was Jefferson, and his agrarianism is more profoundly shaped by his concern for sustainability and environmental integrity. Jefferson hoped a republic of yeomen farmers could avoid the political corruption stemming from concentration of wealth. Berry hopes that a republic of *good* farmers will sustain the environmental conditions necessary for a fully human life.

Indeed, Berry's ideas, which bear some resemblance to social ecology and ecofeminism, are best seen as the maturation of the strain of Jeffersonian agrarianism that inspired the Populist movement and influenced the tradition of African-American political thought. It may be contrasted with the more aristocratic agrarianism that served as a defense of slavery in the antebellum era and was later revived by the Vanderbilt Agrarians or "Twelve Southerners," a philosophical and literary group that took shape in the 1920s around the leadership of John Crowe Ransom, Donald Davidson, Allen Tate, and Robert Penn Warren. While Berry endorses the Vanderbilt Agrarians' critique of industrial capitalism as a threat to stable communities and to the tradition of civic humanism, he rejects the aristocratic ethos that pervades their writings. He focuses instead on the dangers of economic inequality and the concentration of wealth, the erosion of civic virtue, and (especially in its antislavery guise) the impact of such social injustices on environmental stewardship. Berry explores this connection between social justice and stewardship in two early works: *The Long-Legged House* (1969), a collection of essays on the exploitation of Appalachian farmers and their land by coal-mining corporations, and *The Hidden Wound* (1970), an essay exploring the effects of slave agriculture on white Americans' relationship to the land. Both works argue that effective land stewardship requires those who tend the land to have civic equality and equal economic opportunity. A degraded work force leads to a general contempt for the work of stewardship—a contempt that he believes pervades American culture.

Berry's most famous work, *The Unsettling of America* (1977), develops this social theory in conjunction with his emerging virtue ethics. Berry's ethical teaching centers on Odysseus's story as it is recounted in *The Iliad*, which Berry reads as an account of the transition from the virtues of the warrior to the virtues of the good husbandman. He emphasizes in particular the Greek virtue of *sophrosyne*, which may be translated as prudence, self-control, or more broadly the ability to know and keep one's place in the cosmic order. It is the counterpart to the classical vice of hubris, which Berry considers to be at the heart of our contemporary environmental problems. He contends that our desire to control the conditions of our own existence—to be god-like in our autonomy and power—leads to reliance on powerful, dangerous technologies and a corresponding social isolation as we replace conscious dependence on particular people with unconscious dependence on machines and the impersonal social networks that support our technology. Moreover, because reliance on powerful machines masks our interdependencies, it creates an illusion of independence, which in turns weakens our sense of responsibility to the environment and community.

Berry's answer to this failure of responsibility is to emphasize our human condition of vulnerability and dependence, and the virtues we need to live gracefully: *sophrosyne*, fidelity, and the reasonableness of a "sympathetic mind"—an embodied, responsive mind that understands the limits of human knowledge and the proper place of both reason and sentiment in decision making. These virtues constitute the core of his place-based ethics: He envisions the good life as a life rooted in place, where responsibility to particular things and people can be enacted in a meaningful way. Living in place, by relying on local foods, markets, and services, allows us to develop our consciousness of our interdependencies and should enhance our sense of responsibility, thus developing our environmental virtues.

At the center of Berry's agrarianism is a robust conception of the human condition as one of interdependence and vulnerability. Out of that understanding grows his vision of the good life: a life of stewardship in community with co-equal citizens, constrained but not diminished by our biological and intellectual limits, and oriented toward preserving the environmental and social conditions necessary for us to lead fully human lives.

BHOPAL

On December 2, 1984, a pesticide plant in Bhopal, India, built by Union Carbide Corporation and run at that time by Union Carbide India Limited sustained a huge explosion. Forty tons of methyl isocyanate (MIC) gas was released into the air around the plant, forming a lethal mixture of MIC, hydrogen cyanide, monomethyl amine, and carbon monoxide, among other chemicals. The figures are in dispute, but an estimate by Union Carbide put the dead at 3,800 while Amnesty International put the number at more than 7,000 killed within days of the explosion and more than 100,000 suffering from chronic illness related to gas exposure.

The company whose gas exploded into a lethal cloud was largely Indian-owned and completely Indian-operated. It had been founded as a branch of the American corporation in 1934 to provide pesticides for India's agricultural green revolution; the plant at Bhopal dated back to 1969.

THE EXPLOSION AND ITS TOXIC PRODUCTS

There was nothing extraordinarily dangerous in the operation of the plants; the most common kind of pesticide produced in them was carbaryl, an ester of carbamic acid, a reliable and relatively safe product that is marketed in the United States under the brand name Sevin. However, some of the chemicals employed in the process of making the pesticide are dangerous, including phosgene, the deadly gas briefly used in World War I on the battlefield, and hydrogen cyanide. Methyl isocyanate (CH_3NCO) is a member of the cyanide group, of which the highly poisonous hydrogen cyanide (HCN) is the most infamous. MIC is extremely unstable and dangerous and ordinarily is not studied in a laboratory situation. Its boiling point is 39 degrees Centigrade (102.2 degrees Fahrenheit). Lighter than water in liquid form but heavier than air in gaseous form, it hugs the ground when released; that is why it did so much damage to the people in the surrounding neighborhoods. It reacts violently with water (producing breakdown products and high temperatures) whether it is the water that entered the MIC storage tanks or the water in human tissue. Therefore, it is an extremely dangerous human poison, and there is no antidote. No one measured the concentration of the escaped gas at Bhopal, but as 50,000 pounds of it escaped, the heart of the cloud must have exceeded safe limits.

PLANT LOCATION AND DIVIDED RESPONSIBILITY

It made sense to put pesticide plants in India instead of manufacturing the Sevin in the United States and exporting it: Transportation costs and dangers were eliminated, and labor costs were much lower in India, making the whole operation safer and more profitable for Union Carbide. It also provided tax revenues and very good jobs in a chronically depressed economy, in consideration for which the Indian government sought, welcomed, and catered to American companies that were willing to locate plants in their country. The land on which the plant was built was given to Union Carbide by the Indian government for an annual rent of $40 per acre as part of a plan to bring industry into Madhya Pradesh, the largest and one of the poorest Indian states.

The divided ownership and consequent division of responsibility for the safety of the plant—the Americans responsible for the design, the Indians responsible for implementation—fostered an attitude of complacency and lack of concern for the details of safety arrangements and mutual suspicion in regard to decision-making authority. Those attitudes explain the lack of attention to safety lapses before the explosion and the chain of events that followed: recriminations, litigation, political hyperbole, threats of further litigation, no relief for the actual sufferers, and no success in restoring the environment.

INVESTIGATIONS AND AFTERMATH

What is the obligation of an American corporation in such situations? Bhopal is an example of everything that can go wrong in an industrial catastrophe. For over a year the Indian government would not allow industry investigators to examine the scene of the accident or analyze the residues in the wrecked tank. When they finally examined the remains of the plant, they found contaminants in the residue that might have accounted for the violence of the reaction within the tank. None of the safety devices had worked, and the emptying of the huge tank—and the resulting devastation—was inevitable.

Victims of Bhopal Tragedy Protest in New Delhi, 2006. *The explosion of the Union Carbide pesticide plant in Bhopal, India, in 1984 is often used as an example of a worst-case, scenario of the effects of chemical plants. The incident resulted in the loss of several thousand human lives, approximately 200,000 injured, and severe damages to the local environment. Despite concessions offered by the American-based Union Carbide company and various other organizations, the victims of the Bhopal tragedy continue to demand justice for the losses they have suffered.* **MANAN VATSYAYANA/AFP/GETTY IMAGES.**

Early in the investigation they found confirmation for the explanation they had deduced from the core samples. An instrument supervisor from the plant who otherwise was not involved in the explosion had surveyed the area of the tank on the morning after the explosion and had found that a pressure gauge had been unscrewed from the tank and was missing. That would explain how water got into the tank. A hose normally used for cleaning still was attached to the faucet not far from the tank, and water was running out of it. That would account for the source of the water. Further investigation uncovered the name of the employee who had performed the senseless act of sabotage. He recently had been, or was about to be, demoted, and he was angry. He surely had no intention of causing that kind of explosion, and his family probably lived nearby. However, he knew water would ruin the batch, and that was his intention. Union Carbide investigators turned their information over to the local authorities, but the political atmosphere was so violent that the Indian authorities did nothing about the findings.

Many of the victims had suffered horribly. Union Carbide as a corporation and Americans as a nation took immediate action to provide relief: The chief executive officer, Warren Anderson, went to India the day after the explosion, authorized to spend a million dollars immediately to care for the victims; the employees in all of Carbide's locations took up a collection to help the victims, especially the children; others donated medical supplies; and the University of Arizona, responding to information about the limited employment opportunities for the poor, built a vocational and technical college in Bhopal. By March 1985 Union Carbide had placed $7 million in an account for relief of the victims; a year later it proposed $350 million as a settlement for the victims and offered to build a hospital.

No one has been able to explain the reaction of the Indian government to those initiatives. Anderson's money was not accepted; he was jailed and then sent back to the United States without being permitted to talk to anyone. The employees' collection was turned back. Medical supplies were ignored, and in March 1987 the Indian government closed and razed the vocational and technical college when it found out that Union Carbide money had helped build it. Not until February 1989 were any funds transferred, when the Supreme Court of India ordered a final settlement of $470 million, which Union Carbide paid within ten days. Since that time activists have been trying to overturn the settlement and bring criminal charges against Anderson.

The incident that goes under the name of Bhopal has taken on a symbolic importance that is out of line with the actual events. It is interpreted as an example of Western imperialism or colonialism in the placement of the plant;

the fact that India eagerly sought the high-employment industrial works is forgotten. It is considered an example of the callousness of Western industrialism to the suffering of the Third World even though the errors that resulted in nonfunctioning safety equipment and triggered the explosion were under the control of the Indian managers.

The effect of the incident on American business abroad has been significant: No longer do multinational corporations plant their facilities and company flags in the developing world; instead, they work from export platforms or special trade zones or deal with native-owned companies through a series of insulating contracts. No one wants another Bhopal, and safety regulations are taken more seriously. For the same reason, to the extent that they can, American companies keep a safe legal and moral distance from the operation of dangerous plants abroad.

BIBLE

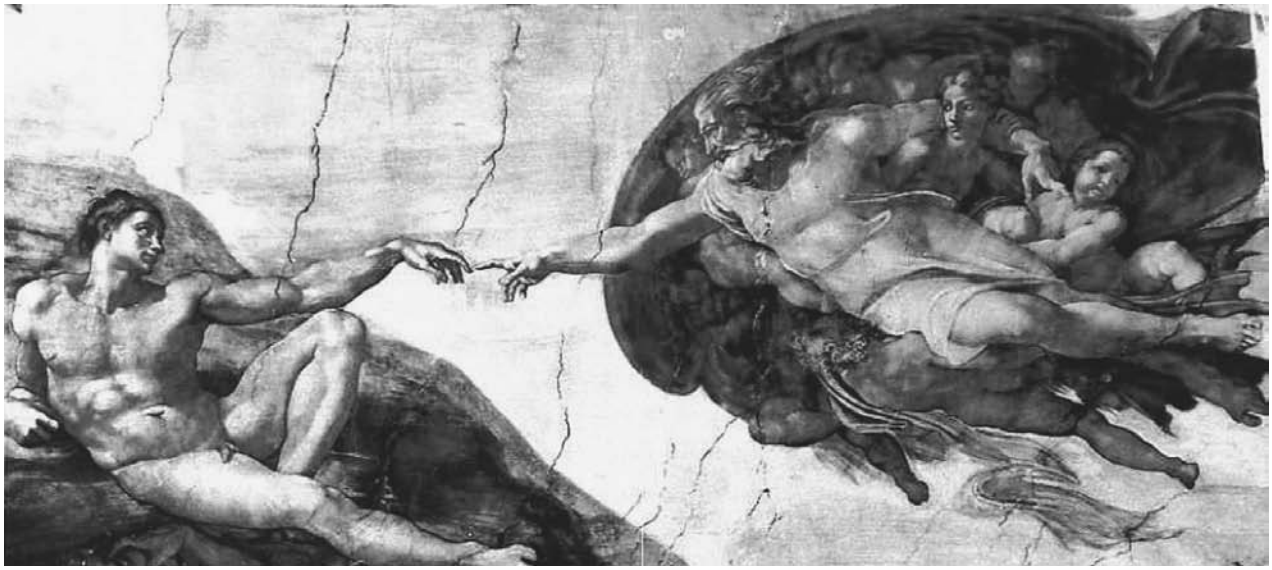
As a fundamental source of doctrine and authority in the Christian and Jewish religions, the Bible has profoundly influenced attitudes toward the environment among cultures shaped by these faith traditions. Whether this legacy has been good or bad in terms of positive concern for the environment is an issue of debate.

What counts as the Bible varies according to religious tradition, with the Jewish scriptures corresponding roughly to what Christians traditionally call the Old Testament (here referred to as the Hebrew Bible). The Catholic Church defines its canon of scripture differently from the Protestant churches, including in the Bible what the Protestant tradition refers to as the Apocrypha. Each of these various forms of the Bible contains a diverse collection of writings spanning a long period of time and reflecting different contexts and points of view. The earliest portions of the Hebrew Bible may date from around the eighth century BCE, while the latest writings of the New Testament probably come from near the end of the first century CE. A good deal of the discussion and debate about the Bible and the environment focuses on biblical interpretation in the Protestant (and especially evangelical) tradition, for two main reasons: First, it is in this tradition that the greatest weight is placed on the status of the Bible as the word of God, understood in evangelicalism to imply that it is infallible. Second, evangelicalism in various forms, some described as fundamentalist, is particularly influential in the United States, which, out of proportion to its size and population, exerts a powerful impact on the global environment and on world politics.

A CRITIQUE OF THE BIBLICAL TRADITION AND ITS IMPACT

Discussion of the impact of biblical texts and the Christian tradition on contemporary environmental attitudes and practices has been hugely influenced by "The Historical Roots of Our Ecologic Crisis," published in 1967 by the medieval historian Lynn White. White argued that the (Western) Christian worldview, rooted in the creation stories and the notion of humanity made in God's image, introduced a dualism between humanity and nature, and established the notion that it was God's will that humanity exploit nature to serve human interests. Thus Christianity, according to White (1967, p. 1206), bears "a huge burden of guilt" for introducing the Western anthropocentric worldview, which has permitted and promoted the active and aggressive conquest of nature to serve human ends. White, giving only a composite overview of the biblical creation stories, does not explicitly cite biblical texts, and his arguments concentrate much more on the historical development of Christian thought and early science during the medieval era, the period of his expertise. Nonetheless, White's forceful critique of the impact of the biblical tradition, especially the creation story of Genesis 1, has stimulated a range of often defensive responses from biblical scholars.

White's critique has helped to focus considerable reflection on the meaning and impact of the Bible's creation stories and especially the mandate given to humanity to subdue and rule the earth (Genesis 1:26–28). Also crucial to consider is the influence of biblical eschatology, that is, the view of the "end-times" (Greek *eschata*, means "last things") presented in various biblical books. A number of biblical texts (Joel 1:15, Amos 5:18–20, 1 Thessalonians 5:2) appear to present images of cosmic destruction in their depictions of what will



Creation of Adam. *Michelangelo's iconic depiction of the creation of Adam, from the ceiling of the Sistine Chapel, highlights the uniqueness of humanity, "made in the image of God" (Genesis 1.27).* **AP IMAGES.**

happen on "the day of the Lord," a biblical label for the coming day of God's judgment and salvation. Some texts suggest that earthly catastrophes will precede this final day of salvation (e.g., Mark 13); others depict Christians as taken up to meet the returning Lord in the air (1 Thessalonians 4:16–17). From such texts various eschatological expectations have developed. For example, some evangelical Christians anticipate a "rapture," an assumption of Christians from the earth into Heaven, prior to a time of great tribulation; some urge that Christ will return suddenly and perhaps soon. Such visions of the future have been popularized in hugely successful books such as Hal Lindsay's *The Late, Great Planet Earth* (1971) and the Left Behind series of the 1990s by Tim LaHaye and Jerry B. Jenkins. It is not hard to see that such beliefs could engender the view that preserving and caring for the earth is not a priority for Christians, and there is some evidence that this set of priorities has influenced decisions and policies at the government as well as individual level. Indeed, a few fundamentalist writers have explicitly opposed environmentalism, depicting it as part of a (satanic) neopagan New Age movement, and as promoting an unbiblical and un-Christian pantheism. These views raise critical questions about the kind of environmental attitudes that the Bible stimulates and supports.

READING THE BIBLE ECOLOGICALLY

Responses to such critical evaluations of the Bible's impact on attitudes toward the environment have taken various forms. Among those committed to environmental care, some, like Matthew Fox, have insisted that the Christian tradition requires radical reconstruction if it is to develop a spirituality appropriate for an ecologically conscious age. Evangelicals and others committed to the authority of the Bible, but also committed to environmental care, have sought to defend the Bible against the charges leveled by White and have tried to show how the Bible can undergird a positive view of the nonhuman world and of humanity's responsibilities toward creation.

A different approach to interpreting the Bible in the light of contemporary environmental issues has been developed by the Earth Bible Team, based in Adelaide, Australia, and published between 2000 and 2002 in the Earth Bible series under the general editorship of Norman C. Habel. In contrast to the approach of many green evangelicals, members of the Earth Bible Team are skeptical of attempts to portray the Bible as consistently supportive of an environmental agenda. They do not deny that there is ecologically valuable and instructive material in the Bible, but they insist that in engaging the Bible, one must be critical, ready also to expose and resist material that is anthropocentric and negative toward the earth. Their approach is guided by a series of "ecojustice principles" that express the value, interconnectedness, and purpose of the whole-earth community (for example, "the principle of intrinsic worth" [Habel 2000, p. 24]). These principles provide a basis for the critical evaluation of biblical texts from the perspective of a commitment to ecological justice. The following sections survey briefly a range of the biblical texts most commonly discussed in relation to the environment in order to examine both the

potential contribution of the Bible to environmental ethics and some of the different ways in which the texts are interpreted.

THE HEBREW BIBLE

As has already become clear in the discussion above of White's article, the creation story of Genesis 1 is a particular focus of debate. Responding to White's critique, some have sought to show that the mandate given to humanity to subdue and rule the earth (Genesis 1:26–28; see also Psalm 8:6) does not legitimate aggressive technological exploitation of creation to serve human ends. A positive proposal is that this text, along with others, is best understood as placing humanity into the role of "stewards" of creation. On this reading, humanity is not entitled to dominate creation for human benefit, but rather is given responsibility for careful and compassionate management of the earth. Central to a realignment of major evangelical leaders and bodies behind a more environmentally conscious vision of Christian responsibility is a focus on stewardship as the biblical image of humanity's role in the world, as expressed, for example, in "An Evangelical Declaration on the Care of Creation" (Berry 2000, pp. 17–22) and "Climate Change: An Evangelical Call to Action" (Evangelical Climate Initiative 2006). Others, such as Norman Habel, remain more skeptical about the possibility of reclaiming this text for an environmental ethic, insisting that it problematically elevates humanity over creation and gives permission for harsh and exploitative domination.

Attention may also be drawn, however, to other facets of the two creation stories placed side by side in Genesis 1 and 2. In the account of Genesis 1, the whole of creation is emphatically and repeatedly referred to as good, and both humans and animals are depicted as herbivores, feeding on green plants without the need (or divine permission) to kill other animals for food (Genesis 1:29–30). In the account presented in Genesis 2, there is no mention of humanity's being made in God's image and given a mandate to subdue and rule. Instead, the first human is made from the dust (Genesis 2:7; a wordplay in Hebrew: *adam* [human] from *adamah* [ground]), and becomes a "living being," like all other creatures (see Genesis 1:20, 24, 30; 2:19; 9:12). Adam is placed in the Garden of Eden "to till it and keep it" (Genesis 2:15), giving some basis for the idea that humanity's role is as stewards of creation.

Sometimes close attention to biblical texts in the light of environmental concerns can yield striking insights that challenge the traditionally anthropocentric character of the theological tradition, with its focus on human salvation and relationship with God. The covenant with Noah, recorded in Genesis 9:1–17, is a good example. While Noah and his descendants are indeed central to this covenant (see verses 1, 9), it is actually and explicitly a covenant made with every living creature and the earth itself (see verses 10–17). So, according to this text, the whole earth is bound in a covenant with God, not just an elect segment of humanity.

Complementing this picture are other texts, particularly in the Psalms, that have grand and poetic depictions of the whole created order as a manifestation of God's glory (e.g., Psalms 19:1–6; 104) and as called upon to praise God (e.g., Psalms 96:11–12; 148). The book of Job, a book focused on the story of a righteous man who endures great suffering, ends with a series of divine speeches in which, rather than console Job, God emphasizes Job's ignorance and insignificance, and lists the manifold wonders of creation (Job 38:1–42:6). This diverse and wondrous creation, it seems, has its own intrinsic value and relation to God, without there being any sense that it exists for the benefit or welfare of human beings. Job, apparently, gets the point, and responds to God's tirade by acknowledging his own insignificance (Job 40:4–5; 42:1–6).

Genesis 1:29–30 depicted an initially vegetarian, nonviolent creation, and it is striking that prophetic visions of the eschatological state also return to this theme. The book of Isaiah offers a vision of the messianic age in which "the wolf shall live with the lamb, the leopard shall lie down with the kid.... The cow and the bear shall graze, their young shall lie down together; and the lion shall eat straw like the ox" (Isaiah 11:6–7; see also 65:25). This, along with a promise of justice and liberation for the poor and oppressed, is what is meant by the establishment of righteousness. These visions provide biblical resources for those who argue that Jewish and Christian ethics should include a concern not only for human welfare but also for the peace and well-being of all creation. Indeed, these texts provide for some a motive for practicing vegetarianism, understood as a return to the original ideal depicted in Genesis 1 and as an anticipation of the peaceable eschatological age to come.

As already noted, however, some biblical depictions of the future also raise certain difficulties for an environmental ethic. Some prophetic visions, echoed later in various New Testament texts, portray the coming day of the Lord as a time when the earth will be shaken and the sun, moon, and stars will cease to shine (e.g., Joel 2:30–3:21). There is debate about how this imagery should be understood—whether as a depiction of real cosmic catastrophe or as a metaphorical portrayal of radical historical upheaval—but, in contrast to some of the texts mentioned above, it hardly contributes easily to a positive view of the environment. So while the Hebrew Bible offers much that might form the basis for a

theological world view and related ethic in which the environment is of central and enduring value, there are also texts that raise difficulties for such a perspective, as well as many that simply do not touch on the topic at all.

NEW TESTAMENT

When we turn to the New Testament, a similar situation pertains: Some texts offer positive resources for an environmental ethic, some raise difficulties, while many are of no direct relevance. Like the Hebrew Bible, but even more so—since the focus shifts from living in the land to salvation in Christ—the New Testament's main preoccupation is with the story of God's dealings with people rather than the value and fate of nonhuman creation. Nonetheless, there are a number of texts that have attracted the attention of ecotheologians. Probably the most cited Gospel texts are the verses in the Sermon on the Mount where Jesus refers to God's care for birds and flowers (Matthew 6:25–34 and Luke 12:22–31; see also Matthew 10:29). These are taken to indicate concern for nonhuman creation on the part of Jesus. It is also often noted that Jesus's parables frequently employ imagery of the natural world and agriculture. Whether these references offer much support for an ethic of environmental care may, however, be questioned. The rural imagery reflects the context of Jesus's life and ministry and does not necessarily say anything about the value he attached to nature, and his references to birds and flowers are primarily intended to illustrate how much more God cares for humans.

In the letters of Paul too there is only a little of obvious relevance. The most important text is undoubtedly Romans 8:19–23, where Paul strikingly depicts the whole of creation as bound up with the suffering of humanity and longing for the eschatological revelation of the sons of God, when creation "will be set free from its bondage to decay and will obtain the freedom of the glory of the children of God" (verse 21). This passage provides the most substantial support in the New Testament for the idea that God's salvation encompasses the whole creation, not just humanity. Romans 8 undergirds a sense of value—it is not merely the dispensable stage on which the drama of human redemption takes place—and declares that humanity, creation, and the Spirit are caught up together in their hopeful groaning for a glorious future. These are important foundations for an ecological theology. Also significant are a number of references in the Pauline letters to "all things" (Greek: *ta panta*, an established term for the universe in Stoic thought), which imply that the scope of God's redemption through Christ is cosmic and not merely focused on humanity. The most extensive of these references is in Colossians 1:15–20, where the writer (scholars debate whether this letter is genuinely from Paul) depicts Christ as the one through whom and for whom all things were made, the one in whom all things hold together, and the one through whom all things are reconciled.

As in the Hebrew Bible, so in the New Testament too, there are difficult texts that depict a coming time of cosmic catastrophe and the establishment of a new creation (e.g., Mark 13, Revelation 21–22). The most problematic of these from an environmental perspective is 2 Peter 3:10–13, which depicts the destruction of the elements of the world by fire, followed by an act of re-creation, and suggests that Christians should look forward to this day and even "hasten" its coming. While evangelical environmentalists struggle to remove from this text negative implications for environmental ethics, other interpreters, such as Keith Dyer (Habel and Balabanski 2002), conclude that such difficulties cannot be overcome, and that they must be critically resisted by those committed to promoting ecological justice. The ambivalence of the New Testament's vision of a new creation is also evident in the famous scenes in Revelation 21–22, with which the Christian Bible ends. Some argue for a positive reading of these texts as the culmination of the story of God's commitment to renew the whole of creation. This vision, they insist, is one of transformation, not one in which the old world is destroyed and replaced by a new one. Others note some of the difficulties in taking the depiction in Revelation as a positive model for an ecological theology, not the least being the massively urban character of the new Jerusalem (see Revelation 21:12–21).

AN AMBIVALENT LEGACY AND PROSPECTS FOR THE FUTURE

As this brief survey of the most pertinent texts shows, the Bible offers an ambivalent legacy to contemporary attempts to develop an environmental ethic. On the one hand, there is much in the biblical tradition that affirms the value of nonhuman creation and depicts the whole created order as bound up with humanity in God's redeeming purposes. As such, the Bible can challenge the traditionally anthropocentric focus of much theology and ethics and help to resource their reconfiguration. On the other hand, some biblical texts arguably depict humans as divinely appointed rulers over creation and apparently anticipate the destruction of the present cosmos, and are therefore problematic from the perspective of environmental ethics. Depending on their particular perspectives and commitments, scholars argue for various interpretations of such texts, but it is hard to conclude that the Bible offers a consistently pro-environmental perspective. Even where the texts suggest the positive value of the nonhuman creation, they give little indication as to what appropriate ethical actions are thus implied.

What is more, in the area of environmental ethics, it is especially clear that our modern, scientifically informed, globalized culture differs hugely from that of the biblical writers. Any use of the Bible in contemporary debate must pay attention to this considerable historical gap. This means that Christian environmental ethics cannot simply be based on attempts to interpret and apply what the Bible says, but, like other major developments in theological ethics, must derive from a fresh and critical reading of the Bible and tradition, shaped by the demands and insights of our contemporary context and informed by dialogue with scientists, theologians, ethicists, and others. Through such a dialog, the Bible can contribute significantly to an ecological reconfiguration of Christian theology and ethics.

BIOCENTRISM

Biocentrism is a life-centered outlook that rejects the view that humanity alone matters in ethics and accepts the moral standing of (at least) all living creatures. It has played a formative role in the development of environmental ethics since the study of this subject became a self-conscious discipline in the 1970s; it was also influential among some key earlier thinkers, including Albert Schweitzer (with his belief in "reverence for life") and Mohandas Gandhi, who regarded even "the destruction of vegetable life as *himsa* (violence)" (Gandhi 1958, vol. 32, p. 43; Gruzalski 2007, p. 230). Not all biocentrists condemn all destruction of life, however, although they all regard the good of living creatures as a morally relevant element in decisions affecting their treatment.

KEY TENETS OF BIOCENTRISM

The common and crucial tenets of biocentrism are the following: (a) all living creatures have a good of their own and, accordingly, have moral standing (that is, they warrant moral attention or consideration for their own sake); and (b) their flourishing or attaining their good is intrinsically valuable. In representing the Deep Ecology movement as "biocentric," Arne Naess probably wanted to go further and include living systems (such as habitats and ecosystems) within the scope of biocentrism (Naess 1973), but the view that such systems have moral standing and a good of their own is nowadays more accurately classified as *ecocentrism.* Characteristically, biocentrists locate moral standing in individual creatures rather than in systems, as holists do; biocentrists respect systems not in themselves but only insofar as they protect or make possible the lives (or the flourishing lives) within them; they view such systems in much the same way that most people regard lifeboats.

EARLY BIOCENTRISTS

Naess may also have intended to embody a form of radical egalitarianism in his version of biocentrism, which endorses "biospherical egalitarianism—in principle" involving "the equal right of all creatures to live and blossom" (Naess 1973, p. 95). But many biocentrists have not endorsed this principle. Although some embrace it, others are closer to the very different egalitarianism of Peter Singer, who adheres to the "principle of equal consideration," according to which equal interests should be given equal consideration (Singer 1999); this principle is compatible with according different treatment to creatures with different interests, whether of the same species or not, thus privileging some creatures over others. Singer is not a biocentrist, because he sets the limits of moral standing at the boundaries of sentience. But there is nothing to prevent biocentrists, whose allocation of

moral standing is much less constrained, from endorsing his equal consideration principle across the broader range of creatures whose standing they recognize. Such biocentrism is not "inegalitarian," as Alan Carter has suggested (2001, 2005), but it does diverge from Schweitzer's radical egalitarianism and possibly Naess's and certainly Taylor's (1981) and Sterba's (1998) in such a way as to make biocentrism both egalitarian and more obviously defensible (Attfield 2003b, 2005).

Biocentrism was given a much clearer rationale in Kenneth Goodpaster's article "On Being Morally Considerable" (1978). To the question, which entities have moral considerability or standing? Goodpaster replies that it is those with a good of their own and that this criterion extends to all living creatures, given the centrality of the concept of beneficence in morality. Here Goodpaster diverges from Feinberg, who partly locates interests in "unconscious drives, aims, goals, latent tendencies, directions of growth and natural fulfilments" or, in summary, in "conations" (1974, p. 49–50), yet he inconsistently restricts the bearers of interests and thus moral standing to sentient creatures. Goodpaster rejects this restriction while incorporating Feinberg's understanding of interests into his biocentrism. But Goodpaster carefully distinguishes his position from belief in the sentience of all life (for he rejects both this belief and the view that sentience is necessary for moral standing) and equally from the view that all holders of moral standing, sentient or nonsentient, have the same moral significance. On that basis, he suggests, life would be unlivable.

Donald Scherer (1982) furnished crucial support for biocentrism through a thought experiment about the presence or absence of value on the imaginary planets Lifeless, Flora (which has vegetation), and Fauna (which has animals, too); he argues that it makes sense to value the states of Flora and Fauna but not of Lifeless. He also seeks to demonstrate that an ethic can be individualistic without being either egoistic or anthropocentric and can recognize independent value while remaining teleological (or consequentialist). Scherer does not entirely reject ethical holism (any more than Goodpaster does) and may actually come close to such holism when he makes values dependent on ecosystems and their value because the relevant creatures are physically dependent on ecosystems. (To this it could be replied that the dependence of the human passengers in a lifeboat on their vessel does not make their value dependent on either the lifeboat or its value.) Yet Scherer's stance shows how a largely individual-centered ethic can avoid the assumption that human concerns must be confined to human interests. An environmental ethic can value the good of all living creatures (present and future) without either making them all of equal significance or privileging the common good over the value of individuals, as ecocentrists are prone to do. Indeed, Scherer's thought experiment supplements Richard Routley's last-man thought experiment by locating intrinsic value in all self-maintaining and self-replicating organisms with a good of their own.

THE BIOCENTRISM OF ATTFIELD, TAYLOR, AND VARNER

A corresponding kind of biocentrism to Goodpaster's was upheld in two works by Robin Attfield: "The Good of Trees" (1981) and *The Ethics of Environmental Concern* (1983). In the former work, Attfield contests the prevailing theories that interests (human, sentient, or nonsentient) are a function of desires and preferences (Feinberg's eventual position) or of prescriptions (as in Hare), and develops arguments such as the last-person thought experiment in support of the good of trees having intrinsic value, thus supplying a reason independent of their instrumental value for their promotion or protection. In the latter work Attfield integrates biocentrism with a form of rule consequentialism and supplements it with a nonanthropocentric theory about which interests should be given priority in interspecies conflicts. Attfield further developed these views into a theory of interspecies priorities harnessed to practice consequentialism in *Value, Obligation and Meta-Ethics* (1995). Earlier, in the second edition of *The Ethics of Environmental Concern* (1991), Attfield replied to Janna Thompson's sentience-based argument that biocentrists have no consistent basis for denying intrinsic value to artifacts. Attfield responded that living creatures are capable of health and can be injured or harmed but that artifacts cannot be injured or harmed but merely damaged.

A different kind of biocentrism was presented in 1981 by the veteran ethicist Paul Taylor. Taylor disowns both anthropocentric and holistic positions and advocates instead a life-centered ethic of respect for nature in which agents recognize that each living thing has a good of its own, the realization of which is intrinsically valuable (or worthy of being preserved or promoted) and is to be pursued for its own sake. Respect for nature is comparable with and supplements a Kantian respect for persons. In Taylor's version of biocentrism, however, not only is human superiority denied, but each living thing is also held to be equally worthy of respect, irrespective of differences of interests, and to have the same moral significance. Accordingly, "biospherical egalitarianism" (the principle propounded, albeit with qualifications, by Naess) here reemerges. Taylor tackles the implications of such egalitarianism in his book *Respect for Nature: A Theory of Environmental Ethics* (1986). In that work he presents defensible practical principles that recognize that human needs have to be satisfied. But these principles are difficult to reconcile with—or to derive from—his

interspecies egalitarianism. A consistent and operational biocentric ethical system probably has to recognize, as Goodpaster does, differences of moral significance among the bearers of moral standing, something that is unattainable in Taylor's radical egalitarianism.

Gerald Paske (1989) later responded to Taylor's views, arguing (cogently) that nonsentient beings lack a point of view and (less cogently) that inanimate objects such as stalactites also have a good of their own, but he conceded that this is metaphorical talk, not to be taken literally in such cases. Thus Paske's claim that talk of the good of plants and of that of inanimate objects having comparable senses is unconvincing, and fails to undermine Taylor's biocentrism.

Some of the biocentrist conclusions of Attfield's "The Good of Trees" were endorsed by Gary E. Varner (1990). Varner added criticisms of Routley's thought experiment but seemed unaware that the version of this argument presented in Attfield's 1983 book was immune to several of these criticisms and that his criticisms of appeals to thought experiments had also been answered in Attfield's article "Methods of Ecological Ethics" (1983). In a later essay (2002) Varner returned to an ingenious defense of the intrinsic value of nonsentient creatures, citing further thought experiments and ably distancing his biocentrism from the versions advocated by Schweitzer, Gandhi, and Taylor. Although Varner has acknowledged problems for these thought experiments (see his 2003 review of Nicholas Agar's *Life's Intrinsic Value*), they are arguably defensible ones.

STERBA'S BIOCENTRISM

James Sterba has defended a different kind of biocentrism that involves a commitment to equality of individual creatures of whatever species (as it does for Taylor). Sterba recognizes that such a stance generates a dilemma, for our practical principles will apparently either be consistent but intolerable through forbidding human self-defense, or will allow human self-defense but will conflict with consistent biocentrism. He advances fundamental species-neutral principles that allow any species to resort to self-defense in certain circumstances. Sterba presents some quite cogent principles that authorize self-defense. But some have doubted whether his thesis coheres without a recognition of the difference made by different interests and capacities of different creatures, or whether, in the absence of a justification through the consequences of action, such principles can be reliably identified merely on a formal basis.

Besides furnishing some cogent interspecies principles (Sterba 1998, pp. 363–364), Sterba introduces a valuable discussion of the difficulties involved in extending biocentrism to ecosystems. Given the widespread abandonment of belief in the balance of nature on the part of ecologists, and a concomitant recognition that disequilibrium is as much the norm as equilibrium, nothing in particular can be recognized as good for ecosystems, even if they can be identified as such in the first place. Yet these problems for ecocentric theories leave biocentrism unscathed. Whether or not Sterba's radically egalitarian ideas are cogent enough, biocentrism in general is more defensible to the extent that it is based on equal consideration for equal interests. Such biocentrism needs to be allied to a defensible interhuman ethic such as practice consequentialism; such an ethical system has been presented and defended in *Value, Obligation and Meta-Ethics* (Attfield 1995) and in *Environmental Ethics* (Attfield 2003).

OBJECTIONS TO BIOCENTRISM

Among objections to biocentrism, Paske's observation that nonsentient creatures lack a point of view was developed by Singer (1993) into the claim that they therefore do not matter in themselves (lack moral standing); Bernard Williams has denied that their interests amount to morally relevant claims (1995). Williams's assertion is hardly an argument, however, and Singer's view accords undue importance to subjectivity as a requirement of moral standing and conflicts with the arguments of Goodpaster, with most people's responses to Goodpaster, and to the thought experiments of Routley, Scherer, and Varner.

Bryan Norton (1991) has argued that nonanthropocentric stances such as biocentrism are redundant because sophisticated anthropocentrism supports the same policies. Biocentrists counter that the recognition of nonhuman interests provides not only stronger reasons for policies of humaneness, compassion, and preservation, but also provides reasons for preserving those species that are of no current concern to humans (for example, those that have not yet been discovered).

The most common objection to objectivist biocentrism (as well as to other forms of objectivist nonanthropocentrism) is the suggestion that all judgments of value, however nonanthropocentric in content, are still anthropogenic (Callicott 1992) because they depend on human valuation, and there can be no value in the absence of valuers; this kind of biocentrism might be labeled "weak biocentrism." Even if argument were granted, it would not affect biocentrism at the normative level but only on the level of human judgments. But there is reason to doubt that things have value only because people decide that they do (Attfield 1991b, 1993a); *valuable* does not mean "valued" but applies to what there is reason to value, whether or not anyone values it; and it is implausible that nothing had value (or, in the case of pain, the

opposite of value) until humanity (or possibly until intelligent vertebrates) first appeared and began making judgments. (Could birds have lacked value in the days of archaeopteryx and acquired it only when first appreciated by primates?) Normative biocentrism claims that the good of living creatures supplies interpersonal reasons for action (some of them nonderivative); such a claim would make it reasonable to treat ethical judgements not as mere expressions of human valuing but as having truth values of the kind widely recognized as belonging both to moral and to value discourse; indeed, there is as much reason to be a realist about intrinsic value as there is for moral matters in general. Hence biocentrists can consistently and reasonably be resolute metaethical realists, even though their normative stance (biocentrism) does not hang upon this affiliation to realism.

Robin Attfield

BIOCULTURAL AND LINGUISTIC DIVERSITY

Three interrelated factors—human language, culture, and the inhabited ecosystems—have helped to shape the evolution of the human species. In the 1990s, numerous studies demonstrated correlations between biological and linguistic diversity, and suggested that these correlations provide evidence about the coevolution of human groups with their local ecosystems.

Humans interact with their environment, modifying it and developing specialized knowledge about it. In order to convey ecological knowledge and practices, humans have also developed specialized ways of talking about the flora, fauna, and ecosystems. The continued use of these local, coevolved languages promotes, in turn,

the continuity of local ecological knowledge and practices. Relationships between local languages and their socioecological environments are particularly apparent in indigenous communities that maintain close material and spiritual ties to their regional ecosystems (Maffi 2001).

LANGUAGE, CULTURE, AND NATURE

Biological and cultural diversity are inextricably interwoven among all peoples for at least two reasons (Rozzi 2001). First, perception and understanding of biological diversity are influenced by human language, culture, and technology. The compound term *biocultural* makes explicit the role of the "cultural lenses" of any observer (including one using academic research methods and taxonomies) in interpreting biological diversity; those interpretive "lenses" in turn influence how humans modify living organisms and processes, from molecular to global scales. For example, the indigenous Amazonian Waorani word *ömö* defines *forests* as "worlds inhabited by countless sentient beings who share with humans a home, dispositions, values, and culture." This human-forest kinship connoted by the word *ömö* gives rise to various rituals and encourages the Waorani people to oppose oil extraction in the Amazonian forests (Sawyer 2004). In contrast, the English word *woodland* implies that forest ecosystems are resources for wood for fuel or building materials. This utilitarian perception has reduced trees to objects that today can be genetically engineered without any consideration of them as integral living beings interacting with other living and non-living beings in forest ecosystems. These contrasting definitions of forests illustrate how concepts embedded in language influence both ecological knowledge (the ways in which humans perceive trees and their ecosystems) and practices (the ways in which humans transform other species and their habitats) (Rozzi 2001). By fostering an understanding of the multiple representations and classifications of biological diversity in various languages, this biocultural method can help to deconstruct the economic-mathematical approach to ecosystems that predominates in European and North American cultures, thereby bringing attention to alternative modes of ecological knowledge and practice.

Second, according to ecology and evolutionary biology, *Homo sapiens* is an animal species that, like other species, participates in the structure, processes, and composition of ecosystems (McDonnell and Pickett 1997). The human species forms part of biodiversity and, with its multiple ethnicities and cultures, generates ramifying networks of biocultural relations that interact with the heterogeneous ecosystems and landscapes in which they unfold. Novel biocultural approaches in anthropological and ecological research indicate that many landscapes previously depicted as pure, pristine expression of nature—wilderness—are in fact *cultural landscapes*, either deliberately created by humans or modified by human activities. Some remarkable cultural landscapes are found in the vast tropical areas of Amazonia, where, since the 1970s, scientists have begun to discern vegetation patterns that are the result of extensive plantations of fruit and nut trees, such as the *apêtê* "forest islands." Through the use of fire, forest management, and planting and transplanting within and between many ecological zones of Amazonia, indigenous people have created a mosaic of forest islands and corridors that attract useful animals. These discoveries within the world's most extensive forested region have obliged scientists to reevaluate these Amazonian landscapes; whereas they once labeled them as purely natural, they now apply the term *cultural forests* to these areas, which include large agricultural zones, open parklands, hills built with clay, and managed wetlands (Heckenberger et al. 2003, Mann 2005).

BIOCULTURAL DIVERSITY AND ECOLINGUISTICS

The biocultural approach contrasts with the prevailing disciplinary compartmentalization that has arisen from the specialized studies of languages, culture, and biodiversity. Despite the important role that language plays in the relationship between knowledge and the environment, the linguistic sciences have devoted scant attention to this link. Andrew Pawley (1996) attributes this neglect to the prevalence of grammar-based models that conceive of languages as autonomous systems that are independent of beliefs about and knowledge of the world. Some scholars argue that the syntactical and lexical description of a language is only a small subset of all its possible characteristics and that such anatomical studies of languages do not take into account the cultural and ecological knowledge that languages both convey and construct. On this view, then, such studies have little to contribute to documenting and conserving that knowledge. In contrast to this "classical" context-free, grammar-focused linguistic science, later subject-matter models of language have called for ecolinguistic approaches that view languages as ecologically embedded (Calvet 2006). These scholars argue that languages are not self-contained systems but are an integral part of larger ecological, social, and cultural environments.

When a human population colonizes a new environment, people have to learn from scratch about its flora and fauna, the relationships among species, and how to talk about them. Based on historical records about settlements of small populations on Polynesian and other islands, Peter Mühlhäusler (1995) has shown how drastic

environmental degradation often takes place at the beginning of human colonization. Negative environmental impacts continue until an attunement is achieved between the "contours of language and knowledge and the contours of the environment" (p. 36). Mühlhäusler's perspective might deepen insights into twenty-first-century patterns of linguistic, cultural, and ecological degradation associated with the rapid, intensive, and abrupt kinds of colonization practiced by homogenous, global, urban-industrial societies. This ecocultural-linguistic degradation has arisen from the imposition of a single cultural-linguistic model—global colonialism, it might be called—on the diverse environments of the planet. This cultural-linguistic imposition leads to the simultaneous loss of local languages and the ecological knowledge and practices embedded in them.

LOSSES OF BIOLOGICAL, CULTURAL AND LINGUISTIC DIVERSITY

Biodiversity loss is a well-known phenomenon. By some estimates, some 20 percent of the world's biological species may cease to exist during the twenty-first century. Less widely appreciated is the diversity loss in the world's languages and cultures. There were an estimated 6,912 languages spoken in the world as of 2005 (Gordon 2005). More than half of these languages, however, are spoken by very small communities of between 1,000 and 10,000 fluent speakers. On the other hand, only ten languages (Chinese, English, Spanish, Hindi, Arabic, Russian, Bengali, Portuguese, German, and French) are spoken by more than half of the world's population. Accompanying this rapidly growing predominance of a few languages is a correlative, if not proportional, loss of the diversity of the many languages that coevolved with unique ecological and cultural environments. This global "language shift" (Harmon 2002) has been accelerated by growing assimilation pressures that lead to the collective abandonment of native languages.

Many threatened languages belong to microlanguage families spoken by fewer than 100 people. For instance, the Fuegian language family in southern South America includes four languages, of which two are already extinct (Selknam and Haush); the other two are nearly extinct, spoken by fewer than ten persons among the Yahgan and Kaweshkar peoples (Rozzi 2001). Worldwide more than 10 percent of the living languages are "nearly extinct," almost 30 percent are highly threatened (there are fewer than 10,000 speakers), and as many as 90 percent of the languages may vanish during the twenty-first century (Krauss 1992, Maffi 2005).

Biocultural diversity, especially among indigenous peoples, faces three major challenges. First, more than 70 percent of the 6,912 languages in the world are endemic; hence the indigenous peoples who speak them represent most of the world's cultural diversity (WGPI 2001). Second, the populations of 5,000 indigenous groups number a mere 300 to 350 million, less than 6 percent of the world total. Third, the areas of highest biological diversity (over a wide biogeographical range from the polar regions to the deserts, from coastal areas to high-altitude zones, from savannas to tropical and temperate rainforests) are inhabited by indigenous people. More than two-thirds of the world's languages are spoken in the 238 ecoregions that the World Wide Fund has identified as the highest-priority targets for biodiversity conservation efforts (Oviedo and Maffi 2000). These three interrelated considerations underscore the fragility of biocultural diversity.

Foreseeing this scenario, Darrell Posey led the way in creating the International Society of Ethnobiology in 1988. That year the group's first international congress, held in Belém, Brazil, issued the Declaration of Belém, which called public attention to the need to better understand and conserve the "inextricable links" between biological and cultural diversity. Four years later, during the Earth Summit, another landmark international conference held in Brazil, these biocultural links were recognized by the Convention on Biological Diversity (CBD). In its preamble the CBD states, "The Contracting Parties … recogniz[e] the close and traditional dependence of many indigenous and local communities embodying traditional lifestyles on biological resources, and the desirability of sharing equitably benefits arising from the use of traditional knowledge, innovations and practices relevant to the conservation of biological diversity and sustainable use of its components. …"

The terms *traditional ecological knowledge* (TEK) and *indigenous knowledge* (IK) were first used in 1979 and 1980 (Maffi 2001). It was only under the influence of the United Nations Conference on the Environment, or Earth Summit, held in Rio de Janeiro in 1992 (Rio 1992), however, that these terms gained wide currency. Rio 1992 generated global awareness about the connections between biodiversity and indigenous knowledge. The CBD, Agenda 21, and the Global Biodiversity Strategy signed in Rio in 1992 affirmed the principle that "cultural diversity is closely linked to biodiversity. Humanity's collective knowledge of biodiversity and its use and management rests in cultural diversity; conversely conserving biodiversity often helps strengthen cultural integrity and values" (WRI, WCU, and UNEP 1992). In turn, the U.S. National Research Council (NRC) stated in 1992 that "a vast heritage about species, ecosystems, and their use exists, but does not appear in the world literature" (National Research Council 1992, p. 179). It therefore recommended that development

agencies place greater emphasis on, and assume a stronger role in, systematizing the local knowledge held by indigenous peoples as recorded in the gray literature (e.g., reports and other non-academically published documents) and in anecdotes. The NRC report declared, ''If indigenous knowledge has not been documented and compiled, doing so should be a research priority of the highest order. Indigenous knowledge is being lost at an unprecedented rate, and its preservation, preferably in data-base form, must take place as quickly as possible'' (National Research Council 1992, p. 113).

FORMAL EDUCATION AND LOSSES OF BIOCULTURAL DIVERSITY

In spite of growing conservation efforts, the juggernauts of cultural assimilation and homogenization are still charging through the global village. One of the main causes of linguistic and cultural diversity loss is formal education. Worldwide fewer than 500 languages are used and taught in formal education, leaving out more than 90 percent of the world's languages. In addition, more than half of the world's 193 sovereign states are officially monolingual. These educational policies are due not only to the dominance of colonial languages such as English and Spanish but also to internal political conflicts. For example, in Africa many states see minority languages as a threat to national unity. Home to 2,092 languages, Africa harbors more than 30 percent of the world's linguistic diversity. According to Herman Batibo (2005), unless ''unmarked bilingualism'' (in which two or more languages of unequal social prestige are treated equally) is achieved in Africa's formal education systems, minority language speakers will continue to face the dilemma of either (a) abandoning their native languages (and the ecocultural forms of knowledge that inhere in them) in order to gain access to the wider society or (b) conserving their languages, but at the price of consigning themselves to the margins of their multiethnic nations.

Languages, like biological species, have undergone extinctions before. The peak of linguistic diversity on earth may have occurred at the beginning of the Neolithic Period, 10,000 years ago, when geographically discrete societies tended to have distinct dialects, contributing to the maintenance of strong group boundaries, internal social cohesion, and coordinated environmental practices (Nettle 1999). During the last 5,000 years the colonial expansions of dominant civilizations have ridden roughshod over tribal languages and cultural traditions, with attendant losses in tribal people's sovereignty and control over their ancestral territories and resources. The temporal rate and biogeographical scale of current global cultural homogenization is, however, unprecedented. The spread of the dominant culture is proceeding by way of linguistic assimilation as the languages of the stronger groups monopolize education, the media, government, and other avenues of public discourse. Because most languages are unwritten, undocumented, and unrecorded, their disappearance will be as irreversible as that of living species (Maffi 2001).

BIODIVERSITY

The neologism *biodiversity* was introduced as a contraction for *biological diversity* in the mid-1980s to describe the intended target of preservation efforts by conservation biologists (Takacs 1996). The new term was meant to include more than the game species, other resource species, and charismatic species that had been the targets of most earlier conservation efforts. All aspects of biological heterogeneity, whether structural, functional, or taxonomic, were to be included in its scope. There was a synergistic interaction between the growing use of the term in the 1990s and the spread of conservation biology, which emerged as an organized discipline in the 1980s (Sarkar 2005). As David Takacs observed: "In 1988, *biodiversity* did not appear as a keyword in *Biological Abstracts,* and *biological diversity* appeared once. In 1993, *biodiversity* appeared seventy-two times, and *biological diversity* nineteen times" (Takacs 1996, p. 39). The first journal with the term in its title, *Canadian Biodiversity,* began publishing in 1991 and changed its name to *Global Biodiversity* in 1993; a second, *Tropical Biodiversity,* began appearing in 1992; *Biodiversity Letters* and *Global Biodiversity* followed in 1993. The Society for Conservation Biology was founded in 1985, and its journal *Conservation Biology* started appearing in 1986. The goal of conservation biology is the preservation of biodiversity.

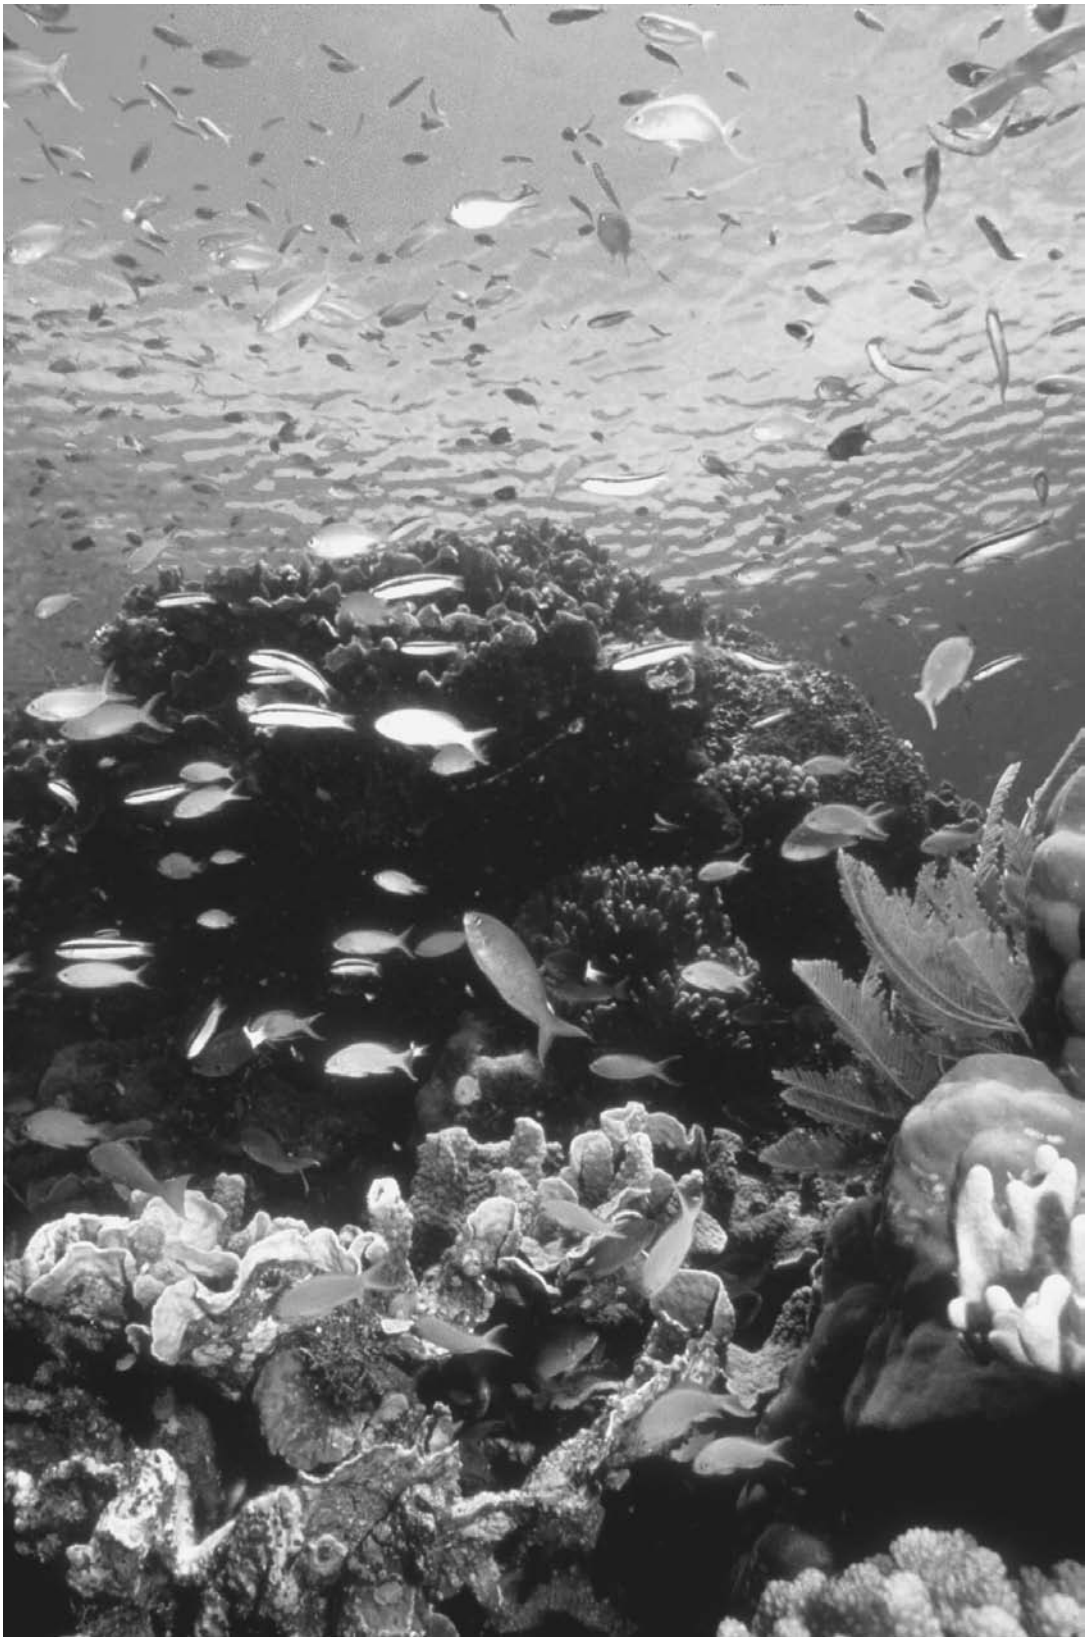
NORMATIVE CONCEPTS AND ISSUES

Because of its origin as the target of a goal-oriented enterprise, conservation biology, the concept of biodiversity has a normative component as well as a descriptive one (Norton 2003a). A useful analog is health, the goal of medicine, and Michael Soulé (1985) and other founders of conservation biology have endorsed the analogy between the two disciplines. The normative aspect of biodiversity is critical to understanding the concept and manifests itself in five ways in the context of the formulation of conservation policy.

Justification of Biodiversity The justification of the normative claim that biodiversity should be conserved remains a contentious issue that is central to environmental ethics. At one extreme are proposals that attribute intrinsic value to biodiversity, to all taxa, and sometimes even to physical features of the environment (Callicott 1986, Naess 1986, O'Neill 1992). However, those attributions are most convincing when they refer to individual organisms rather than abstract entities such as species or, especially, higher taxa. Even this is controversial; some philosophers have held that species are individuals (Hull 1978). At the other extreme is the position that biodiversity deserves protection because of its instrumental value to humans in providing resources and other services. Between those positions are more nuanced forms of anthropocentrism (Norton 1987, Sarkar 2005) that sometimes are coupled to a pragmatic multifaceted approach that admits a plurality of values (Norton 2003b). Environmental ethicists continue to debate these issues. The critical point is that, if there is no adequate normative basis for biodiversity conservation, conservation biology becomes a dubious enterprise because its explicit purpose is the conservation of biodiversity.

Definition of the Normative Basis The way the question of the normative basis for biodiversity conservation is answered influences what counts as conservation. If all individual organisms have intrinsic value, the target of conservation should be each one of them. Even controlling an invasive species to protect the habitat of an endangered endemic species becomes an ethically suspect policy. Conservation becomes a question of protecting lives rather than preventing the extinction of species. If the justification for conservation is purely instrumental, conservation consists of natural resource management and "biodiversity" is little more than a fancy new name for living natural resources. All other proposals require a much broader approach to conservation and thus a more general concept of biodiversity than individual organisms or living natural resources.

Establishment of the Normative Basis The way the normative basis for biodiversity conservation is established influences the way conservation policy is conceptualized and formulated. In particular, conservation planning, which is a central part of the practice of contemporary conservation biology, increasingly is being approached within the formal framework of decision theory and often involves the use of extensive software-based decision support tools (Sarkar et al. 2006, Margules and Sarkar 2007). The use of such a framework presumes that there is an anthropocentric basis for conservation decisions that are ultimately supposed to be evaluated through the use of expected utility functions



Great Barrier Reef, Australia. *Biodiversity is a contentious term used to describe the intended beneficiaries of conservation biology efforts. With one-third of the ecosystem off limits to commercial fishermen and tightened restrictions on shipping, the Great Barrier Reef is the most protected coral reef system on earth.* **STR/AFP/GETTY IMAGES.**

constructed from (human) preferences as elicited through a variety of methods. If biodiversity conservation must be based normatively on intrinsic values, this approach to conservation is not valid.

Characterization and Operationalization The normative component of the concept of biodiversity constrains the way it should be descriptively (scientifically) characterized and operationalized for the field. Suppose that some very eccentric definition of biodiversity gives high values to *Mus musculus* (the house mouse) and *Sturnus vulgaris* (the European starling) in North America. However, independent of this putative definition of biodiversity, there would be little normative basis to expend limited resources on the welfare of either of those species. Both are widespread invasive species whose spread probably should be controlled. Because the purpose of conservation biology is the protection of biodiversity, which is a normative goal, something must have gone wrong with the way biodiversity was defined. Thus, carefully considered normative decisions that specify what is deserving of protection must enter into the definition of biodiversity. Typically, these decisions embody cultural values. As is discussed below, those cultural values influence the selection of ''true surrogates'' for the measurement of biodiversity in the field.

Sonja Vermeulen and Izabella Koziell (2002) emphasized the importance of local cultural values in the definition of biodiversity over global values that are not culturally shared. Arguably, this would come at the cost of not allowing the use of many scientific criteria, which are supposed to reflect universal values but may not be locally appreciated. However, when global values have dictated what counts as biodiversity and how different components of biodiversity are prioritized, the result has been political conflict, sometimes leading to serious deprivation of those with the fewest resources. For instance, conservation refuges have been created throughout the developing world (the South) to protect endangered species in nature reserves because those species are highly valued by northern environmentalists (Dowie 2005). The extent and severity of this problem are contested, but there is little doubt that it is a serious issue (Bogerhoff-Mulder and Coppolillo 2005, Brockington and Igoe 2006). Such situations create troubling ethical problems besides violating every canon of distributive justice, assuming that that is acknowledged as a desired end. Many critics from the South have criticized what they call the arrogance of northern biodiversity conservationists (Guha 1997).

Role in Policy Formulation Because biodiversity is a concept of recent vintage, its role, especially in the context of policy formulation, must be negotiated with the roles of other values, in particular the more traditional natural values that may be related to it. These other natural values include wilderness (''pristine'' habitats), natural resources, ecosystem services, and ecological integrity. There has been a long and unfortunate tradition in some northern countries, especially Australia and the United States, of conflating various natural values, in particular wilderness and biodiversity (Callicott and Nelson 1998, Sarkar 1999, Nelson and Callicott 2008).

The pursuit of these other values is often consistent with biodiversity conservation but sometimes is not. For instance, in a well-known Indian example, human noninterference (wilderness preservation) led to the decline of bird diversity in Keoladeo Ghana National Park (Sarkar 2005). Thus, wilderness preservation was in conflict with biodiversity conservation. Ecological integrity has also been urged as an alternative to biodiversity (Angermeier and Karr 1994) and is a central goal of ecological restoration (Higgs 2003). Because the concept of biodiversity comes with an obligation to protect biodiversity, care must be taken that its definition does not lead to normatively unacceptable conflicts with other values and, preferably, as few practical conflicts as possible.

SCIENTIFIC ASPECTS

With respect to the scientific or descriptive aspect of the concept of biodiversity, the characterization that it includes all taxonomic, functional, and structural biological differences is unexceptionable in principle. However, it is useless in practice because it cannot be estimated in the field. Conservation also is an impractical proposal: Every biological pattern and process becomes a target of conservation. As was stated above, biodiversity must be defined so that it will be an appropriate target of conservation and be amenable to the practical needs of conservation planning. This means that it must be operationalized in such a way that: (1) what it includes is deemed appropriate as a conservation target; (2) it must be estimable from field studies; and (3) preferably, it must be quantifiable.

If biodiversity is defined as all taxonomic, functional, and structural diversity, it falls afoul of the estimability and quantifiability criteria. A standard move at this stage is to suggest that three entities capture what is important about biodiversity: genes (alleles), species, and ecosystems (Meffe and Carroll 1994). As a simplifying proposal in the face of intractable complexity, this suggestion has merit. Conserving all allelic heterogeneity takes care of much of the diversity below the level of species. Conserving all species conserves all higher taxa, though it may not conserve interspecific hybrids. Conserving all ecosystems protects most communities, and so on. However, even this proposal is too broad: In practice it is impossible to

EXOTICS

Animals and plants have natural (native) ranges, some very small (just a few hectares) and some spanning continents. These native or indigenous biota (species, communities, and ecosystems), have adapted to a place in response to a range of physical and biological challenges imposed by the local environments (Elton 1958). These assemblages of species are not constant; some arrive as others leave, spurred by both natural and human-aided causes of dispersal. The concept of exotic species is, therefore, temporally relative and somewhat paradoxical.

When species arrive at a place where they did not evolve, they are often termed exotic or nonnative, and when they become well established and have negative impacts on environmental and production values, they are often termed invasive alien species (IAS). The distinction as used here between an exotic and an IAS is based on the perceived, predicted, or known undesirable impacts of the IAS. In fact if the "tens rule" of Christopher Bright (1998) is correct, 99 percent of exotics either do not establish or do not become invasive. That is, of those species introduced only about 10 percent will become established, and of those, only about 10 percent will cause significant impacts. Consequently, some have criticized as xenophobic the idea that all exotics are "bad."

Society's views of self-introduced exotics are diverse and often lead to controversy. One view is that human-assisted introductions are negative but that natural introductions are not, even though the latter might have significant negative impacts on the invaded ecosystem (Scherer 1994). Exotics, even those that have no negative impacts, are opposed by biological nativists, and Ned Hettinger (2003) defends this stance, arguing that it supports the persistence of regional and local biodiversity in the face of global homogenization and prevents the diminution of the wildness of natural systems.

Because attempts to predict which species will become invasive have had mixed success (Mack et al. 2000), Daniel Simberloff (2003) has argued that, given the possibility of an exotic becoming invasive—and the difficult, if not impossible, task of removing such a species—a philosophy of "guilty until proven innocent" should be used instead of the more widely used policy criterion, "innocent until proven guilty." Although most national policies are based on the latter philosophy, New Zealand's Biosecurity Act of 1993 was the first national law to not presuppose innocence (Simberloff 2003).

Charles Warren (2007) has argued that the conflicts surrounding the native/exotic construct are due partly to the arbitrary spatiotemporal character of the issue. He highlights the possible irony of promoting a multicultural human society while persecuting "foreign" species. Instead he advocates an alternative framework based on a "damage criterion" rather than putative biogeographical origins. On this view, eliminating an exotic (especially a sentient species) might be considered ethically indefensible unless that species were causing some undesirable impact. If that were the case, then the species would shift from being an exotic to an IAS and could then be managed within an ethical framework suggested for IAS.

estimate allelic and species diversity in almost any habitat. The definition also excludes biological processes.

It thus is necessary to choose surrogates for biodiversity ("true surrogates" in the terminology of Sarkar and Margules 2002). The estimability problem is solved by making sure that these are tractable sets of taxa, ecosystems, processes, and so on. The normative question of what should be conserved now plays the role of

determining which set is appropriate. In the United States, for instance, typical true surrogates are endangered and vulnerable species. Some conservation agencies, such as Conservation International, use critically endangered species as defined by the International Union for the Conservation of Nature and Natural Resources Red List along with endemic species. Others, such as the Nature Conservancy in many regions, use carefully delineated habitat types.

From a scientific perspective there is thus a conventional element in the definition of biodiversity through such surrogates in the sense that it is not based entirely on scientific facts. However, from the normative perspective these are not conventional choices. Instead, they reflect deep cultural judgments of what is worth preserving and thus require care in their exercise. For instance, all the choices of true surrogates mentioned above mark a shift in cultural values away from charismatic species to a more inclusive set of taxa.

There is also a further level of complication. In many situations even the true surrogate set (e.g., if it is something broad, such as all vertebrate species or all vascular plant species) is too difficult to measure in the field. (Measuring all species, including microbial species, is nearly impossible in any habitat unit large enough to be of potential conservation interest.) In this situation "estimator-surrogates" must be used to represent true surrogates for biodiversity, especially in biodiversity conservation planning. For instance, a set of environmental parameters (which are much easier to measure and model) may be adequate to represent many taxonomic groups (the true surrogates) in many regions (Sarkar, et al. 2005). Techniques of surrogacy analysis have been developed to quantify the extent to which there is a match between planning outcomes using true and estimator surrogates (Margules and Sarkar 2007). However, there remains the question of how biodiversity or, equivalently, the true surrogate set should be assessed quantitatively.

COMPLEMENTARITY

Since the 1960s, ecologists have distinguished between α-diversity, or the diversity within a study unit; β-diversity, or the diversity between study units; and γ-diversity, or the total diversity of a region (Whittaker 1960). A wide variety of mathematical measures were proposed to quantify each of these three concepts. Typically, the diversity referred to in those studies was diversity at the level of species. In the 1980s several groups of conservation biologists independently began to use a measure of diversity that came to be called complementarity (Vane-Wright, Humphries, and Williams 1991): If areas are being selected iteratively for conservation, the complementarity value of an area is the extent to which it includes new entities not already present in the areas previously selected (Justus and Sarkar 2002). If areas are selected to maximize complementarity, they add the most diversity to the total set of selected areas. There have been many variants of this idea, in particular, the suggestion to include broader measures of taxonomic and phylogenetic diversity than species diversity.

It can be shown that the use of complementarity typically leads to nearly optimal spatial economy in the selection of conservation area networks, that is, to the representation of a full complement of the biodiversity of a region (represented by true surrogates) in as small an area as possible (Margules and Pressey 2000). Sahotra Sarkar (2002) argued that procedures using complementarity provide an implicit quantitative measure of biodiversity that is sufficiently precise for the purposes of conservation, in which all this measure must permit is a comparative assessment of how important different areas are when some but not all of them are to be selected for conservation. Anne Magurran (2004) pointed out that complementarity is essentially a measure of β-diversity because it quantifies the extent to which a new area is different from those already selected.

The recognition that complementarity is a measure of β-diversity establishes an important conceptual link between the measurement of biodiversity in conservation planning and the older work of quantifying ecological diversity, which was not initiated with policy development as an explicit goal (Sarkar 2007). Because the practical selection and implementation of conservation area networks is the central goal of systematic conservation planning, when a (descriptive) diversity measure is used for this purpose, it is incorporated explicitly into (normative) policy formulation. However, the choice of the true surrogate set for which this diversity measure is being assessed quantitatively ultimately must be based on normative judgments about what it is important to conserve. Thus, descriptive and normative judgments are being simultaneously integrated in planning protocols rather than a descriptive judgment being adopted within the policy framework. This means that both the descriptive and the normative aspects of the concept of biodiversity remain central to its use within conservation biology, as they were when the concept was introduced.

SEE *Energy.*

BIOPHILIA

The Harvard biologist Edward O. Wilson, who popularized the term *biophilia,* describes it as an "innately emotional affiliation of human beings to other living organisms" (Wilson 1993, p. 31). Two aspects of that definition are especially important. First, Wilson argues that biophilia is innate and therefore part of humans' genetic heritage and evolved nature. Second, biophilia is an emotional response that can be an end in itself (feeling a sense of pleasure and well-being), or it can stimulate emotions that motivate various kinds of behavior (interest motivates exploration).

If biophilia is an innate human characteristic, how did it evolve? There is general agreement among researchers that Homo sapiens' long history as hunters and gatherers, intimately involved with nature, has influenced how humans perceive and respond to the physical environment. There are differences among researchers, however, about the nature of the adaptation and how it manifests itself. Wilson (1986) describes biophilia as a complex of learning rules that guide adaptive response to natural stimuli. The rules are reinforced through cultural adaptations, such as myths and stories. As Wilson notes, "When human beings

remove themselves from the natural environment, the biophilic learning rules are not replaced by modern versions equally well adapted to artifacts'' (1993, p 31). Thus, the learning rules are fragile and need to be reinforced through contact with nature.

Tooby and Cosmides (1992) take a different perspective. Rather than possessing weak learning rules, the brain, in their view, is composed of thousands of modules designed to solve specific problems that have occurred regularly over the course of human evolution. In this version biophilia consists of hundreds of modules designed to solve problems regularly encountered in ancestral habitats: avoiding predators, separating toxic from nontoxic foods, using clouds to predict weather patterns, and using flowers to signal future resource availability. Each module is rich in content, with its own reasoning process and information-gathering structure. For instance, rules about selecting nutritional plant resources would be different from rules about predators because the problems posed by these two situations are very different.

At this time there is not enough research evidence to support one or the other perspective. However, there is good evidence from cross-cultural studies that the brain has an evolved intelligence that grew out of the need for detailed information about nature (Atran 1992; Mithen 1996). Mithen notes that all known cultures have notions of plant and animal ''species,'' all cultures construct taxa based on morphological patterns, and all cultures have life-form groupings for animals (fish, birds) and plants (trees, flowers, grass).

Further evidence of evolved responses to nature comes from controlled laboratory studies. A series of conditioning experiments by Öhman (1986) showed that physiological and emotional responses to fear-arousing stimuli (snakes and spiders) can occur subliminally, with subjects having no conscious recognition of having seen the stimuli. Similar responses do not occur to modern threats such as guns.

THE SAVANNAH HYPOTHESIS

Humans have gradually come to occupy diverse biomes and habitats across the globe. Gordon Orians argues that the long period of evolutionary development in the savannahs of Africa should have left a positive mark on the human psyche (Orians 1980, 1986; Orians and Heerwagen 1992; Heerwagen and Orians 1993). According to the ''savannah hypothesis,'' people should prefer to be in savannahlike environments because they once provided a better resource base than forest or desert biomes. Key characteristics of the savannah include the following:

- scattered clusters of trees that provided shelter from the sun and protection from terrestrial predators,
- long-distant views that afford surveillance for predator detection and avoidance,
- even ground cover for efficient movement across the terrain,
- a rich diversity of plant and animal species,
- rock outcroppings for surveillance or sleeping,
- seasonal variation in fresh water availability because of rain patterns.

What evidence exists for the savannah hypothesis? Do people prefer to be in landscapes that have these features? Studies in landscape planning unrelated to biophilia have consistently shown that people prefer semiopen landscapes with large trees and water to either dense forests or deserts (Ulrich 1993); people consistently dislike scruffy, dense habitats with rough ground texture. Similar results prevail across cultures.

The strongest results relate to water. Coss (2003, Coss and Moore 1990) argues that selective pressures to find sources of fresh water should have been particularly strong in the savannah habitats of Africa because of the strong seasonal variations in rain. Studies of water perception (summarized in Coss 2003) show that people respond very positively to sparkle, reflections, and surface movements of water. Early humans may have used visual sparkle in particular as a cue to the location of water because it can be seen in the distance, whereas reflections and water-surface movements can be seen only on closer inspection. Reflection and movement may have been used as indicators of water quality.

BENEFITS OF NATURE

Since the mid 1980s, research in a variety of fields has shown that contact with nature generates emotional, physiological, and social benefits. Research on this topic has been conducted in workplaces, hospitals, urban environments, and experimental laboratories. The findings point consistently to the value of features of nature such as large trees, flowers, and water. Studies also show that benefits of nature occur in many ways: through direct contact (sitting in an outdoor garden), indirect contact (through a window view), and from simulations using nature decor (such as posters or paintings).

Nature through the Window Ulrich's research (1984) was the first to focus on the links between nature, emotional functioning, and health associated with window views. His study found that hospital patients in rooms with views of trees had a better recovery from surgery than a matched group of patients whose view was a brick

wall. Patients with the nature had shorter hospital stays, needed less medication, and drew more positive reactions from the nursing staff about their recovery. Studies in office settings have also found reduced stress associated with window views of nature (Kaplan 1992).

Simulated Nature Ulrich's studies have included laboratory experiments using photos and videos in which he has consistently found that subjects recover from stress more quickly and are in more positive moods if they are shown nature scenes or urban scenes with nature rather than urban scenes devoid of natural elements (Ulrich 1993).

Others have shown that nature contact, whether real or simulated, can be beneficial. For instance, a study of windowed and windowless offices by Heerwagen and Orians (1986) found that people in windowless spaces used twice as many nature elements (posters and photos especially) to decorate their office walls than those who had views of natural areas outdoors. A laboratory study of "green exercise" tested the effects of projected scenes on the physiological and psychological outcomes of subjects on a treadmill (Pretty et al. 2005). They found that all subjects benefited similarly in physiological outcomes but that subjects who viewed pleasant nature scenes (both rural and urban) scored higher in measures of self-esteem than those viewing totally urban scenes or "unpleasant" rural scenes with destroyed landscapes.

Outdoor Nature and Gardens Urban nature also has benefits for health and well-being. For instance, a study of public housing projects in Chicago found that large trees had a significant impact on residents' social behavior (Kweon et al. 1995, Sullivan et al. 2004). Using behavioral observations and interviews, the researchers found that housing developments with large trees motivated people to be outdoors and that, once there, they talked to their neighbors and developed stronger social bonds than people in similar housing projects without green space and trees.

There is also growing evidence that both active and passive contact with gardens provides psychological, emotional, and social benefits. Cooper-Marcus and Barnes (1995) found that the benefits of gardens include better recovery from stress, having a place to escape to, and improved moods. Benefits also occur with horticulture therapy, especially in clinical settings and nursing homes. Studies described in Morris (2003) show that dementia and stroke patients who engage in gardening show improved mobility and dexterity, more confidence, and improved social skills.

Indoor Vegetation Indoor plants are commonly used in many workplaces as enhancements of the aesthetic and psychological atmosphere. Researchers in Norway found that plants also had physiological benefits. The field experiment in an office environment found that workers who had a cluster of plants near their desks showed a decrease in neurophysiological symptoms (with the greatest decrease in fatigue) and a decrease in mucous-membrane symptoms when the plants were present (Fjeld et al. 1998).

Outdoor Green Space Researchers in the Netherlands conducted a nationwide study of the benefits of green space—which they call Vitamin G—at the household, community, and regional levels (Groenewegen et al. 2006). Using national health survey data arrayed on a geographical information system, the researchers have found preliminary evidence that residents who are closer to green spaces enjoy better health than residents who are farther away. The data analysis has controlled for socioeconomic factors that have known links to health.

Cognitive Benefits In addition to the emotional and physiological benefits from nature contact, there is some evidence of a linkage to cognitive functioning. Lohr and her coauthors (1996) found that subjects working in a windowless room with plants completed a series of computerized tasks faster, had lower blood pressure readings, and felt more attentive than subjects working in the same room without plants. In study of window views, Tennessen and Cimprich (1995) found that people whose view was predominantly natural had higher scores on a survey assessing directed attention and attention recovery. Hartig and his coauthors (1991) report similar results in a field experiment. People who went for a walk in a mostly natural setting performed better on an editing task than those who walked in a predominantly built setting or who quietly read a magazine indoors. Although the mechanisms underlying the links between nature and cognitive performance are obscure, there are several hypotheses. The first, proposed by Kaplan (1995), focuses on attention. Kaplan argues that visual contact with everyday nature reduces fatigue associated with intense concentration and thereby replenishes the attention system, enabling people to refocus easily after short nature breaks.

The other leading hypothesis, proposed by Ulrich (1993), argues that contact with nature improves cognitive performance through effects on mood. He draws heavily on research by Isen (1990), whose numerous experiments show that subjects in positive moods perform better on tests of creative problem solving than those who are in neutral or negative moods. Isen speculates that positive moods increase the tendency to "break set" and to see relatedness between divergent events or appearances; because good feelings promote diffuse rather than focused attention, people in a good

mood search more broadly for solutions and alternative interpretations. Joseph LeDoux (1996), one of the nation's leading brain researchers, cites neurological evidence to support this hypothesis. He has found that positive feelings lead to heightened activity of the right parietal brain region—the section of the brain that is associated with a more global, expansive cognitive style. Thus, positive feelings directly affect brain processes related to performance on tasks requiring creativity and novel problem solving.

BIOPHILIA AND SUSTAINABILITY

The human desire for contact with pleasant natural settings has many benefits but also presents a potential dilemma for sustainable living and for urban spaces. Humans' innate attraction to water, distant views, and lush vegetation often leads to unsustainable design practices. People create water features and lush gardens in the desert; they raze hilltop forests to build hotels and houses that take advantage of panoramic views. They build expensive houses and resorts along waterfronts rather than creating public access spaces or wildlife refuge. The desire to enhance the biophilic experience is reinforced by economic benefits. Houses and commercial buildings command higher prices and rents when they are located near water and green spaces and/or have lush landscaping (Heerwagen 2006).

Urbanization also presents a dilemma for biophilia. Ironically, it is in urban environments that contact with green spaces, trees, flowers, and water would be most beneficial as an antidote to urban noise, pollution, and other stressors. Yet green spaces and vegetation are not equally distributed in urban neighborhoods. The economically advantaged live in houses and condominiums bordering parks or the water's edge, whereas poorer neighborhoods often are devoid of such amenities. To overcome this deficit, planners, health practitioners, and landscape architects in New York City have banded together to promote the Restorative Commons (Meristem 2006) to bring nature amenities to all neighborhoods. Researchers in Sweden propose a similar idea: to "design communities that balance settlement density with satisfactory access to nature experience" (van den Berg et al. 2007).

BIOSECURITY

Biosecurity is a concept that bridges national security, disaster studies, and, in broader definitions, access to food and biological resources in general. After the terrorist attacks of 2001 in the United States and the subsequent mailing of letters containing anthrax spores, biosecurity increasingly was defined against the risks of premeditated attacks with biological weapons or the risks of disruptive events such as natural disasters. In some circles, such as the Food and Agriculture Organization (FAO), biosecurity continues to be used to refer to a broader array of issues that affect human health and well-being, such as food safety, animal and plant health, and environmental risks, but without mention of bioweapons or bioterrorism or environmental ethics.

DEFINITIONS AND CONSEQUENCES

The more narrow usage is still very broad, including a discourse on dual-use technologies, evaluation of state programs for biological weapons and biodefense, analysis of the capacity and motivations of terrorists, debate over the value of international law in reducing the threat through treaties such as the Biological Weapons Convention, assessment of the environmental harm that could arise from bioweapons programs, and similarities between bioattacks and natural disasters, along with the policy implications of all those issues. This discourse is saturated with ethical judgments and dilemmas, although they rarely are identified as such. Indeed, the addition of environmental impacts to the list of issues under discussion can be seen as a proxy for the trade-offs among competing values across domains that the shift to a national security discourse has entailed.

Because biotechnology is inherently dual-use—that is, it can be used for both civilian and military ends—regulation of military applications is likely to affect civilian uses. Biosecurity in this context means protection from the misuse of knowledge and technology in the life sciences, and policies to enhance biosecurity include regulation of access to pathogens, background screening of laboratory employees, possible censorship of journal articles, and the development of professional codes of conduct and education in ethics. In addition, surveillance measures to detect biological attacks have been introduced in many public places in the United States, and funds have been allocated to develop new vaccines and treatments, build high-security laboratories, and improve the ability of local communities to respond to emergencies. Although historically the main threat has come from state-sponsored programs for biological weapons, assessments since 2001 have been dominated by the risk of bioterrorism. Unfortunately, the U.S. policy responses to that risk have had the unintended consequence of multiplying the number of weapons-relevant facilities, biological agents, and trained personnel; this development may pose an increased security risk because of the increase in opportunities for diversion to weapons use.

Natural disasters may produce many of the same risks as biological attacks without the element of intentionality. Outbreaks of new virulent diseases or the spread of those diseases across national borders may pose a serious threat to human health regardless of whether they originate in an enemy attack or occur in the

aftermath of an earthquake or hurricane, and the same protective measures—surveillance, vaccines, quarantine, and the development of new treatments and response measures—apply. In both cases the threat is a global one, and an effective response requires international cooperation: Pathogens know no borders. Unlike natural disasters, however, for which there are both a large database of past events and tools for modeling risks, in the case of bioterrorism, data are few and methods for risk assessments are highly speculative.

RELATIONSHIP TO ENVIRONMENTAL ETHICS

Environmental ethics has been almost completely absent from the security-based discourse on biosecurity even though it is clear that any use or even tests of biological weapons may have substantial effects on the environment; the contamination of Vozrozhdeniye Island in the Aral Sea from a former Soviet bioweapons laboratory is a case in point. In practice, an accidental escape of pathogens or genetically engineered agents from a research laboratory has been the most frequently mentioned scenario, leading to a focus on safety regulations and the siting of the new high-security biodefense laboratories. Boston University, for example, has been criticized for placing its new laboratory in a poor South Boston neighborhood that is home to a substantial number of minorities rather than on land it owns outside the city.

Framing biosecurity as a national security issue suppresses consideration of environmental ethics because threats to national security generally are considered to trump other concerns: The national security sector was long exempt from environmental regulations and therefore paid little attention to the environment, and important aspects of biological weapons and biodefense programs have been cloaked in secrecy. Thus, the tests of biological weapons in the 1950s at Dugway Proving Ground in Utah, which surely had environmental consequences, were not publicly reported at the time. Moreover, the national security discourse is cast in instrumental terms, allowing little room for assigning intrinsic value to the environment.

A more inclusive treatment of the ethical dimensions of biosecurity would include analyses of how the threat of bioweapons resonates with environmental concerns by invoking images of a desecrated nature and of the risks to the environment of using genetic technologies to create or modify pathogens. The risk of unintended consequences, which haunts all human endeavors, would be linked to people's ethical obligations to future generations, and the specific risks that arise in each stage of a biodefense project from the laboratory, to application, to diffusion to other societies would be scrutinized for their effects on environmental justice. For example, the desire to prevent diversion of dangerous materials or knowledge to unauthorized users limits the opportunities for foreign students to receive training in U.S. laboratories that could help them address environmental problems in their own countries. Ethical analysis could contribute a missing dimension to discussions of the opportunity costs, especially for developing countries, of diverting resources to biodefense projects when immediate health needs lie elsewhere, and the relative merits of national and international approaches to enhance biosecurity in all its dimensions could be debated.

BLACK ELK
1863–1950

Nicholas Black Elk was born in December 1863 on the Little Powder River in present-day Wyoming or Montana; he died in Manderson, South Dakota, on August 19, 1950. A member of the Oglala tribe of the Teton Sioux (Lakota), he became one of the best-known American Indians of the twentieth century through the books written from information he provided. His great visionary experience is a classic expression of Native American spirituality in opposition to the values of twentieth-century America.

Black Elk received his great vision at the age of nine. In a dream he was taken to meet the spiritual embodiments of the universe, the Six Grandfathers—the four directions, the sky, and the earth—and was offered powers to heal and to destroy. At the age of sixteen, he began to publicly enact parts of his vision, the traditional means of validating and activating vision powers. Soon he became renowned as a healer.

Although he was born during the last years of tribal freedom, when the Sioux still made their livelihood from the buffalo herds, by 1881, when he began to use his healing powers, the buffalo were extinct, and the Sioux were confined to reservations. Black Elk settled on Pine Ridge Reservation, in southwestern South Dakota. The poverty, inactivity, and disease that plagued the reservations led Black Elk to question his beliefs, and when the opportunity came in 1886 to experience the world of the white men by traveling to New York and Europe with Buffalo Bill's Wild West show, Black Elk seized it. He embraced Christian teachings, many of which seemed to him compatible with his vision experiences. When he returned to Pine Ridge in 1889, many of his people were engaged in a new religious ritual, the Ghost Dance, a millennial movement that promised a renewal of the earth and the buffalo. In this new religion Black Elk found many parallels with both his visions and with Christianity. However, the Ghost Dance among the Sioux was ended by the massacre at Wounded Knee Creek on December 31, 1890; on that day almost 200 Sioux men, women, and children were killed by the Seventh U.S. Cavalry.

In the years after Wounded Knee, Black Elk continued his traditional healing ceremonies, but in 1904 he abandoned them and joined the Roman Catholic Church, becoming a catechist and a missionary to other Plains tribes. His great vision had placed a heavy burden on him to help his people, but he had failed. By putting it aside and choosing another path, he sought to help the Lakotas adapt to reservation life by adopting the ways of the white people.

Black Elk's life changed in 1930, when John G. Neihardt (1881–1973), the poet laureate of Nebraska, sought him out to learn about Sioux religious life. In Neihardt Black Elk found someone to whom he could entrust his great vision. The next year he told the poet his life story, on the basis of which Neihardt wrote *Black Elk Speaks, Being the Life Story of a Holy Man of the Oglala Sioux* (2004 [1932]). Further interviews with Black Elk in 1944 resulted in another book, Neihardt's historical novel, *When the Tree Flowered* (1991 [1951]). Inspired by reading *Black Elk Speaks,* the scholar Joseph Epes Brown (1920–2000) spent the winter of 1947–1948 recording the material that became *The Sacred Pipe: Black Elk's Account of the Seven Rites of the Oglala Sioux* (1989 [1953]). It is the mature expression of Black Elk's religious thought, an amalgam of traditional Sioux beliefs and rituals and fundamental Christian concepts.

In his childhood vision Black Elk perceived the world as a circle bisected by two roads: the red road of life passing from north to south and the black road of death passing from west to east. Where they crossed in the center, a sacred tree bloomed, symbolizing the harmony of all living things. But for Black Elk, the sacred tree was dead; his vision was supposed to give him the power to make it flower, but, defeated by trying times of rapid change, he could not accomplish this task. The vision, however, showed him his people traveling the red road through four "ascents" (generations), at the end of which the tree bloomed again and the animals and humans lived together in harmony. *Black Elk Speaks,* in a sense, put that journey in motion. Although the book was not immediately successful, when it was reprinted in paperback in 1961, it became an immediate countercultural classic, eloquently expressing a perspective on the natural world that served to fill the spiritual void of the tumultuous 1960s.

In subsequent years scholars argued about the relationship between Black Elk's spirituality and Christianity, but from any perspective his teachings have become the quintessential expression of a North American Indian environmental ethic. Oneness and relationship are the hallmarks of Black Elk's vision. In it, the world is conceptualized as one, symbolized by a circle. All things within the circle are related to one another, and all are holy. Every form of being, such as the two-leggeds (humans), four-leggeds (animals), wingeds (birds), grasses, and stars, is a people. All are kin and bound together in their common mystery, the totality of which is Wakan Tanka (great spirit or god). This Native American ecological vision continues to speak to new generations who are concerned with the perpetuation of the life of the planet.

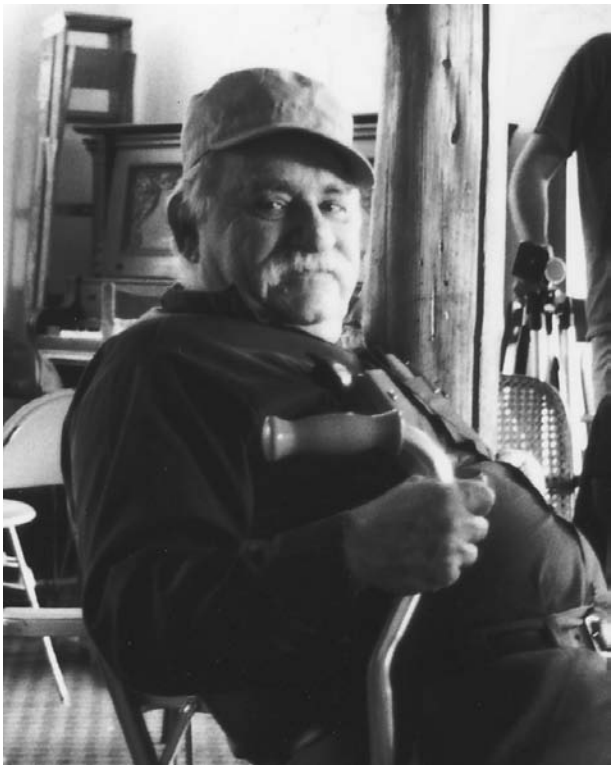
BOOKCHIN, MURRAY
1921–2006

Murray Bookchin was born on January 14, 1921, in New York City to Russian immigrant parents. A founder and ardent defender of the school of thought known as Social Ecology, he was a leading advocate of left-libertarian and anarchist ideas. Early in life he was involved with Marxist, Communist, and Trotskyist movements but broke from these associations as he embraced more antiauthoritarian, ecological, decentralized, and democratic orientations in philosophy, politics, and community organization. Through his many books and direct political action Bookchin exercised lasting influence on the green movement within the United States, introducing and interjecting ecological thought into radical politics, especially the counterculture and New Left during the 1960s and 1970s. He wrote extensively on technology, urbanization, social history, political theory, and grassroots democracy, cofounding in 1971 the Institute for Social Ecology in Plainfield, Vermont.

Bookchin's contributions to environmental philosophy center on the integration of radical social critique with a developmental view of nature and a theoretical and practical vision of ecological communities. His early work on revolutionary ideas and particularly what he called "postscarcity" anarchism provided the underpinnings for his later thought and inspired the growth of ecological anarchism—the wedding of ecological and antihierarchical perspectives.

The theory of Social Ecology stresses the graded emergence of mind from the natural world, the continuities between first (biological) and second (cultural) nature, and their possible synthesis into an ecological society. Bookchin argued that humans can find a ground for ethics and freedom within nature itself, which, in his view, develops dialectically toward ecological complexity, spontaneity, unity-in-diversity, and complementarity.

Influenced by and creatively responding to the work of Aristotle, G. W. F. Hegel, Karl Marx, Peter Kropotkin, Hans Jonas, and the Frankfurt School, Bookchin formulated the notion of dialectical naturalism, which sought to "ecologize" dialectical and historical processes and to anchor ethical judgment in a natural ontology and causality. He propounded a sophisticated theory of how the domination of nature relates to the domination of humans by one another. In so doing Bookchin focused on the ills of hierarchy (as opposed to class analysis), the benefits of freedom (as well as justice), the insights of organic cultures and the anarchist tradition, and the reconstructive and integrative contributions of the science of ecology. He advanced, too, a conception of libertarian municipalism in which free and local institutions emerging from democratic assemblies might oppose and supplant state institutions, helping to foster ecocommunities, greater civic participation, and a closer harmony between city and countryside.



Murray Bookchin. *As founder of the Institute for Social Ecology, Bookchin has had a lasting influence on various ecological movements and philosophies.* **PHOTO COURTESY OF JANET BIEHL.**

Bookchin interpreted environmental problems in terms of distinct social origins and dynamics. His first book, *Our Synthetic Environment* (1962), warned trenchantly of the dangers of chemicals in food and the environment, but it was not as widely read as Rachel Carson's seminal work *Silent Spring*, which appeared half a year later. His influential essay "Ecology and Revolutionary Thought" (1965) anticipated and articulated some of the concerns of later environmentalists and suggested constructive links between the workings of the natural and social worlds, detailing the ways in which humans are simplifying the environment and possibly undoing organic evolution. *The Ecology of Freedom* (1982), perhaps his most important theoretical contribution, explored the history of social hierarchy and proposed that the control and power exercised by humans over other humans through age, sex, politics, religion, and "epistemologies of rule" have led to the demise of organic societies and the rise of vexing ecological predicaments. In this regard, he both critiqued and reversed the view,

espoused by many Marxists and Frankfurt School theorists, that the increasing human dominion over nature had given rise to class differences and social problems.

Bookchin was critical of the market economy—which he claimed is unjust, unethical, and antiecological—contrasting it with a moral economy rooted in emancipatory institutions and community relations. He was also critical of many other philosophical perspectives on the environment. He challenged New Age greens, ecological socialists, Marxists, and even "lifestyle" anarchists while engaging in pointed and often polemical exchanges with Deep Ecologists (especially those allied with Earth First!), characterizing their positions as conceptually confused, irrational, shallow, or politically dangerous. Although Bookchin developed forms of philosophical naturalism in environmental friendly directions, some critics object to the prominence of teleology and naturalistic ethics in his thought in particular and in philosophical or ecological discourse in general. Other critics contest his focus on interpretations of decentralization, hierarchy, technology, and the anarchist or radically libertarian traditions to which he appealed.

Although Social Ecology is closely wedded to the contributions and personality of a single figure in Bookchin, it has constructively and provocatively encouraged many environmentalists—from bioregionalists to ecological feminists—to develop deeper understandings of the emancipatory potential of social and political theory. Bookchin's work, with its ambitious blend of historical analysis, utopian social vision, and ecological awareness, remains an important influence on unfolding dialogues and debates in environmental ethics, environmental philosophy, and environmental politics.

BORLAUG, NORMAN
1914–

Norman E. Borlaug, who generally is known as the father of the Green Revolution, was born on March 25, 1914, in Cresco, Iowa. He received a bachelor of science degree in forestry and a master's and a doctorate in plant pathology from the University of Minnesota. He began working in Mexico after 1944, first as a researcher with the Rockefeller Foundation and then with the International Center for Maize and Wheat Improvement (CIMMYT), where he has held various positions, including that of a senior consultant. He also has been associated with and taught at Texas A&M University.

Borlaug's contributions to global food availability, reduced poverty and hunger, and the management of natural resources are of critical importance to environmental ethics. Because of Borlaug's work in plant breeding and advice to governments, the footprint of agriculture on the environment has become much smaller. Without his work, which dramatically increased agricultural production per unit of land and labor, millions of acres of forests and wilderness areas would have been plowed under, with disastrous implications for biodiversity, land degradation, climate change, and other environmental factors. In addition, many millions of people would not have survived what was predicted by many to become an epidemic of starvation in parts of Asia during the 1960s and 1970s.

The contributions of Borlaug and his colleagues are highly visible in the countryside of many developing countries, including China, India, Pakistan, Bangladesh, and Mexico. Poor farmers gained access to high-yielding varieties of wheat and maize that were developed under the leadership of Borlaug, which helped them double and in many cases triple production on the land they controlled while reducing the cost of producing a bushel of

grain, increasing incomes, and reducing poverty and hunger. Even bigger benefits accrued to wheat and maize consumers, who, because of the reduced costs of producing a bushel of grain, could meet their food needs at lower prices. This was particularly important for the poorest, who spend a large proportion of their incomes on food.

The Green Revolution, a term first used in 1968 by former United States Agency for International Development director William Gaud, made it possible for millions of people to feed their children, get health care for them, and send them to school; construct better houses; buy radios, bicycles, and other necessary items; and invest in income-earning activities within and outside agriculture. The work done by Borlaug and his colleagues started a self-reenforcing cycle that helped millions of people out of poverty and saved millions of children who were expected to die from hunger and malnutrition. Since the beginning of the Green Revolution, Asian food production has increased faster than the population. The Malthusian perspectives that food production would not be able to keep pace with population growth were eliminated from Asia.

Borlaug received the Nobel Peace Prize in 1970 and later was given the Presidential Medal of Freedom and the Congressional Gold Medal, the highest civilian honor that can be bestowed by the U.S. Congress. He is one of only five individuals who received all three of those honors. More than fifty universities in twenty countries bestowed honorary doctoral degrees on Borlaug, who was invited to join a large number of national academies of science and received many other awards and recognitions.

In spite of his advanced age, Borlaug continued to travel extensively in the first decade of the twenty-first century, giving lectures and seminars, advising governments, training younger scientists and agricultural development experts around the world, and, as the leader of the Sasakawa Africa Association, promoting productivity increases in African agriculture. He is a strong supporter of the use of modern science, including molecular biology, to feed future generations without damaging the environment.

BRITISH ECOLOGICAL SOCIETY

The origins of the British Ecological Society (BES) lie in an ad hoc group of botanists that in 1904 formed a "Committee for the Survey and Study of British Vegetation," to explore the factors determining the distribution and associations of the British flora. The members of this Vegetation Committee became in 1913 the Council of BES, the first ecological society in the world. One of the benefits of membership was to be a quarterly journal, the *Journal of Ecology*, the first number of which was printed in time for the inaugural meeting of the Society. The inspiration behind the Society was thus the British tradition of field study, which differed from the more physiological and analytical approaches prevalent at the time in the United States and continental Europe.

The first president of the BES was Sir Arthur George Tansley (1871–1955), a dominant figure in the development of ecology. In 1901 he founded the journal *New Phytologist* to provide an English language medium for botanical notes; in 1935, he propounded the concept of *ecosystem* to counteract the superorganism idea of community and succession associated particularly with Frederic Clements (1874–1945) of the Carnegie Institute in Washington, DC. Tansley chaired a BES Committee in 1942 and 1943 that recommended to the United Kingdom government the establishment of National Nature Reserves, and was then first chairman of the (statutory) Nature Conservancy set up in 1949 to manage these.

The BES membership was almost entirely botanical in its early years. The first zoologist to be elected as president was A. E. Boycott in 1932; since 1940, the presidents of the Society have tended to alternate between botanists and zoologists, each serving a term of two years. In the same year that the BES was founded, Victor Shelford of the zoology department at the University of Chicago (who became the first president of the Ecological Society of America, itself founded two years after the BES) published the first detailed study of a particular animal community. Julian Huxley (1887–1975), then at Oxford University but later to become first secretary-general of UNESCO, gave a copy of Shelford's book to one of his students, Charles Elton (1900–1991). At Huxley's instigation, Elton wrote a seminal text on *Animal Ecology* (1927) and went on to become the founding editor of the second BES journal, *Journal of Animal Ecology,* launched in 1933. In 1931, Elton met Gifford Pinchot (1865–1946), founder and head of the U.S. Forestry Service, an encounter that alerted Elton to the importance of practical conservation and Pinchot to the necessary underpinning of ecological science for conservation practice. In the same year Elton met Aldo Leopold

(1887–1948), who introduced him to the notion of a land ethic.

The Society has around 4,000 members from many countries, mostly professional ecologists. Its mission is: "Advancing ecology and making it count." Besides specialized meetings and symposia, it arranges an annual meeting with a range of sessions grouped under headings, which may include topics such as the ethical implications of particular practices or attitudes, especially as they relate to conservation. In addition to the two original journals, BES publishes a *Journal of Applied Ecology* (launched 1964), *Functional Ecology* (1987), a quarterly *Bulletin* for members, the proceedings of annual symposia, and two occasional series, *Ecological Reviews* and *Ecological Issues*.

The BES maintains an office and secretariat at 26 Blades Court, Putney, London SW15 2NU, United Kingdom. Its website is www.BritishEcologicalSociety.org.

BRUNDTLAND REPORT

In 1983 the United Nations established the World Commission on Environment and Development to create a report that would analyze global environmental challenges and make policy recommendations. The report, presented to the United Nations General Assembly in August 1987, was titled *Our Common Future*. It is also known as the Brundtland Report in honor of the committee chair, Gro Harlem Brundtland. The report analyzes issues and recommends policies related to population, food security, biodiversity, natural resources, energy, and economic growth. It suggests that human impacts on the environment should be evaluated according to the criterion of sustainability. It concludes that sustainable economic development is possible but will require extensive international cooperation and the recognition of limits imposed by natural resources and technology. The report focuses on alleviating poverty, achieving greater equity in the distribution of global resources, and sustaining the natural environment (Sneddon, Howarth, and Norgaard 2006). The report suggests that sustainability requires maintaining essential features of the earth's life-supporting systems and recognizing that there are limits to the ability of these systems and of natural resources to support human activity.

The most enduring insight of the report is its famous definition of sustainable development as a process that "meets the needs of the present without compromising the ability of future generations to meet their own needs" (Brundtland Report 1987, p. 24). Adopted by many authors and organizations, this definition has found its way into most articles and books discussing sustainability. Sneddon, Howarth, and Norgaard suggest that the Brundtland definition of sustainable development is "the most widely accepted starting point for scholars and practitioners concerned with environment and development dilemmas" (2006, p. 255).

Although the report calls for decisive action to protect the environment, in 1987 its conclusions were more palatable for many than the dire predictions in the 1972 report by the Club of Rome titled *Limits to Growth*. The Brundtland Report's characterization of sustainability as a challenge rather than a limit made the idea more acceptable to business leaders and advocates of growth. Redclift suggests, "It was also the first overview of the globe which considered the environmental aspects of development from an economic, social and political perspective" (2005, p. 212). The Brundtland Report has proved to be a seminal document, giving rise to an extensive debate and a new political discourse among groups with widely different views of sustainability (Redclift 2005; Jamieson 1998; and Sneddon, Howarth, and Norgaard 2006).

Although the definition of sustainability used in the Brundtland Report is often the starting point of discussions about sustainability, its ambiguity about what needs sustaining has led to conflicting interpretations. *Weak sustainability*, favored by most economists, means simply sustaining the growth of the market economy by maintaining the capital stock used to produce goods and services (the so-called Hartwick-Solow rule). Weak sustainability is based on the belief that what matters for future generations is per capita income, maintained by the total stock of capital—manufactured, human, and natural. The key assumptions of weak sustainability are the fungibility of the various kinds of capital, per capita economic output as the key measure of social welfare, and an abiding faith in technology's ability to overcome natural-resource scarcity (Gowdy 2000). *Strong sustainability*, favored by ecological economists, means

sustaining the earth's life-support systems and insuring a stable and equitable socioeconomic system. On this view, sustainability is not only an economic problem but also one of maintaining essential, nonreplaceable, and nonfungible features of the environment. *Environmental sustainability* recognizes that ecosystems work by rules that are different from those that govern markets. Driven by evolutionary dynamics that do not favor particular species, ecosystems are often measured in long times scales—tens of thousands of years or more. Hence, the conditions for their dynamic stability are not easily understood. Environmental sustainability also explicitly recognizes our ethical responsibility toward other species.

The discussion in the Brundtland Report seems to align most closely with the notion of strong sustainability. Critics, however, suggest that strong sustainability still focuses on perpetuating human economic activity and does not adequately recognize the extent to which human well-being depends on maintaining the biophysical conditions under which our species evolved. Others object that the report neglects cultural context (Redclift 2005) and fails to uphold an environmental ethic that values nature for its own sake. Redclift argues that the worldview of "sustainable development" presupposes that market capitalism is a recent socioeconomic dynamic that will likely be superseded by other systems. Any notion of long-term sustainability should recognize the evolution of both human institutions and the biological processes.

BUDDHISM

The Buddha was a wandering sage in northeastern India around the sixth century BCE. Little is known about him beyond the legends that accumulated around his person in the first several hundred years after his death. It is unlikely, for instance, that he was the prince that later mythology made him. However, it seems that he lived a life of moderate renunciation after his withdrawal from the life of the world.

Although an innovator in terms of doctrine and practice, the Buddha drew heavily on elements of ancient Indian religious thought. The implications of his first sermon, in which he expounded the Middle Way, the Four Noble Truths, and the Eightfold Path, are that entities in the cycle of continuous birth and death (*samsara*) lack permanency or substance. He applied that insight especially to the human sense of self (*atman*) and, realizing that nothing of enduring value can be found in the intrinsically unsatisfactory (*dukkha*) realm of rebirth, sought a path that leads beyond life and death to the state of *nirvana.* By achieving that goal he became the enlightened one, or Buddha.

The Buddhist tradition accepts the idea that the full implications of enlightenment cannot be articulated in rational speech. Therefore, *nirvana* has tended to be expressed in negative terms. However, part of the Buddha's enlightenment experience was constituted by a profound insight into a universally applicable notion of causation in which all entities are deemed to be the effects of specific causes. The corollary of this is a strong view that there are no independent entities. This doctrine is acknowledged by all schools of Buddhism and is known as the rule of dependent coarising (*pratityasamutpada*).

The Buddha lived a peripatetic life, expounding the implications of those insights for many decades before succumbing to the forces of dissolution intrinsic to all conditioned things. Most Buddhist traditions hold that he died, possibly of dysentery, at the age of eighty. The essence of his message is enshrined in his dying words: "All conditioned things are subject to decay. Strive diligently for salvation" (Digha Nikaya ii.156). The Buddha's teachings were collected by close followers soon after his death, and that oral collection is said to have provided the fundamental point of departure for the development of all the scriptural assemblages of the later Buddhist tradition. However, the elevation of Buddhism into a world-historical tradition did not occur for several centuries after the demise of its founder.

FORMS OF BUDDHISM

The Indian ruler Asoka Maurya (reigned c. 268–239 BCE) appears to have adopted Buddhism after being revolted by the war and destruction he had caused in the early part of his reign. His support for one of the eighteen ancient schools that already had developed—that school now is called the Theravada ("way of the elders")—led to the export of the tradition to neighboring regions of southern and southeastern Asia. By the early Christian centuries

Theravada Buddhism had been established in Sri Lanka, Burma, Cambodia, Thailand, and Laos. However, the championship of Asoka did not prevent other forms of Buddhism from emerging in India, particularly in the northwest, where the Mahayana ("great vehicle"), a form of Buddhism that stressed the supramundane qualities of the Buddha and his advanced disciples more than the Theravada did, eventually spread along trade routes to China, Korea, and Japan. At a later time new forms of the Mahayana, often influenced by pan-Indian currents of Tantrism, a form of practice that emphasized ritual and magic, crossed the Himalayas into Tibet and Mongolia, although by the conclusion of that process Buddhism already was in decline in India. Central Asian Muslim invasions that began in the tenth century effectively uprooted Buddhism from the land of its birth.

The beginnings of significant Western interest in Buddhism can be traced to the period immediately after the European Enlightenment. However, at that time writers as diverse as Schopenhauer and Thoreau regarded Buddhism as a purely philosophical system. It was only in the early twentieth century, largely through personal contacts with Asian culture, that some Europeans and Americans saw its potential for personal transformation and began to take an interest in its practice. This theme was amplified in the post–World War II period, and in the early twenty-first century virtually all forms of Asian Buddhism, together with some that could be said to be unique to Western circumstances, have adherents in the West.

THE NATURAL REALM AND THE CONCEPT OF REBIRTH

Part of the attraction of Buddhism, especially in the West, has been its position on the nature of divinity. Although the Buddha accepted the existence of a host of gods and minor deities, he unambiguously rejected the notion of a supreme deity. He argued strongly that the world is not the creation of a god and that human beings are not creatures. The force that sustains human existence is not supernatural but the natural effect of actions

Stone Head of Buddha. *A sculpted head of Buddha, the "enlightened one," is entangled in the roots of a Banyan tree in Ayutthaya, Thailand. Although many consider Buddhism to be a more ecological religion than the Judeo-Christian tradition, others contest that Buddhism's environmental ethic is a more recent and possibly superficial development.* **AKVA, 2008. USED UNDER LICENSE FROM SHUTTERSTOCK.**

(*karma*). His model of the universe thus precludes any suggestion of a meaning, purpose, or end (*telos*) to existence. Existence is eternally present, but it must be scrutinized for what it is, not for what people imagine it to be.

As was noted above, the Buddha both borrowed from and critiqued the religious ideas of his time. He taught that sentient beings are subject to endless rebirth within *samsara,* although in line with the antimetaphysical bias of his teachings, he repudiated the idea that this process involves the transmigration of any permanent essence, such as the soul. Buddhism accepts the possibility of rebirth in one of six destinies (*gati*): the realms of the gods, the demigods, humans, animals, ghosts, and the denizens of hell. However, there are two peculiarities of this schema as it relates to the environmentalist credentials of Buddhism. First, none of the *gati* are permanent. Second, through the performance of virtuous actions (*karma*) all beings, even animals and denizens of hell, may be reborn in more favorable future states or more unfavorable ones.

The Buddhist cosmological schema assigns a special place to humans. Although gods and demigods live long and comparatively comfortable existences, their lives inevitably end in death. Furthermore, these two *gati* do not supply the necessary stimuli to follow the Buddha's path to its conclusion. The unfavorable existences of animals, ghosts, and hell beings, by contrast, are nasty, brutish, and short, characterized by anxiety and fear. Thus, the possibilities of heeding the Buddha's teaching are restricted. Only the precious human life provides the correct balance of pain and pleasure for the Buddha's words.

ECOPOSITIVE ASPECTS OF THE BUDDHIST TRADITION: ANIMALS AND PLANTS

Buddhism, like all the renunciatory traditions of ancient India, such as Jainism and Yoga, made a great virtue of contentment. However, in line with the Buddha's teaching on the Middle Way, monks were not expected to renounce property completely. Monastic discipline permitted some possessions, but they were to be used to the fullest extent and monks were enjoined to avoid all forms of luxury and wastefulness. Robes, for example, should be repaired repeatedly. Only when they deteriorated beyond a state in which they could be worn decorously could they be cut up and reused.

The Buddha rejected the cultured surroundings of the settled life to live a peripatetic existence as a dweller in forests and other sparsely inhabited places. The defining event of his life, his enlightenment, took place while he was sitting underneath a forest tree. The arc of his life thus was from civilization to nature, and that existence became an enduring model for future generations of his followers. Although few ever attain the ideal, the notion of the wilderness- or forest-dwelling monk has deep roots in all parts of the tradition. Indeed, the joy with which some of his earliest followers embraced that existence is a leitmotif: "Forests are delightful where [ordinary] people find no delight. Those rid of desire will delight here; they are not seekers after sensual pleasures" (Theragatha 992).

However, this is not a simple romantic quest for union with nature. The poet acknowledges that the forest is a place of danger and metaphysical dread that is avoided by most. However, those who are prepared to still the mind from which fear arises and contemplate this place of continual change will gain important insights into impermanence.

The centrality of the doctrine of dependent coarising (*pratityasamutpada*) in Buddhist thought appears to provide powerful support for the modern conception of ecology. If there are no independent entities, the interdependence and interrelatedness of things are established. The doctrine of the *gati* reflects this by pointing to the radical kinship of all living beings. All people have circulated endlessly through the six destinies, and as the Buddha observed to his monks: "Bhikkhus, it is not easy to find a being who has not formerly been your mother, or your father, or your brother, your sister or your son or daughter" (Samyutta Nikaya.ii.189). People's behavior toward other beings should be illuminated by this insight, and the idea was so pervasive that it became part of the ideal of Buddhist kingship in India. The Fifth Pillar and First Rock edicts of Asoka, for example, state that the Buddha satisfied his responsibilities for the protection of animals and birds.

Interrelatedness also underlines the important practice of meditation on loving kindness (*metta*), a staged process with a basic formula that is fully visualized: "May all beings be happy and secure, may they be happy-minded. Whatever living beings there are—feeble or strong, long, stout or medium, short, small or large, seen or unseen, those dwelling far or near, those who are born or those waiting to be reborn—may all beings, without exception be happy-minded" (Anguttara Nikaya ii.129). *Metta* is in fact the first of the four divine abidings (*brahmavihara*), a series of meditative exercises said to culminate in the cultivation of equanimity (*upekkha*), "an even-minded serenity towards beings which balances concern for others with a realization that suffering is an inevitable part of being alive" (Harvey 1990, p. 209).

The first precept, an ethical injunction equally binding on monks and laypersons, has the form "I undertake the precept to abstain from taking life." Yet unlike the Jains, the Buddha adopted the Middle Path in his understanding of the important pan-Indian concept of noninjury (*ahimsa*). For Jainism the ideal of *ahimsa* has absolute

value, and because all living things, vegetables included, suffer by being consumed, the final goal of the Jain ascetic, although rarely achieved, is death by starvation. The Buddha regarded that as too extreme. His monks were allowed to eat in moderation, but their food had to be collected through begging. Almost anything placed in the begging bowl had to be consumed. That included meat, assuming that the monk had not heard or seen the animal's slaughter or suspected that it had been killed on his behalf. Early Buddhist monks were not vegetarians.

The Buddha also laid down rules that prevented the monastic order (*sangha*) from engaging in agricultural activity, for digging the soil inevitably leads to the death of many small creatures. In Indian Buddhism plants were assigned a lack of sentiency, and that meant they were not regarded as being caught up in the round of rebirth. Instead, the plant kingdom was seen as constituting part of the backdrop or scenery of *samsara,* and little thought was given to its significance. However, when Buddhism became established in China and other parts of eastern Asia, it underwent a series of transformations, some arguing for the attainment of buddhahood by nonsentient beings (Japanese: *hijō jōbutsu*) to be applied specifically to the vegetable kingdom.

Monks must not damage plants and seeds intentionally during their wanderings, but these restrictions are not possible for the lay follower who must work the land to live. Although monks can follow the eightfold noble path to the ultimate goal of liberation fully, laypersons clearly are restricted by the manner of their livelihood. They can hope for rebirth in a more favorable *gati,* but it is unlikely that they will reach *nirvana* in this life. Nevertheless, monks need to be fed, and the layperson can cancel some of the demerit associated with his actions with the merit accrued by almsgiving.

Another idea retained by popular Buddhism is that trees may be the residences of tree spirits and other minor spirits. For this reason pious Buddhists traditionally have been reluctant to cut down trees before ensuring that a rite is performed to encourage indwelling spirits to find a new home. One rite is described in the monastic rule (*vinaya*) of the ancient Mulasarvastivadin school:

> If one has to carry out some building activity for the Buddha, and if for this reason one must cut down a tree inhabited by a tree-deity, then one should present that deity with incense, flowers and other offerings and subsequently expound to the deity the wholesome forms of conduct. After that one should ask the deity to move to a different tree because its present home is required for the Buddha. If, however, the deity refuses to move then one should extol the advantages of generosity and explain the disadvantages of miserliness and greed. But if that is of no use and the deity still refuses to go . . . one is not permitted to cut [the tree] down. (Taisho Vol. 23: 776a)

These rules are binding only on monks, but they are not entirely congruent with the injunction not to damage plant and seed life. Requirements for laypersons are significantly less restrictive. One may speculate that similar ideals combined with the general Buddhist preference for contentment and moderation did restrict human exploitation of the forest, but this does not appear to be a prescription that holds sway in the contemporary Buddhist world, particularly in Southeast Asia, where large-scale and often illegal logging is endemic.

CONTRAINDICATIONS

Indian Buddhism showed sporadic awareness of issues similar to those central to the modern discourse of environmental concern, but there also is a large body of counterevidence. The Buddha taught that all conditioned things are impermanent, void of substance, and unsatisfactory (*dukkha*). The ultimate goal for Buddhism is not the better ordering of the world but escape from this realm of perpetual flux. This seems an unlikely base from which to launch a religiously informed environmental ethic. The Buddhist conception of reality is the opposite of teleological: For the Buddha the world is not evolving toward a final purpose or meaning.

This conception is expanded in the *Aggañña Sutta*, a discourse that explains how the world periodically comes into being, declines, and is extinguished before another great cycle starts up and the process is repeated. The overall process is without beginning and without end: Each world is consumed by fire, and all living things are born into an immaterial existence. However, once the ashes of that conflagration have consolidated themselves, some of those subtle beings are reborn on a new earth. However, the conditions of life swiftly begin to deteriorate, and distinctions of many kinds—between men and women, rich and poor, beautiful and ugly—start to emerge. Wars and other forms of instability ensue, and the world commences its inevitable dip down into to its next catastrophic stage. Impermanence governs the whole process. Beings suffer and are reborn. The preservation of sentience is maintained, but progress is illusory. There is no history. One cycle simply follows the next. This seems an unpromising basis on which to develop an environmental ethic.

At the most general level one must consider the applicability of the concept of nature. This multivalent concept has been subjected to far greater scrutiny in the Western philosophical and religious tradition; however it is defined, it is clear that the modern ecological definition

of nature can be understood fully only in the context of the history of Western thought. Nevertheless, because ecological concerns started to impinge on Buddhism in the late 1960s, some modern scholars have looked for Buddhist equivalents. *Samsara* and *pratityasamutpada* have been among the more common offerings, but these terms cover a very wide semantic range. For example, the term *samsara* denotes the totality of sentient beings caught in the endless cycle of birth and death. From the ecological perspective, two problems immediately arise. First, some of these beings—gods and ghosts, for example—are not recognized by the empirical method. Second and perhaps more important, the doctrine of rebirth suggests that the gradual diminution and final extinction of an animal species as a result of adverse environmental change is neither entirely good nor entirely bad. The Buddhist cosmos is a vast, unsupervised recycling plant premised on the preservation of sentiency. Extinction of life forms in any part leads to rebirth somewhere else: Black rhinos may be reborn as humans.

Dealing with *pratityasamutpada* may be more profitable. There is some overlap between this notion and the ecological concept of interdependence, a point developed by the American Buddhist environmentalist Joanna Macy (1991). In her work the idea that all entities depend on specific causes and conditions is transformed into a far more radical position in which all things are mutually interdependent, interrelated, and interpenetrating. Although this may fit with the radically holistic teachings of the East Asian Hua-Yen (Japanese: *Kegon*) schools, it has been argued (Harris 1994) that it is not consistent with the teachings of the early Buddhist texts. There is a conceptual difficulty in the doctrine as well. In the case of an endangered animal species, from Macy's perspective the rest of reality depends and indeed interpenetrates those beings. If they become extinct, that will have an impact on everything else. However, the argument is indiscriminate, applying equally to every apparently discrete entity from mountains, rivers, and fish to dangerous chemicals, cars, and nuclear waste. The consequences of this train of reasoning are deeply paradoxical. Further, in ecology all interdependencies are not equal. The extinction of an organism affects some other organisms or chemical or physical processes more than others.

ECOLOGICAL PRACTICES IN THE BUDDHIST WORLD

Lacking sufficient knowledge of their physical and economic condition before the beginning of the colonial period in the first quarter of the nineteenth century, one must hesitate to ascribe any significantly greater interest in ecological matters in early Buddhist societies than in premodern Western societies. There is evidence that some large Tang period Chinese monasteries engaged in "multifarious commercial and financial activities," including large-scale logging, that undoubtedly had a detrimental effect on the natural environment (Harris 1997, p. 386). In the modern period the evidence is not heartening, for Buddhist cultures have taken environmental concerns seriously only in the last two decades and only in a superficial manner. This may be unsurprising in underdeveloped economies such as Burma and Cambodia, but what of Korea and Japan, the most developed Asian economies with a significant Buddhist presence?

This contradicts the commonplace assumption that Buddhism is ecologically positive in marked contrast to a Judeo-Christian world order commonly assumed to be the prime culprit for the current ecological crisis. This theme became fully manifest in the historian Lynn White Jr.'s 1967 essay "The Historical Roots of Our Ecologic Crisis," but the notion can be traced back to the influential writings of Daisetz Teitaro Suzuki (1959), one of the most important popularizers of Buddhism for Western audiences.

Suzuki came to intellectual maturity in the Meiji period (1868–1912), a time when Buddhism had come under serious criticism for not promoting the ideal of the uniqueness of the Japanese character (*nihonjinron*) sufficiently. In reaction to official disapproval Japanese Buddhism began to adopt new forms that emphasized the fundamental differences between "oriental" and "occidental" ways of thinking. When Suzuki arrived in America in the early years of the twentieth century, he began to champion a "Zen naturalism" that "would assert that the Japanese are racially and/or culturally inclined to experience the world more directly than are the peoples of other nations" (Scharf 1995, p. 124). For example, Suzuki contrasted the Western and Eastern attitudes toward mountains. For Westerners mountains are there to be climbed and tamed, thus underlining the Western desire for the conquest of nature. By contrast, "we of the Orient have never conceived Nature in the form of an opposing power. On the contrary, nature has been our constant friend and companion, who is absolutely trusted.... The idea of conquest is abhorrent" (Suzuki 1959, p. 334). There is some truth here, but the assertion is puzzling in light of Japan's dismal historical record on environmental protection (Parkes 1997).

What of the Buddha's attitude toward plants and forests? It was noted above that the future Buddha was attracted to wild uncivilized surroundings after he renounced his worldly existence. In this he was following the spirit of the age, for he was copying many who had walked that path before him. Yet the evidence is far from unequivocal. In an early discourse on the rule of a

righteous king the Buddha imagines a golden age in which "villages, towns and cities will be so close to one another that a cock could fly from one to the next . . . [and] there will be 84,000 towns with the royal city at their head" (Digha Nikaya iii.75). This vision of hyper-urbanization hardly strikes an ecological note.

The Buddha's enlightenment under the *bodhi* tree provides an interesting link with archaic rites connected with sacred trees. This complex of ideas and practices has been retained by Buddhists, who continue to venerate the many trees still in existence that are believed to have grown from cuttings of that original tree. It also has been reworked as a means of engaging in environmental activism, particularly in Thailand, where the forces of modernization have contributed to massive destruction of forest cover. In its simplest form this has involved the organization of Buddhist-sponsored tree-planting ceremonies, many of which sprang up after the 1982 Bangkok bicentennial. More complex and unorthodox is the practice of tree ordaining, in which a tree endangered by a logger's saw is wrapped ceremonially in a monk's robe as a means of protection (Darlington 2007).

BUILT ENVIRONMENT

The *built environment* includes the flora, non-human fauna, human beings, air, water, soil, and other earthen elements of center-city, suburban, and fringe areas. The built environment has become the center of human settlement and population, a majority of energy use by human beings, and practices and policies responsible for destruction of nonurban habitat, consumption of green space, and other forms of environmental degradation. Philosophical responses to these realities situate the built environment in relation to three questions. First, what is—and what is the basis of—environmental value? When the built environment is factored into the equation, this question can be asked with an eye toward urban environmental values and how the built environment impacts nonurban environmental values. Likewise, one can ask how characterizations of nonurban environmental value impact understandings of environmental values in and associated with the built environment. An environmental value framework that admits of urban and nonurban environmental values problematizes the long-standing assumption that the built environment is unnatural and that human culture is separate from nature. Second, which ethical prescriptions, if any, flow from an account of environmental value? When the built environment is considered, one can ask if and how environmental ethical commitments in urban and nonurban environments are related socially, politically, economically and, most importantly, ecologically. Third, how are and how should environmental priorities be ranked in relation to other priorities? More specifically, how are and how should urban environmental priorities be ranked first in relation to other urban priorities, and second in relation to nonurban environmental priorities? This begs additional questions. For example, how are we to decide where an urban environmental priority ends and a nonurban environmental priority begins, and vice

versa? Moreover, given an ecological understanding of the built environment, are not all urban priorities also environmental priorities?

Despite the merit of exploring these questions from different angles, philosophers have adopted a *de facto* standard view of the built environment. On this view, the built environment, as the primary source of environmental degradation and center of environmentally destructive practices and policies, is that which stands most opposed to nonurban ecological ideal(s). The built environment is not viewed as capable of being a location of most types of environmental value, save anthropocentric instrumental variants. As such, the built environment is viewed as ecologically inferior to those environments thought to have greater ecosystemic value and/or intrinsic value. This standard view runs parallel to the predominant way individuals have understood and acted in relation to the built environment. When it comes to the built environment, instrumental modes of valuation routinely have produced strong anthropocentric environmental commitments. When environmental ethical commitments to the built environment are framed in this way, the actions that follow will be crudely instrumental, which consequently aligns with the negative ecological reputation of the built environment. This negative reputation partly explains why much of what has been written on built environments has been restricted to examining their shortcomings.

At the turn of the twenty-first century, scholars were engaged in a reconsideration of the built environment that challenges the standard view. New direct treatments of the built environment, many of which pick up on themes established in other fields, focus on their positive ecological potential and the need to address the negative role they continue to play in global ecological function. Some treatments address philosophical aspects of urban environmental policy, such as who bears ethical responsibility for urban environmental pollution transfers, or what drives the paradoxical inaction that accompanies urban environmental proposals. Other treatments address philosophical issues that emerge from urban ecology and conservation studies, such as how and if urban ecologies can be restored and/or how urban ecology might be part of what humans take to matter aesthetically. Finally, still other theorists address philosophical aspects of urban sustainability including how the built environment can function as a habitat and be sustained for the sakes of global ecology and future generations in an ecologically less destructive manner, while affording space for current generations' habitat needs. Reconsideration of the built environment, partly informed by the modern environmental justice movement and a renewed interest in urban preservationism prompted by Dale Jamieson (1984) and Avner de-Shalit (1994), is evidenced by the publication of several seminal papers, including those by Bill Lawson (1995), Alastair Gunn (1998), Roger J. H. King (2000), and Andrew Light (2001), the publication of scholarly anthologies (i.e., *Ethics and the Built Environment,* 2000), and the introduction of college courses that focus on philosophical aspects of the built environment.

BURROUGHS, JOHN
1837–1921

The extensive and once enormously popular writings of the naturalist John Burroughs brought him recognition and honors during his lifetime far beyond what one could foresee from his humble birth on April 3, 1837, in the small town of Roxbury, New York. Although he traveled considerably, Burroughs never wavered in his love for the Catskill Mountain region, in which Roxbury lies. The region informs and is the subject of many of his natural-history essays and books. During his long life Burroughs lived modestly in rural settings, but he was a

friend or traveling companion of some of the richest, most famous, and most powerful men of his era, including Henry Ford, E. H. Harriman, Thomas Edison, John Muir, Ralph Waldo Emerson, Walt Whitman, and Theodore Roosevelt.

In his early years Burroughs searched for his proper calling. He worked as a schoolteacher and later as a clerk for the U.S. Treasury Department in Washington, D.C. Shortly after his arrival in Washington, Burroughs met Walt Whitman, who became a close personal and literary friend until Whitman's death. Burroughs greatly admired Whitman's poetry and wrote two books discussing it and defending Whitman against his critics. Burroughs subsequently became a federal bank examiner for the region that included the Catskills and the Hudson River Valley, where he and his wife returned to settle for good. After many years of writing, Burroughs eventually gained enough notoriety and success from his publications to leave government work and write and lecture full-time.

From one perspective, Burroughs's writing about nature complemented those of John Muir, his friend and contemporary. While Muir is known for his exaltation of wild nature, much of Burroughs's attention is on more rural settings and nearby nature. He was not a champion of the wilderness. He always regarded himself as a follower of Emerson, and the latter's writings provide yet another contrast with his. The grand, more philosophical themes of Emerson's writings—the connections among nature, the human mind, and the infinite—are absent from Burroughs's work. Instead, he concentrates on more immediate, concrete aspects of nature, describing the activities of animals, the beauty of the forest, the changes of the seasons.

That interest in seeing and describing nature up close is evident in the major public controversy of Burroughs's life. At the time, there were several popular nature writers who literally invented scenes and events involving animal behavior and other aspects of nature—scenes and behaviors that could never happen in nature—and presented them as true descriptions. Burroughs lashed out, calling such authors "nature fakers." He argued that nature ought to be depicted as it is, not as writers would whimsically like it to be. To present a fictionalized nature creates misunderstanding of actual nature and thus does a disservice to both the reader and nature. The controversy raged in periodicals of the time, leading even President Theodore Roosevelt to make a public renunciation of the "nature fakers."

Although Burroughs's writings are not nearly as popular today as they were in his time, this controversy had a lasting impact. It confirmed and strengthened the expectation among readers of natural history that such works contain depictions of what actually happens in the natural world, rather than what people might like to read. Thus, his reaction helped further define the genre of nature literature.

Throughout his career, but especially in his later years, Burroughs was extremely generous with his time, offering hospitality, conversation, and hikes in the woods around his home to individuals and groups who showed up at his door hoping to meet the famous naturalist and visit the scenes of some of his writings. Those encounters, as well as his many lectures and planned visits by groups from schools and colleges, undoubtedly strengthened the concern for nature that his writings fostered.

The relative lack of attention to Burroughs's work today is regrettable, for his descriptions of the natural world are lively and vivid, conveying an interest in and intimacy with that world. In addition, his focus on immediate nature and his affirmation of agricultural and other human presence in and influences on the larger landscape make him a congenial, though unacknowledged, forbearer of bioregionalism and related approaches to environmental thought. His view of nature includes a spiritual dimension, which would resonate with yet another strand of contemporary environmentalism. He did not accept any form of organized religion, however. Nor did he view nature as leading to God so much as he viewed nature itself as divine.

To promote interest in Burroughs's contributions, the John Burroughs Association maintains his retreat in the Catskills and awards a well-known annual prize for "a distinguished book of natural history," as well as recognizing outstanding nature essays and maintaining a list of "exceptional natural history books for young readers."

C

CALLICOTT, J. BAIRD
1941–

J. Baird Callicott was born in Memphis, Tennessee, on May 9, 1941, and received a master's degree and in 1971 a doctorate from Syracuse University. After three years (1966–1969) at the University of Memphis, he joined the faculty of the University of Wisconsin–Stevens Point (UWSP), where he inaugurated the first college course titled Environmental Ethics. In 1995 he joined the faculty of the University of North Texas. He is one of the founders of academic environmental ethics.

Callicott's position at UWSP situated him in the sand counties of central Wisconsin, the landscape celebrated by Aldo Leopold in *A Sand County Almanac* (1949). Callicott is best known as an exponent and defender of Leopold's land ethic, according to which "A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise" (Leopold 1949, pp. 224–225). For Callicott the land ethic puts primary value on ecological wholes such as species, biotic communities, and ecosystems. In his earlier work he argued that individual interests and lives (including those of human individuals) should be sacrificed if they conflict with the holistic good of the system. That form of holism, which was defended by Callicott in the early 1980s, was criticized as "misanthropic" and "ecofascist" for subordinating the welfare of individual beings to the good of the larger community.

In response, Callicott later developed a multilayered communitarianism. An individual, he argued, is simultaneously a member of many communities, ranging from the immediate family, neighborhood, and nation to the whole human species and also ranging from different ecosystems and bioregions to the global biotic community. Membership in each community generates a distinct set of duties to protect the interests of that community and its members. For example, as members of the human species, all people have duties to maintain the continued survival of the species and also a duty to respect the rights of other people, whereas as members of the global biotic community, people have a duty to preserve its integrity, stability, and beauty. The land ethic therefore is only one of many different layers of moral codes within Callicott's larger communitarianism.

According to Callicott, his communitarianism is "monistic" and should be preferred to pluralist theories in the field. The many layers of moral codes, he has argued, are all theoretically unified under the single idea that community-based sentiments are the ultimate foundation of all values and morality. For Callicott something has intrinsic value if a community of people value it (i.e., share a positive moral sentiment toward it) as an end in itself.

Callicott's value theory is sentimentalist as much as it is communitarian: It reduces facts about values to psychological facts about people living in a community. It implies that there are no values without communities of valuers. This should not be confused with the view that people alone are intrinsically valuable. For Callicott value is anthropogenic (human-generated) without being anthropocentric (human-centered). What gives values and morality stability or even universality, he has argued, is the contingent fact that human beings across times and cultures are similar in their basic needs, affections, and aversions. In particular, he has stated that people are

evolutionarily endowed with the disposition to value the community to which they belong once they recognize that they belong to it. The land ethic, Callicott has argued, is the latest realization of that communitarian disposition in people.

What if people's duties to different communities are in conflict? Callicott introduced the principle that duties to communities closer to people in terms of emotional involvement take priority over those farther away. By itself, however, this principle is unlikely to support a robust environmental ethic: Most people most of the time do not value their biotic communities over their human communities. That is why a second principle is required: The stronger the interest at stake, the higher the priority for its protection. This obliges people to sacrifice trivial human interests (e.g., the pleasure from eating whales) for the protection of significant environmental ones (e.g., the protection of endangered species).

Many important questions remain unanswered. How can one measure the significance of an interest? Is the second prioritizing principle, featuring interests, theoretically unified with the rest of Callicott's monistic communitarianism? What should people do when significant environmental interests conflict with significant human interests? People commonly take more care of those to whom they are closer and give more weight to more significant interests. Both prioritizing principles are already part of commonsense morality. The problem is that they sometimes point in different directions. How can the two be applied together to deliver a robust environmental ethic combined with an appropriate sensitivity to the many human needs, desires, and ambitions? These are difficult questions to which few theorists have concrete solutions. One of Callicott's contributions to environmental ethics has been his ability to provoke a wide range of debates about many fundamental and significant questions on values, morality, and people's relation to the larger environment.

CARIBBEAN

Debates about environmentalism in the Caribbean involve both residents and external actors. International tourism requires a supply of iconic island landscapes; the development community seeks to maintain the renewable resources and ecosystems of the region. Residents worry about natural disasters; urban services; water; pollution from military, mining, and manufacturing activity; the health effects of pesticide-intensive agriculture; urban sprawl; and access to land and resources. The debates focus on sustainability, environmental protection, access to resources, and public health. The locus of environmental decision making also is contested.

POLITICAL ISSUES

Environmental controversy reflects the role of the region in the global economic and political system and its vulnerability to natural hazards. After the eighteenth century colonial governments conducted scientific expeditions to identift strategic resources and to assert political control over the region (Sheller 2003, Momsen 2006, Grove 1995) for purposes, among others, of resource extraction. In the postcolonial era transnational tourism and agricultural and mining firms—often more powerful than the national governments they attempt to influence–have shaped island environmental and development policies. Capital flows to the United States and Europe that divert resources needed by Caribbean governments and rural households result in migration to Caribbean, European, and North American cities. Migrant remittances and investments have contributed to sprawl in the Puerto Rican and Dominican countryside. Migrant remittances to the Caribbean were estimated at $8.38 billion in 2006, accounting for over 20 percent of the gross domestic product in several countries. Caribbean migrants active in U.S. environmental justice movements have influenced regional environmental agendas.

The Caribbean region has strategic importance, and military bases such as the U.S. naval base on Vieques, a small island that is part of Puerto Rico, have become arenas of environmental conflict (McCaffrey 2002). The World Bank and the Inter-American Development Bank; the Caribbean Community Secretariat (CARICOM) and United Nations agencies; nongovernmental organizations such as the World Wildlife Fund, the Nature Conservancy, and the International Union for the Conservation of Nature; bilateral assistance agencies and universities; and trade agreements have shaped and constrained Caribbean environmental agendas. Externally funded environmental research and training programs do not always address residents' concerns, and the power of international actors to set agendas often is contested. In Puerto Rico, an American protectorate, and Martinique, a French

protectorate, environmentalism is coupled with demands for greater autonomy and equal enforcement of the environmental norms prevailing in mainland countries, respectively (Garcia, Ramos, and Rivera 2006, Burac 2006). Local elites in the Anglophone Caribbean have used international planning discourse to serve local interests (Pugh 2006). In attempting to control the terms of integration into the global economy, Cuba and the Dominican Republic have sought foreign investment in agribusiness, mining, tourism, and manufacturing. In those two countries protest against the environmental performance of transnational corporations has been muted (Lynch 2006).

COOPERATION AND SUSTAINABILITY

The cultural, linguistic, and political diversity of the region has impeded environmental collaboration, yet cooperation is essential in light of the ecological vulnerability of the Caribbean. Subject to hurricanes, earthquakes, and volcanic eruptions, island ecosystems have high rates of endemism but little biodiversity. Fish populations are endangered by reef and mangrove destruction, ocean dumping, oil drilling, pesticide runoff, and overfishing inshore and on the open seas. Food production has been pushed to marginal lands and no longer meets local needs, and throughout the islands clean water is becoming scarce.

In this context Caribbean environmentalists are asking questions about how to achieve sustainable development and about the kinds of social and political arrangements implied by different definitions of sustainability. Marian Miller, a Jamaican political scientist, argued that in areas of that country where landscapes are preserved for ecotourism spaces for the preservation of traditional sustainable landscape management practices may be reduced. Faced with the loss of Soviet aid in the 1990s, Cuba defined sustainability as economic self-sufficiency, embracing organic agriculture and energy conservation as survival strategies. Cuba led the region's transition to organic agriculture and supported urban agriculture. Banana producers in the Dominican Republic and eastern Caribbean have promoted organic agriculture as a marketing strategy. Deforestation in Haiti has been the subject of debates about sustainability. These debates focus on the extent to which Haiti's environmental vulnerability is a function or cause of its poverty.

THE GREEN AND THE BROWN

The British sociologist Mimi Scheller argued that tourism requires "an endless supply of 'pristine' beaches, 'untouched' coves, and 'emerald' pools," whereas "many islands struggle with the water and sewage demands of the hotel industry" (Scheller 2003, p. 68). Ecotourists want to visit national parks that have lush vegetation, well-marked trails, and folklore displays but are free of local human economic activity. The United Nations Environmental Program (UNEP) and international nongovernmental organizations (NGOs) emphasize biodiversity and forest and coral reef conservation. This preference is reflected in the ornithologist Jared Diamond's popular work *Collapse* (2005), which argues in favor of the repressive forest policies of the former Dominican president Joaquin Balaguer, which were condemned by human rights and environmental justice groups, including ENDA Caribe, an agroforestry organization in the Dominican Republic that fought to give farmers the right to harvest trees that they planted (Rocheleau and Ross 1995).

Charcoal Workers in Miragoane, Haiti. *In Haiti, charcoal and wood make up 70 percent of the country's energy resources. The use of wood for energy has caused devastating deforestation problems, despite the efforts of conservation organizations such as CARE, whose members plant approximately 800,000 trees per year. Many Caribbean nations are more concerned with "brown" issues, such as waste management and pollution.* **SHAUL SCHWARZ/GETTY IMAGES.**

In contrast, brown issues such as waste management and pollution often top local agendas. The Puerto Rican environmental movement began a critique of Operation Bootstrap, a 1948 industrial promotion package that encouraged polluting chemical and pharmaceutical firms to establish plants on that island (Concepción 1993, García, Ramos, and Rivera 2006, McCaffrey 2002). It went on to mobilize successfully against the contamination of Vieques by the U.S. Navy in the late 1990s. United Nations and United States Agency for International Development (USAID) programs have addressed brown issues with microprojects, but their impacts have been limited. Real estate markets consign poor people to polluted areas. Pollution is aggravated in countries where cars, buses, and trucks run on dirty petroleum fuels. Land markets also encourage sprawl, which raises the cost of urban services and takes land out of agricultural production, making it harder for families to find affordable food. Antisprawl campaigns in Puerto Rico, Martinique, and the Dominican Republic have targeted tourist and airport development.

ENVIRONMENTAL JUSTICE

Caribbean environmental justice movements often address access to water for drinking, bathing, and irrigation; sewer lines; land; renewable resources; beaches and coastal waters. Evictions of Dominicans and Jamaicans from forests have deprived them of resources needed for their livelihoods (Miller 2006, Lynch 2006). Protected area designation has pitted local fishers against environmental planners in Trinidad (Sletto 2002) and Puerto Rico (Griffith and Pizzini 2002). Puerto Rican environmentalists have fought against the development of resorts in coastal zones (Pizzini 2006, McCaffrey 2002) but also oppose regulations that restrict local fishing and recreation. Public health is of fundamental importance to environmental justice movements. Examples are Puerto Rico's Misión Industrial (García, Ramos, and Rivera 2006), the Vieques protests to stop the U.S. Navy from using that island as a bombing range, protests against pollution in the Dominican port of Haina, and the movement against nuclear power in Cuba.

Some Caribbean environmental initiatives are conservationist to the point of exclusion. Others call for continuing access to land and resources coupled with stricter regulation of polluting industries. As the Venezuelan anthropologist Francine Jacôme (1996) noted, conservationist programs abound, receiving funds from international NGOs and local foundations. Environmental justice organizations are often local, although they seek funds from bilateral assistance agencies and the United Nations Development Program. Northern funding has diverted some environmental justice NGOs to less transformative pursuits, but NGOs remain the backbone of the movement and succeed when they link their agendas to residents' broader concerns. For this reason Caribbean environmental debates often are couched in terms of anticolonial and antiglobalization struggles and linked to problems of eviction, worker health and safety, and cultural survival and revival.

Rachel Carson, 1963. *Activist and author Carson testifies before a Senate subcommittee in Washington, D.C., urging the members to curb the sale of chemical pesticides and aerial spraying. Her book* Silent Spring *exposed the dangerous health and environmental effects of pesticides, and helped launched a social critique that continues to resonate in modern-day environmental movements.* **AP IMAGES.**

CARSON, RACHEL
1907–1964

The environmentalist and author Rachel Louise Carson was born in Springdale, Pennsylvania, on May 27, 1907, the youngest child of Robert and Maria McLean Carson. Carson showed early promise as a writer and a keen observer of nature. She studied English and biology at the Pennsylvania College for Women and did graduate work in marine biology at Johns Hopkins University, where she received a master's degree in 1932. Carson worked for the U.S. Fish and Wildlife Service for many years before devoting herself full-time to writing.

Best known for her book *Silent Spring* (1962), Carson was an established nature writer long before its publication. *Under the Sea Wind* (1941), *The Sea around Us* (1951), and *The Edge of the Sea* (1955) brought her critical acclaim and popular success. During the period of the Cold War (1945-1991), oceans were seen as a new frontier and an untapped natural and economic resource. Carson capitalized on the public's fascination with oceans, though she emphasized the mystery and allure of the sea over its utilitarian value. These writings do not contain a full-fledged marine ethic, but Carson saw the study of oceans as an occasion for humility and moral reflection; she highlighted human dependence on ocean waters, reminding readers of human insignificance relative to the vast and ancient sea. Carson tended to view the sea as inexhaustible. Humans might dominate terrestrial environments, but the sea, she believed, would remain largely alien and inviolate, rebuffing attempts to plunder and subdue it.

Carson's belief in the limits of human dominion was shaken by postwar developments in science and technology, particularly the unprecedented introduction of chemical pesticides into the environment. Her response was *Silent Spring,* and its impact was enormous. An exposé of the environmental and health effects of pesticides, *Silent Spring* also familiarized the public with basic ecological concepts and transformed ecology from a science to a social movement. Carson showed how bioaccumulation—increasing concentrations of chemicals in higher levels of the food chain—creates danger for wildlife and humans. *Silent Spring* made explicit the ethical concerns that were more muted in her earlier writings.

Carson defended moral consideration of nonhuman life by appealing to commonly held values—the average person's love of backyard birds and aesthetic appreciation of nature—rather than presenting philosophical arguments. She urged respect for the precarious balance and complex webs of relationship in nature and warned that humans would not escape the effects of their poisons, that people's war with nature was inevitably a war against themselves. The fact that those ideas have become commonplace is a tribute to Carson's work.

Silent Spring also launched a social critique that still resonates in radical ecology movements and grassroots environmentalism. Carson castigated the arrogant shortsightedness of a society that subordinates all other goods, human and natural, to the values of expedience and profit. She promoted scientific literacy but warned that modern scientists, whom she portrayed as giddy with power, had been entrusted with far too much authority. Protection of individuals against the harms inflicted by chemical pesticides is a basic human right, Carson maintained. She urged citizens to educate themselves about the dangers of environmental toxins and take action on behalf of local communities. Carson's death from breast cancer two years after the publication of *Silent Spring* has made her a symbol among ecofeminists of the links between environmental toxins and women's health.

With *Silent Spring,* concern for endangered species became a national preoccupation. A series of environmental laws followed in its wake. DDT was banned in the United States in 1972, and its use is banned or regulated in many other parts of the world. Although Carson's work on pesticides largely has been vindicated, her conclusions still generate controversy. Some charge that *Silent Spring* exaggerated the dangers of DDT for humans and that inordinate concern with the health effects of that chemical has been responsible for increases in mosquito-borne diseases such as malaria in some parts of the world. However, Carson never advocated a complete ban on the use of pesticides or regarded attempts to control nature as utter folly. Instead, she urged responsible use of chemicals and encouraged research into biological approaches to insect control.

Carson's abiding concern for future generations received special emphasis in an essay she wrote for *Woman's Home Companion* in 1956 titled "Help Your Child to Wonder." It was republished posthumously (1965) as an illustrated book, *The Sense of Wonder*, and celebrates the child's innate curiosity and enchantment with nature. Carson argues that direct sensory engagement instills in children a lifelong wholesome bond with nature that fact-based education alone cannot inculcate. *The Sense of Wonder* embodies the philosophy of the nature-study movement that was popular during Carson's childhood and has become a classic in environmental education.

CAVES

What Ludwig Wittgenstein (1889–1951) says about pain in another context could be said about caves: they are "not a *something*, but not a *nothing* either" (Wittgenstein 1958, para. 304). Essentially, a cave is an open space in a geological formation such as rock or ice. Although some large caves are formed in lava fields as a result of volcanic action (lava tubes), most caves are formed in limestone or other rock formations such as chalk, dolomite, marble, granite, salt, sandstone, and gypsum. Normally, for a formation to be considered a cave, there must be a section of the cave that is not lit by daylight. Spaces without such a passage are called rock shelters. Most caves are formed by erosion from water containing carbonic acid (formed when rainwater comes into contact with atmospheric carbon dioxide and organic material such as leaves and dirt). Characteristically, passages form along joints (fractures in rock without vertical movement between the two sides) and faults (factures in rock with vertical movement).

ORIGINS AND FEATURES OF CAVES

Most caves have formed through phreatic action; the phreatic zone is the zone below the water table completely saturated with water, producing huge, rounded tubelike passages filled with water, often under immense hydrostatic pressure. At this stage they are called springs. They become caves when the down cutting of nearby rivers lowers the water table, producing air-filled space (the vadose region). Caves also can be produced through vadose action, erosion on the floor of the cave in air-filled spaces underground but above the water table, probably initially begun in a phreatic state.

Paradise Room in Carroll Cave, Missouri. *Usually for a formation to be considered a cave, there must be some part of it that is not lit by daylight, such as Carroll Cave, in the Ozark mountains. Caves are interesting, environmentally speaking, because of their aesthetic features and their fragility; once damaged, they cannot be repaired or replaced.* **PHOTO BY EUGENE C. HARGROVE.**

Caves produce unusual habitat for animals such as bats, birds, bears, other mammals, fish, and insects. Animals that live permanently in caves often display unusual evolutionary development, for example, white blind fish, blind salamanders, and a variety of insects that sometimes have unusually long life spans (Mohr and Poulson 1966).

AESTHETIC AND ETHICAL ISSUES

In terms of environmental philosophy, caves are of interest both aesthetically and ethically. Aesthetic appreciation mimics the history of nature aesthetics, which began with a fascination with castellated rocks (rock formations resembling castles and ruins). Most people first relate aesthetically to caves through cave formations that resemble parts of animals, plants, and humanly created artifacts. Aesthetic appreciation then extends to stalactites and stalagmites; columns; and a variety of speleothems, such as helectites, gypsum flowers, anthodites, selenite needles, angel hair, and cave pearls, along with the shapes of cave passages. The vocabulary for discussing the beauty of caves is limited. Aesthetic appreciation includes the sublime, although that term rarely is used. Typically, breakdown rooms—large collapsed areas covered with fallen boulders—and vertical shafts called domepits are considered sublime. Cave photography has evolved into an art form and is characterized by the use of light in otherwise totally dark environments.

Because much of the life of caves is repugnant to many people, for example, bats, arguments for the protection of caves usually are based on weak anthropocentric values rather than biocentric values. It is easier to protect the life of a cave with arguments about the aesthetic features of the cave admired by humans than to protect the aesthetic features by arguing that the life of the cave ought to be protected. Often arguing for the life of a cave directly may be counterproductive.

Caves represent a sensitive problem in nature protection because the aesthetically appreciated features of caves are fragile and usually cannot be repaired or replaced once they have been damaged. This aspect of nature protection is stressed by Holmes Rolston III in his chapter ''Natural Value'' in *Environmental Ethics* (1988), where he discusses angel hair in Turner Avenue in

NATIONAL SPELEOLOGICAL SOCIETY CAVE CONSERVATION POLICY

The National Speleological Society believes:

- Caves have unique scientific, recreational, and scenic values.
- These values are endangered by both carelessness and intentional vandalism.
- These values, once gone, cannot be recovered.
- The responsibility for protecting caves must be formed by those who study and enjoy them.

Accordingly, the intention of the Society is to work for the preservation of caves with a realistic policy supported by effective programs for: the encouragement of self-discipline among cavers; education and research concerning the causes and prevention of cave damage; and special projects, including cooperation with other groups similarly dedicated to the conservation of natural areas. Specifically:

All contents of a cave—formations, life, and loose deposits—are significant for their enjoyment and interpretation. Therefore, caving parties should leave a cave as they find it. They should provide means for the removal of waste; limit marking to a few, small, and removable signs as are needed for surveys; and, especially, exercise extreme care not to accidentally break or soil formations, disturb life forms or unnecessarily increase the number of disfiguring paths through an area.

Scientific collection is professional, selective, and minimal. The collecting of mineral or biological material for display purposes, including previously broken or dead specimens, is never justified, as it encourages others to collect and destroy the interest of the cave.

The Society encourages projects such as:

- Establishing cave preserves;
- Placing entrance gates where appropriate;
- Opposing the sale of speleothems [secondary mineral deposits];
- Supporting effective protective measures;
- Cleaning and restoring over-used caves;
- Cooperating with private cave owners by providing them knowledge about their cave and assisting them in protecting their cave and property from damage during cave visits;
- Encouraging commercial cave owners to make use of their opportunity to aid the public in understanding caves and the importance of their conservation.

Where there is reason to believe that publication of cave locations will lead to vandalism before adequate protection can be established, the Society will oppose such publication.

It is the duty of every Society member to:

Take personal responsibility for spreading a consciousness of the cave conservation problem to each potential user of caves. Without this, the beauty and value of our caves will not long remain with us.

SOURCE: NSS Conservation Policy. http://www.caves.org/info/policy.shtml

Mammoth Cave, which is so fragile that it is damaged by human visits of any kind. Three caves are featured in Eugene C. Hargrove's chapter "An Ontological Argument for Environmental Ethics" in *Foundations of Environmental Ethics* (1996 [1989]): Onondaga Cave in Missouri, which once was threatened by a proposed dam; the cave in Lascaux, France, which contains fragile cave paintings; and Mammoth Cave in Kentucky, which contains delicate cave formations. The main issue in Hargrove's discussion as well as Rolston's is whether natural objects have value that should be protected when direct experience of those objects will lead to the irreparable loss of the aesthetically valued features. In the normal account of value in terms of natural area management, value is created by the instrumental triggering of feelings of emotion in visitors by exposure to the natural objects, living and nonliving. In museums objects that are being damaged by visitation are simply removed from view to protect their intrinsic value. Because the aesthetic value of natural objects are considered instrumental, therefore requiring visitor viewing, managers cannot remove the natural objects from view since that would reduce their instrumental aesthetic value to zero. Instead, they reduce visitation to some lower level to prolong the possibility of visitation before the aesthetic consumption of the object is complete. Aside from the writings of these philosophers, little attention has been given to caves in the academic literature on environmental philosophy.

Cave conservationists have shown little interest in the development of cave-related environmental philosophy, relying primarily on the NSS Cave Conservation Policy from the 1960s (see sidebar).

CHÁVEZ, CÉSAR
1927–1993

César Chávez was born on March 31, 1927, in the San Luis Valley near Yuma, Arizona, and died on April 23, 1993, in San Luis, Arizona. He worked as a union organizer, labor activist, Mexican-American civil rights leader, and leader in the farm workers movement in the United States from 1962 to 1993. He was the second of five surviving children: Rita, César, Richard, Librado, and Eduvigis (Vicky). His name was changed from Cesario to César when he started attending public school. His parents, Librado and Juana Estrada, were born in Chihuahua, Mexico, but lived in the United States for most of their lives.

After his parents lost their small farm and adobe farmhouse in 1938, César and his family became migrant farm workers in California. They picked beans, cherries, carrots, onions, broccoli, melons, and other fruits and vegetables. The children attended Mexican-only schools and on the weekends worked up to ten hours a day in the fields. César faced discrimination at diners and cafés in central California that would not serve Mexicans, who were forced to eat outside. They also were segregated in movie theaters in the San Joaquin Valley. In one instance Chávez was asked to leave a section of a theater; when he refused, the police took him to jail, where they kept him for an hour as a warning. He lived in a one-room shack without running water. It was often bitterly cold because the family had only a kerosene camping stove for heat. Chávez served in the U.S. Navy for two years, starting in 1944, and traveled extensively. He married Helen Fabela in 1948, and they had eight children.

Father Donald McDonnell encouraged Chávez to read about the nonviolent strategies for social change of Saint Francis of Assisi and Mohandas Gandhi. In 1952 Chávez met Fred Ross, who persuaded him to join the Community Service Organization (CSO). He worked full time for the CSO until 1958. Chávez used his CSO membership to document the abuse of Mexican farm workers throughout California. After failing to persuade the CSO to organize farm workers into a labor union, he resigned and moved to Delano, California. On September 30, 1962, he created the National Farm Workers Association (NFWA). The NFWA provided its members with burial insurance, an auto-repair cooperative, a credit union, a newspaper, and social activities.

On September 16, 1965, Chávez called a strike with the Filipino Agricultural Workers Organizing Committee (AWOC). The NFWA and the AWOC merged into an organization called the United Farm Workers Organizing Committee (UFWOC) with Chávez as its leader. Chávez led a grape boycott in Delano and other parts of California that lasted five years.

Chávez's nonviolent philosophy and approach to social changed were shaped by his Catholic faith. He also worked closely with mainline Protestants, Pentecostals, and Jews as well as many secular leaders. His philosophy was influenced by the Christian notion of serving the poor, Francis of Assisi's insistence that it is not possible to feel the pain of the poor unless a person is one of them, Pope Leo XIII's Catholic social teachings about the rights of labor, Mohandas Gandhi's notion of satyagraha (nonviolent resistance), Martin Luther King Jr.'s, Montgomery bus boycott, and Our Lady of Guadalupe, who served as a rallying point and source of faith for people of Mexican ancestry.

Chávez embraced a number of strategies for nonviolent social change. He led boycotts, pickets, marches, and spiritual fasts for better wages, the right to organize unions, better housing conditions, and social change. He also fought against the use of dangerous pesticides on behalf of both farm workers and consumers. He and Luis Valdez created *The Plan of Delano* (1965) to highlight the farm workers' struggle. This became the Magna Carta of the United Farm Workers (UFW) and the Mexican-American civil rights movement. In 1966 Chávez led a twenty-five-day, 340-mile pilgrimage march from Delano to Sacramento to attract media attention to the struggle of farm workers. In 1968 he began a twenty-five-day fast as a nonviolent protest that he ended after Senator Robert Kennedy of Massachusetts took communion with him, an event covered by the national media. He also began nonviolent meetings with a prayer, used

the Catholic Cursillo song "De Colores" as the UFW theme song, and led pickets and pilgrimage marches behind the colorful banner of Our Lady of Guadalupe. His pilgrimage, fasts, and picketing led to an end of the five-year grape boycott in 1970. In 1972 he changed the name of his organization to the United Farm Workers of America (UFWA). Chávez continued his struggles on behalf of farm workers until his death; over 50,000 people attended his funeral.

CHERNOBYL

On April 26, 1986, an explosion rocked reactor Unit Four of the Chernobyl nuclear power plant in the Ukraine, then part of the Soviet Union. It spread a deadly plume of radiation through the immediate area and across much of Europe. The health effects were immediately evident, not only in the number of fatalities but also in the number of people (especially children) who developed various types of cancer in the wake of the incident.

FLAWS IN THE REACTOR TECHNOLOGY

At the time of the explosion, nuclear power was widely used across Europe and in the United States. In the light-water reactors favored in the United States, water is used as both the moderator and coolant, circulating constantly among the reactor fuel rods. But, in the RBMK (*reactor bolshoy moshchnosty kanalny*, or high-power channel reactor), the Soviet model that was in operation at Chernobyl, water is used as a coolant, but the moderator is graphite; the fuel rods and the control rods run through chunks of the graphite. The difference in moderator becomes important under the conditions that triggered the Chernobyl accident: In a water-moderated reactor, steam forming in the water will simply slow the reaction by increasing the moderating activity of the water. But steam in the cooling water can increase reactivity in a graphite-moderated reactor. As the cooling water turns to steam, it absorbs fewer neutrons. This means that more neutrons will pass to the graphite, which will slow them down and reflect them back, increasing fission. This process causes the power level to rise, which in turn increases steam formation, and the process can quickly escalate. This feature of the RBMK reactor—the propensity of steam formation and reaction intensity to reinforce each other in fatal positive feedback—is called a "positive void coefficient" (or "positive reactivity coefficient" or "positive-void effect").

The reactor was, therefore, inherently more dangerous and susceptible to explosion than those in use in Western Europe and the United States. Why did the Soviet Union build such reactors when better ones were available? First, in an autocratic society, there is little free dispute or criticism; if the engineers in the industry learn of a better way to do things or see inherent dangers in the way things are being done, they are unlikely to voice their concerns if another design is favored by the political bureaucracy. Second, in a closed society like the old Soviet Union, where access to information was tightly controlled, Soviet engineers were isolated from their Western European and American colleagues and thus had limited access to innovations in technology.

HOW THE EXPLOSION OCCURRED

The problems for reactor Unit Four began shortly after midnight on April 25, 1986, when the engineers decided to run a dangerous experiment to find out if they could squeeze extra work out of the reactor at very low power. The danger was that all the safety systems, which were programmed to shut everything down at once when the power falls, had to be disabled in order to conduct the experiment; if anything went wrong, there would be no way to stop the reaction. And something did indeed go very wrong.

After fiddling with every control on the reactor for over an hour to try to keep the power level where they wanted it, the engineers completely shut off the steam supply to the generator they were testing to see how long it could run on mechanical momentum alone. The first result was that the cooling pumps, which were being powered by that generator, started to run down. The water began to boil out of control, and then, because of that positive void coefficient, the power surged.

The operators spotted the surge and reacted immediately to lower the control rods into the core of the reactor to shut down the reaction (the record indicates that corrective action was taken less than a minute from the initiation of the experimental procedure). But it was already too late. The drive mechanism was slow, for lack of power; when the rods were released to fall of their own weight, the meltdown was already in progress, and they never reached the heart of the reactor. As the intensely

Pripyat, Ukraine, Twenty Years After Chernobyl Explosion. *The town of Pripyat still displays empty houses two decades after the 1986 explosion at the now closed Chernobyl nuclear power plant (in background). Radioactive particles settled over the surrounding communities, killing 31 people and injuring and displacing thousands more. Chernobyl remains a warning of the worst-case-scenario of the construction of nuclear power plants, particularly near humans.* **AP IMAGES.**

hot fuel melted the reactor, parts if which dropped in great pieces into the cooling water, a thermal explosion destroyed what was left of the reactor and most of the building. The blast blew off the thousand-ton lid on the reactor core, tore open the building's side and roof, and sent several tons of uranium dioxide fuel, burning graphite, and fission products (such as cesium 137 and iodine 131) off into the night in a three-mile-wide plume, starting numerous fires.

IMMEDIATE AFTERMATH OF THE EXPLOSION

In the ten days following the explosion, some 50 million curies of radioactivity were released into the air. Beginning with the three engineers who had run to see what had happened to the reactor immediately after the explosion, by September 1986 thirty-one people had died; many of the operators and firemen who dealt directly with the explosion and its fires died of radiation burns and poisoning, and the soldiers and volunteers who labored valiantly to cover the exposed core suffered the rest of the casualties. There were roughly 1,000 immediate injuries. Some 135,000 people within a radius of 19 miles of the plant had to be evacuated from their homes in the Ukraine. Ambient radiation continued to increase for weeks from the decay of the melted core.

About 7,000 kilograms of radioactive materials from the core of reactor Unit Four were released into the environment—50 to 100 million curies of radioactive isotopes. The city of Kiev, with 2.4 million people, fared better than some had feared because the winds blew away from the city during the worst period. But several wind shifts brought the nuclear cloud over nearly all of Europe, extending as far north as the Arctic Circle, as far south as Greece, and as far west as the British Isles. Potentially health-threatening levels of radioactive materials were deposited more than 1,200 miles from the plant, in at least twenty countries. The accident first came to light in Sweden on April 28, when technicians noticed atmospheric traces of radioactive gases, mostly xenon and

krypton, that could have come only from the Soviet Union. Shortly thereafter radiation was found in scattered regions throughout Europe.

LONG-TERM CONSEQUENCES

What consequences have ensued from this nuclear disaster? In addition to the thirty-one deaths from radiation poisoning, some 500 people had to be hospitalized with some form of radiation poisoning. Up to 24,000 of the evacuees received serious doses of radiation. Radiation-caused disorders, including cancer, have been documented in this population, including forty cases of pediatric thyroid cancer, ordinarily a very rare disease, among children from the contaminated villages near Chernobyl. Over the long term, for the region outside the nearest direct exposure, the effects of the disaster remain uncertain.

There are three major health threats from exposure to radioactive materials. First, there is direct exposure, resulting in burns and massive internal injuries, especially to all areas where cells divide rapidly; this type of radiation poisoning killed the operators and rescue workers around the reactor. Second, damage can result from inhaling radioactive dust; many of the citizens of Pripyat may have been injured by such inhalation. Third, there are the radioisotopes that come to rest in the drinking water and the food supply, entering the food chain through the rain and the grass. These are potentially the most worrisome. Iodine-131, entering the body through food or water, was the major threat immediately after the accident; it concentrates in the thyroid and was certainly responsible for the cases of rare thyroid cancer in the children. But iodine-131 has a half-life of eight days and was largely gone from the area in a month or so. Strontium-90, also released in the explosion, has a half-life of twenty-seven years, but it was not present in large quantities.

The worst danger came from cesium-137. It was carried on wind high above the ground and fell where the rain did, along a broad swath of territory from the central Ukraine north across eastern Belarus. Almost 13,100 square miles of agricultural land, dotted with small cities, are contaminated with radioactivity at levels of five or more curies per square kilometer. Cesium contamination forced farmers to destroy produce as far away as Lapland, in northern Sweden, and in Italy and Wales. There is no way of knowing how much damage to health can result from trace contamination of this carcinogenic element. Estimates of cancer deaths attributable to Chernobyl run between 5,000 and 50,000; the wide discrepancy in the estimates indicates how little is known about the long-term health effects of cesium-137.

CHICANA/CHICANO ENVIRONMENTAL ETHICS

Rooted in Mexican American culture, Chicana and Chicano environmental ethics seeks to overcome historical inequity while preserving long-standing wisdom about the land and intimacy with the natural environment. Chicanas and Chicanos express their environmentalism in many ways, including activism, cultural production, and scholarship.

Chicana/o environmental activism centers on land rights and environmental justice. The land-rights movement led by Reies Lopez Tijerina in northern New Mexico in the 1960s brought national attention to denial of lands to many Mexican Americans after the Mexican-American War of 1846–48. Many of these cases involved original land grants from the Spanish and Mexican periods of colonial rule in the Southwest. After the war many grant holders were not able to validate their land grants in U.S. courts; others found their lands auctioned or sold without their consent. As a result many lost their lands. In the 1960s Tijerina organized a cooperative of Mexican American citizens, the Alianza Federal de Mercedes (Federal Land Grant Alliance), to recover lost ancestral lands. The group staged some protests, including a confrontation with local authorities at the Tierra Amarilla courthouse in 1967 and the takeover of a section of the Santa Fe National Forest for three days in 1969. The group primarily organized families to appeal land grants. Some of their cases remain active in courts as of 2008.

Chicana/o environmental activism encompasses the struggles of various groups, both urban and rural, for environmental justice. Groups such as the Mothers of East Los Angeles (MELA) and People Organized in Defense of Earth and Her Resources (PODER) in Austin, Texas, organize people of color and those in urban, low-income communities to protest against disproportionate exposure to toxic contamination. Rural environmental justice groups, such as Ganados del Valle, in

northern New Mexico, organize around agricultural issues. Ganados del Valle formed in the 1980s as a sheep cooperative, with a group of ranchers working together to implement environmentally sustainable practices and to survive the dominance of large-scale agribusinesses. The group helps to preserve Mexican American traditional environmental knowledge and sustainable agriculture in this region.

Chicana/o cultural production evokes the traditional environmental values of the Mexican American community as well as late-twentieth-century environmental justice struggles. María Amparo Ruiz de Burton's novel *The Squatter and the Don* (1997 [1885]) depicts the struggle to protect a land-grant ranch in Southern California from a squatter takeover. The book also portrays the sustainable approach to agriculture practiced by California's Mexican community in the arid climate around San Diego. In the 1930s Jovita González recorded folktales from South Texas for the annual publication of the Texas Folklore Society. Her folktales chronicle a creative natural history of this region through the eyes of Mexican Americans. Set in the region of the Lower Rio Grande Valley, Gloria Anzaldúa's book *Borderlands/La Frontera* (1987) features hybrid indigenous and European views on nonhuman nature that reach into the late twentieth century. Many other late-twentieth-century works explicitly criticize environmental injustice, especially as it pertains to the workplace and structural discrimination. These works include the novels of Ana Castillo (1994) and Helena María Viramontes (1995), the poetry of Cherríe Moraga (1983, 1993, 1994) and Jimmy Santiago Baca (1989), the murals of Judith Baca, and the songs of Tish Hinojosa (1992). Although many Mexican American works engage environmental issues, environmental studies do not center on Chicana/o environmental thought; Chicana/o environmental scholarship challenges the assumption that Mexican Americans have not made significant contributions to environmental thought. This scholarship works in two ways: to highlight Chicana/o environmental thought and to show the ways in which environmental injustice affects the Chicana/o community. There are significant works on Chicana/o environmental ethics in the social sciences, with book-length studies in the fields of cultural anthropology, geography, and urban studies. The humanities are starting to respond as well, with the publication of several journal articles that feature Chicana/o environmental writing and history.

Chicana/o environmental thought influences the academic studies in significant ways. For example, the idea of wilderness does not accord with Chicana/o present and historical sustainable dwelling on the land in North America. Moreover, the limitation of access to public lands by the National Park Service and other U.S. government agencies came at a time when Mexican Americans were fighting for recognition of their rights to remain a part of—and own—some of those areas. Likewise, environmental studies have influenced Chicana/o scholarship, fostering a greater awareness of the social-justice dimension of environmentalism in Chicana and Chicano activism, cultural production, and scholarship.

CHINA

China is the most populous country in the world, with a population estimated at of 1.3 billion in 2007. Since the late 1970s, China's economy has developed rapidly and continuously. During this expansion, many environmental problems that have haunted developed countries in various phases of their industrialization have occurred in China in a compressed time span. In China the conflict between the environment and development is becoming ever more prominent. A relative shortage of resources, a fragile ecology, and insufficient environmental capacity are becoming critical problems hindering China's continued economic development.

ENVIRONMENTAL PROTECTION IN CHINA

To tackle environmental problems arising from rapid economic growth, China has adopted a series of comprehensive measures, with marked achievements to its credit. For example, the amount of industrial waste water and industrial aerosols discharged in generating one unit of GDP in China in 2004 dropped by 58 percent and 39 percent, respectively, from 1995. Nonetheless, industrial pollution of the environment remains severe in China. In 2005 the forest area in China was 175 million hectares, with forests covering 18.21 percent of the country. This coverage ratio increased by a factor of 1.66 percent from 2003 to 2008. The National Coordination Committee on Climate Change was established in 2003, and China's National Climate Change Program was formulated, outlining objectives, basic principles, key areas of actions, as well as policies and measures to address climate change for the period up to 2010. In June 2007 China issued a work plan on energy conservation and pollutant-discharge reduction. According to the plan, the government was to invest 1.35 percent of its GDP each year for the following three years in environmental protection and would reduce its 2005 level of energy consumption by 20 percent by the end of 2010.

Nonetheless, the remaining environmental challenges for China are serious. Energy consumption per unit of GDP in China is eight to ten times of that in developed countries. China's emission of sulfur dioxide is the largest in the world, and its carbon emissions are second to those of the United States and soon to rise to first place. Sixteen cities in China are among the top twenty most heavily polluted cities of the world. Approximately 70 percent of China's water system is polluted. Some 300 million peasants have difficulties in accessing clean water. Species have disappeared or become endangered at the rate of 15 percent to 20 percent during the last twenty years.

MAJOR ENVIRONMENTAL EVENTS IN CHINA

Ethics, values, and major events contribute to the public's awareness of the environment and environmental ethics. The 1998 flood of the Yangzi River Valley made many people think seriously about the relations between humans and nature. The outbreak of severe acute respiratory syndrome (SARS) in 2002 led the public to reflect on its relationship with animals. In May 2004 the announcement by the Beijing Municipal Legal Affairs Office that it had drafted legislation on animal welfare spurred a vigorous debate about whether and in what sense animals have rights. Consequently, many universities have established laboratory animal ethics committees. The 2004 Indonesia tsunami triggered another public debate in China in 2005 about whether humans should revere nature. These events loom large in ethical reflections on environmental issues in China.

The development of Chinese environmental ethics has occurred in two phases. The first phase is the embryonic period, extending from the middle of 1980s to the middle of 1990s. The first Chinese article to argue for the intrinsic value and rights of nature was published in 1987 (Yu 1987). In 1991 Holmes Rolston visited China and encouraged Chinese scholars to explore and promote environmental ethics. The first paper that introduced the perspectives of contemporary European and North American environmental ethics appeared in 1993 (Yang 1993). This first phase came to its high point when the Chinese Society for Environmental Ethics was established and the First National Conference for Environmental Ethics was held at Renmin University in 1994. Several books on ecological ethics were published in China during this period (Xiangrong Liu 1992, Ye 1994, Yu 1995).

The second phrase is the growth and development period, which began in the late 1990s. Chinese scholars

Flooding in Yueyang, China, 1998. *The 1998 flooding in China's Yangzi river valley was one of the major environmental events that caused many in the country to start thinking about the relationship between man and nature. As the most populated country in the world, China faces many environmental challenges: around 70 percent of its water system is polluted, and some 300 million people have difficulty accessing clean water.* **AP IMAGES.**

made many advances during this period. The study of environmental ethics became more comprehensive, systemic, and deep. European and North American environmental ethics have been extensively explored (Yang 2000, Lei 2001), and many books, such as Roderick Nash's *The Rights of Nature* and Rolston's *Environmental Ethics* and *Philosophy Gone Wild*, have been translated into Chinese. Benefiting from the perspective of modern environmental ethics, some scholars expound systematically traditional Chinese conceptual resources and wisdom concerning the environment (She 2002, Meng 2004). Many textbooks and original academic writings on environmental ethics appeared during this period. (He 2002, Yu 2003, Yu and Wang 2004, Yang 2007).

In addition, many universities (such as Renmin University, Peking University, and Tsinghua University) and institutions (such as the Chinese Academy of Social Sciences) offer master's and doctoral degrees in environmental ethics. There are at least sixty universities that offer environmental ethics courses for undergraduate students. The first doctoral dissertation on environmental ethics in China was completed in 1998 (Yang 1998). In 2003 the Environmental Philosophy Committee of the Chinese National Association of Natural Dialectics was established. Academic activities in environmental ethics have also increased rapidly. The First National Conference on Environmental Philosophy, which Rolston attended, was held at Harbin Industry University in 1998. There has been at least one academic conference on environmental ethics or environmental philosophy each year since 1998. The First International Conference on Environmental Ethics was held at Nanjing University in 2004; among those in attendance were Dale Jamieson, Eugene Hargrove, Andrew Brennan, and Freya Mathews. The International Seminar for Environmental Ethics, the aim of which is to train teachers who teach environmental ethics for college students, was held at College for Environmental Management of China in 2006. Hargrove, Brennan, Mathews, and other scholars gave presentations for this seminar. Chinese scholars have also begun to go abroad to study environmental ethics and participate in international research programs (Yang 2006), among them Gao Shan at the University of North Texas doctoral program.

ACADEMIC DEBATES

Environmental issues that Chinese scholars have focused on include the following: the nature of environmental ethics, environmental justice (especially international environmental justice), intergenerational duties, sustainable-development ethics, the moral status of animals, ethical issues concerning animal experimentation, the contours of an ecological worldview, ecological culture, and green civilization. The following three debates are the most important theoretical focus of Chinese environmental ethics:

The Debate over Anthropocentrism In 1994 Yu published "Go Beyond Anthropocentrism" and triggered an unexpectedly enthusiastic and pertinent debate over anthropocentrism in academic circles. Roughly speaking, three camps developed around this debate. The anthropocentrism camp insists that (a) moral norms can apply meaningfully only to interhuman relations; (b) nonhuman beings are not members of the moral community; (c) the moral foundations of environmental protection are the interests of human beings as a whole. Therefore, human beings do not have direct duties toward nonhuman beings (Fu 2002, Zhang 1997, Han 2005). The nonanthropocentic camp argues that (a) nature has intrinsic values and rights; (b) the narrow metaethical

definition of morality as interhuman norms is not defensible; (c) and the moral community has been extended—therefore, human beings owe moral duties to nonhuman beings (Yu 1999, Lu 1996, Li 2001).

The third can be called the syncretism camp, which takes an open and inclusive approach to the issue and tries to achieve a Hegelian synthesis of the perspectives of the other two opposing camps of environmental ethicists (Yu and Wang 2004, Chao 2004). From the perspective of such syncretism, there are merits and limits in both anthropocentrism and nonanthropocentrism, so we should go beyond the dichotomy and integrate ideas from both camps. The Confucian theory about moral ideas can provide a foundation for such an integration. According to this approach, we can clarify and search for four moral ideals (or moral horizons): to love human beings, to sympathize with animals, to care for all life, and to respect nature as a whole. The first ideal belongs to the category of required morality, and the latter three belong to that of expected morality. The four major schools of environmental ethics—enlightened anthropocentrism, animal liberation/rights theory, biocentrism, and ecocentrism—can be understood as the theoretical expression of these four moral ideals. As when climbing a mountain, one can practice and realize these ideals gradually, beginning with the ideal of loving human beings and ending with the ideal of respecting nature. The more ideals one can practice, the more excellence humanity can realize and exhibit (Yang 2000, 2007).

The Debate over the Intrinsic Value of Nature Most Chinese scholars who have worked in environmental ethics argue that nature has intrinsic value. The main argument they provide is that living beings and natural systems (a) have their own *teloi* (ends, goals, purposes); (b) some are conscious beings with different subjectivities; and (c) some have their own wisdom about how to live and their own ability to value (Yu 1995, 2003; Li 2001). Those who reject the intrinsic value of nature contend that (a) value by its definition means utility of things for humans; (b) human beings are the only beings with self-consciousness and language, which are the presuppositions of valuing; and (c) to equate the being of nature with the value of nature is to move to ought from is to commit the "naturalistic fallacy" (Fushen Liu 1997, Han 2005).

The Debate over the Rights of Nature Some scholars argue that nature has rights. The rights of nature, according those thinkers, refer to a species' rights to exist by ecological laws; such rights, they argue, are natural and equal for all species. A species' rights are based on its intrinsic value and its role in maintaining the stability of an ecosystem (Xiangrong Liu 1992, Ye 1994, Yu 1995). But those who deny nature's rights argue that only those beings can have rights who (a) can understand the meanings of rights; (b) have moral autonomy; and (c) have the idea of intersubjectivity and reciprocity. On this view, therefore, nature cannot have rights (Fu 2002, Han 2005).

PROSPECTS AND PROMISES

Chinese environmental ethics has made much progress after two decades of development, and new trends are emerging.

1. First, more and more scholars focus on the practical policy application of environmental ethics. They try to make environmental ethics more policy- and problem-oriented, and focus on helping the environmental community to make better ethical arguments in support of environmental-protection policies. Ethical issues concerned with poverty, sustainable development, corporate responsibility, and war also capture the attention of many scholars.
2. Second, many environmental ethicists try to reflect critically on environmental ethics from new perspectives (such as Marxism, feminism, and virtue ethics) and explore new foundations, metaphysical and scientific, for environmental ethics.
3. Third, many efforts have been made to uncover and adapt the environmental ethical resources of Chinese cultural traditions (such as Confucianism, Taoism, and Buddhism). Thus, the forging of environmental ethics with distinctive Chinese characteristics is under way.
4. Fourth, many scholars make it their priority to deal with environmental justice, especially international environmental justice. They have come to realize that a whole and healthy environment is one of the basic human rights and that unjust social systems and structures, domestic as well as international, maintain and reinforce environmental injustice, allowing the privileged classes to enjoy environmental advantages while the disadvantaged classes disproportionately bear environmental disadvantages. Environmental-justice issues represent the greatest potential for Chinese environmental ethics to have a practical impact.

CHIPKO MOVEMENT

Chipko is a grassroots environmental movement that began in 1973 in the Chamoli district of the Indian State of Uttaranchal, then Uttar Pradesh in northern India. Its concern was to save the forests from contract lumbering, a practice inimical to the local economy. Its name is derived from its strategy of hugging (*chipko*) the trees to shield them from the lumberman's axe. The movement brought about a ban on the felling of trees for commercial purposes above an altitude of 1,000 meters in Uttar Pradesh and spread to South India as *Appiko* (to embrace), successfully protecting the tropical forests of India's Western Ghats. The influence of the movement is evident in other mountain regions of India and in other countries.

Chipko was part of a protracted struggle by village people against forest policy going back to the nineteenth century that limited their access to the forests for household needs, while supporting commercial exploitation of the forest that brought revenue to the state. By the mid-1900s forest policy had impoverished the hill villages, as jobs in the forest industry tended to go to workers whom contractors hired from outside the region. Those who did find employment usually found jobs on the plains, where they lived for long periods at a great distance from their families. The system of contract felling lumbering also led to environmental degradation. Severe floods in 1970 raised local awareness of the threat of deforestation. In the 1960s, social workers occupied with Gandhi's constructive program, began labor cooperatives that established small, forest-based industries to provide local employment. While thesey enjoyed some success, they had to compete for raw materials with established industries in the plains.

The Chipko movement began when the State Forest Department denied permission to a local organization called the Dashauli Gram Swarajya Mandal, or Dashauli Village Self Reliance Cooperative (DGSM) for to fell a small number of ash trees for the manufacture of farming implements. (The leaves of the ash trees were also important to the villagers because they provided fodder during the scarce season.) The forest department denied permission to this organization to cut five of ash trees, but granted permission to a sporting goods manufacturer based in Allahabad to cut an entire forest of ash trees only 13 thirteen kilometers away. The people resolved to enter the forest and if necessary to hug the trees marked for felling in order to shield them from the lumberman's axe. When the contract workers were unable to take away the trees they had been promised, the people's resolve spread to other areas where contract felling was in progress. The Garhwali folk singer Ghanshyam Sailani joined activist Sunderlal Bahuguna (b. 1927) on long *padyathras* or foot marches through the hills where he composed songs in support of the movement: "Embrace the trees / Save them from felling / The wealth of the hills / Don't let it be looted!"

Environmental Activist Sunderlal Bahuguna. *Bahuguna, a key figure behind the Chipko Movement in India, is seen here participating in a Save the Ganges march in New Delhi, 2006. The Chipko Movement began in 1973, when Bahuguna and others prevented the felling of ash trees in India by hugging those targeted by loggers.* **MANAN VATSYAYANA/AFP/GETTY IMAGES.**

Women took a decisive role in a demonstration in the Reni forest (near the Indo-Tibetan border) where they announced to contract workers that they came to the forest for fruit, herbs, and other products upon which their families depended. They saw the forest as their mother and they intended to protect it, if necessary, with their lives. The following years saw many similar demonstrations.

Such protests put a stop to the felling of trees in many places, but did not immediately alter forest policy. While the contract system remained in place, the forest department made concessions to local forest-based industries. In 1977, the tension between the concern for raw materials for small forest industries and the concern over deforestation began to come into focus. Over the protest of thousands in October of 1977, the forest department auctioned two forests in the Tehri district and scheduled them for felling the following December. For a week in December, women from fifteen villages guarded the forest. During demonstrations in this region, activists versed in the religious traditions of India gave discourses from the *Bhagavata Purana*, the Hindu text that tells the story of the earthly childhood of Lord Krishna in the forests of Vrindavan. Here the most celebrated slogan of the Chipko movement came to be widely known: "What do the forests bear? Soil, water, and pure air! Soil, water, and pure air are the basis of life." Unable to take any trees, the lumbermen departed but returned on February 1, 1978, with two truckloads of police. The villagers now engaged in the first mass tree hugging in the movement. Eventually the police and the workers departed, leaving the forest intact.

While the forest cooperatives wanted to save the forests for raw materials for small forest industries, many of the villagers, the women in particular, saw the forest as the source of food, fodder, and fuel for domestic needs. In 1973 the interests of the two had converged. Bahuguna understood the women's perspective and began to spread a message about the ecological demise of the hills. In 1981 Bahuguna brought the issues of the hills to Indira Gandhi, then prime minister of India. Through her influence, the state government imposed a ban on the felling of trees for commercial purposes above the altitude of 1,000 meters. The ban eventually extended to the mountain state of Himachal Pradesh.

The ideological viewpoints of Chipko were varied. The Uttarakhand Sangharsh Vahini (USV), an organization active in the region of Kumaun in the 1970s, was strongly influenced by Marxism and held that the ecological crisis of the hills was rooted in the destruction of nature by powerful economic interests had produced the ecological crisis of the hills. With a positive attitude towards science and technology, they were suspicious of tradition and of government programs. Less confident about science, Chandi Prasad Bhatt (b. 1934) and the DGSM advocated appropriate technologies. He favored cooperation with government programs and initiated prodigious efforts towards reforestation. He engaged the villagers with eco-development camps. Bahuguna shared the Marxists' concern with social and economic injustice. But his principal inspiration came from Gandhi. For him, the ecological crisis in the hills is caused by materialism—which makes man the butcher of the Earth. It has generated a mistaken notion of development that enriches the few at the expense of the many. For his approach Bahaguna found support both in ecology and in the spiritual traditions of India. From 1981 to 1983 he took this message to the villagers by means of a *padyathra* of 4,870 kilometers from Srinagar, in Kashmir, to Kohima, in Nagaland. During this time Chipko received international attention

and became an inspiration for environmentalism in India and abroad.

CHRISTIANITY

There are over 2.5 billion practicing Christians on earth, approximately 1 billion of whom are Roman Catholic. Orthodox and Coptic Christianity have roots as ancient as those of Roman Catholicism, and Protestant churches originated in the break with Rome in Europe during the Reformation in the sixteenth century or have developed through further schisms since that time. The twentieth century saw the proliferation of a range of new denominations. The largest of these is the Pentecostals, whose numbers are estimated at 600 million.

Christians are present on all continents, the largest proportions being found in Africa and North and South America, with far smaller portions in Asia than elsewhere. Europe has a predominantly Christian culture emanating originally from the Holy Roman Empire. Myriad religious buildings, legal customs, ethical mores, cultural artifacts and symbols, and educational and medical institutions survive as a shared cultural heritage from the era of Christendom. But far fewer twenty-first-century Europeans regularly participate in Christian worship than Christians on other continents, and knowledge of biblical narratives and Christian doctrine is declining rapidly among the young. European intellectuals have tended to assume that this European pattern of secularization would be repeated throughout the world, but there are signs of a resurgence of religion on other continents, and also in some parts of Europe, particularly in the East. In many regions—including the United States, the Middle East, Latin America, South and East Asia, Africa, and Eastern Europe—religious affiliation plays a significant role in shaping voter opinion, and hence public policy, on a range of issues. This rise in the public influence of religion is significant for environmental concerns, since it may indicate that in these regions, environmental beliefs and practices will need to find a central place in religious beliefs, ethics, and practices.

THE ENVIRONMENT IN CHRISTIAN HISTORY

Historically, there has been stronger environmental concern associated with Protestantism than with other religious traditions. Countries with the strongest array of environmental laws and regulations and the largest number of environmental nongovernmental organizations include Germany, Sweden, Switzerland, the United Kingdom, the United States, and New Zealand. Although environmental concern first arose in these Protestant countries in the 1960s, when formal churchgoing was in decline, elements of Protestant Christian culture are friendly toward environmental protest and democratically expressed pressure for restraints on capitalism and industrialism. Catholic and Orthodox Christian countries, by contrast, have seen much less environmental mobilization, and these countries have much laxer environmental regulations than most Protestant countries. Similarly, environmental pressure is weak in Islamic countries and countries with an Asian religious complexion. In the Asian context, the commonest form of environmental protest has not occurred in the formal political arena. Rather, it has taken the form of the environmentalism of the poor, in which communities whose natural resources are degraded or destroyed by the actions of corporations, governments, or private landowners protest or resist such abuse of their local habitats by forms of direct action, such as that of Chipko women who hugged trees to prevent them from being cut down by timber companies around their villages in North India.

Some argue that environmentalism arose in Protestant Christian countries because these countries were the first to experience significant rises in living standards in the mid-twentieth century. This produced a greater emphasis on quality of life, including the environment, in public concern and hence in public policy (Northcott 1996). These countries were also the early adopters of modern democratic practices, which have historical roots in the congregational culture of Protestantism. The open-meeting style of the early reformed churches in Geneva and Edinburgh paved the way for the open meeting of commoners in democratic parliaments. Similarly, the multiparty form of modern democratic polities mirrors the multidenominational character of many post-Reformation Protestant countries. Hence, in fostering democratic cultures, in which individuals claimed rights against monarchs' claims to divine authority, Protestantism may be said to have paved the way for the emergence of a culture of open debate

and plural political parties, in which environmental protest, and then green political parties, first arose in the twentieth century.

There is, however, little theoretical understanding of the association between Protestantism and environmentalism. Part of the reason for this is that Lynn White's famous essay "The Historical Roots of Our Ecologic Crisis" suggested that far from Protestantism's being friendly to environmental concerns, traditional Christianity in both Catholic and Protestant forms was the major ideational source of the antiecological tendencies of Western industrial societies and technologies. White argued that the Christian doctrine of creation involved a clear separation of the divine from the biosphere. This, combined with the Genesis teaching about human dominion over other species, fostered the desacralization of the nonhuman world in the West. It also fostered a strongly anthropocentric view of the biosphere and of other species that emphasized their instrumental value to humans, rather than their intrinsic value. By contrast, White claimed, other cultural and religious traditions have sustained a greater emphasis on divine immanence in the physical world and on the interrelationships between humans and other creatures, such as the belief in reincarnation in some Asian traditions. White also acknowledged, however, that the Christian tradition is not homogenous, and that Christian teachers such as Saint Francis and others have emphasized a less domineering and more democratic relationship between humans and other creatures. White's arguments that the Christian tradition is the root of the environmental crisis in Western civilization, and that it contains resources to repair that crisis, have been influential and have helped provoke an extensive array of Christian responses to the environmental crisis.

NATURE AND BELIEF IN THE CHRISTIAN TRADITION

Christian traditions in East and West have held a range of positions on the relationships between God, humanity, and nature, rooted mostly in the Biblical narratives of creation and redemption, the life of Jesus, and the early Christians. Genesis occupies a pivotal role in historical Christian reflection on the place of humans in the cosmos, particularly the first three chapters, on which the early Christian fathers commented extensively and to which modern Christians have returned for a source of traditional wisdom on the current environmental crisis. Christians have traditionally held that the Genesis narratives indicate that God created the world out of nothing (ex nihilo), and that it was created to reflect God's glory and to serve humanity. Christians, unlike Jews, have also held that the story of Adam and Eve and the forbidden apple indicates not only a changed relationship between humans and the Creator, but the entry of evil into the created order. The early Christian fathers adopted the Platonic view that humanity is a microcosm of the natural world and that the destiny of humans therefore has central significance to the destiny of all creatures. But for most of the early fathers, this unique status did not make humans the center or destiny of Creation. Rather, all life, all being in time, was conceived of as being in motion from birth to death. They saw creation in time and space as a realm set apart from the eternal, infinite divine yet teleologically ordered to return to God. As interpreted by the Greek fathers such as Gregory of Nazianzus (Bergman 2005), the Fall of Adam and Eve has consequences that are not confined to the human species but infect all creatures, and hence the whole biosphere.

Thus the doctrines of the Fall and of original sin have an important place in explaining the modern ecological crisis as both evangelicals, such as Francis Schaeffer, and Orthodox theologians, such as Patriarch Bartholomew, have argued. The Fall is the first instance in history in which humans pridefully set themselves in place of the Creator. In consequence, out of their created freedom they bring into the world evil, which sets humans at odds not only with God and with one another but also with other creatures. This new reality, evil, disturbs the original peace and harmony of the created order. In this perspective, the modern environmental crisis is the outcome of this sinful disturbance to the cosmos and is as much a moral and spiritual crisis as an economic and scientific one.

The prologue of the Gospel of Saint John acts as a significant supplement to the early chapters of Genesis. It indicates that the world was created through the action of the divine Word, which is Jesus Christ, as well as by the creator Spirit referred to in the Genesis narrative. This Trinitarian account of creation provides the principal doctrinal ground on which Christians have understood the relations between God and the earth, the one and the many, infinity and finitude. It also provides an account of the immanence of God as Spirit in the Creation, as well as the transcendence of God as Father, Son, and Spirit. Early Christians interpreted the events of Christ's life, death, and resurrection as indicating a renewal and redemption of the whole Creation, and as presaging a recovery of the original goodness of Creation before the Fall of humanity, whose effects marred and polluted all of Creation. This sense of the redemption of embodied life finds expression in the lives of the fourth- and fifth-century desert fathers, who, through their ascetic practices, are said to have achieved harmony with the divine and a new companionship with wild animals. This is illustrated in accounts of Saint Jerome (ca. 347–419/20) plucking a thorn from a lion's paw; in the rule of Saint Benedict of Nursia (c. 480–c. 547), founder of

Niccolo Colantonio,* Saint Jerome Extracting a Thorn from the Lion's Paw*, circa 1440–1470. *Colantonio's painting of Saint Jerome depicts the early Christian account of the saint removing a thorn from a lion's paw. The story is an example of one of the "desert fathers," who achieved harmony with the divine and companionship with wild animals.* **SCALA/MINISTERO PER I BENI E LE ATTIVIT CULTURALI/ART RESOURCE, NY.**

Benedictine order, in which agrarian work and related crafts redeem one from the effects of the Fall; and in the life and traditions of Saint Francis of Assisi (1181/82–1226), who preached to birds and animals and who, like the Hebrew Psalmists, taught that humans, together with all other creatures, owe celebration and praise to the Creator.

From the perspective of the ecological crisis of the twenty-first century, a crucial feature of the Genesis narrative is the distinctive role conferred on human beings to "rule over" other creatures and Creation. The teaching on dominion in Genesis 1 and 2 has received particular emphasis in theological teaching since the Protestant Reformation. This mandate of dominion was also frequently invoked by the missionaries who followed the traders and warships of modern European imperialism. The contiguity of Christian missions and the extinctions and ecological calamities that followed the introduction of nonnative species and the spread of European agricultural practices around the earth have led many environmentalists to argue, like White, that Christianity is the root of the ecologic crisis. However although such prominent figures in Western Christianity as Augustine (354–430) and Thomas Aquinas (1224/25–1274) have emphasized the dominion over Creation given to Adam and Eve as creatures made in the image of God, others such as Symeon the New Theologian (949–1022), Hildegaard of Bingen (1098–1179), and Francis have emphasized that humans and other animals share the status of being divinely made creatures called to

multiply on the earth, and that, according to the Genesis narrative, animals are created as companions for humans.

MEDIEVAL AND RENAISSANCE CHRISTIANITY

Michael Northcott (1996) has argued that it is not so much historical Christianity but the Protestant Reformation that paved the way for the environmental crisis in the modern West. He points to thinkers like the West's most influential theologian Thomas Aquinas. Though Aquinas held an instrumental view of the relationships of humanity to nature and argued that humans may use Creation as they see fit, since it was created primarily to serve them; he nonetheless enjoined careful use of animals when he suggested that abusive human relations with other animals will tend to deprave humans. Cruelty to animals diminishes human virtue, and so should be avoided. For Aquinas, the relation of humans to creatures is indicative of human holiness and human sin. Therefore, dominion cannot be rightly exercised unless it is framed by the theological virtues of faith, hope, and love, and the cardinal virtues of courage, justice, prudence, and temperance. In this perspective, destruction of ecosystems in pursuit of material satiety indicates a moral and spiritual lack in humans who pursue such a path, while the virtuous individual, whose life is directed to love of the Creator, will express that love in just and temperate relations with other creatures, as well as other persons.

In Western medieval Christianity, a dominant metaphor for relations among creatures was the "great chain of being." This organic metaphor, which may be traced from medieval theology back through Plotinus (205–270) and Neoplatonism more generally to Plato (c. 428–347/8 BCE) and Aristotle (384–322 BCE) represents all life as existing in a hierarchy of interdependent biotic relations. This metaphor carried with it the conception that all physical reality is ensouled and has its origins in the divine mind. It also carried with it the claim, first advanced by Plotinus, that the earth is "the best of all possible worlds" because of the beauty, diversity, and fecundity of the forms that inhabit it. In the early modern era, the concepts of the great chain of being and the ensoulment of all reality were increasingly replaced by a cosmology of mechanism, which from the time of Isaac Newton (1642–1727) grew in significance in Western theology and philosophy, as well as in Western science and technology.

Renaissance thinkers restated a significant element from ancient Greek philosophy: Protagoras's claim that "man is the measure of all things." The appropriation of this claim in the Italian Renaissance was an important moment in the displacement of earlier Christian accounts of God as the sovereign Lord of Creation, and of the status of humans as creatures who in important respects stand *with* other creatures rather than over and above them. The philosophical fruit of the cosmology of mechanism and the relativizing claim that man is the measure of all things was modern Deism. Deist theologians such as William Paley (1743–1805) represented the Creator as a temporally and spatially distant being or "first cause," whose principal relation to Creation was one of instigator or maker (as watchmaker to watch), instead of that of immanent Spirit and sustainer. By the nineteenth century, Deist ideas could be found in much Western Christian culture, across traditions from the evangelical to the Roman Catholic. The rise of Pentecostalism, with its reemphasis on the divine Spirit, may be seen as one response to Deism. Yet this in itself does not mean that Pentecostalism can provide an ecological theology. Pentecostalism recovers the doctrine of the Spirit in a very anthropocentric way, its millennialism suggesting that the present material earth will be burned up in a final conflagration.

CHRISTIANITY SINCE THE RENAISSANCE

The increasingly anthropocentric trajectory of Western Christianity since the Renaissance is charted by Keith Thomas (1986) in a valuable study of English preaching and other religious practices. He shows a consistent decline in respect for animals and other parts of material Creation since the late Middle Ages. A significant root of the increasingly anthropocentric tendency of Western Christianity lay in late medieval theology, and especially in the rise of nominalism, whose advocates, most notably William of Ockham (c. 1285–1349?), argued for a more radical break between the divine intent of the creator and the accidental appearances of species and kinds than had early Christian theologians. This ontological break paved the way for the Renaissance recovery of an earlier classical Greek view of matter as ontologically insecure and inferior to spirit. It was given added cultural force by the tendency of late medieval Catholicism to confine the action of grace and the sacred to the ordinances of priests, and especially to the divinely ordained sacraments. The Reformers protested at the consequent hierarchical control of the means of grace and proposed instead a democratization of the interpretation of scripture and the sanctifying actions of grace in the lives of individual Christians, in the "priesthood of all believers." Nonetheless, their ritual and theological reforms did nothing to reverse, and instead advanced, the gradual evacuation of the sacred from the everyday lives of European Christians, and hence promoted growing anthropocentrism in the relations of humans to nature.

After the Reformation in Europe, the desacralization of everyday life proceeded apace and was accompanied by a growing instrumentalism in the treatment of animals and the use of "wild" lands. This instrumentalism took theological form in the teachings of John Calvin (1509–1564), who argued that nature was redeemed from the Fall by being transformed by human work. This perspective found its most influential advocacy in the political theology of John Locke (1632–1704), who gave theological warrant to colonial expropriation of native lands. Settlers acquired rights to native lands because the settlers tilled the soil, and thus fulfilled a mandate from the book of Genesis, while natives had merely gathered fruits and hunted animals on the land while leaving it wild and disordered in the eyes of Europeans.

AFTER WHITE 1967

Lynn White (1967) suggested that the problem of a desacralized natural world could be resolved by recovering a Franciscan theology of Creation that reemphasizes the companionship of all creatures and the immanence of the divine Spirit in all life. White's challenge to Western theology received a range of answers from Christian churches and theologians of ecumenical, evangelical, Orthodox, and Catholic hue in the late twentieth century. John Cobb and Charles Birch argued that the relation between Western Christianity and the earth could be healed by abandoning traditional Christian metaphysics and adopting a process view of reality more in accord with modern evolutionary beliefs. Birch was particularly influential in the ecumenical body known as the World Council of Churches, which represents most major Protestant and Orthodox churches and was established after the Second World War. Through its Geneva office, assemblies, boards, and reports, the World Council of Churches became an influential advocate of the human duty to care for the Creation. The World Council of Churches framed a program for the justice, peace, and integrity of Creation that was designed to raise awareness in churches and public life of the threats to the biosphere from industrial civilization. The World Council of Churches also linked these threats with injustices in human society and suggested that addressing the ecological problems of habitat destruction, air and water pollution, deforestation, and the loss of biodiversity would also help address the injustices in the distribution of access to the riches of the earth between the wealthy and the poor.

Under the program for the justice, peace, and integrity of Creation, the World Council of Churches produced many ecumenically agreed-on reports on the importance of respecting the integrity of Creation and the need for societies to regulate industrial capitalism to reduce its ecological impacts, and to restrain economic growth and technological manipulation of the nonhuman world. Among the fruits of the program was a major study of the ethics of technology and of nuclear power. The World Council of Churches also played a significant role in efforts to inaugurate the United Nations Framework Convention on Climate Change, and it has been prominent in emphasizing the ethical urgency of preventing dangerous climate change at the Conferences of the Parties, which met under the convention and negotiated the Kyoto Protocol. The program has also fostered liturgies and rituals, performed at ecumenical gatherings, that focus on the beauty and diversity of Creation, the immanence of the Holy Spirit in Creation, and the representative role of the Church in calling people to care for Creation. A significant emphasis in the reports of the World Council of Churches was the theme of a "sustainable society," which maintains that people need to live lives characterized by health, social justice, ecological sustainability, peace, and spiritual fulfillment. This approach required a radical revision to the mainstream model of economic development and challenged the consumerist lifestyle it promoted.

Under the process of the program for the justice, peace, and integrity of Creation, many member churches of the World Council of Churches began to focus more directly on environmental concerns in the 1980s. Other faith groups were also drawn into dialogue on ecological issues, and in 1991 the World Council of Churches hosted a consultation of faith groups that laid the groundwork for the development of an Earth Charter, which was taken up at the Rio de Janeiro Earth Summit in 1992. The Earth Charter consists of a number of principles, including respect and care for the community of life, ecological integrity, socioeconomic justice, democracy, nonviolence, and peace. The charter was drafted over a three-year period and was reviewed by faith groups, nongovernmental organizations, international business groups, and religious communities, and it was formally presented to the international community at the Peace Palace in the Hague on June 29, 2000, and to the United Nations General Assembly in New York in 2002.

CURRENT ORTHODOX CHRISTIANITY AND THE ENVIRONMENT

Ecumenical interest in ecological concerns is deeply informed by Orthodox Christian perspectives that have roots in the writings of the Greek Fathers and their emphasis on humanity as a microcosm of Creation. Orthodox theologians, who are often Bishops and priests instead of professional scholars, have been notable in advocating a conception of salvation that includes all embodied life, and not just human beings. The liturgy in the Orthodox tradition is the focus for celebrating the

divine will said to be revealed in the scriptures and presenting the teachings of the Eastern Fathers that all creatures will eventually participate in the restoration of all things, set in train by the bodily resurrection of Christ. Creation was polluted by the corruption and pride of human beings, and human participation in the divine liturgy anticipates the redirection and restoration of all creatures to the good ends toward which Creation was originally directed by the Creator.

Orthodox theology has not only been a significant source of theological and liturgical renewal in the Western churches that are members of the World Council of Churches; Orthodox theologians, most notably Patriarch Bartholomew, have also become leaders of ecological action through the offices of the church. Bartholomew, who has become known as the Green Patriarch, has led annual pilgrimages to several great bodies of water to draw attention to the threats faced by them, the species that dwell in them, and the human communities that live around them, from industrial pollution, excessive modern water extraction, and introduced nonnative species. Bartholomew has gathered religious leaders, scientists, regional politicians, and conservationists to study what is happening to the Black Sea, the Mediterranean, and the Amazon, among other bodies of water. The meetings themselves and the published proceedings that followed have played an important role in highlighting the threat that modern industrial practices and technologies represent to that essential element, water, that is sufficiently abundant to generate and sustain life only on the earth. They have also provided a powerful model of the social significance of environmental leadership when it is offered by people of faith drawing on rich ancient traditions and teachings.

CURRENT EVANGELICAL TRADITIONS AND THE ENVIRONMENT

In contrast to the relative alacrity with which ecumenical and orthodox leaders and theologians have taken up modern environmental concerns, evangelical and Roman Catholic traditions have been more resistant. One of the earliest attempts to address the environmental crisis from a faith perspective was penned by the conservative evangelical theologian Francis Schaeffer. In 1962 Schaeffer founded an evangelical theological, therapeutic, and artistic community called l'Abri (the Shelter) in Switzerland, with sister communities in Britain and the United States. The position of the community at Champéry in the midst of the Swiss Alps indicated his own particular love for the mountain environment. Schaeffer argued that environmental pollution and the destruction of the environment were consequences of human sin and rebellion against God, and represented the profound disrespect for the Creator in modern Enlightenment philosophy and modern mechanistic science. For Schaeffer (1992), the problem was not with Biblical teaching, but with secular humanism and the modern abandonment of the divine command to love God and neighbor. Schaeffer believes that the ecological problem is connected with a spiritual crisis in modern humanism. Humanists do not perceive the beauty of the biosphere as reflecting the glory of God, and hence they no longer love it as the divine Creation.

Though evangelicals have been slow to take up Schaeffer's prophetic call, a range of evangelical ecological initiatives emerged in Europe and North America in the 1990s and early twenty-first century. Prominent among these was the founding by Peter Harris of the

Operation Noah Banner, London, 2007. *Operation Noah campaigners march in London to bring attention to the issue of global climate change. The organization was founded in 2001 by Christian Ecology Link, to promote the idea of a more simple, liveable, and supportable lifestyle in the name of God. While the religion has not been traditionally considered to be "nature loving," many denominations are disproving this stereotype by pointing out the links between Christianity and a more eco-friendly lifestyle.* **© MARK BOULTON/ALAMY.**

evangelical conservation trust A Rocha, which focuses on conserving habitats crucial to migrant and wetland birds. First in the Algarve (Portugal); later in Provence (France), the East End of London, and Kenya; and now in a number of other locations; A Rocha has become associated with efforts to conserve and restore habitats for migrant and wetland birds, and efforts to enhance evangelical consciousness of the plight of Creation through this faith-based witness to a conservation effort informed by science. Among its patrons, the prominent evangelical leader John Stott is a significant guiding light, and Stott is himself an avid bird watcher.

British evangelicals have also played a significant role in drawing evangelical leaders in North America toward great ecological sensitivity. Sir John Houghton, former chair of the science panel of the Intergovernmental Panel on Climate Change and also an evangelical Christian, has spoken at meetings of evangelical leaders in Britain and the United States about the close relationship between the Christian mission to witness to Jesus Christ and the ecological imperative to redeem Creation from the effects of industrial pollution and habitat destruction. These transatlantic friendships have played a crucial role in promulgating in the United States an evangelical statement on climate change arguing that climate change is a faith issue for all Bible-believing Christians. In this statement and in other initiatives, evangelical leaders such as Richard Cizik, president of the National Alliance of Evangelicals, attempted to use the influence that evangelicals had on the U.S. Republican Party and the administration of George W. Bush to persuade political leaders in Washington, D.C., as well as evangelical Americans, that they had a God-given duty to conserve the earth from ecological destruction.

CURRENT ROMAN CATHOLICISM AND THE ENVIRONMENT

The largest Christian communion on earth in terms of present membership is the Roman Catholic Church, and here again there has been notable resistance to official comment on the environmental crisis. The most prominent focus of Catholic criticism of modern technology and the lifestyle and ethics it has promoted is not the ecological crisis, but the use of contraception and abortion to control human sexual reproduction and family size. In many parts of the developing world, the Catholic Church has used its considerable influence in schools, in hospitals, and in public life in Catholic countries to suppress knowledge of birth-control techniques other than abstinence. The Catholic pro-life ethic has yet to consider fully how the dramatic expansion of the human species that occurred in the twentieth century will affect the lives of other creatures on earth. At international gatherings such as the Rio Earth Summit, Catholic influence has been used to suppress reference to the pressure of the human population on the planet and the need to restrain further expansion of the human species.

Some detect a shift in the last decade of the papacy of Pope John Paul II (r. 1978–2005), during which he seemed to have awoken to the significance of the environmental crisis as another of the threats to life furthered by the "culture of death," which, the Church has traditionally maintained, fostered the growing use of abortion and modern methods of preventing conception. In his first sermon as pope, Benedict XVI used the metaphor of the desert to link the spiritual vacuity of materialism and consumerism with ecological destruction. As he put it, "The deserts of the world are spreading because of the growing desert in the human heart." This reference suggests that the new pope harbors a stronger ecological awareness than that of his predecessor. Pope Benedict XVI has begun to address the ecological, and especially climatic, impacts of the Vatican on the environment, using Vatican funds to purchase a formerly forested area in Hungary, where the Vatican will sponsor the replanting of forest to offset the greenhouse-gas emissions of Vatican flights and other activities. The pope has also installed solar panels on the roof of the papal residency in Vatican City. In this respect, Benedict XVI may be said to be following the lead of such Catholic theologians as Leonardo Boff and Sean McDonagh, who have been adumbrating a Catholic ecotheology for more than thirty years, and of Catholic lay communities in South America and the Philippines that have witnessed environmental problems arising from industrial development and agribusiness in Catholic countries in the South.

The environmental turn of some Catholic theologians, particularly in the South, is now mirrored by a green turn in religious communities in the developed world. Thus, communities of nuns in North America are recovering a traditional connection between the religious vocation and the care of Creation. These "green sisters" or "eco-nuns" are using the Church's ownership of agricultural land and the buildings, diets, and lifestyles of religious communities to create a new sensitivity to Creation. Some have started using organic methods on their farms and market gardens. Others are utilizing renewable energy in their community houses. This move toward a religious practice of care for the Creation is part of a larger refocusing of the Christian tradition in the late twentieth and early twenty-first centuries. Many of the new liturgies written under the influence of the liturgical movement since the mid-1960s have given a more prominent role to the doctrine of creation and to the place of nonhuman creatures as revelatory points of contact with the divine Spirit. And many congregations and ecumenical associations have been endeavoring locally and regionally to practice care for the Creation in their

material relations with the nonhuman world. Thus church buildings on every continent may now be seen displaying solar panels as a symbolic witness to their members and communities for the need for modern humans to live within the carbon budget of the planet, rather than profligately burning stored carbon in ways that damage the earth for present and future generations. There is also growing Christian involvement in secular environmental initiatives as Christians overcome their suspicion that such movements represent not only a turn to the earth but a denial of the role of the Creator in creating the earth.

In a historical sense, modern environmental protest is a child of religious Protestantism inasmuch as Protestantism gave rise to the culture of multiparty democracy of modern nation-states. And with the turn of Orthodox, Catholic, and Protestant Christians toward environmental awareness, the ecological alienation that was manifest in both Catholic and Protestant teachings about creation after the Reformation may at last be being healed. For in ethics, practice, and theology, there is increasing emphasis on the ecological effects of the life, death, and resurrection of Jesus Christ, the creative Word, in healing human-earth relations, as well as the human body and soul.

CIVIL DISOBEDIENCE

Civil disobedience is a form of political protest that is intended to counter injustice and immorality. It has been used to object to such matters as racism, sexism, animal experimentation and testing, warfare, abortion, exploitation of workers and the poor, violations of human rights, and the devastation of nature. While there are disagreements about some of its features, it is commonly defined as a deliberately unlawful, nonviolent act of resistance that is conscientiously motivated by moral, religious, or political reasons, some having to do with environmental ethics and philosophy. It is addressed to the community at large and must be "civil"—that is, publicly and openly done. It can involve disobeying a law directly or selecting some other, illegal means to object to that law. The standard definition also implies that it is not a revolutionary attack on a government or legal system, and reflects fidelity to that system. Moreover it is sometimes asserted that practitioners must be willing to accept the consequences of their disobedient behavior, including arrest and lawful penalties, and that it should be a "last resort," used only after all available means of legal redress have been tried and failed.

HISTORIC USES OF CIVIL DISOBEDIENCE

Civil disobedience in the nineteenth and twentieth centuries has been closely associated with Henry David Thoreau and Martin Luther King Jr. in the United States, and Mohandas (Mahatma) Gandhi in South Africa and India. In July 1846 Thoreau refused to pay his taxes and was jailed overnight in Concord, Massachusetts. He subsequently advocated civil disobedience in an 1849 essay in which he criticized the federal government for waging war against Mexico and supporting slavery. Gandhi was strongly influenced by Thoreau, and after

World War I advocated non-cooperation with the British colonial government as a means to achieve independence from British rule. He called his version of resistance *Satyagraha* and thought its use would bolster the inner, spiritual strength of his followers. Britain ultimately ceded independence to India in 1947, after a long campaign carried out by Indian protestors and leaders. Martin Luther King Jr. promoted the use of civil disobedience during the civil rights movement of the 1950s and 1960s. He was impressed with the power of nonviolent action to eliminate unjust laws and was able to mobilize many African Americans to oppose racial segregation and support economic justice for the poor.

DISOBEDIENCE IN DEFENSE OF NATURE

Since the late 1960s, some environmental groups such as Earth First! have adopted civil disobedience as one of several tactics—including clandestine law-breaking—to defend wild animals and wilderness from harm. This has grown out of a keen awareness of the negative environmental impacts of humans, increasing dissatisfaction with mainstream environmentalism, and a growing commitment to eco-centered philosophies such as deep ecology and ecofeminism. Activists and citizens have used the tactic to protest nuclear testing in the South Pacific, illegal whaling in the earth's oceans, fur sealing in Eastern Canada, destructive fishing by factory trawlers in the Pacific, logging in western North America, India, and Southeast Asia, air and water pollution by multinational corporations in many countries, and fox hunting and new road construction in England.

An example from reports by Mike Roselle and George Draffan of protests in the forests of western Oregon in the United States will illustrate this tactic and some of the reasoning behind it. From May through July 1984, members of the Cathedral Forest Action Group (CFAG) participated in acts of civil disobedience aimed at stopping old-growth, clear-cut logging in the Middle Santiam area of the Willamette National Forest (WNF), in the Central Oregon Cascade Mountains. One of their protests involved hiking into a federal timber sale area in the Middle Santiam and blocking the path of logging trucks by forming lines across a bridge into the area. The sale area was closed to the public while a private logging company under contract with the United States Forest Service logged it. Over the summer, twenty-seven members of CFAG were arrested when they refused to move off the bridge. Other members cooperated with sheriff deputies and Forest Service agents by getting up voluntarily when asked to do so. Those arrested were booked and taken to a county jail. CFAG members stated that their arrests would not deter them from continuing their protests, and they kept coming back to the timber sale area for several months. Most of those arrested were charged with misdemeanors, such as obstructing work in progress and disorderly conduct. They subsequently pleaded innocent and were brought to a jury trial in a local county court.

Greenpeace Logging Protest, 2004. *Greenpeace activists attach themselves to trees on Kupreanof Island's Tonka Mountain, near Petersburg, Alaska, to protest a plan they believe would weaken logging restrictions. Greenpeace, along with several other environmental activism groups, employs the technique of civil disobedience as a means of protecting nature.* **AP IMAGES.**

CFAG protestors justified their actions in terms of following their consciences and trying to protect valuable life on earth, namely, plants and animals that have intrinsic value and should be preserved in perpetuity for their own sake. They were concerned about the diminishing amount of wildlife habitat and old growth forest in the WNF, and the destruction of the Middle Santiam de facto wilderness area. They claimed that logging in the Middle Santiam posed an imminent threat to the Central Cascade environment because an increasingly rare

Douglas-fir ecosystem was being endangered. Once the logging was completed, they argued, it would be impossible to redo what nature had built up over many centuries. Several protestors also stated that the area was a "spiritual haven" because of its "cathedral" groves of large, ancient trees. The protestors also pointed out that they had exhausted all other means of halting logging in the Middle Santiam and hoped to arouse the public into calling for new legislation from the U.S. Congress to preserve more of the area as wilderness. Only 20 percent of the area had been designated as wilderness, and the rest was available for logging. They had tried for years to get federal protection for the whole Middle Santiam wilderness, writing letters to politicians and government officials, testifying at public hearings, and filing ineffective lawsuits, leaving them no choice but to blockade the road. The protesters were ultimately unsuccessful in gaining wilderness designation for the whole of the Middle Santiam, but their actions were some of the first in a lengthy series of protests against old growth logging that has continued in the western United States and western Canada for more than twenty years. In time, environmental protestors have helped to turn public opinion against this kind of industrial forestry and to significantly reduce old growth harvesting in federal forests.

This and other cases illustrate that civil disobedience can be effective in changing the environmental practices of governments and corporations. However, it can also harden the resolve of authorities and resource users to proceed with environmental exploitation and has sometimes been counterproductive. Much depends then on the particular social and political circumstances in which this tactic is used.

COGNITIVE ETHOLOGY

Cognitive ethology generally is viewed as an area of comparative cognition or animal learning that is both naturalistic in its emphasis and open to consideration of the experiential, cognitive, and subjective aspects of animal behavior. In regard to environmental ethics, the way in which one views the mental abilities of other species will have a bearing on how one treats them and whether one exploits them.

DEVELOPMENT OF THE FIELD

Cognitive ethology is in many respects a descendant of the nineteenth-century post-Darwinian search for the evolutionary and comparative roots of human mental and emotional life in ancestral species. George John Romanes, Charles Darwin's protégé and successor in the study of animal minds, wrote a number of books on the subject, including *Mental Evolution in Animals* and *Mental Evolution in Man,* and produced several editions of the popular *Animal Intelligence.*

Those and many other books of that period relied almost exclusively, as did Darwin, on anecdotal reports. Those stories about remarkable animals, recounted by frequently unreliable observers who tended to endow nonhuman animals with humanlike characteristics (anthropomorphism), were easy to criticize. However, they constituted the main body of work in comparative psychology at that time.

A backlash appeared by the end of the nineteenth century, primarily as a result of the work of Edward L. Thorndike. That tendency reached its height with the rise and dominance of behaviorism in the 1920s, led by James B. Watson, who was inspired by the writings of

Ivan Pavlov (Burghardt 1985, Boakes 1984). The hallmark of the behaviorist approach was that empirical data largely collected experimentally and in controlled laboratory settings using domesticated animals were essential. Basic processes such as Pavlovian conditioning and instrumental (trial-and-error) learning were the main methods for interpreting findings on animal learning and intelligence. Mentalistic attributions were frowned on even if they were based on experimental evidence. Thus, consciousness, emotion, insight, imitation, awareness, problem solving, and other concepts essentially were ignored or rejected.

In contrast, natural history studies, which flourished before Darwin, became even more popular as explorers and field biologists with an evolutionary perspective continued to study exotic species in the field or in relatively naturalistic captive environments. Animals collected from the wild ended up in zoos around the world, where they could be studied as well as provide entertainment for visitors. Such studies also became more experimental and less anthropomorphic and were extended to include a wide range of species. Studies on spiders by the Peckhams, insects by Henri Fabre, mimicry by Edward B. Poulton, ''lower'' invertebrates by Herbert S. Jennings, tropisms by J. Loeb, and doves and pigeons by Charles O. Whitman and Wallace Craig were systematic and accomplished for their time. Those authors were not averse to using anthropomorphic labels in interpreting the behavior of their subjects.

Originating in zoology and natural history, European ethology, led by Oscar Heinroth, Julian Huxley, Jacob von Uexküll, A. F. J. Portielje, Konrad Lorenz, and Niko Tinbergen, became established in the period from about 1910 to 1940. Although those scientists did not focus on mental processes in animals, they diverged from the behaviorists by emphasizing the importance of studying natural behavior in diverse species and applying interpretations informed by comparative evolution. Those comparisons differed from the more linear arrangement of species often used by comparative psychologists. From the late nineteenth century through the behaviorist era and into the 1960s, many psychologists attempted to characterize the intelligence of the fish, the frog, the lizard, the bird, the monkey, and so on, and such efforts still are found in some popular writing on animals. In the contemporary period, because of the work of ethologists, it is known that it is necessary to compare closely related species, as their differing ecologies and behaviors can lead to divergent behavioral and cognitive characteristics.

The ethologists were eager to make their naturalistic, ecological, and evolutionary approach to behavior more biologically sound than typical behaviorist studies of animal behavior while being equally objective and adhering to the procedures of empirical science. However, the ethologists' resuscitation of the notions of animal instinct, long decried by comparative psychologists, drew the attention and often criticism of comparative psychologist. Nonetheless, by the 1960s fruitful collaborations were under way (Dewsbury 1984). Many ethologists, including pioneers such as Niko Tinbergen, were adamant about the need to exclude anything ''mentalistic'' from ethology (Tinbergen 1963).

However, one U.S. researcher, Donald R. Griffin, a zoologist and physiologist, took exception to that exclusion. In the mid-1970s Griffin was both well placed among U.S. elite scientists and sympathetic to the goals of the still largely European ethological movement. As an undergraduate student Griffin had codiscovered the echolocation abilities of bats, and he continued that work throughout his career. He also studied bird migration. A member of the United States National Academy of Sciences who spent his career at Harvard and Rockefeller universities, Griffin was highly respected in the biology research community in the United States. Aware that the echolocation abilities of bats raised issues of perception and cognition, he became fascinated by the studies of Karl von Frisch demonstrating language-like communication in honeybees, the field studies by Jane Goodall reporting tool making and tool use in chimpanzees, and the success of Beatrice and R. Allen Gardner in training human-reared chimpanzees to communicate with humans and one another with American Sign Language.

Jane Goodall and Chimpanzee Nana. *Cognitive Ethnology is essentially the study of non-human animal minds, searching for the mental and emotional life we as humans are used to experiencing. Jane Goodall, a British primatologist, began her pioneering field studies of chimps in the 1960s in Tanzania, revealing their remarkably human-like qualities, inculding the ability to use tools.* **JENS SCHLUETER/AFP/GETTY IMAGES.**

Griffin was convinced that those accomplishments by animals could not be incorporated readily within the framework of traditional behaviorism and experimental psychology. They were also outside traditional natural behavior–oriented ethology. To Griffin such studies indicated that scientists had underestimated the abilities of nonhuman animals to accomplish complex mental tasks that in humans were accompanied by subjective processes. The behavior of such mentally aware animals seemed to be based on more than chaining reflexes (linking stimulus and response in series through associative and reinforcement processes) and operant responses to stimuli. Griffin gave an address to the International Ethological Conference in 1975, followed in 1976 by the seminal book *The Question of Animal Awareness*. That book was reviewed widely, though often critically, and set Griffin on the course that dominated his career for the next twenty-five years. He influenced many people, wrote and edited many books (e.g., *Animal Minds* 2001), was instrumental in the founding of the journal *Animal Cognition,* and wrote the initial essay in that journal.

CURRENT STATUS AND RECENT DEVELOPMENTS

There have been numerous semipopular books on animal mentality by writers who have used the mentalistic aspects of Griffin's work to expand people's regard for animal intelligence and consciousness (Balcombe 2006, Bekoff 2007). Many established scientists have expanded Griffin's work in a sympathetic but rigorous manner. Others have been more wary of being closely associated with cognitive ethology because of Griffin's reliance in his later work on anecdotal examples and tendency to attribute fairly advanced mental states to insects with very small brains and simple nervous systems. Griffin even argued that animals with small brains cannot have as many hardwired or instinctive responses as animals with larger brains and thus should be expected to rely even more on complex assessments and decision making and could be conscious. The various kinds of meanings attributed to the term *consciousness* and some of the evidence presented is discussed in several works (Radner and Radner 1989, Mitchell, Thompson, Nicholas, and Miles 1997, Allen and Bekoff 2007).

Other scientists, especially in the growing field of comparative cognition, do not identify with cognitive ethology but have been influenced by it. Griffin was aware that he was taking an extreme and perhaps untenable stance on animal consciousness and cognition. His goal was to shift the field from a rigid behaviorism reluctant to look at complex and diverse animal behavior as evidence of mental experiences to a position that would entertain possibilities of their existence. By taking an extreme stance he hoped to shift the field more effectively than he could by being a reasonable moderate with a balanced perspective. In retrospect he was successful. He in effect sacrificed his scientific reputation to reshape the field of animal behavior to one in which animals' cognitive and emotional abilities are considered more sympathetically.

There have been other consequences of his work. Many scientists are exploring aspects of animal mentality and experiences. As in the understanding of other human beings, researchers make inferences about animal subjects' cognitive and emotional states that are based on their behavior. Brain imaging studies are allowing researchers to identify whether brain processes similar to those in humans are activated when other animals make decisions, perceive events, or have experiences. Although such evidence is not conclusive, it makes it harder to dismiss the possibility of psychological similarities between people and animals.

In the past the study of comparative psychology was based largely on how quickly animals could learn and repeat rote tasks such as bar pressing and pecking a colored disk. At the beginning of the twenty-first century animals were being trained in many complex tasks, including spatial learning, the use of numbers, and symbolic communication. Chimpanzees and many other species can learn by observing other animals, including people. They can learn the correct stimulus or the correct response to make to obtain a reward or even how to deceive another animal about the location of a reward.

Animal also have been shown to use arbitrary symbols and gestures in communication, count, and even add and subtract. Some animals, such as chimpanzees, can recognize themselves in a mirror and use the mirror image to examine their own bodies; that ability often is interpreted as suggesting self-recognition. Animals also can signal intentions and desires. Cats, for example, can convey when they want to eat, what they want to play with, when they want to be scratched, and when they want to go outside.

In the mid-twentieth century most scholars thought that animals could not use tools, but it has been established that some animals can. Galapagos woodpecker finches, for example, routinely use cactus spines to stab insects in crevices or holes. Jane Goodall's observations about tool manufacture and use by chimpanzees refuted the human-exclusive claims made in books with titles such as *Man the Toolmaker*.

Another phenomenon once thought to be linked to big brains and advanced intelligence is play behavior. As late as the 1980s claims were made that only mammals play, though some authorities would include a few birds. By the beginning of the twenty-first century it was

known, after the development of improved definitions to aid in identifying play, that that behavior is found in reptiles, amphibians, fish, and insects and other invertebrates. The more closely scientists look objectively at diverse species of animals, the more they see evidence of thought and sophisticated emotional processing. Among other remarkable talents, fish can watch other fish courting and mating and then make decisions about the most appropriate mate for them (Bshary et al. 2002).

ENVIRONMENTAL AND ETHICAL IMPLICATIONS

After the firewall of symbolic communication, tool construction, and other major phenomena separating humans from other species was breached, new hurdles were erected to maintain human uniqueness. It was claimed that animals live only in the present, with no sense of the past or the future other than mechanically conditioned repertoires of stimulus and response. However, it now is known that animals from rats to monkeys have the ability to recall events in a narrativelike manner. Later it was claimed that animals do not have the ability to employ abstract concepts such as cause and effect, but it has been shown that they have causal understanding at some level.

Animals are not identical to people mentally. All species differ and are unique in differing ways. However, scientists have found that Darwin was correct in a more profound way. Nonhuman animals have at least incipient or rudimentary versions of almost all aspects of human behavior, and the corollary also is true: People harbor in their behavior the complex legacy of the human evolutionary heritage.

However it is characterized, the essential continuity of human and nonhuman in the mental and behavioral as well as anatomical and genetic realms makes it difficult to maintain the kind of ethically sharp distinction between humans and other species that has characterized Western history from at least the time of the ancient Greeks to the present (Adler 1967). It is hard to argue any longer that animals lack capacities such as sentience, memory, feelings, and even consciousness as a way to justify their use for food, clothing, recreation, and research. The recognition of animals as beings with minds and emotions, simple beliefs and desires, has ecological implications as well. Cognitive ethology will continue to make an important contribution to environmental and animal ethics.

COMMONER, BARRY
1917–

Barry Commoner, a cellular biologist and eco-socialist, helped initiate the modern environmental movement. He was born in Brooklyn, New York, on May 28, 1917. Commoner taught for many years at Washington University in

St. Louis, Missouri. In 1981 he left Washington University for Queens College in New York. After his retirement in 2000, he was a senior scientist at Queens College.

Commoner's contribution to environmental ethics is implicit in his activities as a public advocate for the environment. These activities began in the 1950s, when Commoner played a role in the movement to end aboveground nuclear testing. On this occasion he displayed his flair for bringing scientific knowledge to bear on public-policy debates. His advocacy organization, the Committee for Nuclear Information, collected and analyzed baby teeth from children in the Midwest. The analysis demonstrated that their growing bones picked up radioactive fallout from nuclear tests in Nevada. Commoner's interests soon widened to take in the issue of environmental pollution. His book *The Closing Circle* (1971) was an early environmental bestseller. Since none of the presidential candidates seemed to be dealing seriously with environmental concerns, Commoner decided to run in the 1980 U.S. presidential election on the Citizens Party ticket. The campaign gave him an opportunity to speak to thousands of people around the country. Later Commoner became an advocate for solar power and other alternative forms of energy.

These activities illustrate a primary ethical principle underlying Commoner's vision: his belief that scientists are responsible for informing the citizenry about the products of their research. Nuclear weapons was the first technology that made it impossible for scientists to remain in their ivory towers. But Commoner identified many other technological changes in the economy after World War II that had massive environmental impacts. Thus not only physicists but also chemists, biologists, and other scientists and engineers became responsible for participating in public debate.

Commoner's most important contribution to these debates concerned the role of technology in environmental pollution. In the early 1970s, as the environmental movement gained a wide audience for the first time, Commoner was critical of Paul Ehrlich and other advocates of population control. He argued that not the size of the population but the impact of the technology it used should be the focus of environmental reform. He believed that an emphasis on lifestyle changes (having fewer children) would make it more difficult to impose regulations on business.

Commoner was also concerned that some advocates of population control are willing to abridge the rights of individuals to have children, the most extreme among them having even proposed suspending food aid to poor countries lacking coercive population controls. Commoner followed the views of many demographers in arguing that increased prosperity and reduced infant mortality will naturally stabilize populations in such countries. Wealthy nations were often partly responsible for overpopulation in their former colonies. They should now help these poor countries develop their economies as a morally acceptable way of bringing population growth under control.

Important ethical principles underlie these positions of his. After World War II, scientists acquired enormous authority in the eyes of the public through their success in creating the atom bomb. To many scientists, this authority was an essential tool needed to convince the public to take seriously the threat of nuclear war. Later, scientists involved in the environmental movement attempted to rely on the authority of science to achieve public influence. Some environmentalists asked Commoner to abstain from criticizing population control to protect the image of science in the community. But Commoner believed that the serious disagreements in the environmental movement made a show of unity undesirable. The public needs to be informed and to make its own choice when scientists disagree.

In the cases of both the environmental regulation of business and the demographic transition in poor countries, Commoner followed a principle of social ethics: the preference, wherever possible, to achieve social goals through democratic control over social processes rather than through restrictions on the private activities of individuals. Commoner's democratic socialist politics conform with this principle. The rights of businesses were to be curtailed rather than the rights of individuals.

Commoner's argument for regulating business has another important implication for environmental ethics. Too often philosophers conceive technology as a fixed, quasi-natural background condition of human action. This view tends to individualize responses to environmental problems by artificially freezing one of the main social factors involved. Commoner realized the implications of this static view of technology and rejected it. Commoner argued that the good delivered by a technology can be distinguished from the contingent form in which it is delivered, for example, mobility from automobiles or cleanliness from detergents. This distinction made it possible for him to argue that environmental reform is compatible with prosperity at a time when many in the environmental movement advocated voluntary poverty or de-development. In Commoner's view, the great task facing contemporary democracy is reconciling economic and environmental goals, and this task, he believed, is a technical challenge capable of being met, rather than a necessary tradeoff.

COMMUNITARIANISM

Communitarianism surfaced in the Anglo-American political philosophy of the 1970s and 1980s as a critical reaction to political liberalism. After the publication of John Rawls's *A Theory of Justice* (1971), political philosophers such as Alasdair MacIntyre (1984), Michael Sandel, Charles Taylor, and Michael Walzer disputed Rawls's claim that the principal task of government is to secure the liberties of its citizens to lead freely chosen lives. Although these philosophers never identified themselves as communitarians, they developed a core set of arguments that laid the philosophical groundwork for a political philosophy meant to contrast with liberalism's devaluation of community.

Communitarians frequently perceive modern social phenomena such as alienation, economic greed, loneliness, urban crime, and high divorce rates as byproducts of liberalism. In the 1990s a second wave of communitarians such as Amitai Etzioni and William Galston turned from a primarily philosophical debate to more practical political concerns such as social responsibility and countering the erosion of communal life. Etzioni is the director of the Institute for Communitarian Policy Studies, a policy think tank located at George Washington University in Washington, D.C. The institute's chief goals are fostering a greater sense of personal and social responsibility among individual citizens; strengthening the cohesion of families and local communities; encouraging reconciliation among various racial, ethnic, and religious groups; and fostering a national policy about humankind's moral horizon and the social responsibilities of the individual and the community (Institute for Communitarian Policy Studies 2008). In another example of contemporary political action based on communitarian philosophy, Don Eberly leads the nonprofit Civil Society Project, an organization dedicated to engendering a "civic renaissance" that will renew civil society, voluntary social institutions, civic responsibility, and philanthropy.

CHALLENGE TO UNIVERSALISM

Communitarians maintain that the standards of justice are contextual and must be found in the traditions and cultures of particular societies. This view is in contrast to liberalism's claims to universality, especially with regard to issues such as human rights. This is one of the most controversial aspects of the communitarian position, as liberal universalism includes such values as universal human rights. However, some communitarians argue that there is little real debate about the desirability of universal human rights and that the real question is whether there are other, contingent rights that may vary based on culture and context. One example of this appeal to cultural and contextual diversity is the call, which became popular in the 1990s, for a better comprehension of non-European values and ethical standards.

Daniel Bell noted three persuasive East Asian arguments for cultural particularism that contrast with traditional European and North American arguments for liberal universalism (2000). The first is that cultural factors can affect the prioritizing of rights, which matters when a conflict of rights demands a decision about which right to sacrifice. Second, cultural factors can affect the *justification* of rights; rights may be justified not only by abstract universal principles but also by specific examples and contexts. Third, cultural factors can provide moral foundations for *distinctive* political practices and institutions, such as the Confucian value that children have a profound duty to provide for their parents. The consequence of such a value would be a political obligation to foster the social and economic conditions that conduce to the realization of this duty.

TYPES OF COMMUNITIES

Communitarians commonly invoke three types of communities (Bell 1993): First, there are communities of place, which are based on geographical location. This is perhaps the most common meaning associated with the notion of community. Communitarians suggest that planners and decision makers consider the character of the local community when considering plans for development. Second, there are communities of memory, or groups of people who share a morally significant history. These are communities of collective consciousness that may go back several generations or even thousands of years. Members strive to maintain values and traditions associated with such communities. Politically this entails nation building meant to strengthen the bonds of commonality. Civic engagement and public-spiritedness are important components of this type of community. Third, there are psychological communities, or communities of face-to-face interaction. These are groups that participate in common activities and experience a psychological connection in

striving toward common goals. These communities are governed by sentiments of trust, cooperation, and altruism insofar as individual members act with the good of the community in mind. Examples include the family unit and small school or work communities. Among these kinds of communities, allegiance to one, such as the workplace, can undermine responsibilities to another, such as the family.

COMMUNITARIAN ENVIRONMENTAL ETHICS

Many environmental philosophers use the concept of community to portray the relationship between humans and the natural environment. J. Baird Callicott defends a communitarian environmental ethic founded on humans' shared kinship and community with the natural world. Callicott writes, "All our duties—to people, to animals, to nature—are expressible in a common vocabulary of community" (Callicott 1994, p. 53). Callicott's notion of community is based on Aldo Leopold's land ethic. Leopold claims that we have inherited a concept of land as a commodity belonging to us, but "when we see land as a community to which we belong, we may begin to use it with love and respect" (1949, p. viii). Further, he claims that we ourselves are but "plain members and citizens of the biotic community" (1949, p. 204). Callicott considers this a communitarian environmental ethic in which the well-being of the entire community, or ecosystem, matters no less than the well-being of any one individual or group (i.e., humans). Callicott finds the philosophical antecedents to ethical communitarianism in David Hume's moral philosophy and in Charles Darwin's account of the origins and evolution of the "moral sense" among *Homo sapiens*.

Callicott's communitarian environmental ethic—and, by implication, the Leopold land ethic, which he purports to represent and elaborate—has been criticized as a form of ecofascism because it seems to imply that human welfare should be subordinated to the integrity, stability, and beauty of the biotic community. Callicott answers this objection by claiming that the land ethic merely calls attention to one of humans' recently discovered community memberships; it does not cancel or replace memberships in other kinds of communities or the duties implied by them.

Nevertheless, there remains a possibility of conflict between the protection of members of the human (and mixed human–domestic animal) community and the protection of the biotic community as a whole. Callicott provides a two-stage algorithm to resolve such conflicts: Priority should be given first to duties and obligations generated by membership in more intimate and venerable communities, such as family; for example, care for one's sick children or aged parents should take precedence over volunteering to serve the homeless in a soup kitchen. Likewise, priority should be given to the duties and obligations generated by membership in the human "family" over those generated by membership in biotic communities.

How, then, would humans' distinctly environmental duties and obligations—as generated by membership in biotic communities—ever become operative? Callicott answers with the second-stage of the algorithm: Stronger interests should prevail over weaker interests. Thus, although one's own children have an interest in receiving birthday presents, such an interest is weaker than the interest of neighbor children in having adequate nutrition. Thus, one might well be required to forego giving one's own (thus disappointed) child an expensive birthday present in order to buy food for one's neighbor's children if they would not be able to eat otherwise. Likewise, weak human interests in having such things as huge houses and gas-guzzling cars should be trumped by the strong "interests" of endangered species to survive or ecosystems to remain healthy.

Another challenge to a communitarian environmental ethic is one's identification with one's community. Though ecosystems are communities that may warrant respect, they may not inspire as intense a commitment as social communities do. On the other hand, ecosystems do inspire such a strong sense of commitment in the works of authors such as Henry David Thoreau, John Muir, Henry Beston, Annie Dillard, and Edward Abbey, to say nothing of Aldo Leopold himself.

Bioregionalism provides another way of conceiving of a communitarian environmental ethic. Bioregionalism is the view that natural features should provide the defining conditions for places of community and that achieving a secure and satisfying life means knowing a place, learning its lore, and developing its potential within ecological limits. Critics of this view have puzzled over exactly which natural features should provide the basis for community—geological, ecological, climatic, or hydrological. Further, given its emphasis on identification with local communities, a question arises over whether bioregionalism is relevant in a globalized planet.

CONFUCIANISM

Confucianism has conventionally been described as a humanistic tradition that focuses on the roles and responsibilities of people in regard to family, society, and government. Thus, Confucianism is considered primarily as an ethical or political system of thought with an anthropocentric focus. However, on further examination and as more translations become available in western languages, this narrow perspective has to be reexamined. Confucianism is not simply anthropocentric; it is, rather, anthropocosmic.

Some of the most important results of this reexamination are the insights that have emerged in seeing Confucianism as not simply an ethical, political, or ideological system. Instead, Confucianism is being appreciated as a profoundly religious tradition that is different from Western traditions (Tu and Tucker 2003–2004). This may result in an expansion of the idea of religion to include more than criteria adopted from Western traditions, such as notions of God, salvation, and redemption. Moreover, Confucianism is being recognized for its affirmation of relationality not only between and among humans but also between humans and the natural world (Tucker and Berthrong 1998).

The Confucian worldview might be described as a series of concentric circles in which the human is the center not as an isolated individual but embedded in rings of family, society, and government. This is especially clear in the text of the *Great Learning* (De Bary and Bloom 1999). All these circles are contained within the vast cosmos itself. Thus, the ultimate context for the human is the "10,000 things," nature in all its remarkable variety and abundance.

HISTORICAL DEVELOPMENT

Scholars have identified four major periods of Confucian thought and practice. The first is classical Confucianism, which lasted from approximately the sixth century BCE to the second century BCE. This was the era of the flourishing of the early Confucian thinkers: Confucius and Mencius. The second period is that of Han Confucianism, in which the classical tradition was shaped into a political orthodoxy under the Han empire (202 BCE–220 CE) and began to spread to other parts of East Asia. The Han period saw the development of the theory of correspondences of the microcosm of the human world with the macrocosm of the natural world. The third major period was the Neo-Confucian era from the eleventh century to the early twentieth century. This includes the comprehensive synthesis of Zhu Xi in the eleventh century and the distinctive contributions of Wang Yangming in the fifteenth and sixteenth centuries. The influence of both Confucianism and Neo-Confucianism as an educational and philosophical system spread beyond China and shaped East Asian societies, especially Korea and Japan, along with Taiwan, Hong Kong, and Singapore.

In the twentieth century a new epoch of Confucian humanism emerged that is called New Confucianism. This represents a revival of the tradition under the influence of scholars who came to Taiwan and Hong Kong after the ascendancy of Mao Zedong in 1949. Mao maintained that Confucianism was essentially a feudal tradition anchored in history and that for his ideas to flourish, a radical break had to be made with the past. The anti-Confucian campaigns during Mao's rule were virulent, especially in the Cultural Revolution of the 1960s and 1970s. However, since Mao's death there has been a resurgence of interest in Confucian values, some of which has been encouraged by the government. The International Confucian Society held two major conferences in Beijing and in Confucius's birthplace, Qufu, to explore the future of the Confucian Way. Those conferences were held to commemorate the 2,540th anniversary of Confucius's birth and marked a renewed interest in Confucianism to balance the unsettling effects of the rapid industrialization and modernization of China.

MAJOR THINKERS AND TEXTS

The acknowledged founder of the Confucian tradition was known as the sage-teacher Kongzi (551–479 BCE). His name was Latinized by Jesuit missionaries as Confucius. Born in a time of rapid social change, Confucius was concerned with reestablishing political and social order through rectification of the individual and the state. The principal teachings of Confucius are contained in his conversations, which were recorded in the *Analects*. In that work Confucius emphasized the cultivation of moral virtues, especially humaneness (*ren*) and the practice of civility or ritual decorum (*li*), which includes filiality (*xiao*). Virtue and civility were exemplified by the noble person (*junzi*), particularly within the five relations: between ruler and minister, parent and child, husband and wife, older and younger siblings, and friend and friend. The essence of Confucian thinking was that to establish order in society one had to begin with harmony, filiality, and decorum in the family. Then, like concentric circles, the effects of virtue would reach outward to the society. Similarly, if the ruler was moral, it would have a ripple effect on the rest of society and beyond to nature, like a pebble dropped into a pond.

At the heart of the classical Confucian worldview was a profound commitment to humaneness and civility. Those two virtues defined the means of human relatedness as a spiritual path. Through civility, beginning with filiality, one could repay the gifts of life both to one's parents and ancestors and to the whole natural world. Through humaneness one could extend that sensibility to other humans and to all living things. In doing so one became more fully human. The root of humaneness was considered to be filial relations. When a person extended those relations from his or her family and ancestors to the human family and the cosmic family of the natural world, those primary biological ties provided that person with the roots, trunks, and branches of an interconnected spiritual path. Humans, nature, and the cosmos were joined in the stream of filiality. From the lineages of ancestors to future progeny, intergenerational connections and ethical bonding arose. Reverence and reciprocity were considered a natural response to the gift of life from parents and ancestors. Analogously, through reverence for heaven and earth as the parents of all life, one realized one's full cosmological being and one's place in the natural order.

Confucian thought was developed further in the writings of Mencius (c. 385–c. 312 BCE) and Xunzi (c. 310–c. 219 BCE), who debated whether human nature is intrinsically good or evil. Mencius's argument for the inherent goodness of human nature became dominant among Confucian thinkers and gave an optimistic flavor to Confucian educational philosophy and political theory. That perspective also influenced the spiritual aspects of the tradition because self-cultivation was seen as a means of uncovering this innate good nature.

Mencius contributed an understanding of the process required for self-cultivation by identifying the innate seeds of virtues in the human and suggesting ways in which they could be cultivated toward their full realization as virtues. Analogies taken from the natural world extended the idea of self-cultivation of the individual for the sake of family and society to a frame of reference that encompassed the natural environment. This can be described as a path of botanical cultivation. In addition to his teachings on personal cultivation, Mencius advocated humane government as a means to promote the flourishing of a larger common good. His political thought embraced appropriate agricultural practices and the proper use of natural resources. In particular, he urged that the ruler attend to the basic needs of the people and follow the way of righteousness, not that of profit.

Xunzi contributed a strong sense of the importance of ritual practice as a means of self-cultivation. He noted that human desires had to be satisfied and that emotions such as joy and sorrow should be expressed to the appropriate degree. Rituals provided the form for such expression in daily human exchange as well as in rites of passage such as marriage and death. Moreover, because Xunzi saw human nature as innately flawed, he emphasized the need for education to shape human nature. He had a highly developed sense of the interdependent triad of heaven, earth, and humanity that was emphasized also by many later Confucian thinkers. He wrote, "Heaven has its seasons; earth has its riches; humans have their government." Heaven was understood as the guiding force of the universe; the earth was the natural world within which people lived and flourished.

Confucianism blossomed in a Neo-Confucian revival in the eleventh and twelfth centuries that resulted in a new synthesis of the earlier teachings. The major Neo-Confucian thinker, Zhu Xi (1130–1200), designated four texts from the canon of historical writings as containing the central ideas of Confucian thought. In 1315 those texts and Zhu Xi's commentaries on them became the basis of the Chinese civil service examination system, which endured for nearly six hundred years, until 1905. Every prospective government official had to take the civil service exams based on Zhu Xi's commentaries on the *Four Books*. The idea was to provide educated, moral officials for the large government bureaucracy that ruled China.

The influence, then, of Neo-Confucian thought on government, education, agriculture, land use, and social values was extensive. Views regarding nature, agriculture, and management of resources were derived from Neo-Confucian understandings of the importance of people

working to cultivate and care for nature as a way to fulfill their role in the triad of heaven and earth.

Zhu Xi's synthesis of Neo-Confucianism was recorded in his classic anthology *Reflections on Things at Hand* (*Jinsilu*). In that work Zhu formulated a this-worldly spirituality based on a balance of cosmological orientation, ethical and ritual practices, scholarly reflection, and political participation. The aim was to balance inner cultivation with outward investigation of things in concert with the dynamic changes of the natural world. Zhu Xi affirmed those changes as the source of transformation in both the cosmos and the person. Thus, Neo-Confucian spiritual discipline involved cultivating one's moral nature to bring it into harmony with the larger pattern of change in the cosmos. Each moral virtue had its cosmological component. For example, the central virtue of humaneness was seen as the source of fecundity and growth in both the individual and the cosmos. By practicing humaneness, one could effect the transformation of things in oneself, in society, and in the cosmos. In so doing, one's deeper identity with reality was recognized as forming one body with all things. As the *Doctrine of the Mean* stated, "being able to assist in the transforming and nourishing powers of Heaven and Earth, one can form a triad with Heaven and Earth."

CONFUCIAN RELATIONALITY AND NATURE

From the classical texts to the later Neo-Confucian writings there is a strong sense of nature as a relational whole in which human life and society flourishes. Confucian thought recognizes that the rhythms of nature sustain life in both its biological needs and its sociocultural expressions. For Confucians the biological dimensions of life are dependent on nature as a holistic, organic continuum. Everything in nature is interdependent and interrelated. Most important, Confucians see nature as dynamic and transformational. These ideas are evident in the *Book of Changes* and are expressed in the *Four Books,* especially in *Mencius*, *Doctrine of the Mean*, and *Great Learning*. The ideas come to full flowering in the Neo-Confucian tradition of the Sung and Ming periods. Nature in this context has an inherent unity in that it has a primary ontological source (*Taiji*). It has patterned processes of transformation (*yin/yang*) and is interrelated in the interaction of the five elements and the ten thousand things. Nature is dynamic and fluid with the movements of material force (*qi*).

For Confucians, humans are anthropocosmic beings, not anthropocentric individuals. The human is viewed as a microcosm in relation to the macrocosm of the universe. This is expressed most succinctly in the metaphor of humans forming a triad with heaven and earth. These relations were developed during the Han period with a complex synthesis of correlative correspondences involving the elements, directions, colors, seasons, and virtues. This need to make a conscious connection between the patterns of nature and the rhythms of human society is ancient in Confucian culture. It is the basis of the anthropocosmic worldview, in which humans are seen as working with heaven and earth in correlative relationships to create harmonious societies. The mutually related resonances between self, society, and nature are described repeatedly in the Confucian texts and are evident in art and architecture as well.

For Confucians, nature is not only inherently valuable, it is morally good. Nature thus embodies the normative standard for all things; it is not judged from an anthropocentric perspective. There is not a fact-value division in the Confucian worldview, for nature is seen as an intrinsic source of value. In particular, value lies in the ongoing transformation and productivity of nature. A term repeated frequently in Neo-Confucian sources is *sheng sheng,* reflecting the ever-renewing fecundity of life itself. The dynamic transformation of life is seen as emerging in recurring cycles of growth, fruition, harvesting, and abundance. This reflects the natural processes of flourishing and decay in nature, human life, and human society. Change thus is seen as a dynamic force with which humans should harmonize and interact rather than withdraw from.

In this context Confucians do not view hierarchy as leading inevitably to domination. Rather, they see that value rests in each thing, though not in each thing equally. Everything in nature and society has its appropriate role and place and should be treated accordingly. The use of nature for human ends must recognize the intrinsic value of each element of nature and also its value in relation to the larger context of the environment. Each entity is considered not simply equal to every other; each interrelated part of nature has a particular value according to its nature and function. Thus, there is a differentiated sense of appropriate roles for humans and for all other species. For Confucians hierarchy is seen as a necessary way for each being to fulfill its function. Thus, no individual being has an exclusive privileged status in relation to nature. Rather, the processes of nature and its ongoing logic of transformation (*yin/yang*) is the norm that takes priority for the good of the whole society.

Confucians were mindful that nature was the basis of a stable society and that without the careful tending of nature, imbalance would result. There are numerous passages in *Mencius* advocating humane government based on the appropriate management of natural resources and family practices. There also are passages in

Confucian texts urging people not to cut down trees or kill animals needlessly.

However, the establishment of humane society, government, and culture inevitably results in the use of nature for housing, production, and governance. In this sense Confucians might be seen as pragmatic social ecologists (rather than deep ecologists) who recognize the necessity of forming human institutions—both educational and political—for a stable society. Nonetheless, for Confucians human cultural values and practices are grounded in nature and are part of its structure, and thus humans are dependent on its beneficence. In addition, the agricultural base of Confucian societies has always been recognized as essential to the political and social well-being of the country. Humans prosper by living within nature's boundaries and are refreshed by its beauty, restored by its seasons, and fulfilled by its rhythms. For Confucians, human flourishing is dependent on fostering nature in its variety and abundance; going against nature's processes is self-destructive. Human moral growth means cultivating one's desires not to interfere with nature but to be in accord with the great Dao of nature. Thus, the "human mind" expands in relation to the "Mind of the Way."

For Confucians, harmony with nature is essential and human self-realization is achieved in relation to nature. The great triad of Confucianism—heaven, earth, and humans—signifies the understanding that humans can attain their full humanity only in relationship to both heaven and earth. This became a foundation for a cosmological ethical system of relationality applicable to spheres of family, society, politics, and nature.

CONSCIOUSNESS

In environmental ethics, the issue of consciousness arises primarily in controversies concerning the moral status of animals. These debates often center on the degree to which animals possess consciousness–or whether they possess it at all.

VARIETIES OF CONSCIOUSNESS

The word *consciousness* can be used in a bewildering variety of ways. Here are some of the most common:

1. *Waking State*: A creature is conscious when it is awake as opposed to asleep or otherwise unconscious.
2. *Sensitivity*: A creature is able to detect salient features of its environment.
3. *Access consciousness*: A creature's mental representations (neural states that carry information about the environment) are poised for use in the control of action (including, but not restricted to, verbal action).
4. *Phenomenal consciousness*: A creature has experiences, and there is *something that it is like* to have these experiences. Suppose you stub your toe. This feels a certain way–it hurts. This way that it feels to stub your toe is one example of what philosophers have in mind when they talk of phenomenal consciousness.
5. *Self-consciousness*: This mode of consciousness can take two forms (a) awareness of oneself as an entity that is distinct from other entities and which persists through time, and (b) awareness of one's own mental states.
6. *Mentality*. In discussions of non-human animals the term *consciousness* is often used as a catchall for mental states or abilities; judging whether an animal is conscious or not is often seen as tantamount to working out whether it can believe, think, remember, reason, and so on.

There are two other complicating factors. First, the defining concepts of each of these six categories are often obscure or otherwise controversial. For example, some accounts of cognition eschew appeals to mental representations, and therefore dispute the characterization of access consciousness contained in category 3. Second, depending on how they are interpreted, some of these categories can overlap or even collapse into each other. For example, higher-order representation accounts (see below) explain phenomenal consciousness in terms of self-consciousness, specifically form 5(b). The truth of such accounts, therefore, requires the collapse of category 4 into the second form of category 5. This is by no means an isolated example.

The prospects of a unified definition of consciousness are, therefore, bleak because it is unlikely that there is any unified phenomenon to be defined. However, some scientific and philosophical discussions of consciousness have tended to focus on consciousness in the sense described by categories 4 to 6.

PHENOMENAL CONSCIOUSNESS AND ANIMALS (CATEGORY 4)

Far from being part of popular wisdom, the idea that phenomenal consciousness is restricted to humans is a deeply counterintuitive idea. The common sense attribution of consciousness to animals has found support in the work of cognitive ethologists who study emotions in animals (Bekoff 2003, 2008). The burden of proof is, therefore, on those who deny that animals are phenomenally conscious. The idea that many animals are conscious in this sense can be further supported by three types of consideration: *behavioral*, *neuropsychological*, and *evolutionary*.

There are broad similarities in the responses of nonhuman animals and humans to various circumstances. For example, both humans and animals try to avoid sources of pain (noxious stimuli); if they fail they are both likely to cry out. Following exposure to noxious stimuli, animals, like humans, will usually try to avoid further exposure and might limit the use of an injured body part. Thus, the behavior of many humans and nonhuman animals can be similar enough to invite the same kind of explanation: they are both phenomenally consciousness. That is, they experience the world in similar–though not necessarily exactly the same–ways.

Anatomical and physiological evidence also supports the idea that animals are phenomenally consciousness. For example, the presence of endogenous opiates has been demonstrated in all mammals, birds, reptiles, amphibians, fish, and in some invertebrates such as earthworms. These are the body's natural opiates, and their function is to alleviate pain following major injury (a possible survival mechanism that allows an injured animal to function normally until the immediate danger has been avoided). It is difficult to see why an animal would possess such a substance unless it is capable of feeling pain. Finally, the enormous evolutionary continuity between human and non-human animals makes it unlikely that phenomenal consciousness should be confined only to humans.

These arguments do not strictly entail that non-humans are phenomenally conscious. However, collectively, they seem to provide as much reason for thinking non-humans are conscious as for thinking that pre-linguistic humans are conscious.

Carruthers (1992, 1996), however, objects to the ascription of phenomenal consciousness to animals. His objection is based on the *higher-order thought* (HOT) model of phenomenal consciousness. According to this model, in order to be in a phenomenally conscious state–such as pain–it is necessary that a creature also possess a thought about this pain: a thought to the effect that it is in pain. Animals, Carruthers claims, cannot do this because they do not possess the requisite concepts. Therefore, he concludes, animals cannot be the subjects of even the most primitive of phenomenally conscious states.

The HOT account of consciousness, especially in the form developed by Carruthers, seems to have some deeply implausible consequences. It precludes the attribution of phenomenal consciousness not only to animals but also to young children–those too young to have acquired concepts of mental states, and therefore incapable of having thoughts about them. This restriction of phenomenal consciousness to creatures that have, in this sense, a *theory of mind* is wildly implausible. Moreover, among the principal defenders of HOT accounts only Carruthers is willing to embrace this implication of the theory. Other proponents typically attempt to show why HOT accounts do not have this highly counterintuitive consequence. And to the extent they are successful, HOT will also be compatible with the attribution of phenomenal consciousness to animals. It is also worth noting that HOT accounts are implausible on other grounds. Most notably, they face a nasty dilemma (Rowlands 2001a, b). My thought that I am in pain, for example, is either conscious or it is not. If it is conscious, the HOT account has not explained consciousness but presupposed it. That is, it can explain the consciousness of my pain only by presupposing the consciousness of my thought. If, on the other hand, my thought is not conscious, then it is difficult to see how it can make my pain conscious: my unconscious thoughts typically do not make me aware of what they are about: that is precisely what makes them unconscious.

BELIEFS, DESIRES AND ANIMALS (CATEGORY 6)

As is the case with phenomenal consciousness, the attribution of cognitive and affective states (such as beliefs and desires) to animals appeals to common sense. This practice is based largely on behavioral considerations. Suppose a dog chases a squirrel up a tree. The dog sits at the foot of the tree barking. However, unbeknownst to her, the squirrel has long since jumped to another tree and disappeared. It seems natural to assume that the dog believes the squirrel is in the tree. For what else would explain her behavior?

There are, however, various philosophical objections to this commonsense assumption. One criticism is loosely associated with the ideas of the Austrian philosopher Ludwig Wittgenstein (1889-1951). Humans learn

to attribute beliefs and desires to other humans and then, by analogy, extend this attribution to nonhuman animals. Many critics argue that this extension by analogy is not justifiable (Leahy 1993). This objection, however, fails to recognize that, in many cases, the practice of belief-desire attribution is learned through its application both to humans and non-humans at the same time. For example, a child who grows up in the company of a dog will acquire his ability to attribute beliefs, desires, and other psychological states partly by observing how his or her parents use this sort of psychological language in connection with the dog (Gaita 2003).

Another objection to the attribution of beliefs and desires to animals has been developed by the late Berkeley philosopher, Donald Davidson. In order to have the belief that the squirrel is in the tree, the dog would have to have the concept of a squirrel (and a tree). But, in order to have the concept of a squirrel, the dog would have to know various things about squirrels; for example, that squirrels are mammals, that they are warm-blooded, that they have skeletons, etc. Therefore, on Davidson's view, in order to have a single belief, one has to have many beliefs, and this *holism of the mental* precludes the possession of beliefs, desires and other propositional attitudes by non-human animals.

However, it is not exactly clear is why this is so. The holism of the mental is, of course, compatible with the *de re* ascription of propositional attitudes to animals–where *de re* means *of the thing*. Thus, Davidson accepts that it is legitimate to say that the dog believes *of* the squirrel that it is in the tree. It is the so-called *de dicto* ascription of squirrel-beliefs that is precluded by the holism of the mental. A belief *de dicto* is about an object only under a *mode of presentation*. So, the dog might be able to think *of* the squirrel that it is in the tree. But, according to Davidson, it cannot think of this object that is in the tree *as* a squirrel. This would be to think of it under a mode of presentation that, because of its conceptual poverty, the dog cannot posses.

However, if this correctly captures Davidson's rather difficult argument, then it is not clear why the squirrel cannot be presented to the dog under a mode of presentation at all. It is true that the dog might not identify the squirrel as, say, a mammal, or as warm-blooded, etc. But this does not mean that there could not be other modes in which the squirrel might be presented to the dog (Rowlands 1998). These might be *affordance*-related modes of presentation in which the squirrel is represented as a *chaseable* thing or an *eatable* thing; this form of presentation might categorize squirrels and rabbits as belonging to the same kind. To say that a squirrel is presented to a dog in a very different way from which it is presented to a human does not, of course, negate the fact that it is presented to the dog in some way or other. Thus, Davidson's argument notwithstanding, it is not clear why the holism of the mental rules out the attribution of propositional attitudes to nonhumans.

SELF-CONSCIOUSNESS AND ANIMALS (CATEGORY 5)

Discussions of self-consciousness in animals typically focus on whether they are able to recognize themselves in the sense of being able to distinguish themselves from others. These discussions thus pertain to category 5(a) of the above classification. Here, the well-known 'mirror test' has tended to dominate discussion (Gallup 1970, Gallup et al 2002). According to Gallup et al. (2002) mirror self-recognition is an indicator of self-awareness. This may be true, but the claim is, at the very least, unclear in two important ways. First, it is not clear whether mirror-self recognition is proposed as a necessary condition of self awareness, or as a sufficient condition, or both. Second, it is not immediately obvious what constitutes success in the mirror test. The classical version of the test involved putting a visible mark on the face of the animal, and seeing whether their attention was drawn to the mark when it viewed itself in a mirror. Chimpanzees and orangutans are the only non-human species that consistently pass the mirror test in this form.

This version of the test is, however, simplistic. First, as Allen and Bekoff note, the test depends on "the ability to match motor to visual information, a skill that may not have needed to evolve in a majority of species, for example those species that depend more on chemical or auditory clues." (2007, p. 60). Secondly, to suppose that manually inspecting the visible mark placed on one's face is the only way to pass the mirror test is implausible. Such a response would be appropriate to creatures that engage in manual exploration of their bodies–such as chimpanzees and orangutans. However, obviously this standard can't be applied to creatures that do not engage in such manual self-exploration. On the other hand, if it is the elicitation of surprise or its behavioral analogue, that is thought to be decisive, then it is far from clear why the mirror test, when properly understood, is not passed by many creatures. There is no reason to suppose that a dog, for example, would be in any way surprised by a new mark appearing on her face: they are frequently covered in such marks in the form of mud, burrs, etc. and can do little about them. What a dog would be surprised by is the presence of a new, unfamiliar, dog in her environment. By that standard, the dog's indifference to her image in the mirror is the clearest indication imaginable that she passes the mirror test.

CONSERVATION

Built on eighteenth- and nineteenth-century ideas and practices but rooted deeply in history and even prehistory, conservation emerged as a conscious goal of public policy, citizen action, and professional endeavor in the early twentieth century. Since then conservation has evolved in response to varied forces: new findings in the natural sciences; emerging environmental concerns; shifts in philosophical assumptions and aesthetic standards; novel technologies and techniques; expanding legal mandates; and changing constituencies, cultural influences, and social, economic, and political conditions. The complex interplay of these forces has produced a movement whose goals, approaches, and philosophical foundations remain in flux.

Because of this complexity, conservation has always been a sensitive indicator of changing philosophical premises and principles. As a manifestation of ethics, conservation has demarcated how humans understand, value, and choose to act in relation to nonhuman nature. In all its permutations, however, conservation has sought to define and achieve a more responsible relationship between people and nature.

PREHISTORIC PRECEDENTS

The term *conservation* acquired its modern meaning during the Progressive-Era conservation crusade in the United States in the early twentieth century. As an expression of a cultural commitment to an enduring relationship with the natural world, however, conservation has deep historical and prehistoric foundations in older traditions of resource management, nature protection, and veneration of natural events, features, and processes.

Prehistoric cultures did not exist in a stable state of coexistence with their natural surroundings. Converging lines of evidence from paleontology, paleoecology, archaeology, and anthropology suggest, in fact, a sobering picture of human dispersal over the last 120,000 years, accompanied by waves of continental and insular extinction and other forms of environmental degradation. Against this record, however, there is countervailing evidence of many cultures that have achieved relatively sustainable ways of life. For centuries and even millennia native peoples in landscapes around the world have developed sophisticated belief systems and land-use practices that recognize cultural connections to and dependence on the nonhuman world. Some of these traditions have survived into the modern era, although they now cope with intense pressures from diminished resources, human population growth, a globalized economy, and rapid economic and technological change.

In many native cultures social mechanisms evolved to reinforce an attitude of respect and deference toward nature, to evoke nature's bounty, and to sanction appropriate human use of that bounty. These mechanisms included hunting and planting rituals, fertility and birth-control practices, and recognition of sacred spaces, taboos, totems, stories, and myths. The conservation movement may be thought of as modern society's conscious effort to develop and exercise such social practices and restraints in its relations with the nonhuman world.

HISTORIC PRECEDENTS

Evidence of early conservation practices can be found in the history of Europe, North America, and other cultures. These include efforts to protect particular species and special lands, to maintain or enhance populations of wild plants and animals, and to sustain the productivity of agroecosystems. European traditions of forestry and game keeping date to the Middle Ages. The establishment of game preserves and royal forests on the land estates of feudal Europe led to the development of customs and, later, formalized laws regulating hunting and

the use of forests. Germany and France in particular developed silvicultural systems and techniques to prevent the wholesale destruction of their forest estates.

Europeans carried these protoconservation traditions to their expanding empires, even as colonization disrupted traditional patterns of land tenure and resource use. In North America unchecked resource exploitation was the norm as European settlement proceeded. Despite this record, seeds of the later conservation movement were apparent in efforts in the American colonies to protect wild game populations, forests, soils, and special natural features. Through the 1800s the new American states intermittently passed laws establishing closed seasons, prohibiting the hunting of nongame birds, and mandating bounties on predators.

The exploitation of North America's abundant native forests—for conversion of land to agriculture, for housing and naval construction materials, and for charcoal and domestic fuel supplies—drove economic development throughout the colonial and early American era. Depletion of the eastern forests and settlement of the interior of North America shifted the focus of forest exploitation to the Great Lakes region. The swift destruction of the Great Lakes forests marked a turning point in the development of American forestry and conservation thought. A parallel pattern of resource degradation and early conservation response is evident in the response to widespread soil erosion, loss of wild landscapes and natural features, and overexploited game populations. The trend toward protection or regulated exploitation of economically or esthetically important components of the landscape or ecosystem provided the foundation upon which a coherent conservation movement began to form.

PRELUDE TO A MOVEMENT

The conservation movement arose in the eighteenth and nineteenth centuries as a result of changes in demographic and environmental conditions and in human perceptions and understanding of the natural world. Global exploration ushered in a golden age of natural-history studies. These studies provided essential foundations for the development of evolutionary theory in the work of Alfred Russel Wallace (1823–1913) and Charles Darwin (1809–1882). These advances occurred as the Industrial Revolution altered the scale, pace, and character of human environmental impacts.

Coincident with these scientific, cultural, and environmental changes, the Enlightenment and romantic movements were reshaping European and North American conceptions of order, value, and beauty in the natural world. The natural philosophers of the Enlightenment stressed the smooth workings and stability of a mechanistic natural order. The romantic philosophers and poets perceived unity and wholeness in a spontaneously creative organic nature. Although offering very different, even opposed, conceptions of nature, both outlooks encouraged human comprehension of natural objects and processes and thus provided a foundation for greater appreciation of human impacts upon the natural world. The writings of Thomas Malthus (1766–1834) and other early economic philosophers provided the basic framework for considering the interwoven fate of the human population, human economies, and natural resources.

George Perkins Marsh's *Man and Nature: Or, Physical Geography as Modified by Human Action* (1864) is widely regarded as the first philosophical and ethical landmark in modern conservation literature. Drawing on extensive personal observations of long-term landscape change in New England and the Mediterranean, Marsh argued that human actions had caused widespread disruption of the "harmonies" of the natural world, and that "all nature is linked together by invisible bonds" (p. 66). The publication of Marsh's book provided direction to the conservation movement as it gained definition through the remainder of the 1800s.

In North America dispossession of Native Americans, enactment of liberal land-distribution policies, and the flow of settlers and capital into "virgin" landscapes resulted in an unprecedented wave of exploitation of forests, wildlife, fisheries, agricultural lands, rangelands, and aquatic systems. The last quarter of the nineteenth century also produced the first concerted efforts to address the causes and consequences of these extensive environmental changes through policy reforms, land protection, and the rise of a public and professional forestry movement. By the turn of the twentieth century, varied strands of conservation concern had emerged in the United States, but they were only loosely connected. They drew together as the Progressive movement came to the fore in the political arena.

PROGRESSIVE-ERA CONSERVATION

When Theodore Roosevelt assumed the American presidency in 1901, the stage was set for a revolution in conservation policy. In his first address to the U.S. Congress, Roosevelt spoke at length of the importance of the nation's forests, stating that "We have come to see clearly that whatever destroys the forest ... threatens our well-being" (Pinchot 1947, p. 190). Conservation became a cornerstone of the Progressive movement and of Roosevelt's presidency. Roosevelt's partner in political innovation was his "chief forester," Gifford Pinchot (1865–1946). As head of the U.S. Forest Service, established in 1905, Pinchot embodied the Progressive approach to bureaucratic responsibilities, administering the nation's newly created national forests according to the utilitarian

credo of "the greatest good of the greatest number over the long run." Applied not only to forests but also to natural resources in general, the "resource-conservation ethic" provided the dominant paradigm of the early movement (Callicott 1990). In Pinchot's words, "The first great fact of conservation is that it stands for development" (Pinchot 1910, p. 42).

At the core of utilitarian conservation was the concept of *sustained yield* through wise use. As Aldo Leopold later observed in his text *Game Management*, under the Progressive banner

> wild life, forests, ranges, and waterpower were conceived ... to be *renewable organic* resources, which might last forever if they *were harvested scientifically, and not faster than they reproduced*. "Conservation" had until then been a lowly word, sleeping obscurely in the dictionary. The public never heard of it. It carried no connotation of woods or waters. Overnight it became the label of a national issue. (1933, p. 17)

As the leading edge of the movement, the Forest Service became a model for other resource-management agencies and for Progressive-Era government.

Absent from many of the Progressive-Era initiatives were the voices of the increasingly influential nature preservationists, led by the naturalist and writer John Muir (1838–1914). As Pinchot appropriated the term *conservation*, its meaning became subject to lasting confusion and debate: *conservation* is sometimes understood, in contradistinction to *preservation*, to mean "wise use of natural resources" and is sometimes understood more broadly to encompass the idea of preservation. In contrast to the utilitarian approach, adherents of the "romantic-transcendental preservation ethic" emphasized wild nature's aesthetic and spiritual values and the need to safeguard those values through strict prohibitions on development and manipulation (Callicott 1990). The tensions between the utilitarian and preservationist approaches intensified as the conservation movement, broadly understood, coalesced.

These tensions surfaced in the changing relationships between the principal players. Pinchot and Muir had been personal friends, but their differing approaches to conservation of the nation's forests caused a rift between them beginning in the late 1890s. Their differences came to a head in the protracted political struggle over plans to dam the Tuolomne River in Yosemite National Park's Hetch Hetchy Valley. The battle culminated in 1913 with the adoption of national legislation providing federal support for the dam. Although Muir and his colleagues lost the battle, they had aroused a national constituency in favor of nature protection that in turn led to establishment in 1916 of the U.S. National Park Service. Nevertheless, the rift between the utilitarian and preservationist camps in conservation persisted for decades, with only a gradual and partial rapprochement as conservation science, philosophy, policy, and practice coevolved through the twentieth century.

INSTITUTIONALIZING AND INTERNATIONALIZING CONSERVATION

The first half of the twentieth century saw the consolidation of the Progressive Era's conservation gains in the United States and the gradual growth of an increasingly international movement. As conservation became institutionalized, it tended to follow the tenets of Pinchot's resource-conservation ethic. The principles of utilitarian resource conservation were applied beyond forests to other "useful" components of the biota and the landscape: rangelands, game animals, sport and commercial fisheries, scenic areas, agricultural soils, and river systems. New policies, laws, academic disciplines, research and training programs, and professional societies arose to promote sustained yields of and from these various "resources."

Although increasingly defined by this enhanced structure of agencies, disciplines, and professions, the conservation movement in the U.S. remained a battleground for competing approaches and philosophies. Even as conservation became professionalized, growing numbers of citizens became active as members of nongovernment conservation organizations. The preservationist approach found renewed vigor as campaigns to protect wildlife, natural areas, and wildlands reemerged. In the international arena early conventions and treaties addressed such problems as the protection of marine mammals and migratory birds. After World War I international conferences on conservation became more frequent, primarily in Europe and North America.

The social, economic, and environmental convulsions of the 1930s and 1940s fundamentally altered priorities and perspectives in the conservation movement. With the outbreak of World War II conservation issues fell into the background of concerns, proving the difficulty of maintaining mindfulness of human-nature relationships when social crises erupt. Yet, as in no other time since the advent of conservation, these years of crisis demonstrated the complex nature of environmental problems. Moreover, they forced the conservation movement to again confront its own internal tensions.

Beneath the very active surface of conservation, there remained the unresolved philosophical split between the utilitarian and preservationist approaches. Neither approach adequately addressed extensive problems such as soil erosion or the loss of wildlife. In the United States these problems stimulated new efforts to address the root causes of

Dust Storms. *A dust storm is set to engulf the town of Spearman, Texas on April 14, 1935. Storms like these could build clouds thousands of feet into the sky and carry millions of tons of dirt. In response, programs were developed to teach farmers new farming practices that would make soils less vulnerable to water and wind erosion.* **NATIONAL OCEANIC AND ATMOSPHERIC ADMINISTRATION/ DEPARTMENT OF COMMERCE.**

conservation ills. Drawing upon both utilitarian and preservationist frameworks, a new generation of conservationists embraced both the preservationist critique of human hubris, with its emphasis on aesthetic appreciation of wild nature, and the utilitarian commitment to wise use and stewardship of resources. This evolving synthesis also reflected a basic shift in conservation's scientific foundations, as ecology and evolutionary biology were revolutionizing the understanding of the structure and functioning of biological communities, landscapes, and systems.

For at least some conservationists, these advances suggested a new need: to marry ecology and the various fields of resource management in the effort to sustain not simply the yields of particular commodities but also the healthy functioning of entire systems. Writing in 1939, Aldo Leopold noted that ecology provided "a new fusion point for the all the natural sciences," that its emergence had "lift[ed] the veil from a biota so complex, so conditioned by interwoven cooperations and competitions, that no man can say where utility begins or ends" (Leopold 1991, pp. 266–267). Leopold's expanded conservation philosophy, as finally expressed in his landmark essay "The Land Ethic" in *A Sand County Almanac* (1949), emphasizes the integrity, stability, and beauty of what he called the "biotic community" and rejects the view of nature as a mere collection of disaggregated natural resources. It "changes the role of *Homo sapiens* from conqueror of the land community to plain member and citizen of it" (Leopold 1949, p. 204). Leopold's "evolutionary-ecological land ethic" redefined resources as components within complex and diverse systems, connected to and interacting in complex ways with other parts of the system (including human beings) (Callicott 1990). It followed that the conservation professions had

to develop better integrated approaches to resource management and stewardship.

FROM CONSERVATION TO ENVIRONMENTALISM

Conservation emerged from World War II into a world transformed. The war had altered conservation's social and ecological context. As the bonds of empire dissolved in the postwar decades, former colonies and colonial powers alike struggled to somehow reconcile development and conservation priorities. These changes in international relations occurred as human population growth, land degradation, air and water pollution, and overexploitation of marine resources fully emerged as global conservation issues. Reflecting the broader scale of concern, a wide spectrum of national and international organizations and governments met in 1948 and formed the International Union for the Protection of Nature (now called the World Conservation Union). The newly formed United Nations also became involved in international conservation programs. These were early expressions of what became an increasingly global response to conservation problems.

Conservation was subject to the social and economic forces rising in aftermath of the war. The postwar years brought a new generation into forestry, wildlife management, agriculture, and other conservation fields. As the pressure to meet rising material demands increased, the professions became more specialized, more focused on commodity outputs, and more inclined to adopt technological solutions to conservation problems. These changes overwhelmed the integrated approach that had emerged before the war. Resource managers confronted complex environmental problems with an increasingly rigid framework of disciplines, agencies, and institutions.

These same years, however, also gave rise to countervailing forces. New tools in the earth sciences provided greater understanding of natural systems. Through the 1950s and 1960s, revolutions in fields from genetics and evolutionary biology to geology and atmospheric chemistry reshaped humans' understanding of the global biosphere and their place in it. Meanwhile, the indiscriminate adoption of novel technologies—especially agricultural pesticides, industrial chemicals, and nuclear power—created new concerns about their effects on human health and ecological systems.

With the publication in 1962 of Rachel Carson's landmark book *Silent Spring*, the modern environmental movement began to assume an identity of its own, distinct from but still connected to the older conservation movement. Over the next decade, the U.S. Congress adopted a series of important environmental protection laws, responding to a rising wave of environmental awareness, popular support, and organized advocacy. The movement achieved symbolic and political maturity with the observance of the first Earth Day on April 22, 1970.

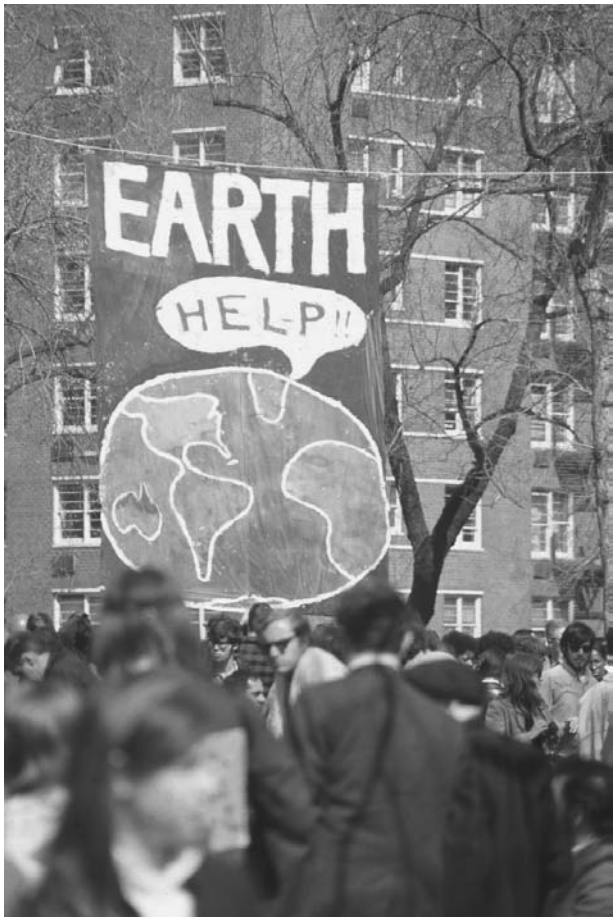
THE REINTEGRATION OF CONSERVATION

The years following Earth Day saw an increasing acceptance of environmental values in the conservation professions and in society. Those values, however, were not easily transformed into effective conservation action. The tendency toward overspecialization was difficult to overcome. Conservation programs usually focused on single species, particular economic resources, discrete goals, or separate jurisdictions within a given landscape. As the long-term adverse impacts of such fragmented approaches became evident, the traditional conservation fields came under increasing public scrutiny. While environmentalists pressed for change through legal means, the evolution of conservation philosophy, policy, and practice required years of incremental change.

At the international level differences in perspective and priorities between the wealthier, developed nations of the north and the poorer developing countries of the south likewise proved difficult to overcome. International conservation continued to make gains through a series of conventions, treaties, and global conferences. Nevertheless, international development policies only gradually incorporated stronger conservation and environmental provisions, as the need to connect economic development and long-term environmental security became evident.

Even as these broad patterns of change unfolded, conservation's scientific foundations were again shifting. Ecology in particular moved away from its classic paradigm, which emphasized singular, stable, deterministic equilibria, and toward a multiscalar view of ecosystems characterized by constant flux, inherent uncertainty, and contingency. Increasingly, conservation strategies required the integration of knowledge from the many branches of science and across the science-humanities divide. This need to rethink conservation across disciplinary lines was driven not only by changes in the foundational sciences but also by accelerating changes in the environment itself, including the worldwide loss of biological diversity, degradation of aquatic and marine systems, and climate change. These concerns prompted the growth, in the 1980s, of such synthetic disciplines as conservation biology, agroecology, restoration ecology, ecological economics, and environmental history. They brought to the fore new core concepts such as *sustainability*, *biodiversity*, and *ecosystem management*.

The trend toward integrated conservation approaches has meant a move away from narrow economic criteria and



Earth Day 1970, New York City. *The modern environmental movement achieved a symbolic and political height with the celebration of the first Earth Day conservation awareness celebration on April 22, 1970. Since then, environmental values have continued to become more acceptable in the mainstream.* **HULTON ARCHIVE/GETTY IMAGES.**

toward broader ecological standards of success; away from a mathematically derived goal of sustained yield and toward the more complex objective of healthy and resilient ecosystems; away from a restrictive focus on the goods and services provided to humans by ecosystems and toward the sustaining of the biological diversity and ecological functions that yield such goods and services. These changes also began to redefine the value of wildlands within a broader conceptual framework of conservation—as repositories of biodiversity, as core protected areas and corridors in greater ecosystems, and as "controls" against which to compare human impacts on more intensively utilized lands.

In many ways these trends toward increasing integration in conservation harked back to the synthesis that Leopold and others had articulated decades before. Since then the science of ecology has advanced; its analytical tools have grown vastly more sophisticated; and the social and economic context of conservation has changed dramatically. Nevertheless, there has been a continuity between modern efforts to expand conservation's cultural and natural connections and Leopold's call to "[enlarge] the boundaries of the community to include soils, waters, plants, and animals, or collectively: the land" (Leopold 1949, p. 204).

EMERGING THEMES IN CONSERVATION

As in the past, conservation movements remain responsive to new information, demands, and realities. The forces that have reshaped conservation since World War II will continue to register in its changing philosophical premises, human dimensions, and practical methods. Conservation will likely continue to seek greater collaboration among the sciences, even while reaching beyond the sciences to strengthen connections with philosophy, theology, economics, history, literature, and the arts. Although ecology remains the "fusion point" of the sciences, conservation faces a continuing challenge of incorporating ecology's systems perspective into the various resource-management professions. The new integrated fields that have arisen to meet this challenge will confront the tendency toward specialization and reductionism to which even interdisciplinary fields are prone.

Meanwhile, a suite of interacting threats is making the work of conservation ever more daunting. These threats include the now-unavoidable impacts of global climate change; the rapid spread of invasive exotic species (especially as the human economy continues to globalize); the seemingly relentless fragmentation of landscapes and ecosystems; increasing human demand for freshwater; the increased presence of genetically modified organisms in the landscape and growing pressure to devote cultivated and uncultivated landscapes alike to biofuel feedstock production; the advent of new emerging diseases; and the degradation of ocean ecosystems and marine fisheries.

The continued growth in human population and resource-consumption rates remains a profound influence on conservation theory and practice. Conservationists are seeking novel ways in which to integrate sustainable economies with effective environmental protection, management, and restoration programs. Conservation-planning efforts are expanding their reach across jurisdictional boundaries and across the landscape, recognizing the ecological connectivity of wildlands, semiwild lands, "working" landscapes, and suburban and urban environments. Such cross-boundary, landscape-scale approaches have few precedents in conservation history. They represent an important departure from the past,

spurring the expansion of the land ethic to encompass the entire continuum of land uses.

In the past conservation has focused primarily on natural systems while neglecting human and cultural relationships. Increasingly conservationists recognize the need to build connections between the natural sciences, cultural traditions, and human communities in the effort to protect, restore, and sustain healthy landscapes. In seeking a better fit between the built environment and the surrounding landscapes, conservationists have begun to work with colleagues from varied fields to incorporate and apply emerging principles from conservation biology and landscape design. Likewise, conservationists and their colleagues in the medical fields increasingly work together to understand the links between ecosystem health and human health.

As a social movement conservation itself continues to diversify as individuals from varied backgrounds come into conservation as both professionals and committed amateurs. Local nongovernmental organizations are now important and increasingly influential conservation stakeholders. Although international action remains necessary to address global threats and to support local initiatives, the assumption of greater local responsibility for ecosystem health is increasingly urgent. A vital community-based conservation movement has arisen to meet that need. As these experiments in ''bottom-up'' conservation continue, they seek to create not just an enhanced conservation movement but also an enduring culture of conservation. In so doing, they both embody and extend a conservation ethic that has been evolving continually since the movement first emerged.

CONSERVATION BIOLOGY

Concern for the protection of useful species goes back to ancient cultures. In India the Mauryan emperor Asoka (299–237 BCE) ordered the preservation of forests that provided a critical habitat for the Indian elephant, an important component of his army. Shortly after the turn of first millennium CE limited forest management practices began to be advocated in many regions, including China, Japan, and Europe. Since the eighteenth century there has been a continuous history of forestry in European countries and their colonies and ex-colonies, starting primarily in Germany. The goal was to ensure the sustained availability of forest products, primarily timber. By the early twentieth century those practices had been extended to include the

management of game and other charismatic species as well as forests (Sarkar 2005). After World War II wildlife conservation emerged as an important transnational goal for organizations such as the United Nations Educational, Scientific and Cultural Organization (UNESCO). In 1968 a new European journal, *Biological Conservation*, began to provide an outlet for research based on this broadened scope of species conservation.

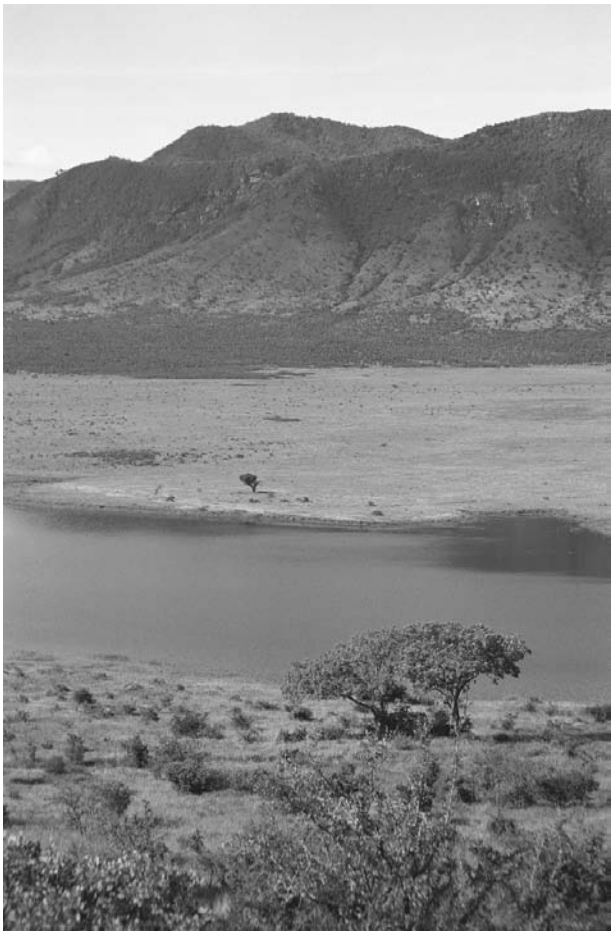
EARLY YEARS OF CONSERVATION BIOLOGY

An organized discipline of conservation biology did not emerge until the 1980s, initially primarily in the United States. In the late 1970s conservation practice and research in the United States was dominated by legislative developments, in particular the Endangered Species Act (ESA) of 1973 and the National Forest Management Act (NFMA) of 1976. The ESA led to a focus on endangered and threatened species and the enactment of policies to assist their recovery. Those policies typically required the designation on scientific grounds of critical habitats for the persistence of those species. Meanwhile, guidelines for the implementation of the NFMA required the maintenance of ''viable'' populations of native mammals in all national forests. Techniques of population viability analysis (PVA) were invented, starting in the late 1970s, to carry out that task (Shaffer 1978). Because most endangered or threatened species were at risk as a result of the small size of their populations, PVA methods were primarily used to generate models of populations that were under threat of stochastic (random) extinction.

In the United States and elsewhere concern was spreading among ecologists about the increased rate of destruction of neotropical natural habitats, especially rain forests, since the 1960s (Gómez-Pompa, Vásquez-Yanes, and Guevera 1972). At the sociocultural level one problem with generating political will for the protection of those habitats was the absence of conspicuous charismatic species found elsewhere, for instance, in Africa and Asia. Ecologists began to urge attention to all habitats and all biota in an explicit effort to generate such public support. An influential edited book titled *Conservation Biology* (Soulé and Wilcox 1980) documented the gradual emergence of a new discipline concerned with the protection of all biota, not just wildlife.

THEORETICAL ISSUES

Early research in the new discipline became bogged down in a series of seemingly intractable theoretical problems the reverberations of which continue to be felt today. First, PVA was supposed to establish minimum viable populations (MVPs) for individual species that would guarantee their survival with a specified probability (typically 0.95) for a certain number of years (typically 100 years). However, ecological PVA models were often subject to serious structural instabilities: Slight changes in assumptions led to serious divergence of results (Sarkar 2005). The MVP seemed to be highly sensitive to details of ecological context, and the concept fell into disuse by the 1990s. Even after three decades of sustained research, though new techniques for PVA, including new software packages typically based on computer simulations, have continued to be developed, detailed predictions of expected population extinction times and other parameters are often not considered reliable for small populations. A meta-analysis of three decades of work on this problem confirmed the context-sensitivity of the MVP (Traill, Bradshaw, and Brook 2007); the only general conclusion is that the MVP for most species exceeds a few thousand individuals.



Mkomazi Game Reserve, Tanzania. *The Mkomazi Game Reserve, in northeastern Tanzania, on the Kenyan border, was established in 1951. It is one of the only places in the country where one can spot a black rhinoceros. Like many conservation areas and national parks, Mkomazi has dealt with contention. To construct the reserve, government conservation officials evicted groups of pastoral herders from the land.* **© SYLVIE RALUY/BIOS/PETER ARNOLD, INC.**

Graeme Caughley (1994) urged that PVA concentrate on large populations for which model reliability can be tested in properly designed experiments with adequate controls. It has become clear that reliable PVA requires access to a range of demographic and other data for populations (typically intrinsic growth rates, carrying capacities of environments, age and spatial structures, etc.) that are not available except for a tiny fraction of species that are of conservation interest. Difficulties with PVA contributed to a shift in focus from individual species to habitats (or landscape elements) as units of conservation concern in the 1980s. This shift perhaps has been least pronounced in the United States, where the legal requirements of the ESA have continued to dominate conservation planning. Some major nongovernmental organizations (NGOs) continue to focus primarily on critically endangered species, but by and large conservation planning has taken a different route.

In the 1970s, when conservation biology was gradually becoming an independent discipline, the design of networks of reserves to protect habitats emerged as a major theoretical problem that generated several disputes. The problem of area prioritization for conservation attention has continued to be central to conservation biology, though the term *conservation area* has replaced *reserve* to indicate that managing habitats as traditional reserves is only one policy option (Sarkar 2003). In the 1970s and 1980s it was assumed that all areas managed for conservation should be similar to "wildernesses," which exclude permanent human presence or use. However, the determination of the most appropriate management plan to maintain species or habitats should be based on empirical research, not traditional intuition, in this case biased toward Northern conceptions of protected nature (Sarkar 1999).

ETHICAL AND PRAGMATIC ISSUES

Besides these scientific qualms, the wilderness model of conservation areas has been criticized on ethical and pragmatic grounds, most forcefully by social ecologists from the developing countries of the South (Guha 1989). Mark Dowie (2005) documented the creation of a new class of "conservation refugees" throughout the South created by the expulsion of people from their homes to create nature reserves. The Southern countries also typically have the most biota of conservation concern, in part because of the latitudinal species richness gradient (that is, the increase of richness with latitude) and in part because of the necessity of economic expansion to alleviate poverty. In such contexts excluding people from habitats to protect other species is both morally suspect and prone to generate local conflict that is inimical to the success of conservation plans. In response, proponents of conservation have urged that conservation areas be policed by armed militias (Brockington 2002). The resulting "fortress conservation" model has been challenged by anthropologists, political and social ecologists, philosophers, and social activists. Whether conservation biology still is committed to the fortress conservation model in the first decade of the twenty-first century remains a matter of controversy.

A lack of attention to empirical detail manifested itself in early attempts to solve the conservation area network (CAN) design problem in the 1970s in yet another way. The first attempts were based on applying island biogeography theory to the problem on the assumption that conservation areas in a landscape matrix are analogous to islands in oceans (Diamond 1975). This assumption was criticized on the ground that the analogy is misleading because the regions between conservation areas are not as inhospitable as oceans are to terrestrial species (Margules, Higgs, and Rafe 1982). Nevertheless, design principles based on such assumptions were promoted with vigor and sometimes advocated by NGOs that were beginning to become influential during the late 1970s. Research on the CAN problem also generated the "single large or several small" (SLOSS) debate, which was based on species-area curves as models for species distributions across landscapes. As with the MVP problem, it eventually was realized that any answer to the SLOSS question must be highly context-dependent (Soulé and Simberloff 1986).

ORGANIZATIONS AND MANIFESTOS

In 1985 the Society for Conservation Biology was founded in the United States to promote the new field (Soulé 1987). Its activities included the publication of a new journal, *Conservation Biology*. In a coordinated move, Michael Soulé (1986) published a manifesto that set the agenda for the new discipline. Two aspects of that agenda merit attention in this context. First, conservation biology was explicitly conceived of as a hybrid interdisciplinary field drawing insights from a variety of social sciences and philosophy besides biological disciplines. (However, conservation biology during the 1980s and 1990s rarely seriously engaged the social sciences and still only pays lip service to the humanities.) Second, the new discipline also had an explicit normative component based on assumptions such as evolution is good but extinction is not and that biological diversity has intrinsic value. Those normative assumptions were supposed to make conservation biology analogous to medicine, and Soulé drew an analogy to cancer biology. The fact that the manifesto took a stand on an issue as philosophically contentious as the ascription of intrinsic value to nonhuman entities has encouraged a refusal to countenance trade-offs between biodiversity protection and other legitimate human interests and has thus promoted the fortress conservation model.

Shortly after Soulé's manifesto, in 1986 Daniel Janzen exhorted ecologists to undertake the political activism

necessary to make conservation happen in the real world. Between 1986 and 1988 a new term, *biodiversity*, was introduced to refer to diversity at all levels of organization (Takacs 1996). The goal of conservation biology was the protection of biodiversity. Because of that goal, the concept of biodiversity has had a normative component since its introduction (Norton 2003). The first journal with *biodiversity* in its title, *Canadian Biodiversity,* appeared in 1991 and changed its name to *Global Biodiversity* in 1993; a second, *Tropical Biodiversity,* began appearing in 1992; *Biodiversity Letters* and *Global Biodiversity* followed in 1993. There was a sociologically synergistic interaction between the growing popularity of the term and the new field of conservation biology. In 1989 Soulé and Kathryn Kohm published a primer on research priorities for the field. In 1993 Richard Primack produced the first textbook of conservation biology, followed by Gary Meffe and C. Ronald Carroll (1994) a year later.

Those developments show that in spite of the theoretical impasses mentioned above, the early practitioners of conservation biology in North America succeeded in establishing research traditions that were independent from both academic ecology and traditional resource management studies such as forestry and fisheries science. However, in the late 1980s and early 1990s much of the theoretical progress and technical innovations in the field initially came from Australia. A 1989 volume of *Biological Conservation* (Margules 1989) recorded those developments, as did a textbook (Caughley and Gunn 1996).

Australian researchers were the first to advocate the use of computer-based and Geographical Information Systems (GIS) tools in the field. They also took planning for conservation—with all its pragmatic aspects and sociopolitical constraints—to be an integral part of the discipline. In the late 1980s they made significant progress in solving the CAN design problem (Margules, Nicholls, and Pressey 1988) by showing that a modified measure of beta-diversity called complementarity can be used to select conservation areas so that a maximal amount of biodiversity is represented in as minimal an area as possible. This ensures that resources are not wasted through ad hoc selection of areas for conservation management. Area selection algorithms have been implemented in software packages that can process large amounts of remote-sensed and other data as represented in GIS models. Beyond the many disciplines that Soulé (1985) envisioned as playing a role within conservation biology, the information sciences have emerged as a major component of the field.

SYSTEMATIC CONSERVATION PLANNING

Since, the mid-1990s the Australian innovations have been combined with the ongoing more traditional work on species' persistence, particularly in the United States, to generate an integrated framework that has come to be called systematic conservation planning (Margules and Pressey 2000). This framework is an incomplete synthesis because determining appropriate management options to ensure the persistence of biota remains an area of ongoing research. Single-species management continues to be driven by a species' autoecological requirements. For multiple species, ecosystem management, which focuses on the maintenance of basic ecological processes, has been proposed as a solution but also criticized (Simberloff 1998). It also has been argued that management be "adaptive" in the sense that goals and protocols should be updated periodically and systematically to reflect changes in the field (Holling 1978, Margules and Sarkar 2007).

The goals of systematic conservation planning are (1) adequately representing all components of biodiversity in CANs; (2) ensuring their persistence into the future; and (3) achieving those ends with maximum economy of resources (Margules and Sarkar 2007). Besides the requirement of economical resource allocation, sociopolitical considerations are incorporated into systematic conservation planning by requiring the explicit involvement of stakeholders from the beginning of the planning process. This requires attention to normative issues, including an answer to the question: Who is a legitimate stakeholder when the future of an area is being negotiated?

THE NEED FOR NORMATIVE ANALYSIS

The fact that this question remains relatively unexplored shows that in spite of Soulé's (1985) early recognition that conservation biology has an important normative component, ethics and associated normative disciplines have never been incorporated adequately into the field. Environmental ethics is rarely a required component of conservation biology curricula even though philosophers have pointed out the significance of normative issues for the field (Callicott, Crowder, and Mumford 1999, Norton 2003). Philosophers also have stressed the importance of decision theory and rational choice theory in analyzing decision making in the field; this aspect of normative analysis has gained some traction within the practice of conservation biology (Moffett and Sarkar 2006).

Besides incorporating normative issues completely, the goal of "integrative habitat planning," which generalizes systematic conservation planning, is to develop plans for entire land- and seascapes that optimize options for production (resource extraction, agriculture, etc.) and habitation in addition to management for conservation. In light of the extent of anthropogenic transformation of both land- and seascapes that has occurred, habitat reconstruction may be unavoidable in achieving such an end.

Conservation biology may benefit from increased interaction with restoration ecology. However, if the goals of the field are broadened to such an extent, conservation biology may become a misnomer that will be replaced by a more general term that reflects the increasing interdisciplinarity of the enterprise, going well beyond its origin in the biological sciences.

All planning and practice in conservation biology is fraught with uncertainty, from predicting the fate of a species or habitat to predicting the prospects for practical implementation of a management plan. All those uncertainties are compounded by projected global changes, in particular climate change, whose effects are difficult to predict. With respect to addressing issues relating to uncertainty, an interaction between conservation biology and epistemology has already begun (Reagan, Colyvan, and Burgman 2002), and further interaction with the philosophy of science has been urged (Sarkar 2005).

CONSUMPTION

The primary source of environmental damage is the population's production, use, and disposal of material goods. The only source of the material used in production is the natural environment, which is also the only place where the waste products associated with production and use can be disposed of. Consequently, higher levels of production and use of material goods cause higher levels of environmental stress and degradation.

THE RISE OF CONSUMERISM

Modern market economies have been labeled consumer economies because their productivity and the overall economic well-being of participants are often measured in terms of the delivery of an ever-expanding variety and quantity of goods and services to people. That flow of goods and services from our commercial businesses to our households far exceeds what is necessary to satisfy biological or even comfort needs. Consumerism and the consumer economy are a reflection of the affluence of at least some segments of most contemporary societies. In this economic context, people are increasingly described as consumers rather than as workers or citizens. Their primary economic function is to express their preferences for goods and services through their market purchases; a well-functioning economy is expected to respond to that effective demand by producing goods and services that match those preferences at affordable prices. It is not surprising, therefore, that those concerned with environmental degradation see high and growing levels of consumption as the primary source of environmental destruction. The more we consume, the more raw materials have to be extracted from the earth's crust and the more waste has to be dumped back into the earth's land, water, and atmosphere.

CONSUMERISM AND THE ENVIRONMENT

Although many environmental observers have argued that overpopulation is the primary source of environmental damage, it is clear that each person does not have the same environmental impact. A household's environmental impact is proportional to the level of consumption of goods and services and the technologies used in production, use, and waste disposal. A hunter-gatherer household using traditional means of livelihood may be compatible with sustainable natural systems. On the other hand, an economy supporting a contemporary upper-middle-class American suburban or exurban household may have an environmental impact 100 or 1,000 times as great. Population matters, but consumption levels and the technology deployed matter even more.

Given that much of what the economies of developed countries produce is not "necessary" for biological survival but rather seeks to satisfy consumers' discretionary subjective preferences, a potential for a serious ethical conflict arises. Under what circumstances does the pursuit of a discretionary subjective preference justify serious, perhaps permanent damage, direct or indirect, to the environment and other living things, including other people?

PROSPERITY VS. THE ENVIRONMENT?

If high and growing levels of consumption are the chief source of environmental damage, then it might appear logical to conclude that in a consumer-driven economy, there is an unavoidable conflict between environmental protection and economic well-being. On this view, reduced environmental damage would require reduced consumption, which, in turn, would translate into reduced economic activity. To be greener, a society would have to become poorer. Many in both the business and environmental communities have come to that conclusion. The business community sees environmental regulation as necessarily discouraging or banning certain types of economic activity. Some environmentalists insist that the only way out of growing environmental dangers is the voluntary adoption or governmental imposition of a simpler and more austere lifestyle that involves much lower levels of consumption (and economic activity).

This conventional analysis of the link between consumption, environmental degradation, and economic well-being confuses or ignores several important distinctions. First, it equates commercial businesses with the "economy" and treats those businesses as the sole source of economic well-being. Second, it assumes that economic well-being is primarily tied to material flows. Third, it ignores the flexibility people have in how they pursue their preferences—in the kinds of technology they deploy. Correcting these conceptual errors undermines the assumption that improvements in economic well-being necessarily bode ill for the natural environment.

In fact, economic well-being is heavily determined outside the commercial business sectors. A reduction in the level of commercial economic activity does not imply a reduction in prosperity. It is necessary to consider the productivity of the "total economy," including the productivity of natural systems and noncommercial sectors. Although some argue that the commitment to "consumption" is evidence of "materialism," often the purchase of material goods indicates a quest for subjective experiences, not the materials themselves. The purchase of an audio system does not imply a concern about the character of the material components: Consider the shift from vinyl records to magnetic-tape cassettes to CDs and DVDs to the direct digital download of music onto a variety of storage devices. People do not typically want

Landfill Overflowing with Trash. *While some environmentalists argue that overpopulation is the primary source of environmental degradation, others believe that consumption is the real culprit. This scene at a landfill in Ohio illustrates the large amount of materials that are discarded daily in a consumer-driven society.* **AP IMAGES.**

discs or tapes or even big speakers; they seek mainly the subjective experience of the music and the convenience of reproducing it, not the particular material form of the technology. The same is true of many consumer goods—they satisfy a desire for particular types of subjective experiences, styles, tastes, or conveniences, but not necessarily a desire for the accumulation of materials.

THE SERVICE ECONOMY AND MATERIAL THROUGHPUT

In addition, consumers are increasingly pursuing ''services,'' not goods—so much so that the U.S. economy is often described as a ''service economy.'' Services involve people or organizations assisting other people in realizing their needs, preferences, or desires. Services are labor- rather than material-intensive activities that run the gamut from health care to recreation guides to household repair to personal appearance to teaching. People go to restaurants because they are seeking an attractive human-designed atmosphere or environment in which to eat aesthetically attractive and expertly prepared food. The objective is not primarily the materials in use but the subjective, nonmaterial qualities that are added to them.

This development opens up the possibility of creating more valuable qualities and services with the same or even reduced material throughput. It is not clear, for example, that rearing more graceful, inquisitive, and imaginative children requires an ever larger environmental footprint. Nor is it likely that better-informed citizens, more beautiful poetry and music, or more skilled athletes are necessarily the result of increased greenhouse gas emissions. These and other aspects of human well-being need not be tied to material throughput and the resulting environmental disruption.

The scarce and productive resources that we protect and develop can be combined in many different ways to produce goods and services. This potential flexibility in production technologies and the mix of goods and services provides numerous possibilities for reducing environmental impacts while sustaining economic well-being. This

does not mean that every such possibility will be realized. Most countries' national economic policies are committed to expanding the levels of consumption rather than finding other means of protecting and improving levels of well-being. Continuous worldwide expansion in the levels of material consumption seems incompatible with environmental stability and long-run human well-being.

The important public policy question is how to shift from efforts to enhance well-being mainly through expanding material throughput, with its accompanying environmental disruption, to fostering noncommercial sectors and commercial businesses that can boost prosperity without harming the planet. Markets cannot do this because many of the important sources of well-being are nonmarket and noncommercial in character, for example, family life, culture and education, supportive communities, the rule of law and respect for diversity, and other elements of rich, productive, and stable social and natural environments. Cultural, social, and political institutions will have to direct this change. Once the legal framework has been imposed for steering toward this objective, markets might help to attain it in the most cost-efficient manner.

ETHICAL AND PHILOSOPHICAL ISSUES

Environmental ethics and philosophy are central to understanding the likely cost or gain of modifying the economy to make it ecologically sustainable. Central to this issue is the question of what incremental changes in material consumption contribute to well-being as opposed to, say, the contribution made by changes in activities, social status, aesthetic enjoyment, social and cultural solidarity, and interaction with natural systems. What are the important elements of the good life, and how can their attainment be made consistent the long-term human habitation of a natural world?

This is not an ethical or philosophical inquiry that can be carried out in the abstract. The social sciences make important contributions to the understanding of the subjective experience of well-being and the collective management of its pursuit in ways that respect both the autonomy and the basic social character of individuals. One example is the accumulating evidence that, after people have reached a minimum level of insulation from the harsh pangs of biological necessity, their experience of well-being is correlated with their perceived social status. That is, people often judge well-being in relative, not absolute, terms, immersing themselves in a costly game of competitive consumption in which most of them end up losers while exhausting themselves and their families and inflicting damage to the social and natural environments. It will require the combined resources of environmental ethics, philosophy, and critical social science to find ways to promote greater consciousness of the broad range of the sources of human well-being and the serious costs of consumption in the quest for an environmentally sustainable prosperity.

CONVENTION ON BIODIVERSITY

The Convention on Biological Diversity is an international treaty for conservation of biological diversity, sustainable use of the environment, and equitable sharing of the benefits of genetic resources (see Table 1). The convention addresses some of the central topics in contemporary environmental ethics and philosophy, such as the concept of biodiversity and anthropocentrism versus ecocentrism (Yamin 1995). Other philosophical issues dealt with by the convention include the moral status of nation-states and the ethical obligations of the present generation to future generations.

HISTORY

The World Conservation Strategy of 1980 adopted by the World Conservation Union, World Wide Fund for Nature, and the United Nations Environment Programme is considered the starting point of negotiations at the United Nations (UN) throughout the 1980s that culminated in the Convention on Biological Diversity (Shine and Kohona 1992, Boyle 1996, Stoianoff 2004). Whereas the World Conservation Strategy focused on the loss of biological diversity, the UN Environment Programme's Governing Council also wanted to address socioeconomic

Main Goals of the United Nations Convention on Biological Diversity

Article	Article Topic or Goal
Preamble	**Characterizes the conservation of biological diversity as a "common concern of humankind."**
1	Describes convention's objectives: conservation and sustainable use of biodiversity and equitable sharing of genetic resources.
2	Defines *biological diversity* and *sustainable use*.
3	Affirms states' rights to exploit their own resources.
6	Delineates requirements for national and international conservation plans.
7	Describes directives for biodiversity monitoring. Each state creates its own list of important ecosystems and species.
8	In situ conservation: conservation of ecosystems and species in their natural habitats.
9	Ex situ conservation: conservation in seed and gene banks and zoos.
10	Sustainable use of biological resources to prevent their long-term decline.
11	Incentive measures.
12	Establishment of scientific training programs related to biodiversity and support for such training for developing countries.
13	Public awareness and education.
14	Environmental impact assessment and the minimization of adverse impacts.
15	Rights of states to genetic resources. Requirements for sustainable use limit state sovereignty over genetic resources.
16	Transfer of biotechnology.
18	Improvement of the research and technical capabilities of developing countries.
19	Distribution of the benefits of biotechnology.
20	Financing of the convention, including the transfer of funds from developed nations to developing nations.
24	Establishment of the convention secretariat (located in Montreal), which organizes meetings of the Conference of the Parties.
25	Establishment of a subsidiary body to provide scientific, technological, and technical advice.
27	Dispute resolution.
39	Establishment of the Conference of the Parties and designation of the financial mechanism of the convention.

CENGAGE LEARNING, GALE.

issues in developing countries that contributed to that loss. In 1986 the World Commission on Environment and Development proposed legal principles that would require states to maintain maximum biological diversity. In 1987 the UN Environment Programme Ad Hoc Working Group of Experts on Biological Diversity proposed a convention on biological diversity, the drafting of which began in 1989 (Secretariat of the Convention on Biological Diversity 2005). From 1991 to 1992 the UN Environment Programme Working Group of Legal and Technical Experts negotiated the treaty in seven sessions. The Convention on Biological Diversity was opened for signature at the UN Conference on Environment and Development on June 5, 1992, in Rio de Janeiro. One hundred eighty-seven countries and the European Union (EU) have subscribed to the convention, which entered into force on December 29, 1993.

SIGNIFICANCE

In contrast with previous environmental treaties, which were designed to protect particular ecosystems, species, or resources, the Convention on Biological Diversity represents a new development in international law to the extent that it formulates a comprehensive framework for the conservation of global biological diversity (Boyle 1996). However, the term *biological diversity*, as used in the convention, has several meanings. For example, the preamble of the convention ascribes "intrinsic value" to biological diversity, but its articles exemplify anthropocentrism insofar as they characterize utility to human beings as the fundamental purpose for conserving the environment (Yamin 1995). The convention equates biological diversity with "variability among living organisms" (Article 2) but also lists wilderness as a component of biological diversity (Annex I) (Sarkar 1999). The conflation of biodiversity and wilderness is not justified on scientific grounds and may have been added to the convention for political reasons.

The convention constitutes a case study in ethics because of its use of the principle of distributive justice. Recognizing that biodiversity is concentrated in southern countries but wealth is concentrated in northern countries, Article 8 directs northern countries to provide

financial support to developing countries for biodiversity conservation, scientific education, and training. In addition, the convention acknowledges the ethical obligations of present-day human beings to posterity, prescribing that biological diversity be used to "meet the needs of present and future generations" (Article 2).

PROPOSAL OF THE CONVENTION

Serious disagreements between developed nations and the Group of Seventy-Seven nonaligned developing nations complicated the negotiations for the convention. Developing states sought access to biotechnology and compensation for providing biological resources to developed nations. The United States objected that the directives of the convention for the transfer of biotechnology would erode intellectual property rights; ultimately, the convention was signed by the Clinton administration but not ratified by Congress (Boyle 1996). Drafts of the convention characterized biological diversity as the "common heritage" of humankind, but that wording was dropped from the final version because developing nations were concerned that it could justify infringement on national sovereignty.

ACCEPTANCE AND EFFECTS OF THE CONVENTION

Since the convention entered into force, it has become standard practice to obtain informed consent from developing countries for natural products discovery programs intended to produce new drugs or improved crop plants; however, not enough time has passed for this practice to provide royalties to developing countries (Davis 2007, Miller 2007). Administrative bodies created by the convention include the convention secretariat and the Conference of the Parties, which reviews the implementation of the convention and can amend it. However, the convention does not create an international authority to manage shared biological resources (Boyle 1996). This is problematic because it is sometimes unclear where the authority to regulate a sought-after biological resource resides within the government of the country that has that resource (Lesser 1998, Chaves 2004). To address this issue, the convention secretariat created a list of national focal points to help organize negotiations on the sharing of genetic resources.

Since 1998, sixteen developed countries have provided $1 billion per year to fund the objectives of the convention, but such financing has been in decline or stagnant (Secretariat of the Convention on Biological Diversity 2006). Nevertheless, the convention secretariat has set the agenda for international environmental agreements such as the Cartagena Protocol on Biosafety, which regulates the international transportation of genetically modified organisms; the Bonn Guidelines on Access to Genetic Resources; and the 2010 Target, a program to establish an ecologically representative network of terrestrial protected areas by 2010 and marine protected areas by 2012 (Secretariat of the Convention on Biological Diversity 2006).

Since ratifying the convention, the EU has developed laws to promote the sustainable use of biodiversity (as required by Article 6) and to protect wildlife through conservation areas, seed and gene banks, and zoos, as required by Articles 8 and 9 (European Commission 2006). The EU also has provided €60 to €200 million per year since 2001 for biodiversity-related projects in developing countries. Since the convention entered into force, the governments of Ecuador and the states of Queensland and Western Australia in Australia have enacted legislation conferring on their citizens the right to profits generated by biodiversity; in addition, Costa Rica, Fiji, Mexico, and Peru have passed laws to ensure that access to genetic resources is based on prior informed consent (Stoianoff 2004).

CONVERGENCE HYPOTHESIS

Bryan Norton's convergence hypothesis, a controversial argument about the predicted policy implications of alternative environmental ethical theories, is best understood against the backdrop of the rise and dominance of nonanthropocentric approaches in environmental ethics in the 1980s and early 1990s. The human-centeredness of the conventional Western ethical system was singled out by the first wave of environmental philosophers for its failure to extend the boundaries of moral considerability—which often was understood as the attribution of intrinsic value—to nonhumans (including animals and plants), species, and ecological communities. The primary intellectual task for most environmental ethicists since the early years of the field thus has been the articulation of a new nature-centered or nonanthropocentric worldview and an accompanying normative system that can account for the good of nonhumans and nature as a whole and compel the promotion of that good in ethical decision making.

ANTHROPOCENTRIC AND NONANTHROPOCENTRIC PERSPECTIVES

This mandate to combat unbridled anthropocentrism in environmental ethics always has harbored a serious policy ambition. By raising the flag of nonanthropocentrism, philosophers were hoping to advance a persuasive moral justification for a robust environmental policy agenda and a general rationalization of proenvironmental practices. If an ethical defense could be mounted successfully, public policies directing the protection of endangered species, wetlands, wilderness, natural areas, and so on, would appear to rest on solid and perhaps unassailable foundations.

The judgment that a nonanthropocentric program is necessary to combat moral humanism and underwrite stringent environmental policies and practices did not go unchallenged. One of the more visible and historically important dissents was voiced in the mid-1980s by Norton, who argued that the adoption of a nonanthropocentric worldview was neither philosophically viable nor politically necessary (Norton 1984). Norton disputed the prevailing view in environmental ethics that humanism was the enemy of environmental protection by advancing a less aggressive, pluralistic version of anthropocentrism. Calling the new approach "weak" anthropocentrism, Norton proffered a kinder and gentler vision of humanist environmentalism that marked a departure from the generally hostile reception of the anthropocentric worldview within environmental ethics.

Norton's alternative anthropocentric project was articulated most fully in his influential 1991 book *Toward Unity among Environmentalists.* He made the provocative claim that what had been presented as the foundational rupture in the moral bedrock of environmental concern—the deep rift between anthropocentrism and nonanthropocentrism—was vastly overestimated. Norton wrote that nonanthropocentric claims and his own formulation of weak anthropocentrism should, in practice, "converge" on the same set of environmental policy goals. He named this argument the convergence hypothesis and stressed that it was both an "article of environmentalists' faith" and an empirical hypothesis that could be falsified by subjecting it to experimental text (Norton 1991, p. 240). Logically, the convergence thesis was a hypothetical conditional: It predicted that if individual A is a consistent weak anthropocentrist (embracing the full range of human values in the environment—aesthetic, spiritual, recreational, educational values—over time) and individual B is a nonanthropocentrist who endorses a consistent notion of the intrinsic value of the environment, both A and B will end up supporting the same environmental policy positions.

Norton predicted this convergence because he believed that despite their different philosophical starting points, weak anthropocentrists and nonanthropocentrists embraced values that were ultimately dependent on the long-term ecological sustainability of natural systems. The maintenance of multigenerational ecological processes, he argued, was the only way to preserve ecological health,

integrity, and biological diversity over the long run whether this was done for the good of present and future generations of humans (the weak anthropocentrist position) or for the value that such ecological health, integrity and biological diversity possesses in or for itself (the nonanthropocentrist position). In *Toward Unity*, Norton illustrated the hypothesis by referring to environmentalists' efforts to protect wetlands, a policy goal that united advocates of a variety of value and ethical orientations, including hunters and traditional conservation organizations such as Ducks Unlimited and the National Wildlife Federation as well as nature/wildlife appreciation societies such as Audubon and Defenders Of Wildlife (Norton 1991).

THE PRAGMATIST MOVEMENT IN ENVIRONMENTAL ETHICS

Although Norton's prediction of the policy convergence of nonanthropocentric and anthropocentric positions was a bold move in environmental ethics, he drew a further conclusion that ensured that the convergence hypothesis would become a lightning rod for criticism. Because he believed in the empirical validity of the convergence thesis and also believed that a number of thorny and insurmountable philosophical and practical problems afflicted nonanthropocentric theory, he concluded that it was more effective to argue for environmental policy goals from the weak anthropocentric point of view, that is, from the standpoint of the maintenance of options for future generations (Norton 1999). The convergence thesis thus took a pragmatic and consequentialist line on value debates in environmental ethics. He favored normative arguments, such as the claim that the environment should be protected for its ability to provide a harvest of cultural values for present and future generations, that he believed would lead most effectively to the resolution of actual environmental controversies.

In taking this position, Norton tended to cast aside other arguments, such as the nonanthropocentrist appeal to the intrinsic value of nature, that he felt would not resonate as strongly with mostly anthropocentric-minded decision makers and citizens. The turn to naturalistic methods and empirical tests to resolve value disputes in environmental ethics and Norton's work in the field generally have become fixtures in the pragmatist movement in environmental ethics and philosophy, an alternative set of approaches emphasizing value pluralism, experimentalism, and the search for policy consensus despite value differences (Light and Katz 1996, Norton 2003).

DEBATE AND CRITICISM

Norton's argument for convergence and discussion of the implications of convergence for environmental ethics and environmental policy have generated a great deal of debate. Critics such as Brian K. Steverson, J. Baird Callicott, Laura Westra, and Mikael Stenmark have rejected the convergence argument, declaring Norton's prediction of the policy junction of weak anthropocentric and nonanthropocentric positions suspect or, in Callicott's words, "dead wrong." Callicott, Westra, and others insist that it makes a great practical difference whether one argues from anthropocentric or nonanthropocentric principles in discussions of policy and conservation. These "divergence" proponents argue that humanist and nature-centered moral stances ultimately will lead to very different environmental policy agendas and practices (Minteer 2009). Most criticisms of Norton's thesis, however, have been largely conceptual and hypothetical. One attempt to test his thesis with experimental methods (Minteer and Manning 2000), however, provided empirical confirmation of Norton's argument by demonstrating the convergence of Vermont citizens' ethical attitudes on a common agenda for ecosystem management.

In more recent work Norton (2005) argued that the convergence hypothesis may be only temporarily valid because it is premised on a philosophical dualism that he hoped will be replaced by a more integrated, less antagonistic account of the relationship between environmental and human values. In such a nondualistic worldview, Norton believes, the convergence hypothesis no longer will be necessary; indeed, it will "wither away for lack of polarized interests to be brought together" (Norton 2005, p. 510).

CORAL BLEACHING

Coral bleaching occurs when corals expel the symbiotic algae that live within them, giving the remaining live tissue a whitish or bleached appearance. Corals normally function as both animals and plants because they obtain energy in two ways: by breaking down organic molecules caught by the tentacles of the coral polyps and by means of photosynthesis in the symbiotic algae. Bleaching therefore significantly reduces the ability of a coral to obtain energy, and although corals can recover from a bleaching event, mortality of the entire colony may result if the bleaching is too extensive or persists for too long.

PHYSICAL CAUSES

The causes of bleaching are not always clear, and a number of factors may be involved. There is general agreement that high water temperatures usually result in bleaching, but other factors, such as bacteria and disease, have been implicated. This suggests that bleaching is caused by multiple stress factors. Corals can withstand a certain level of stress, but they expel their algae when the total of all stress factors passes a threshold level (which varies for different species). It seems counterintuitive that corals respond to stress by doing something that places additional stress on them by reducing their energy intake, but corals may still see the symbiotic algae as "foreign" tissue and reject the algae under conditions of severe strain.

Stresses interact in that a coral that is stressed by high temperature, for example, and expels its algae is weakened and therefore is less able to resist bacterial infection. This is why bleaching can have a devastating effect on a stressed reef, whereas an unstressed reef in pristine conditions can recover. In general, therefore, increased stress on corals leads to increased frequency of disease and mortality.

ANTHROPOGENIC CAUSES

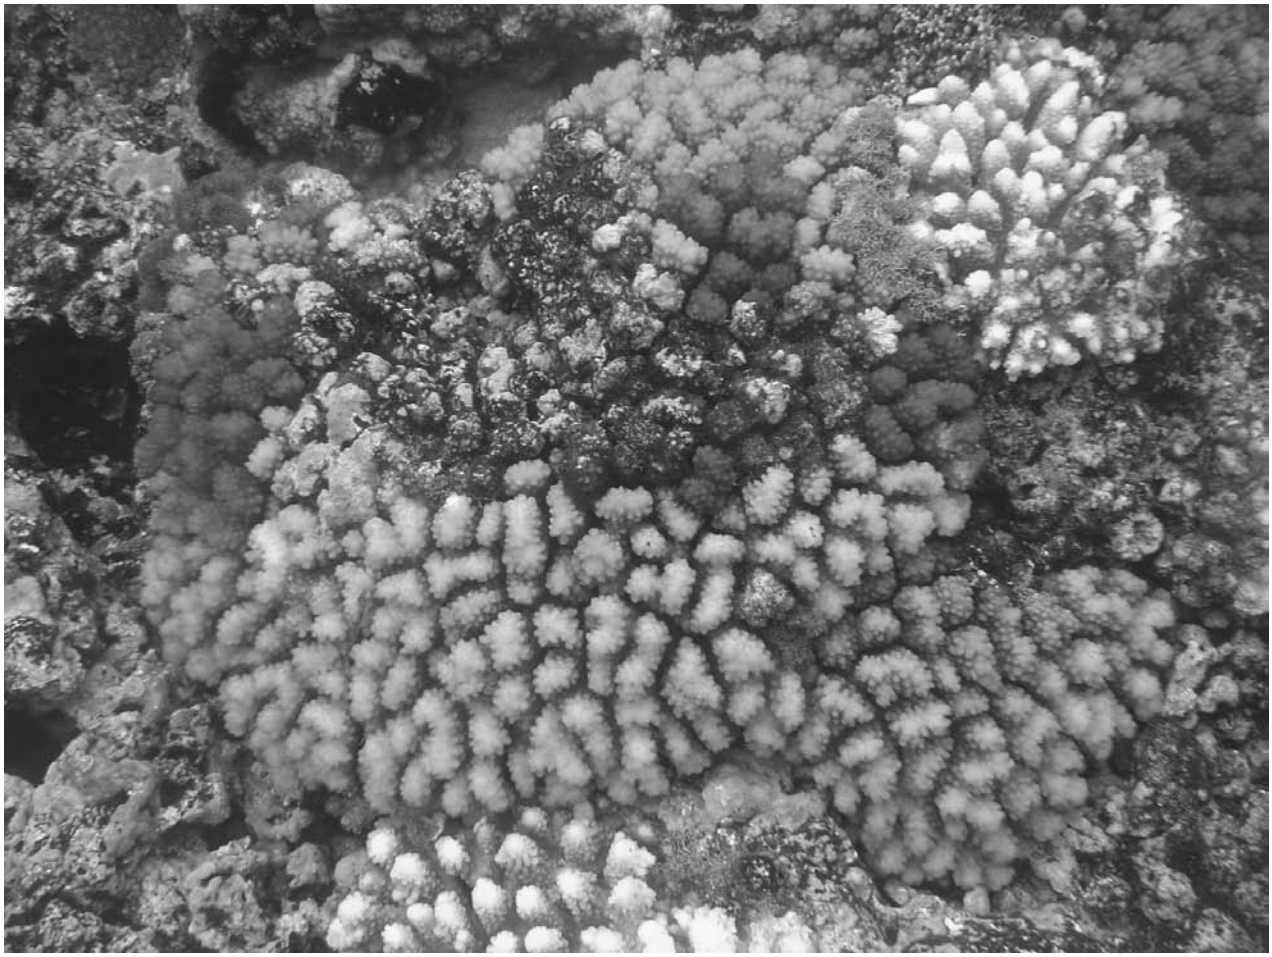
A number of anthropogenic features can increase the frequency and extent of bleaching events, including global climate change. The documented incremental increase in average daily temperatures has been relatively small so far; National Aeronautics and Space Administration (NASA) figures showed a mean increase of 0.6°C in global sea surface temperatures between 1976 and 2005. However, this small increase in the average temperature can be misleading because sea temperatures fluctuate. This means that a small increase in the average temperature can cause two serious problems: substantial increases in peak temperatures and increases in the total number of days on which temperatures exceed coral thermal tolerance levels. For shallow-water coral species in the Caribbean, for example, bleaching is common when water temperatures exceed 31°C. Thus the modest average increase in sea temperatures has resulted in a substantial increase in both the number and the extent of yearly bleaching events. Between 1979 and 1990 there were more than 60 recorded coral reef bleaching events out of a total of 105 coral mortality events, compared with just 3 recorded bleaching events out of a total of 63 coral mortality events over the previous 103 years. The warmest twelve-month sea temperatures on record occurred in 1998, a period that was associated with exceptionally severe coral bleaching.

However, the interrelationship between human influences and bleaching is complex, as local warming factors in one section of the globe can lead to disruption of the prevailing currents in another section, as occurs with the El Niño and La Niña periodic events. This can lead to increased cooling and less extensive bleaching at some localities in some years.

Another complicating factor is the fact that different coral species in different localities around the world are adapted to different temperature regimes. Coral species in the Persian/Arabian Gulf, for example, can tolerate temperatures over 31°C and seasonal temperature variations of over 9°C, but Caribbean and Indo-Pacific species subjected to a similar regime would experience extensive bleaching and high mortality rates. Similarly, shallow-water coral species are subjected to higher temperatures and greater temperature ranges than are their deeper-water counterparts, and some researchers have suggested that the shallow-water species are more resilient, either bleaching less or being more likely to recover from bleaching once it has occurred.

Thus the connection between anthropogenic climate change and coral bleaching is complex and not well established. However, there are strong grounds for thinking that it is an important cause of bleaching in regions such as the Caribbean.

More generally, it is clear that a range of human activities have led to a significant decline in coral reefs around the world. The most vulnerable reefs are usually those in shallow water close to human population centers.



Coral Bleaching in Guam, Mariana Islands. *One environmental cause known to increase the frequency and extent of coral bleaching is global climate change, although many factors are involved in the causal mechanisms. While coral can recover from a bleaching event, if it is severe enough bleaching can lead to the death of the entire coral colony.* **DAVID BURDICK/NATIONAL OCEANIC AND ATMOSPHERIC ADMINISTRATION/DEPARTMENT OF COMMERCE.**

These areas are typically under stress from many anthropogenic factors, such as the following:

- The discharge of nutrients in the form of human wastes and agricultural runoff into shallow coastal waters can result in the increased presence and growth of algal species, which then overgrow the coral reef. This algal cover prevents coral growth and settlement and in some cases can cause coral death by cutting off access to oxygen and sunlight.
- Overfishing can remove many of the species involved in the complex predator-prey dynamics of the reef. Overfishing primarily removes the large fish that are terminal predators in the food chain, leading to an increase in boring and encrusting organisms that compete with or kill corals.
- Pathogens can spread to different regions through the discharge of ballast waters from ships.
- Silt from eroding soils or construction work can flow down rivers into coastal waters, cover reefs, and kill them by cutting off their oxygen and sunlight.

These problems also interact. Increased pollution, for example, often leads to increased water turbidity as algal microorganisms proliferate at higher levels of phosphates and nitrates, decreasing sunlight and thus photosynthesis. A surge in algal growth normally supports an increase in herbivorous fish and other organisms that eat algae, but growing fishing pressure may remove too many of those organisms and prevent herbivorous fish populations from increasing. This allows the algae to spread unchecked. Increased sediment levels also can decrease photosynthesis and at the same time increase energy expenditure by the corals as they secrete extra mucus to rid themselves of the deposited sediment particles.

If a coral is subjected to a number of these pressures as well as to higher water temperatures than it can tolerate, it is unlikely to survive for long. As a result of these combined pressures, many inshore corals around the world have suffered extensive and sustained bleaching from which they have not been able to recover.

CONSEQUENCES AND POSSIBLE SOLUTIONS

The death of coral has a number of serious consequences, such as loss of biodiversity, including potentially valuable sources of new pharmaceuticals; collapse of fisheries; and loss of coastal protection. Some of the sources of stress—such as climate change—are difficult to remediate, but others—such as overfishing, sewage runoff, and ballast discharge—can be controlled. This might be sufficient to reduce the stress back to a tolerable level in many cases. Thus much of the damage could be prevented.

COST-BENEFIT ANALYSIS

Cost-benefit analysis (CBA) is a method of evaluating investments in public projects, programs, and policies. The analysis seeks to determine whether the initial costs of the investment will yield commensurate benefits later. The theoretical foundations and empirical methods of CBA are shaped by the ideas of publicness and investment. From publicness comes the concept of benefits as aggregate public willingness to pay (WTP; as opposed, say, to owners' profit), and from investment theory comes the notion of expressing the benefit and cost streams in present-value terms.

CONCEPTS OF COST AND BENEFIT: HISTORICAL ROOTS

In 1776 the Scottish moral philosopher and pioneering political economist Adam Smith (1723–1790) asked us to imagine a group of neighboring farmers: All could benefit from extending a canal into their district, but none acting alone would profit enough to bear the cost. Yet, if they all cooperated, the total benefits would exceed the cost. Furthermore, it should be possible to calculate a set of individual contributions that would cover the cost and allow every one of the farmers to profit from extending the canal. This idea was extended in the work of several nineteenth-century thinkers: The English utilitarian philosopher Jeremy Bentham (1748–1832) popularized the view that public virtue resides in whatever policy yields the greatest good for the greatest number; in 1844 the French civil engineer and economist Jules Dupuit (1804–1866) advanced the argument that the benefit of building a bridge was the sum of the users' willingness to pay. In the late nineteenth century the Italian sociologist, economist, and philosopher Vilfredo Pareto (1848–1923) argued that public action is justified if it benefits at least one person at the expense of none (actions that meet this test became known as Pareto-improvements). Around 1940 the Cambridge economist Nicholas Kaldor (1908–1986) and the Oxford economist John Hicks (1904–1989) independently offered a way around Pareto's demanding test: If the gainers from a proposed action could hypothetically compensate the losers, the action would constitute a potential Pareto-improvement (PPI). The PPI implements Bentham's criterion by aggregating individual benefits and costs, but with an important twist: Individuals will be the judges of the costs and benefits they (expect to) experience.

APPLICATION OF CBA: A BRIEF HISTORY

In the United States the Flood Control Act of 1937 enabled the allocation of federal funds to water-resources projects so long as the benefits conferred on the recipients exceeded the costs. Intentionally or otherwise, Congress thus unleashed a continuing process of developing and refining formal CBA procedures, punctuated by periodically updated principles and guidelines. By the early 1950s the World Bank, faced with the problem of making prudent investments in impoverished countries with premodern economies, began to incorporate modern CBA into the tradition of financial-feasibility analysis and thereby generated contributions to the professional literature and operational manuals for practitioners. About the same time U.S. water-resource agencies began looking toward recreational benefits to help justify additional projects, focusing attention on nonmarket valuation to estimate WTP that is not revealed in markets.

KEY CONCEPTS

Benefit: Benefits are the value of goods and services received. To get these goods and services, people are willing to pay as much but no more than the benefits. It follows that willingness to pay (WTP) is a measure of benefits.

Cost: Costs are the value of goods and services given-up or foregone. To induce people to give-up these goods and services voluntarily, they would need to be given acceptable compensation. It follows that willingness to accept compensation (WTA) is a measure of costs.

Present Value and Discounting: To induce commitment of capital now in expectation of benefits later, the acceptable net benefit must be at least as great as the amount of interest that could be earned by simply banking the money. In cost-benefit analysis, it is standard practice to systematically account for the value of capital committed over time by discounting future benefits and costs by the rate of interest, which reduces future costs and benefits to present value.

Laws requiring CBA remain the exception, but well-entrenched executive practice routinely considers benefits and costs for a considerable set of public activities in many countries. Many countries and international agencies have issued detailed manuals for conducting CBA in both general and specialized applications. Furthermore, public agencies often conduct CBA where it is not formally required, as part of the public process that attends controversial proposals. CBAs produced in academic institutions and research organizations are likely to have informal influence even when they have no formal standing in reaching a decision.

CONTEMPORARY CBA

By the 1970s the theory of welfare-change measurement (basically, utilitarian accounting consistent with modern microeconomic theory) was well established as the foundation of modern CBA. WTP for gains and WTA (willingness to accept) for losses have been recognized as the ideal measures of value in CBA; market prices, demand, and supply are also acceptable insofar as they reflect WTP and WTA accurately.

If value is not revealed directly in markets, it must be inferred from actual consumer decisions or from choices in hypothetical or contingent contexts. The travel-cost method estimates demand for outdoor recreation by inference from the time spent and costs incurred in accessing the recreation site. Because air quality is an attribute of houses and workplace safety is an attribute of jobs, hedonic price analysis (which decomposes the value of a product or service into the value contributed by its various attributes) estimates the marginal WTP for these amenities through econometric analysis (the application of statistical methods to economic problems and data) of housing and job markets, respectively. Contingent-choice experiments infer nonmarket amenity values from hypothetical choices among, say, vacation resorts with different features and costs. Contingent valuation uses survey or experimental methods to discover citizens' stated WTP for environmental amenities directly or by inference from their choices in hypothetical referenda. A large body of literature addresses theoretical and estimation issues with each of these methods and reports empirical results; meta-analyses (statistical analyses of findings from previous research) have proved useful in generalizing the findings of site- or project-specific studies. Nevertheless, nonmarket valuation remains challenging, and some controversies endure. For example, charges persist that contingent valuation fails various rationality tests despite the accumulating evidence that people's choices deviate systematically from expected rational choices in general, not just in matters of contingent choice.

Modern CBA seeks to conform to the theory of welfare-change measurement, but there is some hesitancy to embrace WTA fully, and some skepticism about nonmarket values. WTA, as the measure of losses, is susceptible to the holdout problem—one individual refusing even huge amounts of (hypothetical) compensation would, if taken literally, doom any public-goods proposal. Nonmarket values have equal standing with market values, other things being equal. But other things are not always equal—markets may be incomplete and misleading about value (where, for example, trade is impeded, or polluters can escape the costs of the damage they cause), and nonmarket value estimates may be based on evidence thought by some to be thin and controversial (experts under contract to the Exxon Corporation raised these kinds of charges in response to nonmarket estimates of economic damages from the *Exxon Valdez* oil spill).

ETHICAL FOUNDATIONS OF THE COST-BENEFIT CRITERION

Economists are likely to justify the cost-benefit (CB) criterion (acceptable projects are those that yield positive net present value) as a filter for inefficient public investment and as a defense against rent seeking (the promotion of proposed projects by prospective beneficiaries,

even when positive net benefits for society are unlikely). A better ethical justification for the CB criterion is possible: It evaluates proposed actions by offering a reasonably good accounting of their prospective contribution to the satisfaction of human preferences (Hubin 1994). This kind of account places a high value on the goodness of outcomes. It aggregates benefits and costs across gainers and losers anonymously (i.e., without consideration of who, and what sorts of people, stand to gain and lose), and it makes individual preferences the foundation of value (Randall 1999). So the CB criterion has coherent ethical foundations, even though they are controversial and have elicited objections from adherents of other ethical systems.

CB CONTROVERSIES

The CB criterion gives voice to human preferences for environmental goods and services that would likely be ignored or undervalued in ordinary accounts of private gains and losses. Yet it remains controversial from several standpoints.

Philosophical When applied to environmental issues, the CB criterion encounters objections from proponents of alternative ethical theories.

- *Preferences may be ill-considered and ephemeral, which would distort estimates of benefits (and costs, which are also subjective).* Decisions about environmental matters may commit society to long-lived outcomes (at worst, some natural asset, such as a forest, may be lost forever); some critics worry, therefore, that, because human preferences might be whimsical, ill-considered, and shaped by the past, they might travel poorly into the future. The sense that preferences are impermanent may lead to a quest for some more enduring foundation for value.
- *Value may involve more than preference*. The German philosopher Immanuel Kant (1724–1804) insisted that aesthetic judgments, although subjective, involve much more than mere personal preference—such judgments can make a claim to interpersonal agreement because they arise from good reasons and shared experiences. The view implies that certain natural entities have intrinsic value—a good of their own, independent of human concern.
- *The great moral questions should be addressed by principles, not values.* Kant also contended that universal moral principles could address the important decisions of human and social life, an argument that relegates mere preferences to a lower order of ethical significance. This perspective leads to a search for moral principles that imply human duties toward natural entities.
- *The great moral questions are best addressed in terms of rights that must be respected.* Rights-based theories of the good offer an array of positions. For example, contractarians (those who believe that moral standards derive their legitimacy from a social contract or common agreement) object to the PPI criterion, arguing that hypothetical compensation is a kind of hypothesis, not a kind of compensation. Libertarians might argue that people's rights to enjoy nature oblige other people not to befoul it.
- *It is not just about humans.* Standard economics assumes, along with many other strands of philosophy, that humans are the only entities whose concerns matter. This position has been attacked from many quarters: Some Utilitarians argue that animal welfare matters, some Kantian aesthetes ascribe intrinsic value to natural entities, and some rights-based deontologists (those who stress the inherent rightness or wrongness of actions rather than their consequences) contend that rights should be extended to natural entities.
- *Perhaps it is not about humans at all.* The basic program of deep ecology is to take any or all of the basic approaches of moral philosophy and expand the set of entities that matter—that is, entities whose welfare counts, that have a good of their own, and/or that have rights—independently of human concern or patronage.

Issues That Engage Economists The claim that CBA offers a reasonably good accounting of prospective welfare change invites this question: Even if this proposition is true, what are the caveats underlying the qualifier ''reasonably''?

- The PPI values and prices used in CBA, WTP, and WTA are consistent with the standard concepts of market value (buyer's best offer, seller's reservation price, and, ideally at the margin, market price). This consistency (imperfect as it may be) with market value has evidentiary value in cases where market observations are available and grounds the claim that the CB criterion is a filter for proposed actions that would increase the size of the game. Because individual WTP is constrained by the ability to pay, however, the preferences of the well-off count for more in CBA. Economists have considered various valuation frameworks that give added weight to contributions to basic needs or gains to the worst-off households, but in the end economists usually decide against such amendments and in favor of consistency with the PPI criterion.

- Issues of risky future outcomes are usually addressed in CBA by expressing costs and benefits in expected value terms, an approach that is appropriate when probabilities can be specified and the decision maker is risk-neutral. Uncertainty is usually addressed through option values, and risk aversion sometimes enters into the CB calculations. These accommodations to risk and uncertainty may be inadequate to deal with gross ignorance (a condition in which we are unable even to enumerate the possible outcomes) about the workings of environmental systems under increasing levels of stress from human activities; some economists are sympathetic to precautionary restraints invoked for threats beyond an appropriate threshold. Precautionary restraints may take the form of interruptions in the activities that stress the system (e.g., resource harvest, waste disposal, or introduction of new technologies with unknown consequences) to provide scope for the system to recover (as with a safe minimum standard of conservation) or allowing time for people to learn more about the dangers involved and the potential for mitigating harmful prospects (UNESCO 2005).
- Calculating net present values discounts future prospects and serves as a lightning rod for critics who interpret discounting as devaluing future welfare. Discounting does in fact devalue future prospects in the "cake-eating" case, which is all about determining the ideal rate at which to consume an endowment (e.g., a cake of given dimensions). However, a cake is a poor metaphor for a productive economy. It turns out that positive discount rates are necessary to maximize long-run welfare in a productive economy, because capital is productive and scarce. In the productive economy case, discounting does not devalue future welfare, so long as utility itself is not discounted.

Objections from Environmentalists

- Some environmentally concerned critics claim that CBA is an economic tool that is out of place in the environmental arena. This view seems to express an intuition that the economy (and economics) is the problem, not the solution.
- Environmentalists often object that CBA views everything in terms of its monetary value. But money is not the real issue. Money, after all, is just a convenient token of value in exchange. The real issue is that this monetary outlook assumes the economic fungibility of environmental entities: that they can be exchanged for, and substituted for, equivalents in ordinary goods and services, and that tradeoffs across these two categories are meaningful. The notion of fungibility is opposed by those who believe that tradeoffs between natural entities and ordinary goods and services are inappropriate, in general or in particular circumstances. Some environmental economists are sympathetic to arguments that some natural entities merit preservation for reasons that are independent of quantifiable costs and benefits.

Practical Concerns

- Some object that the claims for ethical foundations of ideal CBA are undermined when implementation diverges (perhaps systematically) from ideal welfare change measurement.
- Other critics worry that because CBA fosters the illusion of a science-based, empirical criterion for decision making, it may command more authority than it merits.
- It makes sense to treat these concerns as problems to guard against in particular applications—be on the watch for attempts to cut theoretical and methodological corners in CBA application, and appeals to the authority of CBA as a science-based decision tool—rather than problems endemic to CBA.

CBA IN PUBLIC LIFE, GOVERNMENT, AND THE COURTS

Some have argued that CBA, by focusing on tradeoffs in an environment of scarcity rather than on unyielding principles, serves a civilizing and democratizing role in public decision making (Sunstein 2004). CBA sometimes has been applied selectively as a barrier to rent seeking. Former President Jimmy Carter promoted rigorous CBA of water-resources project proposals in order to rein in the responsible agencies. His example was not lost on his successor, Ronald Reagan, who issued executive orders prescribing CBA of regulatory initiatives. But CBA does not always raise barriers to public action. Particularly in the nonmarket domain, CBA that attends to nonmarket evidence of WTP may well help justify public actions that might otherwise be thought well-meaning but impractical. For example, air quality standards often are shown by WTP to improve human health.

Where public debate, government, and the courts are responsive to CB evidence, CBA is susceptible to all the pitfalls of the politicization of science. When CBA is applied systematically to environmental issues, the theory and methods of nonmarket valuation may become targets of "junk science" charges. One strategy to tilt the playing field toward commercial interests is to insist upon a CB

filter while arguing that nonmarket valuation methods should be ruled out as evidentially inferior. The rigorous theoretical foundations and empirical methods of CBA provide the best defenses against these sorts of attacks.

CONCLUSION

Despite some persistent criticisms of the application of CBA to environmental issues, CBA based on the PPI can provide a more plausible account of value than its practicable utilitarian competitors; PPIs are at least correlated with the good of society (Hubin 1994). It makes sense, then, to take benefits and costs seriously in public life, perhaps even to the extent of using them as a basis for public decisions when there is nothing more important at stake. There are, however, clear limits to the applicability of CBA to public policy decisions: For example, CBA may be insufficiently alert to the value of unique environmental entities and/or the possibility of conservation crises arising from ignorance about the workings of environmental systems and the failure to foresee the consequences of various proposals. Such concerns can help policy makers to define both the potential and the limits of business-as-usual CB as a yardstick of the public good (Randall 1999).

CREATIONISM AND INTELLIGENT DESIGN

Creationism has a long and colorful history in America. Creationists often object to the perceived moral and theological implications of Darwinian theory of evolution. For some, morality is undermined by the idea that humans are evolved from other species, rather than having been specially created in God's image (Genesis 1), as it implies that humans are morally no different from (other) animals. Christian theology sees humans as sinful and fallen from a more perfect state, and the remedy for this fallen state lies in God's saving grace and the sacrifice of Jesus to redeem human sin. If science contradicts the Genesis account of the special creation and fall of humans, then divine sacrifice and the promise of redemption may also be called into question. Evolutionary accounts of human origins thus appear to threaten cherished sacred history and views of human destiny. Accordingly, creationists past and present have charged Darwinian theory with eroding personal morality and promoting a host of social ills.

THE SCIENTIFIC CREATIONISTS

Creationists who believe that a literal reading of Genesis must be maintained to preserve faith and morality have devised various ways of reconciling Genesis with observations of the natural world. One important belief among creationists concerns their view of the earth's age. In post-Darwin America, the first wave of creationists generally accepted the conventional geological account of an earth billions of years old but rejected the idea that the earth is the product of undirected natural processes. Even William Jennings Bryan, known for his 1920s crusade to ban evolution from public schools, believed the earth to be older than do many early-twenty-first-century "scientific creationists." One approach of old-earth creationists is the day-age theory, which interprets the six days of the Genesis account as corresponding to vast stretches of geological time, rather than twenty-four-hour periods. Gap theorists too accept the antiquity of the earth, but posit a gap of geological time between the first two verses of Genesis—that is, between the original creation "in the beginning," which occurred many eons ago, and much more recent creation, including the creation of Adam and Eve, which occurred within six days. Some gap theorists hold that geological formations were produced during that first phase, a time of serial cataclysms and creations that preceded the supernatural creation of humans.

Young-earth creationists estimate the age of the earth as between six and ten thousand years. Flood geologists, a subset of the young-earth contingent, maintain that life recently appeared on the earth and attribute existing geological formations to Noah's flood. In *The New Geology* (1923), George McCready Price, an early advocate of this view, argued that the Noachian deluge is the central explanatory event in a scientific reading of Genesis. John C. Whitcomb and Henry M. Morris revived and popularized Price's theory in *The Genesis Flood* (1961), abandoning gap and day-age theories. Though their "scientific creationism" downplayed Biblical references, it made radical claims about the brief history of life on earth.

After this book was published, Morris and other young-earth creationists formed the Creation Research Society and eventually set up the Institute for Creation Research in San Diego. Unlike earlier creationists, many members of the Creation Research Society had advanced degrees in science and engineering. Scientific creationists present their theory as a viable alternative to evolution, deserving equal time in biology classrooms. Simultaneously, they attempt to discredit evolutionary theory by pointing to apparent gaps in the fossil record and lack of transitional forms, and by recasting natural selection as unproven theory rather than fact, although nobody denies that evolutionary theory is in fact a theory. Many creationists hold that only a fixed number of kinds were created (by God), and believe that while there is no problem in maintaining microevolution, for example, genetic modifications within a species, larger-scale macroevolution does not occur.

Many creationists are concerned that evolutionary theory undermines morality, but in fact the emergence of environmental and animal ethics owes much to the recognition of all life forms as biological kin worthy of our moral consideration. Creationists who reject evolutionary kinship might nevertheless construct an environmental ethic based on Biblical sources, as some evangelicals active in environmentalism have done. Firm belief in the world as God's creation may promote care and respect for the environment. Biblical concepts of a Sabbath for the land, Biblical injunctions governing humane treatment of animals, and Noah's preservation of species during the flood provide just a few examples of an environmentalism based on the Bible. Nevertheless, creationists' complete rejection of evolution raises problems for environmental ethics. For example, environmentalists often seek to protect not only species but also natural processes like speciation, which some creationists deny. Interpretations such as Whitcomb and Morris's also assume that prior to the fall, death and predatory strife among animals did not occur. The conviction that death and carnivory are part of God's curse for Adam and Eve makes it difficult to positively value natural processes that are integral to nature's functioning. It is also questionable whether an interpretation of the Bible that lays such heavy stress on the special creation of humans in God's image can support a nonanthropocentric assessment of nature's value.

T-Rex Model at Dinosaur World, in Cave City, Kentucky. *While Darwin's Theory of Evolution holds that humans evolved from other species, creationists refute this claim, believing instead that God made man in His image. According to some "Young-earth" creationists, the world is only between six and ten thousand years old, whereas scientists estimate that dinosaurs were present on earth between approximately 250 and 65 million years ago.* **AP IMAGES.**

INTELLIGENT DESIGN

While scientific creationists have continued their efforts unabated into the twenty-first century, a new form of creationism, intelligent design, began garnering attention in the 1990s. Intelligent design is a revised and updated form of arguments from design. Proponents claim empirical evidence for intelligent agency, but most do not explicitly identify this agency with the God of Christianity, nor even necessarily with a benevolent deity. In general, intelligent design eschews ties with creationism. Its advocates make no attempt to reconcile natural science with interpretations of Genesis, literal or otherwise, and they accept some core ideas of evolutionary theory, including the antiquity of the earth and the development of life from a common ancestor. Like creationism, however, intelligent design casts doubt on evolution by claiming that it is conjectural rather than a well-confirmed, settled theory. They create the impression that evolution is a contested and incomplete theory in the scientific community. They contest details of the theory of evolution—for example, continuous gradual change or rapid change followed by relative stability (punctuated equilibrium)—but the general theory remains uncontested and well confirmed. Proponents of intelligent design also express ethical misgivings about the worldview promoted by modern Darwinism, though in ways different from traditional creationists.

Intelligent design arose in part as a reaction to the alleged atheistic, materialistic naturalism of neo-Darwinian theory (that is, the modern synthesis of Darwin's theory with Mendelian genetics). The origins of intelligent design can be traced to a 1984 work titled *The Mystery of Life's*

Origin, by Charles B. Thaxton, Walter L. Bradley, and Roger L. Olsen. The authors claimed that the complex origin of life on earth pointed to a divine Creator. This was followed in 1986 by Michael Denton's *Evolution: A Theory in Crisis*, in which the author insisted on the evidence for divine design and the inadequacy of the neo-Darwinian paradigm. Yet the first intelligent-design-inspired book to make a noticeable impact was a supplement to high-school-biology textbooks titled *Of Pandas and People: The Central Question of Biological Origins* (1989), by Dean H. Kenyon and Percival Davis. It presented case studies and guided students toward the conclusion that intelligent design, rather than evolutionary theory, provided the better explanation. In the early 1990s Phillip E. Johnson, a law professor at the University of California, took up the cause of intelligent design and mounted an attack on naturalism. In works such as *Darwin on Trial* (1991), Johnson claimed that naturalism in science—the practice of excluding explanatory references to divine action—is no neutral methodology, but rather an unwarranted, dogmatic bias against theistic forms of explanation.

In 1996 Michael Behe, a Catholic biochemist at Lehigh University, published *Darwin's Black Box*. Behe argued that structures such as the cell confront biologists with a degree of complexity that remains inexplicable in Darwinian terms. Intelligent design, he maintained, was clearly at work, because complex, functional systems could not arise in a gradual, stepwise fashion. Behe labeled his challenge "irreducible complexity." Another prominent supporter of intelligent design is the mathematician and philosopher William Dembski, who, in *The Design Inference* (1998), argued for what he termed specified complexity. Invoking probability theory, Dembski maintained that it is implausible for certain structures to arise by any means other than design. Dembski also decried the ascendancy of ideological, atheistic naturalism, arguing that the concept of design has a rightful place in a scientist's explanatory toolbox.

A key strategy of intelligent design is its appeal to the values of a democratic, pluralistic society, such as tolerance for differing viewpoints and free and critical inquiry in education. Purveyors of intelligent design urge educators to teach the controversy: to present the available evidence and alternative theories and allow students to decide for themselves. Reasonable as it sounds, critics object that this approach falsely encourages students to perceive a controversy in biology where none exists. Nevertheless, this tactic, combined with arguments for redefining scientific method, proved successful in some school districts, particularly in Kansas in the late 1990s. The political struggles came to a head in Dover, Pennsylvania, following a school board decision instructing teachers to read a statement to their classes characterizing evolution as "theory, not fact." A highly publicized trial ensued and on December 20, 2005, Judge John E. Jones III ruled that intelligent design failed to qualify as science because it relied on supernatural causation. This was a significant blow to intelligent design, but proponents continue their struggle.

Although intelligent design is not obviously linked to environmental ethics, some forms of environmental thought bear a resemblance to intelligent design. The convergence results from a shared distaste for the perceived excesses of materialism in neo-Darwinism and in modern science generally. Like advocates of intelligent design, some environmental philosophers, ecotheologians, and ecofeminists promote a more active and creative view of matter than modern, gene-centered biology seems to allow. They criticize the mechanistic worldview that permeates scientific investigation and perpetuates harmful attitudes toward nonhumans. These environmentalists join advocates of intelligent design in lamenting the materialist commitments of science and its reduction of all natural phenomena to valueless material components. Like intelligent-design advocates, they discern such biases particularly in the polemical neo-Darwinism popularized by Richard Dawkins (*The Blind Watchmaker*, 1986; *The God Delusion*, 2006) and Daniel Dennett (*Darwin's Dangerous Idea*, 1995). But while they share intelligent-design advocates' distaste for the mechanistic paradigm and for evolutionary ideologues like Dawkins, few environmental thinkers make the stronger claim that the boundaries of science should be reconfigured to allow a place for supernatural causation.

Some environmental thinkers occupy a middle ground between the twin dogmas of intelligent design and atheistic evolutionism, advocating theistic forms of evolution that confer great value to nature without claiming empirical evidence for a designer. On the whole, environmental philosophers have been somewhat more successful than ecotheologians in presenting environmental ethics from a Darwinian standpoint. Controversies surrounding creationism and intelligent design serve as a reminder that while embracing evolution remains difficult for many Christians, it is necessary for religious environmentalists who hope to engage in dialogue with scientists and influence the public.

DAMS

A dam is an artificial structure that impounds stream flow to yield diverse benefits. The oldest dams in North America are prehistoric. Natural twig and branch constructs engineered by beavers can reach up to 850 meters wide and can wreak considerable ecological disturbance. However, for economic, ethical, and philosophical purposes this entry deals only with human-built dams, from a six-foot-high farm pond to the Three Gorges Dam in China.

HISTORICAL BACKGROUND

Dams are not a new technology. Water storage dams in Jordan, Egypt, and other parts of the Middle East were built 5,000 years ago. Long before the Columbus's voyages to the New World, Native Americans diverted rivers with small dams to irrigate arid land crops in the Southwest; other tribes built temporary dams to channel fish into traps. However, as the social structure of the country became larger, more permanent, more politically centralized, and more economically complex, so did the dams on which Americans depended.

HISTORY AND NUMBERS OF U.S. DAMS

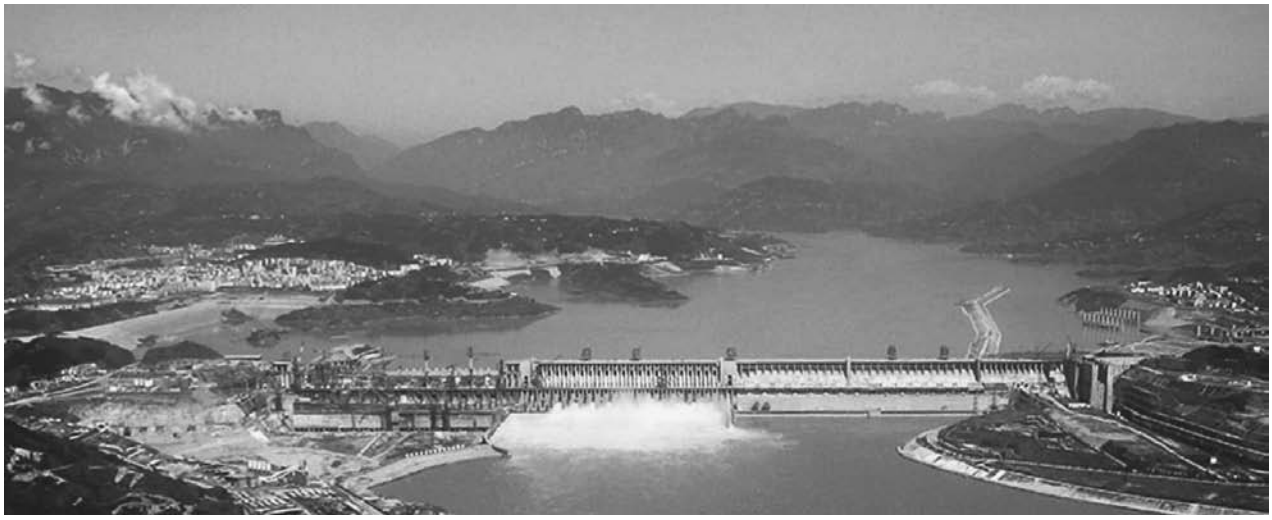
In early U.S. history dams became political and economic cornerstones. Hundreds of dams turned water mills or allowed barge transport. Thousands soon absorbed flood surges, diverted water for irrigation, and provided water for livestock. Later, tens of thousands generated electrical power, cooled industry, stored drinking water for cities, and provided recreation. Today virtually every river in the 48 contiguous states has been dammed, diked, diverted, or dewatered by human intervention.

The number of American dams varies widely according to size, scope and classifying institution. The Natural Resources Conservation Service estimated in 1977 that there were over 2.5 million small dams. The National Inventory of Dams lists 78,747 structures so large that they require federal hazard safety oversight. Some 99,000 dams are regulated by states and listed in the U.S. Fish & Wildlife Service Database. The Federal Energy Regulatory Commission licenses and exempts roughly 2,500 hydropower dams to private and public utility owners. No one knows how many dams there are in the United States.

ECONOMICS AND PURPOSES

Every dam arose as an economic creation. A new dam is born when public bondholders, taxpayers, or private investors are persuaded that the potential goods and services will outweigh the immediate costs of investment significantly. Initially most dams fulfill those expectations. As productive architecture, dams embody human values; they reflect human ethics set in stone, wood, debris, earth fill, and cement. Some embrace the collective philosophy of a country, whether nation building or the conquest of nature. Large engineering feats such as Hoover Dam—a smooth concave wall consisting of 66 million tons of concrete and rising 726 feet high, backing up 9 trillion gallons of Colorado River water into a 115-mile-long reservoir—are regarded as heroic works and national monuments.

North America built 13 percent of its largest dams for flood control, 11 percent for irrigation, 10 percent for



Three Gorges Dam, Yichang, China. *Spanning 1.2 miles and standing 600 feet about normal river level, environmentalists criticize the Three Gorges Dam on the grounds that it will reduce fish stocks, eliminate 78,000 acres (32,000 ha) of important agricultural lands, and threaten habitats of critically endangered species.* **AP IMAGES.**

water supply, 11 percent for hydropower, 24 percent for another single purpose such as recreation or navigation, and 30 percent for a mix of these purposes. Contemporary dams are built primarily for domestic water storage and, to a very small extent, hydropower.

Abstract figures shape people's evolving perception far less than do the cumulative, qualitative impacts of dams. All dams began as productive "liquid assets," but time and change have transformed the types, extents, and perceptions of dam benefits until eventually some dams have come to be regarded as fixed liabilities, environmental travesties, and even public nuisances.

ETHICAL ISSUES

Three interwoven forces drive ethical changes in regard to dams: growing risk, changing economics, and shifting social values. First, all dams are mortal; their days are numbered. As they stop stream flow, dams trap much more than water. River silt or sediment annually accumulates behind walls at average rates of 0.5 percent to 1 percent of storage capacity and sometimes much more. As it becomes shallow and warm, more water evaporates under rising heat, and the water that remains often blooms with algae and deteriorates in quality until eventually no impoundment remains. Wear and tear also takes a toll on dam structures, sometimes exacerbated by climate changes. By the middle of the twenty-first century 85 percent of U.S. dams will have surpassed what engineers consider their average 50-year life span. The American Society of Civil Engineers currently gave U.S. dams a grade of D because they put lives, property, and the environment at risk.

Second, as static dams age in place, the surrounding human demographics and economics grow more dynamic, diverse, and complex. Old mills became shopping malls; transport canals became freeways; farms became subdivisions; fly-fishing and rafting replace flat water recreation. Tribal groups have gained economic clout and political influence. As the social economy has evolved, dams that cannot adapt become anachronistic remnants. Some historical societies seek to preserve them as a record of days gone by, but upkeep to meet safety and ecological standards grows increasingly expensive. In the United States the backlog of projected expenses to bring dam infrastructure into safety compliance is from $10 to $36 billion. That price tag leads some 12 percent of "indeterminate owners" to abandon even more "deadbeat dams." However, neglect is equally costly. From the Civil War to the present, dam failures have caused extensive damage to river ecosystems, destroyed billions of dollars in property, and killed over 5,128 people.

Third, that's when social values change. Economic surplus and leisure allow an honest assessment not only of the obvious benefits of dams but of their less noticed substantial social costs and ecological losses. Peer-reviewed studies have documented how over the twentieth century large dams uprooted whole populations, displacing 40 million to 80 million people worldwide. Though the United States was less densely populated, federal dams on the Columbia River extinguished the oldest continuous civilization on the continent when they drowned the 10,000-year-old salmon fishery at Celilo Falls.

Even small dams disrupted the natural cycles of flooding and fish passage, sediment transport, riparian vegetation, and

channel shape. In fact, small dams and culvert crossings are responsible for the vast majority of habitat fragmentation in river systems. Upstream, dams cause algal blooms, raise water temperature, accumulate pollutants, submerge and smother streambed habitat, and trap nutrients and sediment. Downstream, dams alter the dissolved oxygen, biological stability, and chemical integrity of "natural" water and can result in severely degraded riverbeds. As a result of the accumulated impacts of dams, a third of American aquatic biodiversity has become endangered.

In comparison to climate change, dirty coal, and escalating oil prices, dam energy seems clean. However, fewer than 2 percent of U.S. dams produce power. While some contest the findings, all existing peer-reviewed scientific research has demonstrated how dam reservoirs trap rotting vegetation from the entire watershed, trapped in upstream water until released by dam gates emitting methane, a potent greenhouse gas. The National Institute for Space Research in Brazil calculated that the 52,000 large dams (typically 50 feet or higher) worldwide contribute more than 4 percent of the total warming impact of human activities. These dam reservoirs contribute 25 percent of human-caused methane emissions, the largest single source.

POLITICAL CONFLICT

People's philosophical values in regard to dams may shift incrementally and peacefully over the course of a century or switch overnight. This can lead to aggressive political conflict with angry protests mounting before the first concrete can be poured.

Widespread ethical confrontations over the impact of dams on wild places and wild rivers date back to the first dams. Indeed, dams may be the founding cornerstone not just for raising the American civilization but for giving birth to American civil disobedience. Henry David Thoreau was famous for remarks such as "that government is best which governs least" and "in wildness is the preservation of the world," but first he was a critic of the consequences of enslaving wild rivers. While paddling with his brother for *A Week on the Concord and Merrimack Rivers* in 1839, Thoreau lamented, on Saturday the disappearance of formerly abundant salmon, shad, and alewives. Those species had vanished because "the dam, and afterward the canal at Billerica . . . put an end to their migrations hitherward." His elegy read like an Earth First! manifesto: "Poor shad! where is thy redress? . . . armed only with innocence and a *just cause.* . . . I for one am with thee, and who knows what may avail a crow-bar against that Billerica dam?" (1961 [1849], p. 39). Thoreau restrained himself from vigilante dam busting, but he sowed the seeds of activism and resistance that would grow over the years as dam impacts multiplied in number and size.

The highest-profile American showdown pitted John Muir against Theodore Roosevelt and Gifford Pinchot in a fierce political crusade. O'Shaughnessy Dam was designed to fill Hetch Hetchy, Yosemite Valley's national park twin, to provide water and power for San Francisco. Muir's loss, his drowned "cathedral" and martyrdom, gave rise to the powerful Sierra Club.

The first incidence of American domestic terrorism may have occurred when California farmers blew up dam infrastructure that diverted water from the Owens River away from their valley to Los Angeles. A few decades later fishers in Idaho blew up a dam that blocked salmon migration.

Muir's post-World War II successors, David Brower foremost among them, opposed dams in the Grand Canyon. Preserving Dinosaur Canyon intact but sacrificing Glen Canyon was a trade-off that Brower regretted to his dying day. During the 1960s and 1970s dam opposition grew more assertive; in acts of civil disobedience activists handcuffed themselves to boulders in Sierra Nevada rivers so that they would be drowned if dam reservoirs filled. Edward Abbey's fictional *Monkey Wrench Gang* (1975) planned to blow up Glen Canyon Dam through "eco-tage," a nonviolent but disruptive tactic later embraced by radical groups. Among the first tests of the Endangered Species Act was a political eruption over construction of the Tennessee Valley Authority's Tellico Dam. Economic studies triggered by a Supreme Court injunction based on threats to the endangered snail darter fish demonstrated the economic dysfunctions of the dam, though the public works lobbies ultimately pushed the dam to completion.

Internationally, dams have been opposed less for ecological or scenic reasons than for their impact on human rights. Medha Patkar and her group Save the Narmada have borrowed passive resistance techniques from Thoreau and Mahatma Gandhi to oppose dams that would destroy hundreds of thousands of homes and livelihoods. The Internet has linked formerly isolated, muted, and marginalized antidam groups into a coordinated, vociferous, and formidable opposition. Private and public backers of dams such as Three Gorges have been boycotted, and protests have forced them to amend the terms of financing and compensation for the social and environmental mitigation for 1.3 million people who were displaced.

In developed countries, there have been fewer protests against raising new dams than against razing old ones. From 1994 to 2000, Democratic Interior Secretary Bruce Babbitt led a nationwide campaign to remove obsolete dams; over the next three years his Republican successor, Gale Norton, removed twice as many in half the time. From the Klamath River in California to the Snake River in Idaho, protesters once waved placards,

shouting "Save our rivers!" and "Save our salmon!" However, reservoirs have their own special interest support groups, motivated by cheap electricity and barge traffic, fishing for alien catfish and carp, or simply a strong sense of nostalgia, leading to protests from Glen Canyon to Maine to North Carolina to the Pacific Northwest at which protesters have shouted, "Save our dams!"

DAOISM

In her popular 1988 book, *Sacred Land, Sacred Sex–Rapture of the Deep*, the environmental thinker Doris LaChapelle announced that a "'new idea' for saving the planet" had already been discovered by Daoist thinkers in China two millennia ago. All that is now needed, therefore, is to "follow … the Way of Lao Tzu and Chuang Tzu" (cited in Miller 2003, p. 139). Her announcement illustrated the widely shared conviction of that time that among all Asian traditions, Daoism has the most to contribute to environmental thought. Despite skeptical responses such as those of Holmes Rolston (1987) and David E. Cooper (1994), this conviction persists in some circles. Among informed scholars of Daoism, however, something of a consensus was emerging by the beginning of the twenty-first century. Although Daoism displays an "ecological sensitivity" that "exerts a positive influence" on environmental attitudes (Miller 1998), its potential contribution does not consist in an important new idea and it is not one that is easy to integrate with the main tendencies of Western environmental philosophy.

After a brief review of the origins and development of Daoism and some of its central concepts, this entry discusses the character of the possible contribution of Daoism to environmental ethics and policy.

[In the remainder of this article, the newer Pinyin system of romanizing Chinese terms is used, but the older Wade-Giles spellings of especially important names and words are given in parentheses.]

ORIGINS AND DEVELOPMENT

The Chinese term translated as Daoism (or Taoism) was coined around 100 BCE to refer to a style of thought preeminently found in two texts compiled at least two hundred years earlier, during the so-called Period of the Warring States. Those two classic texts are the *Daode jing* (*Tao Te Ching* [The book of the way and its power]) and the *Zhuangzi* (*Chuang Tzu* [The book of Master Zhuang]). According to tradition, the first text was written by Laozi (Lao Tzu, or "Old Master"), a sixth-century BCE contemporary of Confucius, and the second by a minor official from Honan during the fourth century BCE. Modern scholarship, however, favors the view that the earliest of those works was the first seven ("inner") chapters of the *Zhuangzi,* written by Master Zhuang himself, with the remainder of that book and the whole of the *Daode jing* being later compilations by followers of Zhuangzi. Much of Zhuangzi's critical irony is directed against the Confucians, and the *Daode jing* probably was ascribed to Laozi because that was the title given to a man in one of the Confucian classics to whom Confucius seems to defer.

Both Daoist classics invoke the idea of a "nameless" Dao (or Way) that is the ground or "mother" of everything and whose essential nature human beings should emulate. In the *Daode jing* the main focus is on how in times of war the ruler of a state might govern effectively by following the Way. The *Zhuangzi* is concerned more generally with life led "in the Way."

During the second century CE there emerged the first of several organized religious "Ways" that have since been labeled "religious Daoism," partly because of their invocation of Laozi, who by that time was held to be divine and immortal. The primary concern of religious Daoism—the main indigenous religious tradition of China—has been with the ritual and "biospiritual" endeavor to achieve longevity, even immortality, by "purifying" bodily energy to an extremely refined, subtle form.

The relationship between the philosophical Daoism of the classic texts and the later religious tradition remains in dispute. The older view of many Western

Ma Yuan,* Scholar Viewing a Waterfall*, late 12th–early 13th century. *Flowing water is the most common of the many Daoist metaphors, taken from the natural world, for the effortless process of the dao. The Dao ideal of "wuwei" seems to be the basis for the religion's connection to ecological sensitivity. This involves living a simple life free from the ambitions that may contribute to environmental degradation, and respecting the perspectives of other living beings by simply letting them be.*

scholars—that religious Daoism was a superstitious perversion of authentic Daoism—has given way to a more nuanced perception. Although the classics do not anticipate the alchemical and "magical" interests of Daoist religious adepts, they convey a spiritual outlook on human life. At the same time, the huge corpus of Daoist religious texts contains, alongside the magic, some interesting elaborations on the cosmology that is only hinted at in the two classics. It would be limiting in the context of environmental debate to ignore religious Daoism in light of the growing perception that, in Jordan Paper's words, it "offers the most useful possibilities for saving the planet" (Paper 2001, p. 15).

Like other ancient philosophies and religions, Daoism was persecuted—its temples destroyed and its priests murdered—during Mao Zedong's Cultural Revolution.

Since 1980, however, Daoist religious institutions have been reestablished in China, and the popularity of Daoism has grown abroad. In the United States organizations such as Orthodox Daoism of America have stimulated interest in a religion some of whose associated practices, such as Tai Chi and feng shui, also have been attractive to Western audiences.

DAO, *DE*, AND *WUWEI*

In Confucian texts the term *Dao* generally referred to the ways human beings should follow to prosper and live harmoniously. In the Daoist texts, however, the term refers primarily to something wider and more nebulous: the "complete, universal, all-inclusive" (*Zhuangzi*,Chap. 22), the "beginning of heaven and earth," and "the mother of the world" (*Daode jing*, Chaps. 1 and 25).

These gnomic remarks have been interpreted in different ways. For some, the Dao is an entirely naturalistic concept: the general order of nature or the combined laws of nature. However, this is hard to reconcile with the insistence that the Dao is ineffable, that, as the opening sentence of the *Daode jing* puts it, "The Way that can be spoken of is not the constant Way." The perception that the Dao is "mysterious" has encouraged some to construe it as a transcendent power akin to the creator god of monotheistic religions. However, this reading is difficult to square with what Roger T. Ames (1989, p. 134) calls "the mutual dependence of *dao* and *de,*" that is, the doctrine that although the Dao is somehow responsible for the existence of things, it has no being in isolation from those things and their "powers" (*de*).

The Dao is best thought of perhaps as a "matrix" that enables the emergence of things without being disjoined from them, rather as a language might be thought of as a matrix that enables the generation of words that become parts of itself. This analogy with language would help explain a salient feature of Daoism: its *holism*. Just as a language is not a collection of separate words (words have meaning only in relation to one another and to the language as a whole), so it is an error, according to the *Zhuangzi,* to become rigidly fixated on the distinctions that humans, for pragmatic reasons, draw between separate things.

This holistic emphasis both reflects and inspires an ideal of harmony (*he*). According to one scripture, where there is "Central Harmony . . . the thousand things will flourish [and] people will live harmoniously" (cited in Lai 2001, p. 102). Harmony will prevail, it is held, if beings act in accordance with the Dao, but this is something that certain beings—namely, humans—typically fail to do. For this reason, Laozi laments, the Way largely has been "lost," and the great task for human beings is to rediscover it.

In Daoist religious practice, various techniques—ritualistic, bodily, meditative—are employed in this "human mission to preserve, protect, and circulate harmonious communication between the realms of cosmos and humanity" (Lai 2001, p. 104). In the ancient classics, however, the primary strategy is *wuwei*, variously translated as "nonaction," "doing nothing," and "noncontending action." *Wuwei* is the form of human conduct that emulates the Way, for "The Way never acts, yet nothing is left undone" (*Daode jing,* Chap. 37). The examples given include Laozi's "lords and princes" who barely intervene in their subjects' affairs and Zhuangzi's craftsmen whose "know-how" enables them to dispense with deliberation and effort.

Wuwei cannot literally mean doing nothing, and it is not simply "cost-effective" action that uses minimal effort to get maximum results. As A. C. Graham (1981) proposes, *wuwei* is behavior that is optimally responsive to situations as they are and therefore is not dictated by inflexible preconceptions, desires, or rules. It is spontaneous behavior not in the sense of being impulsive but in the sense of being supple, of "going with the flow." The Dao, which achieves everything, often is likened to water, which by never contending succeeds in bypassing obstacles and reaching its natural level. Similarly, the responsive, supple strategy of *wuwei* enables human beings to achieve their ends and live harmoniously and naturally.

DAOISM AND ECOLOGY

Some ancient Daoist texts exhibit a concern for the treatment of nonhuman life and nature. Passages in the *Zhuangzi* criticize inappropriate treatment of wild animals, and several of the *One Hundred and Eighty Precepts* (c. third century CE) prescribe environmental protection. One example is "You shall not wantonly fell trees" (Schipper 2001).

What is less apparent is the basis for such concerns. One should not foist upon Daoism the notion that nature has rights that it is people's duty to honor. As the *Daode jing* advises, such moralistic-cum-legalistic talk is a sign that the Dao has "fallen into disuse," so that people should "discard rectitude" and "principles" if they are to recapture spontaneity (Chaps. 18 and 19). Nor should Daoism be credited with a "biocentric egalitarianism" that assigns equal value to all life. Although the *Zhuangzi* (Chap. 17) holds that "in the light of the Dao . . . no one thing stands out as better," the point is not that fish, flowers, and people have equal value but that only in relation to human schemes of evaluation does the idea of having value make sense.

Perhaps it is in the holistic conception of "harmonious communication . . . between cosmos and humanity"

that Daoist ecological sensitivity is located. However, it is in rituals and biospiritual disciplines of self-cultivation, not in relations with the environment, that Daoist religious practice has sought the means of such communication. (The point of the precept against tree felling seems to have been to protect the purity of particular sacred sites.) Also, this harmonious communication is too embedded in a complex cosmology—*qi* ("breath of life"), the polar forces of *yin* and *yang,* the "astral translucence of the body," and so on—to be appropriated by people outside of this cosmological tradition. When extracted from the tradition, harmonious communication between cosmos and humanity becomes a slogan for ecologically responsible behavior rather than a basis for it. However, religious rhetoric concerning the integrated and responsible position of humans within the cosmos may serve to promote ecological awareness.

Arguably, it is less to cosmology than to the ideal of *wuwei* that one should turn for a Daoist contribution to environmental ethics. Two features of *wuwei* are especially relevant in this context. First, to become spontaneous and responsive, a person must "have little thought of self and as few desires as possible" (*Daode jing,* Chap. 19). Fixation on one's own ends is the main obstacle to fluent living; hence, the life of a Daoist sage will be simple and undemanding, free from the acquisitive ambitions that are responsible for environmental exploitation. Second, *wuwei* entails freedom from the rigid and partial perspectives that shape conventional judgments. When *Zhuangzi* (Chap. 3) tells of the bird that prefers to struggle for its food than to live well fed in a cage, his point is that one should heed a creature's own idea of what is good for it. One should be responsive to the good of animals and other living things as it appears to them, respecting their perspectives and letting them be what they are.

The ecological sensitivity of the Daoist is that of someone whose awareness of the world is determined neither by selfish desires nor by a particular conceptual grid. Instead, that person is able to appreciate and respond to things on their own terms.

ENVIRONMENTAL ACTION

Although Daoist ecological sensitivity is benign, it is unlikely to translate into dramatic interventions to save the planet. The posture of *wuwei* is unsympathetic to the evangelism characteristic of environmental activism at the turn of the twenty-first century. There is a Daoist reluctance, moreover, to accept the idea that an environmental catastrophe is occurring. "I see no crisis," wrote the founder of Orthodox Daoism of America (cited in Girardot, Miller, and Xiaogan 2001, p. 379). This is the case because it is only from the vantage point of human or other creaturely interests—not of the Dao itself—that it makes sense to judge that the world is in bad shape. Also, if the Dao is the mother of everything, including the current state of the planet, that state is just one more stage in an evolutionary and patterned process that cannot be lamented.

When looking for a metaphor to characterize Daoist comportment in regard to the natural environment, several writers draw on an activity that has always formed an important part of Daoist culture: gardening. As James Miller (2003, p. 46) puts it, Daoists are "the gardeners of the cosmos." This is perceptive, for it is in responsible gardening that heeds the good of plants and animals that one finds an appropriate vehicle for those virtues of restraint, impartiality, and humility that are integral to the way of *wuwei*.

DARWIN, CHARLES
1809–1882

Charles Robert Darwin was born in Shrewsbury, Shropshire, England, on February 12, 1809, and died in Kent, England, on April 19, 1882. He was the grandson of the noted physician and naturalist Erasmus Darwin and the famous potter Josiah Wedgwood. Educated at the University of Edinburgh and Cambridge University, Darwin, upon graduation, was invited by his mentor John Henslow to become the naturalist on the survey voyage of Captain Robert Fitzroy's ship the *Beagle*. It was on this voyage that Darwin began to formulate what would become his greatest and most lasting biological theory. Darwin first hinted at ideas that later made up his theory of evolution by natural selection in *The Voyage of the Beagle* (2001; originally titled *Journal and Remarks*), published in 1839. Then building on the work of scholars such as Jean-Baptiste Lamarck, Charles Lyell, and Thomas Malthus, Darwin fully formulated his theory of evolution in *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life*, published in 1859. Though reluctant to publish what he knew would be a controversial theory, he was prompted to do so by a letter from Alfred Russel Wallace proposing much the same theory. His book *The Descent of Man, and Selection in Relation to Sex*, published in 1871, rounded out his main works on the theory of evolution.

DARWIN'S THEORY OF EVOLUTION

In the most basic terms, evolution is a reference to the cumulative process of change within a population over time. Natural selection is the specific mechanism that Darwin employed to explain this change. Genetic variations in living beings manifest themselves in morphological variations in those beings, though Darwin himself knew nothing about genes. Given limited resources and environmental variations, those individuals, within a species, possessing morphological variations that allow them best to adapt to this limited and variable environment will be the ones most likely to survive, reproduce, and pass those successful genetic and morphological traits on to their offspring. This ability to survive and reproduce is known as fitness.

Darwin's theory has been revolutionary, and like nearly every discipline within the academy, philosophy has been greatly influenced by it. One of the immediate and profound implications of Darwin's theory was the underlying metaphysical image of variability and change. In his 1910 essay "The Influence of Darwin on Philosophy," John Dewey spoke of the influence of Darwin in drawing philosophers away from the Aristotelian notion of nature (*phusis*), ruled by a kind of permanence or changelessness, and toward a more Heraclitean nature in flux. The influence of Darwin, Dewey wrote, "conquered the phenomena of life for the principle of transition" (p. 8). Perhaps the other important ontological implication of Darwin's theory was the idea that entities in the world (including humans) are shaped over time by the world in which they are embedded. That is, things in the world are what they are because of the context in which they live and evolve over time, not in spite of that context.

THE DESCENT OF MAN

The last of Darwin's great works, *The Descent of Man*, has had a dual impact on environmental philosophy and ethics. First, Darwin's work served to challenge and blur the boundaries that humans had, until that time, always been assured existed between themselves and their nonhuman animal counterparts. Darwin argued that humans, like all living organisms, are subject to the biological process of natural selection. After demonstrating physical continuity between humans and nonhuman animals in chapter 1 of *Descent*, Darwin, in chapter 2, works through an exhaustive list of mental attributes—from lower-level instinct and desire to higher-level reason and abstraction—and likewise concludes "that there is no fundamental difference between man and the higher mammals in their mental faculties" (p. 35). This Darwinian challenge was important for early versions of nonhuman-centered ethics (most notably, animal ethics) because justifications for the ethical exclusion of nonhuman animals are usually premised on an alleged fundamental distinction between humans and nonhumans on the basis of some quality that humans are said to possess and all nonhumans are said to lack. In blurring the metaphysical boundaries assumed to exist between humans and nonhumans, Darwin paved the way for the expansion of the moral community that we began to see in the 1970s with the advent of animal ethics. A good contemporary example of Darwin's influence on the extension of ethics is the Great Ape Project. This project "demand[s] the extension of the community of equals to include all great apes: human beings, chimpanzees, gorillas, orang-utans," because humans are members of the biological family of great apes and the other members of this family are therefore "the species that are our closest relatives" (Cavalieri and Singer 1994, pp. 4, 1).

Second, Darwin's portrayal of the biological world profoundly influenced natural scientists with ethical interests, such as Aldo Leopold. In his environmental classic *A Sand County Almanac* (1949), Leopold suggested that there are ethical implications that follow from Darwin's more metaphysical message that "men are only fellow voyagers with other creatures in the odyssey of evolution." An internalization of Darwinism, according to Leopold, implies "a sense of kinship with other creatures," from which follows "a wish to live and let live"

(p. 109). More abstractly, it might be argued that a Darwinian vision ought to inspire in us certain virtuous attitudes toward nature: wonder, humility, respect, and caring being chief among them.

In chapter 3 of *The Descent of Man*, Darwin develops a purely biological account of the origin, existence, and nature of ethics. Inspired by the theory of moral sentiments put forward by the philosophers David Hume and Adam Smith, Darwin suggests that ethical sentiments are traits like other traits we possess—traits that facilitate survival. For animals such as humans, whose fitness is positively affected by being members of cohesive societies, ethics are necessary for social cohesiveness, and hence facilitate survival: "No tribe could hold together if murder, robbery, treachery, etc. were common; consequently such crimes within the limits of the same tribe are 'branded with everlasting infamy'" (Darwin 1981 [1871], p. 93). Hence, certain "limitations on freedom of action in the struggle for existence," as Leopold ecologically defines ethics (1949, p. 202), increase fitness by increasing social cohesion. Darwin even suggested that this ability to extend ethical consideration to other individuals is not unique to humans: "Any animal whatever, endowed with well-marked social instincts, would inevitably acquire a moral sense or conscience, as soon as its intellectual powers had become as well developed, or nearly as well developed, as in man" (1981 [1871], pp. 71–72). Darwin also realized that the focus of these moral sentiments can extend beyond the human community:

> As man advances in civilization, and small tribes are united into larger communities, the simplest reason would tell each individual that he ought to extend his social instincts and sympathies to all the members of the same nation, though personally unknown to him. This point being once reached, there is only an artificial barrier to prevent his sympathies extending to the men of all nations and races. . . . *Sympathy beyond the confines of man, that is humanity to the lower animals, seems to be one of the latest moral acquisitions.* (1981 [1871], pp. 100–101; emphasis added)

DARWIN AND THE BIOTIC COMMUNITY

Darwin ultimately demonstrates that there exists a correlative relationship between our sense of ethical inclusiveness and our sense of community. As our sense of community becomes more (or less) inclusive, our sense of ethics changes in kind. Hence, if humans could somehow come to see themselves as members of an integrated biotic community, inclusive of the nonhuman world, then a land ethic—an ethic that "enlarges the boundaries of the community to include soils, waters, plants, and animals, or collectively: the land" (Leopold 1949, p. 204)—would follow. If Leopold is correct—if "the problem we face is the extension of the social conscience from people to the land," and if "no important change in ethics was ever accomplished without an internal change in our intellectual emphasis, loyalties, affections, and convictions" (1949, pp. 209–210)—then a main focus of our efforts to solve environmental problems ought to be facilitating biotic community. Darwin, then, explains the mechanism that allows us to extend ethical consideration to the land (to nature, to the environment). As Leopold famously put it, we can measure the extent to which an action, policy, or program is good or bad, right or wrong, on the basis of its environmental impact; we can say, "A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise" (1949, pp. 224–225). While many environmental philosophers see Leopold as an inspiration for their positions, J. Baird Callicott (1989, 1999) is the philosopher advancing an environmental ethic most directly in line with Darwin's and Leopold's ideas about ethical evolution and expansion.

As summarized in Pickett and Ostfeld's essay "The Shifting Paradigm in Ecology" (1995), more recent work in theoretical ecology challenges the image of natural units (e.g., biotic communities) thought to be implied by early thinkers such as Darwin and Leopold. This work seeks to move away from static and uniform images of biotic communities and the like, and toward more indefinite and dynamic biological collectives. Since images of nature and natural units are inevitably reflected in ecologically rooted environmental philosophies and ethics, this shift has prompted environmental ethicists to make their theories dynamically correspond to changing images of biological groupings (see Callicott 1999 for an example).

DEEP ECOLOGY

Adherents of the *deep ecology* movement share a dislike of the human-centered value system at the core of European and North American industrial culture. Deep ecologists argue that environmental philosophy must recognize the values that inhere objectively in nature independently of human wants, needs or desires.

The popularity of deep ecology spans from headline-grabbing environmental activists dressed in coyote costumes to scholars of an astonishing assortment of backgrounds and interests. Authors have made connections between deep ecology and ecological science (Golley 1987), religions from around the world (Barnhill and Gottlieb 2001), New Age spirituality (LaChapelle 1978), direct action/ecological sabotage (Foreman 1991), the poetry of Robinson Jeffers (Sessions 1977), the land ethic of Aldo Leopold (Devall and Sessions 1985), the monism of Baruch Spinoza (Sessions 1977, 1979, 1985; Naess 2005), and the phenomenology of Martin Heidegger (Zimmerman 1986). Such variety is invigorating, but it makes it difficult to find the common thread in all these diverse manifestations of deep ecology. As one commentator has observed, "Any one who attempts to reconcile Heidegger's with Leopold's contributions to deep ecology finds the going rugged" (Oelschlaeger 1991, p. 304). (To differentiate between the broad popular and narrow academic usages of *deep ecology,* the term *Deep Ecology* will be used to denote the latter.)

Much more narrowly, deep ecology represents the psychologization of environmental philosophy. Deep ecology in this sense refers to an *egalitarian* and *holistic* environmental philosophy founded on phenomenological methodology. By way of direct experience of nonhuman nature, one recognizes the equal intrinsic worth of all biota as well as one's own ecological interconnectedness with the lifeworld in all its plenitude.

Understanding Deep Ecology in its academic sense demands reading the work of four environmental philosophers: the Norwegian Arne Naess, the Americans George Sessions and David Rothenberg, and the Australian Warwick Fox. Deep Ecology is inextricably associated with Naess (Katz et al. 2000, p. xv) and owes its prominence to him. Naess's many strengths—strong will, humble demeanor, playful personality, estimable academic reputation, aversion to judgment, predilection for inclusivity, and an odd mix of interests—have stimulated many others to spend considerable amounts of time, talent, and energy teasing out the nuances of his creative insights.

ORIGINS OF THE DEEP ECOLOGY MOVEMENT

Arne Naess invented the term *deep ecology* in a famous 1973 English-language article, "The Shallow and the Deep, Long-Range Ecology Movement: A Summary." By "ecology movement" Naess means a cosmology or worldview. Naess faults European and North American civilization for the arrogance of its human-centered instrumentalization of nonhuman nature. He contrasts his new "deep" (or radical) ecological worldview with the dominant "shallow" (or reform) paradigm. The shallow worldview, which he finds to be typical of mainstream environmentalism, is merely an extension of European and North American anthropocentrism—its reasons for conserving wilderness and preserving biodiversity are invariably tied to human welfare, and it prizes nonhuman nature mainly for its *use*-value. The deep ecological worldview, in contrast, questions the fundamental assumptions of European and North American anthropocentrism—that is, it digs conceptually *deeper* (Fox 1995, pp. 91-94). In doing so, deep ecological thinking "is not a slight reform of our present society, but a *substantial reorientation of our whole civilization*" (Naess 1989, p. 45 [italics in original]). This radicalism has inspired environmental activists of many stripes to hoist up Deep Ecology as their banner in calling for nothing less than the redirection of human history (Manes 1990).

Naess, like Socrates, makes no claims to certainty. In word and deed, Naess instead has inspired others to engage in deep philosophical questioning through example. Naess's own environmental philosophy, ecosophy T (1986, pp. 26–29)—named for his secluded boreal hut, Tvergastein (Naess 1989, p. 4)—is meant to serve as a template for other personal ecosophies (philosophies of ecology).

ACADEMIC DEFINITIONS OF DEEP ECOLOGY

Deep ecology in its narrow academic sense rests on two fundaments: an axiology (The study of the criteria of value systems in ethics) of "biocentric egalitarianism" and an ontology (the study of existence) of metaphysical

holism which asserts that the biosphere does not consist of discrete entities but rather internally related individuals that make up an ontologically unbroken whole. Both principles are rooted in an intuitive epistemology reminiscent of Descartes' "clear and distinct" criteria—once you grasp them, their truth is beyond doubt.

The first principle, biocentric egalitarianism—known also by other phrases that combine *biocentric, biospherical,* and *ecological* with *equality* and *egalitarianism* (Naess 1973, p. 95; Devall and Sessions 1985, pp. 67-69)—holds that biota have *equal* intrinsic value; it denies differential valuation of organisms. In the words of Naess, "*the equal right to live and blossom* is an intuitively clear and obvious value axiom" (1973, p. 96 [Naess's emphasis]). In the words of the sociologist Bill Devall, writing with George Sessions, "all organisms and entities in the ecosphere, as parts of the interrelated whole, are equal in intrinsic worth" (1985, p. 67). Naess shrewdly preempts invariable attacks on this idea of the equal worth of all organisms by adding the qualifier "in principle" because "any realistic praxis necessitates some killing, exploitation, and suppression" (1973, p. 95). This qualifier has not, however, staved off criticisms of biocentric egalitarianism.

The valuing of human beings over other life forms in the teleology of a great chain of being (Lovejoy 1936) has been a key feature of the European–North American intellectual tradition—and, to the dismay of deep ecologists, also a feature of some prominent variants of environmental ethics (Birch and Cobb 1981; Bookchin 1982; Rolston 1988). Biocentric egalitarianism aims directly at this target. By denying humans special moral consideration, Deep Ecology is not just nonanthropocentric, but *anti*-anthropocentric (Watson 1983).

Sessions has categorically rejected any differential axiology on the grounds that hierarchies of value lay the groundwork for claims of moral superiority. Quoting John Rodman (1977, p. 94), Sessions cautions that any comparative axiology merely reinstates a "pecking order in this moral barnyard" (Sessions 1985, p. 230). At a 1979 conference devoted to reminding philosophers of the purpose of their discipline (namely, deep questioning), Sessions warned environmental ethicists of the temptation of looking to a metaphysics based on intensity of sentience. "The point is not whether humans in fact do have the greatest degree of sentience on this planet (although dolphins and whales might provide a counterinstance), deep ecologists argue that the degree of sentience is *irrelevant* in terms of how humans relate to the rest of Nature" (Sessions 1985, p. 18). The second principle is *metaphysical holism*. One can apprehend ontological interconnectedness through enlightenment or "self-realization" (Devall and Sessions 1985, pp. 67–69; Naess 1987). As Fox says, "It is the idea that we can make no firm ontological divide in reality between the human and the nonhuman realms. . . . [T]o the extent that we perceive boundaries, we fall short of deep ecological consciousness" (Fox 1984, p. 196). Through this awakening, the ontological boundaries of the self extend outward, incorporating more and more of the lifeworld into the self. This insight discloses that there is in reality only one big Self, the lifeworld, a notion developed in the article "The World Is Your Body" (Watts 1966).

This method of self-realization is identification: By recognizing the intrinsic worth of other living beings, one recognizes the solidarity of all life forms. Naess, upon watching a flea immolate itself in an acid bath under a microscope, empathized with the suffering flea, identified with it, and thereby felt deeply connected with the entire lifeworld (1987, p. 36).

Once ontological boundaries between living beings are recognized as illusory, one realizes that biospherical interests are one's own. Devall and Sessions assert that "if we harm the rest of Nature then we are harming ourselves. There are no boundaries and everything is interrelated" (1985, p. 68). In the words of the environmental activist John Seed, the statement "I am protecting the rain forest" develops into "'I am part of the rain forest protecting myself.' I am that part of the rain forest recently emerged into thinking. . . . [T]he change is a spiritual one, thinking like a mountain, sometimes referred to as 'Deep Ecology'" (Devall and Sessions 1985, p. 199). Because the rainforest is part of the activist Seed, he is inherently obliged to look after its welfare. The rainforest's well-being and needs are indistinguishable from Seed's.

Naess and Sessions have emphatically emphasized the phenomenological spirit of deep ecology and downplayed dicta; the psychological realization of metaphysical holism makes ethics superfluous. As Naess has said, "I'm not much interested in ethics or morals. I'm interested in how we experience the world. . . . " (Fox 1995, p. 219). In Sessions words, "The search . . . is not for environmental ethics but for ecological consciousness" (Fox 1995, p. 225).

THE EIGHT-POINT PLATFORM

Growing out of the knowledge of nature's concrete contents is the recognition of the need for some kind of political action. To this end Naess and Sessions laid out an oft-cited eight-point program (that they conjured while camping in Death Valley in 1984) For example (Naess 1986, p. 24), in the diagram Buddhist, secular philosophical, and Christian first principles (the bust) converge in the eight-point platform (the waist), which then justifies an array of activisms (the skirt [see Figure 1]). Buddhist metaphysics might channel through the waist of deep ecological principles calling for environmental action to

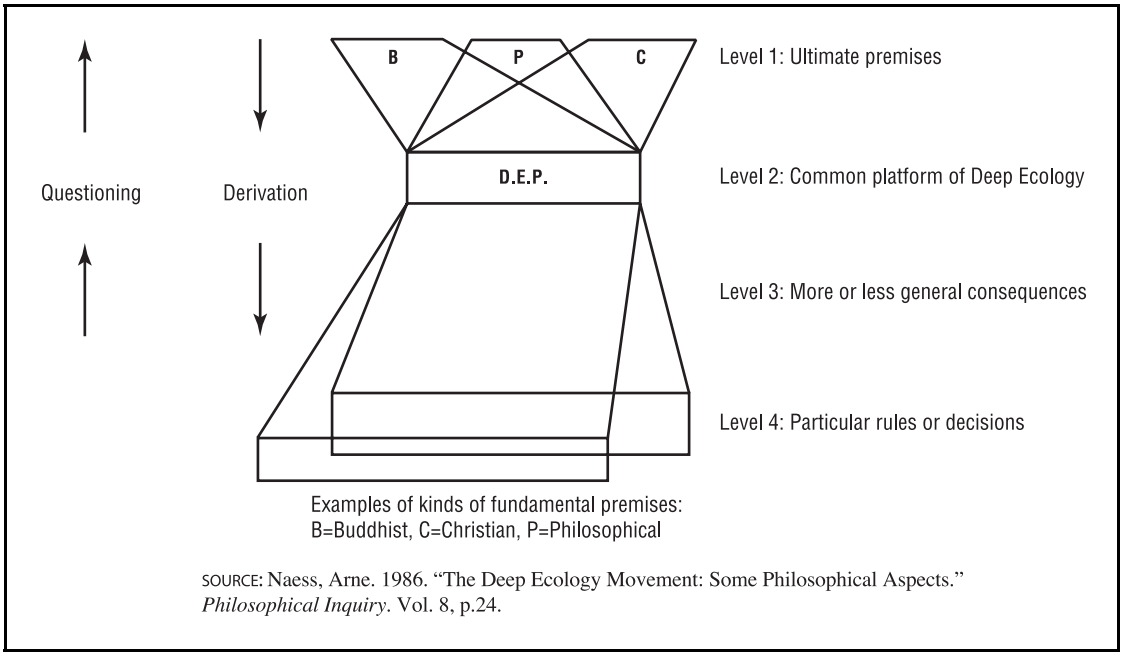

Figure 1. *Arne Naess's Apron Diagram.* **CENGAGE LEARNING, GALE.**

reduce consumption; secular metaphysics might channel through the waist of Deep Ecology calling for action to reduce human population growth; or Christian metaphysics might channel through the waist of Deep Ecology to call for action to preserve biodiversity. Both the eight-point platform and the apron diagram imply that Deep Ecology is above all an ontology and incidentally an ethic.

CRITIQUES OF DEEP ECOLOGY

The deep-ecological principles of biocentric egalitarianism and metaphysical holism have elicited robust critiques. Some of the most interesting debates have centered on the normative status of Deep Ecology. Naess maintains that Deep Ecology is essentially *descriptive*. For Naess unmitigated empiricism or "ecophenomenology" (Brown and Toadvine 2003) promotes a direct experience of the qualities of nature—its "concrete contents" (Naess 1985). Deep Ecology, he argues, is simply an enumeration of general principles that command the assent of persons open to the direct apprehension of nature.

Scholars have found the disclaimer that Deep Ecology is not a normative system—and ought not be judged as such—disingenuous. They have treated Deep Ecology as the legitimate object of the analysis of moral philosophy. Some regard Deep Ecology as strident axiological egalitarianism that is useless in adjudicating conflicting interests. If all organisms are of equal value, then there is no basis upon which to make prescriptions because the kind of value distinctions necessary for evaluating the moral situations of environmental ethics are deliberately disqualified. The principle of biocentric egalitarianism, on this view, renders Deep Ecology impotent as an ethical theory. Environmental ethics is predicated on the possibility of a *nonegalitarian* axiology. In the words of the American philosopher Bryan Norton, "The 120,000th elk cannot be treated equally with one of the last California condors—not, at least, on a reasonable *environmental* ethic" (1991, p. 224). Baird Callicott has surmised that environmental ethics must manifestly not "accord equal moral worth to each and every member of the biotic community" (1980, p. 327). These scholars argue, therefore, that biocentric egalitarianism must be scrapped (Sylvan 1985).

In a similar vein Fox has argued that the leveling axiology of orthodox Deep Ecology must be forsworn. If all organisms are really of equal intrinsic worth, the deep-ecological doctrinaire might just as well eat veal as vegetables (Fox 1984). In reality, Fox predicted, deep ecologists probably tend to be vegetarians, because—in the words of Alan Watts—"cows scream louder than carrots" (Fox 1984, p. 198). Orthodox Deep Ecology, Fox contends,

> does itself a disservice by employing a definition of anthropocentrism which is so overly exclusive that it condemns more or less *any* theory of value that attempts to guide "realistic praxis. . . ." Unless deep ecologists take up this challenge and employ a workable definition of anthropocentrism, they may well become known as the

> advocates of "Procrustean Ethics" as they attempt to fit all organisms to the same dimensions of intrinsic value. (Fox 1984, pp. 198–99).

Not eager to be labeled a procrustean ethicist, Fox persuasively argues for a position that abandons biocentric egalitarianism and instead asserts that all biota *have* intrinsic value but are not *equal* in intrinsic value because the "richness of experience" differs (Fox 1984, p. 198). On this point Fox aligns himself with the Whiteheadian-inspired environmental ethics based on intensity of sentience(Ferré 1994) that Sessions so adamantly opposes.

To mark the difference between his sophisticated reformulation of deep ecological thinking from orthodox Deep Ecology, Fox rechristened his theory transpersonal ecology (1995). Fox has since moved beyond Deep Ecology and has developed a more integrated approach that encompasses interhuman ethics, the ethics of the natural environment, and the ethics of the human-constructed environment (Fox 2006). In contrast, Sessions has reasserted the importance of deep ecology's ecological realism as opposed to social constructivism (2006) as the philosophical foundation for a "new environmentalism of the twenty-first century" (1995).

Naess has steadfastly resisted any gradations or differentiations of intrinsic value among organisms in light of such criticisms. Responding to Fox, Naess wrote that *some* intrinsic values *may* differ, but not the kind he talks about. He and Fox, said Naess, "probably do not speak about the same intrinsic view" (Naess 1984, p. 202). Naess has reiterated his intuition that "living beings have a right, or an intrinsic or inherent value, or value in themselves, that is *the same* for all of them" (Naess 1984, p. 202). As Naess conceded early on (1973), brute biospherical reality entails some forms of killing, exploitation, and suppression of other living beings; the aim is to do more good than harm, to respect on an equal basis the right of every life form to flourish (Naess 1984). Nevertheless, some philosophers have found such a guideline essentially vacuous, like vowing honesty until lying is warranted (Sylvan 1985a), thus undermining the very foundation of the principle itself. If any realistic practice deals with few situations where biota may be valued equally, then the principle is empty.

According to some critics, there are irresolvable structural tensions between biocentric egalitarianism and metaphysical holism in ecological value systems (Keller 1997). They argue that, in light of the real functions of living natural systems, it is impossible to even come close to affirming both the ability of all individuals to flourish to old age and the integrity and stability of ecosystems. The necessity of exterminating ungulates such as goats and pigs for the sake of the health of fragile tropical-island ecosystems is but one example. Regard for the health of whole ecosystems might, therefore, require treating individuals differently, because individuals of different species have unequal utility (or disutility) for wholes; if that were the case, then viewed from the standpoint of an entire ecosystem, biocentric egalitarianism and metaphysical holism might be mutually exclusive and inconsistent with each other to the extent that at least one would have to be abandoned—or perhaps both (Keller 1997).

DEEP ECOLOGY, SOCIAL ECOLOGY, AND ECOFEMINISM

Social Ecologists and ecofeminists have also formulated robust critiques of Deep Ecology. Social Ecologists, speaking as secular humanists of the European Enlightenment tradition, have excoriated biocentric egalitarianism as misanthropic. In particular Murray Bookchin criticized Deep Ecology for reducing humans from complex social beings to a simple species, a scourge that is "overpopulating" the planet and "devouring" its resources (1988, p. 13). Bookchin argues that Deep Ecologists' ahistorical "zoologization" prevents them from seeing the real *cultural* causes of environmental problems (1988, p. 18).

In the estimation of ecological feminists, the idea of self-realization is patriarchal. The Australian philosopher Val Plumwood, for instance, argued that the notion of the expanded self results in "boundary problems" stemming from the impulse of subordination (Plumwood 1993, p. 178). There are serious conflicts of interest between constituent members of larger wholes, and, she has argued, expansionary selfhood does not adequately recognize the reality of these conflicts. In the political arena, she contends, the expansionary holist is forced into the arrogant position of implying that anyone in disagreement does not in fact *understand* what is in her or his own best interest. Instead of approaching a situation of conflicting interests with a conciliatory attitude (e.g., "I realize your interests are different from my interests, so here we have a real conflict of interest that we need to resolve by compromise"), the expansionary holist approaches the situation, tacitly or overtly, self-righteously (e.g., "I know what your *real* interests are, and here we have a conflict because you don't seem to understand what your own interests are—whereas I do, fortunately for you.") Ecofeminists suspect that self-realization is a front for an imperialistic philosophy of self, springing from "the same motive to control which runs a continuous thread through the history of patriarchy" (Salleh 1984, p. 344).

Consider the activist John Seed. According to the ecofeminist critique, there is nothing to guarantee that the needs of the rainforest should govern those of Seed: Why should Seed's needs not dictate the needs of the rainforest? (Plumwood 1993). Or why should the needs of unemployed loggers not trump the needs of Seed and the forest?

THE EIGHT-POINT PLATFORM OF DEEP ECOLOGY

1. The well-being and flourishing of human and non-human life on Earth have value in themselves (synonyms: intrinsic value, inherent worth). These values are independent of the usefulness of the non-human world for human purposes.
2. Richness and diversity of life forms contribute to the realization of these values and are also values in themselves.
3. Humans have no right to reduce this richness and diversity except to satisfy vital needs.
4. The flourishing of human life and cultures is compatible with a substantially smaller human population. The flourishing of non-human life *requires* a smaller human population.
5. Present human interference with the non-human world is excessive, and the situation is rapidly worsening.
6. Policies must therefore be changed. These policies affect basic economic, technological, and ideological structures. The resulting state of affairs will be deeply different from the present.
7. The ideological change will be mainly that of appreciating life quality (dwelling in situations of inherent value) rather than adhering to an increasingly higher standard of living. There will be a profound awareness of the difference between bigness and greatness.
8. Those who subscribe to the foregoing points have an obligation directly or indirectly to try to implement the necessary changes (Naess 1986, p. 14).

Even while consenting to some of the insights of deep ecological questioning, for the unemployed logger the need to feed and cloth her or his children might easily outweigh any concern for ecosystemic integrity and stability.

Furthermore, some ecofeminists argue, affirming the ontological interconnectedness of all human and nonhuman organisms and the nonliving environment does not necessitate an embrace of the holism of self-realization. In an article that has become required reading for students of Deep Ecology, the Australian philosopher Richard Sylvan notes that the premise that individuals are not absolutely discrete does not entail the conclusion that all relations are internal and that individuals are ontological chimeras: "Certainly, removing human apartheid and cutting back human supremacy are crucial in getting the deeper value theory going. But for this it is quite unnecessary to go the full metaphysical distance to extreme holism, to the shocker that there are no separate things in the world, no wilderness to traverse or for Muir to save. A much less drastic holism suffices for these purposes" (1985b, p. 10).

CONCLUSION

Taken together, these various critiques have contributed to a significant consensus that Deep Ecology has reached its logical conclusion and has exhausted itself (Fox 1995). For example, in the respected textbook *Environmental Philosophy* (Zimmerman et al. 2005), the section on Deep Ecology, which enjoyed a coveted place in the first three editions, was eliminated in the fourth.

Compared to other prominent theories, Deep Ecology has not crystallized into a complete system. As Rothenberg states in the English revision of Naess's earlier *Økologi, samfunn, og livsstil*, deep ecological thinking is process without end (Naess 1989, Rothenberg 1996). For Rothenberg (1996), Deep Ecology is a set of prescient "hints" about the real relations of culture and nature. These hints are to environmental philosophy as a tree trunk is to roots and branches (Rothenberg 1987). Inverting the apron diagram, Rothenberg visualizes the platform of Deep Ecology as a tree, its conceptual roots deriving nourishment from various religious, aesthetic, and speculative soils and its branches reaching out into the world, enjoining various types of political action (1987). Rothenberg's ideas have stimulated new ways of thinking about the ways in which humans experience nature and about the limits of human language (1996).

Deep Ecology is less a finished product than a continuing, impassioned plea for the development of ecosophies (roots and branches) that merge shared nonanthropocentric core principles (the trunk). At the same time it is clear that Deep Ecology has earned a permanent and well-deserved place in the history of environmental philosophy; that this outlook has generated an abundance of academic articles and books in the field of environmental philosophy is ample testimony to its enduring influence and importance.

DEFENDERS OF WILDLIFE

With its howling wolf logo, the environmental group Defenders of Wildlife is one of the better-known North American nongovernmental organizations (NGOs) that

defend biodiversity conservation. Founded in 1947 under the name Defenders of Furbearers, this group initially focused on preventing the trapping of coyotes and wolves with conventional steel leg traps. Over the years, though, Defenders has broadened its geographical compass and its species concerns, helping to spur national legislation in the United States such as the Endangered Species Act of 1973 and later emerging in the twenty-first century as one of the leading forces for broader biological-protection initiatives. Although defending wolf populations, which were nearly eradicated in the lower forty-eight states in the mid-twentieth century, is still high among Defenders' priorities, the group's agenda has expanded to include not only an array of threatened and endangered species (such as grizzly bears, manatees, prairie dogs, bison, and butterflies) but also entire ecosystems. Since 2002 Defenders has expanded from its U.S. base to sponsor programs in Canada and Mexico.

Addressing the problems of large-range predators such as wolves and grizzly bears dictated this geographic shift. Because predators require large swaths of territory, groups such as Defenders have fought to protect the 19.6 million acre Arctic National Wildlife Refuge (ANWR) from petroleum exploration, reflecting a commitment to broader habitat health amid the intensifying pressures of corporate globalization. Arctic foxes and caribou as well as significant offshore den habitats for polar bears are among the chief biodiversity concerns in the campaign to keep Big Oil out of ANWR. In July 2005 Defenders became one of the six founding members of Exxpose Exxon, a consortium that encourages a boycott of Exxon-Mobil in order to pressure the oil giant to recognize global climate change as a legitimate, human-caused threat, to halt efforts to drill in ANWR, and to lessen America's dependence on carbon fuels.

As a 501(c) 3 charitable organization under the United States tax code, Defenders is prohibited from electoral campaigning and legislative lobbying in the United States. To circumvent this restriction, Defenders created a sister organization, the Defenders of Wildlife Action Fund, in February 2001. As a 501(c) 4 organization, donations to which are not tax-deductible, any Action Fund monies may be used to lobby for specific legislation or to campaign for or against members of Congress. The Action Fund's successful 2006 Conservation Majority Project, which targeted a number of representatives deemed unfriendly to the environment such as Richard Pombo (R-CA), is an example of this kind of activity. The fund publishes a regularly updated Congressional Report Card, which details how both senators and representatives vote on environmental legislation, and conducts a "Heads in the Sand" campaign to unseat members of Congress who continue to challenge scientific consensus on climate change.

The dawn of the Internet era in the mid-1990s created fresh opportunities for grassroots networking and educational outreach for activist groups like Defenders. The organization still publishes traditional documents such as the attractive quarterly magazine *Defenders,* but it was its Internet presence that sparked a jump in membership from 62,000 in 1991 to more than 500,000 in 2008. The Defenders Wildlife Action Center helps members find nearby wildlife educational events, join or start online discussions with one another and Defenders staff, and send out electronic activist letters to various officials around the country.

As a nongovernmental organization, Defenders can affect environmental policy only indirectly. It seeks to influence policy by promoting public awareness and then mobilizing civil society to pressure government officials and agencies. The reintroduction of wolves in the Northern Rockies, especially in Yellowstone National Park, in 1995 is a notable example of the success of such work. President Bill Clinton's Secretary of the Interior, Bruce Babbitt, instituted the formal policy, clearing the path for the Fish and Wildlife Service with a final 1994 environmental impact statement (EIS) that concluded that the reintroduction of wolves would not threaten the greater Yellowstone area. In early 1995 United States District Court Judge William Downes removed the last obstacle, a temporary injunction, by rejecting the American Farm Bureau Federation's argument that reintroduction would cause irreparable harm to ranching interests in the community. But it was Defenders' years of relentless pressure and dialogue on this issue that helped to bring about these government actions; a key early initiative was the 1987 establishment of a trust by Defenders to reimburse ranchers who lost livestock to wolf attacks. Such initiatives, which cannily combine dialogue and financial assistance, continue in the form of the Defenders' Bailey Wildlife Foundation Wolf Compensation Trust.

DESCARTES, RENÉ
1596–1650

René Descartes was born at La Haye near Tours in France on March 31, 1596, into a family that belonged to the landed gentry. He was sent at a young age to the Jesuit college of La Flèche, where he received a thorough grounding in Scholastic philosophy. That philosophy was deeply rooted in Aristotle's views, and Descartes later challenged those views. After taking a degree in law, he spent his early adult life moving around the European continent, part of the time as a gentleman soldier. A large part of his later life was spent in Holland. Between 1637 and 1649 he published various works in philosophy and science. In 1649 he went to Sweden at the invitation of Queen Christina. He died in Stockholm.

VIEWS ON KNOWLEDGE AND NATURE

Descartes's views usually are seen as completely antithetical to those of animal ethicists and environmental philosophers. In his best-known work, the *Meditations on First Philosophy*, Descartes sets out to establish a system of knowledge founded wholly on certain truths. To achieve this, he resolves in the First Meditation to set aside any opinion that is open to doubt and skeptical challenge. He then shows that the existence of an external world is open to doubt: Any particular "experience" of the world may turn out to be part of a dream. Moreover, the entire external world may be a "fiction" induced in him by a deceiving evil demon.

In the Second Meditation, Descartes establishes that to be deceived in this manner, he must exist as a conscious thinker. On the basis of this first certainty about his own conscious existence, he shows that there is a nondeceiving God who guarantees that any proposition that he is certain of (i.e., that he "clearly and distinctly perceives") is true. God's nondeception then enables him to reestablish that an external material world exists. In the Sixth Meditation, Descartes states clearly his dualist position, in which the created world is composed of two kinds of substances: conscious minds (the repositories of all experience) and an external material world. Human beings are composites, consisting of a mind and a body that is part of the material world. The mind and body causally interact with each other. For example, the mental decision to raise an arm causes the bodily arm to go up, and injury to the body causes a mental perception of pain.

Descartes's basic views as encapsulated in the *Meditations* are thought to lead to controversial doctrines about nature. The external world Descartes reintroduces toward the end of the *Meditations* is very different from the natural world of his medieval predecessors. Medieval scholars, following Aristotle, had seen all living things as having specific sets of capacities. For example, blades of grass have the capacity for nutrition and growth; cats have those capacities and the additional capacities of movement and sensation; and so on. Human beings have all the capacities of nutrition, growth, movement, and sensation, as well as the unique capacity to reason. In contrast, Descartes was a supporter of the scientific revolution that replaced Aristotle's views with a conception of nature as wholly mechanical in character. Thus, the external world reintroduced in his *Meditations* consists of "dead" matter whose behavior can be understood by reference to a set of mathematical laws.

The *Meditations* also is seen as privileging the conscious thinker and his or her experiences over the "dead" material world, which is seen as the "other" that lies outside the mind. Thus, although Descartes saw human beings as composites of mind and matter, he is held to have ascribed moral standing to them solely on the grounds that they have minds and are capable of conscious experience.

In the *Discourse on Method*, Descartes argued that there are no grounds for thinking that animals have minds or the capacity to reason, as all their behavior is explicable if they are conceived of as clockwork machines that operate according to mechanical laws. Descartes thus indicated that animals belong wholly to the material realm. As clockwork machines without minds, they do not see, hear, or feel pain. They also have no moral standing and can be used as conscious human beings wish.

Again, Descartes thought that the entire physical universe, of which animals are parts, is dead matter governed by the same uniform set of mechanical laws. It too has no moral standing and can be treated as an instrument to be exploited for human ends and goals. In the *Discourse on Method,* Descartes exhorts human beings to harness the various powers of nature so that they may become the "masters and possessors of nature."

CRITIQUES

Descartes's views have met with strong objections in recent times. Gilbert Ryle famously described Descartes's dualist position as "the Dogma of the Ghost in the Machine"

(1949, pp.15–16). In Descartes's view, the human body, like the animal, is a clockwork machine. Unlike animal machines, however, it is driven by a ghost that is "invisible, inaudible and has no size and weight" (p. 20). Ryle argues that it is hard to conceive of causal transactions between the clockwork machine and the "ghost" or mind. Other philosophers point out that Descartes's material universe is a closed system that proceeds inexorably according to its own laws. How, then, can the thinker's mental decisions causally affect the human body and, by extension, the wider processes in the universe?

Animal ethicists also disagree with Descartes's views. Descartes posits that animals are clockwork machines and hence have no moral standing. This is in clear contrast to the views held by many animal ethicists. Peter Singer, for instance, maintains that animals have the capacity to feel pain and pleasure and are entitled to moral consideration precisely because they have that capacity (Singer 1998).

Environmental ethicists such as Aldo Leopold, J Baird Callicott, and Holmes Rolston would object to Descartes's position that the physical universe can be exploited for human goals and ends. They would maintain that the physical universe, in particular its various ecosystems, have moral standing and should not be exploited or destroyed.

Ecofeminists also have also been critical of Descartes's views. Descartes's dualism privileges the conscious thinker over the material world, which is seen as an alien object to be mastered. That perspective deprives humans of ("feminine") sympathy and connection with nature. Carolyn Merchant (1980) also notes that historically Descartes was a major figure who helped displace earlier conceptions of the earth as a nurturing mother with the view of nature as a machine to be used and abused at will.

ALTERNATIVE INTERPRETATIONS

The interpretation presented above is a standard reading of Descartes's views. Although there is considerable textual basis for this reading, some recent writers have argued that Descartes's views may have been more nuanced and perhaps more ambiguous than this reading allows. For example, philosophers such as John Cottingham (1978) have argued that although Descartes denies that animals have reason, he accepts the idea that animals experience passions and sensations. It also has been claimed that Descartes thinks that the physical universe as a whole should be accorded moral standing insofar as it is God's creation.

DESERTS AND DESERTIFICATION

A desert is most often defined as an area where annual rainfall is between 10 and 20 inches. More specifically, semiarid deserts receive less than 23.6 inches of rain annually, arid deserts less than 7.8 inches, and hyperarid deserts less than .98 inches. Major deserts today include the Sahara, the world's largest at 3.5 million square miles; the Arabian Desert; the Great Sandy, Great Victorian, and Simpson deserts of Australia; the Thar Desert of India and Pakistan; the Sonoran Desert of North America; the Atacama Desert of South America; the Takla Makan Desert of China; and the Gobi Desert, which covers parts of China and Mongolia. Many of these deserts include or adjoin other, smaller deserts.

Desertification—land degradation that is caused by climatic variation and human activities—has occurred for thousands of years. Desertification can be either a physical or a chemical process. An example of physical desertification is Greece over the last 4,000 years: The clearing of forests to cultivate sloping land initiated progressive soil erosion over millennia, causing a shift from cultivation to grazing—often overgrazing—which then further accelerated soil degradation. Mesopotamia, the "cradle of civilization" between the Tigris and Euphrates rivers in present-day Iraq, has been transformed into arid desert by chemical desertification. Excessive irrigation, beginning around 5000 to 4000 BCE, raised the water table so high that water repeatedly pooled in sloughs to evaporate, leaving the salts from the water on the surface of the land, where it inhibits plant growth.

Desert near Dunhuang, China. *A woman walks through the desert that threatens to engulf her onion farm in China's northwest Gansu province. Desertification is increasingly becoming a major problem in the destitute province, along the historic Silk Road. The ancient city of Dunhuang is in danger of being completely lost to the sands of the Kumtag Desert, which are creeping closer at a rate of up to four meters each year.* **PETER PARKS/AFP/GETTY IMAGES.**

The Sahara was largely uninhabited until roughly 8500 BCE because of extreme desiccation; rainfall greatly increased between 8500 and 3500 BCE, attracting many plants, varieties of wildlife, and human settlements into its valleys and oases. When rainfall declined again around 3500 BCE, the Sahara returned to desert. Yet today the borders of the Sahara advance .6 miles per year because of human deforestation, overgrazing, inappropriate cropping, and, in some areas, salinization from overirrigation.

Deserts make up about one-third of the earth's land surface. But desert area is growing because of the impoverishment of arid, semiarid, and some subhumid ecosystems by the combined impact of human activities and drought. These impacts can be measured by reduced plant productivity, alterations in the biomass and the diversity of the micro and macro fauna and flora, accelerated soil deterioration, and rising risks for human occupancy. In addition to areas that are threatened with desertification, many deserts themselves are endangered. The 250,000-square-mile Rub'al-Khali, the southern part of the Arabian Desert and one of the driest, hottest, and least hospitable places on earth, contains only thirty-seven species of plants, seventeen of which are on its periphery. The primary threats to the Rub'al-Khali today are overgrazing, roadbuilding, oil wells, and war**.** In the 1991 Gulf War, not only did American tanks damage the thin, fragile crust that protected sand dunes from erosion, creating a massive, slow-moving sand dune that will soon threaten Kuwait City while Iraqi forces turned 1,164 Kuwaiti oil wells into oil lakes in the same Arabian Desert, but Iraqi forces also punished Saudi support for the war by shooting missiles into Saudi wells, leaving lakes of over 60 million barrels of oil in the Rub'al-Khali Desert covering over 30 square miles of land. In the Arabian Desert a number of native species, including the striped hyena, the jackal, and the honey badger, are now extinct because of hunting and habitat loss. But a few species which had disappeared, such as the endangered white oryx and the sand gazelle, have now been reestablished and, with the protection of some reserves—the first of which were established by Abu Dhabi—seem to be recovering numbers.

Almost one-third of China is made up of deserts that produce seasonal sandstorms that scour the northern cities, including Beijing. Across China many semiarid and dry subhumid zones have experienced temperature increases and precipitation decreases since the 1970s. As precipitation has decreased, animals, both wild and domestic, have overgrazed the diminished vegetation, killing vegetation and inviting erosion, a further cause of desertification. Humans followed the example of animals; instead of easing the strain on the land caused by lowered precipitation by cutting herd size and moving to other areas, they have remained in place, shifting their herds and ploughs to those border areas not yet destroyed, thus hastening desertification of nearby land.

Global climate change may be an even greater cause of desertification in the future because the Tibetan glaciers that feed China's streams are melting. According to the Millennium Ecosystem Assessment (2005), desertification is not an inexorable process; degraded land can often be restored if local communities are involved and funds and infrastructures are provided. China has begun a number of projects aimed at addressing desertification.

The U.N. Convention to Combat Desertification, together with the Conventions on Biological Diversity and Climate Change, can provide an initial roadmap for combating desertification. Drylands (a collective noun for a variety of arid regions, including deserts) have variable climatic conditions; droughts are periodic. Human impacts must be adjusted to account for these variations. The most common action taken to halt desertification is tree planting, which, if well planned, can counter more than one aspect of this process. Trees help hold soil in place, thus decreasing wind and water erosion, while providing shade and habitat for other plants and animals. Tree planting, however, is not a cure-all for the complex causes of desertification; each degraded area must be individually assessed.

Increasing desertification is a threat not only to the earth's human population, but also to its overall biodiversity. Since the agricultural revolution of 8000 BCE, humans have been governed by an agricultural mindset that dismisses as unimportant any land not usable for farming; this attitude must be overcome to preserve the health of both existing deserts (which, like other biomes, have an ecology all their own) and drylands, lest they, too, become deserts.

DISEASE

Definitions of disease affect policy decisions and social roles: where money should be spent, what doctors may do, who is excused from normal social obligations. Definitions can also have an impact on the environment, since prevention or cure can draw upon natural resources, and seems more legitimate, if the condition to be treated is classified as disease.

The boundaries of the concept of disease, like those of most concepts, are not precise. In general, conditions that cause pain, disability, disfigurement, or early death count as diseases, particularly when the conditions are in some sense atypical. What is considered abnormal pain, disability, disfigurement, and lifespan differ somewhat across cultures and through time. Hence, whether a condition is a disease is not a simple empirical fact, but a conclusion shaped partly by human norms and projects. There is less controversy about disease in animals and plants. If an infection does not limit the animal's activities or (so far as we can tell) its experiences, there can be disagreement about whether the infection constitutes a disease. Yet if the animal is stressed in some way, the infection can weaken its ability to respond, in which case we are likely to classify the condition as a disease. An organism may carry some pathogen affecting others without itself being sick. But here too human purposes will operate: A condition that makes an organism less useful or even dangerous to human beings is more likely to be called a disease.

Black Legged, or Deer, Tick Through Microscope. *Deer ticks, like the specimen shown here, are the carriers of Lyme Disease to humans. Diseases transmitted between humans and animals raise many other issues related to the environment, such as the ethical nature of recreational hunting and the effects of human population growth on species extinction.* **AP IMAGES.**

Other physical conditions are not ordinarily called diseases, but have been treated medically, sometimes in ways that affect the natural world. After menopause, women are often considered estrogen-deficient, because their supply of the hormone declines significantly, a condition resulting in an increased risk of osteoporosis and cardiovascular disease. To mitigate this risk, such women have sometimes been given estrogen replacements. In addition, fertility (never considered a disease, but certainly a biological fact of great significance) has been regulated for many years with estrogen-containing oral contraceptives. Estrogen in the urine of these women reaches the broader environment and may be implicated in, for instance, an increased incidence of malformed frogs and fishes.

Health is even harder to define than disease; sometimes one concept is defined in terms of the other (e.g., health is the absence of disease), but often more positive terms are used (e.g., health is the ability to respond to challenge or restore homeostasis). The most all-encompassing definition comes from the World Health Organization: Health is a state of complete physical, mental, and social well-being. Whatever the definition, the concept of health does imply some conception of an ideal life. Some environmentalists, drawing a parallel with Attention Deficit Disorder, a recently accepted category, suggest a Nature Deficit Disorder. The suggestion is that lives divorced from the natural world are deficient in themselves and likely to result in other problems.

In most ways a healthy ecosystem contributes substantially to human well-being, so much so that environmentalists often frame their cause in terms of public health. As the ozone layer thins, skin cancer increases, and so do cataracts. When air pollution worsens, respiratory diseases increase. The causal web can be complex. Global warming, for instance, allows temperature-sensitive mosquitoes to fly higher, at which altitudes they infect more migratory birds, and infected birds then spread diseases more widely.

Yet there are also many apparent tensions between human health and that of the natural world. For example, vitamin A deficiency causes compromised vision or blindness, and seriously compromises the immune system. It is a significant cause of death in many poor countries. Genetically modified Golden Rice, a promising intervention to ward off vitamin A deficiency, raises all the environmental issues associated with any genetically modified organism. In another example, the anticancer drug Paclitaxel was derived from the Pacific yew tree, an endangered species. Such tensions, however, can be apparent rather than real, temporary rather than permanent. Vitamin A can be provided in the form of inexpensive drops, and Paclitaxel is now made in laboratories. There are generally many different ways of protecting human health, some of which are costly, disruptive, or inconvenient, and some of which affect the environment. It is ethically important to consider the wide array of possible strategies.

Many infectious diseases are either zoonotic (transmitted between animals and humans) or carried by insect vectors. Both categories raise ethical issues. Zoonosis, the source of about 70 percent of newly identified diseases, increases as contact between human beings and wildlife increases. Human beings settle or work or play in what was once wilderness, and wild animals, dislodged or deprived of habitat, move closer to human beings. The prevalence of household pets, high-density food-animal production, and international trade in exotic animals also play a role. Habitat destruction and climate change, as well as extermination campaigns, can eliminate predators and dramatically increase some animal populations. For example, New Zealand possums, introduced by colonists, have no natural predators; in North America, campaigns against wolves contributed to the large number of deer. Both possums and deer carry bovine tuberculosis, a zoonotic disease.

Sometimes, however, managing disease seems to require environmental destruction with no benefit except to human beings. Dichlorodiphenyltrichloroethane (DDT) is the best known example. The pesticide, effective against

malaria- and typhus-bearing mosquitoes, was originally used in the developed world not only for disease eradication but also as a pesticide in agriculture. In the 1950s and 1960s its use was widespread and heavy. As a persistent organic pollutant, DDT accumulates in living tissue, and concentrations increase at higher levels in the food chain. Because of eggshell thinning, DDT decimated some bird species. Moreover, it is toxic in varying degrees to many kinds of fish, shellfish, and amphibians. For these reasons, DDT became widely banned, even though typhus and especially malaria remain major problems in the poorer countries. Years later it became evident that occasional indoor use of DDT on walls and bed nets can dramatically lessen the incidence of malaria with little negative effect on the environment. In 2006 the World Health Organization endorsed the use of DDT for vector control.

Human beings also carry disease to animals, in a variety of ways. Using minnows caught in one lake as bait in another can spread viral diseases among fish. Primate tourism may increase disease in the great-ape population, whether from increased contact with human beings, increased stress, or other changes in the local environment. Curtailing the recreational activities that spread these diseases probably raises more political issues than ethical ones, since fishers and tourists ultimately benefit from restrictions on what they do. But there are larger and more difficult issues: Human population growth, technological intensification, and climate change lead, in many complicated ways, to increased disease in animals and to species extinction. One example is the mercury poisoning of loons, due to emissions from coal-burning plants. Yet here again, the ethical difficulty diminishes when the issue is seen on a larger scale: The environmental mercury that sickens fish threatens people too.

Finally, disease in human beings can affect the environment indirectly. Diseases to which Native Americans had no immunity were largely responsible for their replacement by Europeans, who responded to the natural world differently. Conversely, quinine allowed Europeans to colonize areas where malaria would otherwise have made it impossible. Ecological concerns pale, however, in comparison with ethical considerations about the cruelty and carnage to human beings that often accompanied colonization.

EARTH CHARTER

The Earth Charter is a people's declaration on global interdependence and universal responsibility that sets forth fundamental principles for building a just, sustainable, and peaceful world. It endeavors to identify the critical challenges and choices facing humanity in the twenty-first century. Its principles are designed to serve "as a common standard by which the conduct of all individuals, organizations, businesses, governments, and transnational institutions is to be guided and assessed" (Earth Charter Initiative 2000).

The Earth Charter is the product of a decade-long, worldwide, cross-cultural dialogue on common goals and shared values conducted during the 1990s. This process, which involved the most open and participatory consultation process ever associated with the drafting of an international document, is the primary source of the legitimacy of the Earth Charter as an ethical guide.

ORIGINS OF THE EARTH CHARTER

Among the many recommendations in *Our Common Future* (1987)—the report of the World Commission on Environment and Development (WCED)—is a call for creation of a "Universal Declaration on Environmental Protection and Sustainable Development" in the form of a "new charter" with principles to guide nations in the transition to sustainable development. Building on this recommendation, Maurice F. Strong, the United Nations secretary-general of the 1992 Rio Earth Summit, proposed in 1990 that the summit draft and adopt an Earth Charter. Intergovernmental consultations were held on the Earth Charter during the preparatory process for the Rio Earth Summit, but an intergovernmental agreement on principles for an Earth Charter could not be reached. Therefore, in 1994, Strong, as chairman of the Earth Council, joined with Mikhail Gorbachev in his capacity as president of Green Cross International to launch a new Earth Charter initiative. This partnership was formed with the support of Jim McNeill, secretary-general of the WCED, and Queen Beatrix and Prime Minister Ruud Lubbers of the Netherlands. The plan was to draft a charter that articulates the consensus that is taking shape in the emerging global civil society on values and principles that promote a sustainable way of life.

Ambassador Mohamed Sahnoun of Algeria served as the first executive director of the Earth Charter project during 1995, as new research in the fields of environmental ethics, sustainable development, and international law was initiated and a new international consultation process got under way. An Earth Charter secretariat was established at the Earth Council in Costa Rica under the management of the executive director of the Earth Council, Maximo Kalaw of the Philippines. In 1996 Mirian Vilela of Brazil became coordinator of Earth Charter activities at the Earth Council. Toward the end of 1996, an Earth Charter Commission was formed to oversee the drafting process. It was cochaired by Strong and Gorbachev and included eminent persons from twenty-one nations. The commission invited Steven C. Rockefeller, a professor of religion and ethics from the United States, to chair and form an international drafting committee. The drafting process, which began in January 1997, required three years.

Hundreds of organizations and thousands of individuals participated in the creation of the Earth Charter.

Forty-five Earth Charter national committees were formed. Earth Charter dialogues were conducted throughout the world and on the Internet, and major regional conferences were held in Asia, Africa, Central and South America, North America, and Europe. The ideas and values in the Earth Charter reflect the influence of a great variety of intellectual sources and social movements. These include the new scientific worldview being shaped by physics, cosmology, and ecology, and the wisdom of the world's religions and great philosophical traditions and of indigenous peoples.

The Earth Charter should be seen as a product of the global ethics movement that inspired the Universal Declaration of Human Rights and gained wide support in the 1990s. The drafting committee worked closely with the Commission on Environmental Law of the International Union for the Conservation of Nature (IUCN) (often referred to as the World Conservation Union) and carefully reviewed all relevant international-law declarations and treaties and more than 200 civil-society declarations and people's treaties. The Earth Charter builds on and extends international environmental and sustainable-development law. It reflects the concerns and aspirations expressed at the seven UN summit meetings held during the 1990s on the environment, human rights, population, children, women, social development, and the city. It recognizes the importance of the spread of democracy for human development and environmental protection.

THE CONTENT OF THE EARTH CHARTER

The final text of the Earth Charter, which was approved at a meeting of the Earth Charter Commission at the UNESCO headquarters in Paris in March 2000, contains a preamble, sixteen main principles, sixty-one supporting principles, and a conclusion titled "The Way Forward." The preamble affirms that "we are one human family and one Earth community with a common destiny," and the Earth Charter encourages all people to recognize their shared responsibility, each according to his or her situation and capacity, for the well-being of the whole human family, the greater community of life, and future generations (2000). According to the Earth Charter, all life forms are worthy of respect and ethical consideration, regardless of their utilitarian value to human beings. Recognizing the interrelationship of humanity's environmental, economic, social, and cultural problems, the Earth Charter presents an inclusive, integrated ethical framework. The titles of the four sections into which the principles are divided indicate the breadth of the vision: I. Respect and Care for the Community of Life; II. Ecological Integrity; III. Social and Economic Justice; and IV. Democracy, Nonviolence, and Peace. The Earth Charter identifies a number of widely shared spiritual attitudes and values that can strengthen commitment to its ethical principles, and the document culminates with a vision of peace and the joyful celebration of life.

THE CONTINUING EARTH CHARTER INITIATIVE

The Earth Charter was formally launched at the Peace Palace in The Hague in June 2000. It has been translated into forty languages and endorsed by more than 2,500 organizations representing the interests of hundreds of millions of people. Among the endorsing organizations are UNESCO, IUCN, the International Council of Local Environmental Initiatives (ICLEI), and the U.S. Conference of Mayors. A number of international lawyers recognize the Earth Charter as an increasingly influential soft-law document, and efforts to seek formal recognition of the Earth Charter by the United Nations General Assembly are continuing.

The Earth Charter provides an excellent overview of the essential elements of sustainable development and world peace, and it is widely used as a teaching tool in schools, colleges, universities, and nonformal education programs. In 2006 the Earth Charter Secretariat was reorganized as Earth Charter International (ECI). An ECI Council was formed to oversee ECI's core programs and small staff, which has its headquarters at the University for Peace in Costa Rica. The mission of ECI is to help establish a sound ethical foundation for the emerging global society and to promote education for sustainable development and implementation of Earth Charter principles by civil society, business, and government. ECI encourages decentralized Earth Charter initiatives throughout the world and has affiliate organizations and partners in more than fifty-seven countries.

EARTH FIRST!

Earth First! is an American environmental advocacy group formed in 1980 at a highway rest stop north of Tucson, Arizona (Cahalan 2001, p. 192). Angered by the federal government's continued failure to protect and preserve wilderness (Scarce 2006, p. 58), a small cadre of friends acted on impulse and inspiration, vowing "No Compromise in Defense of Mother Earth" (Cahalan 2001, p. 192). The group gained members instantly, becoming known, politically, for its cynicism of regular legislative process and its penchant for direct action, and, prophetically, for anticipating ecological apocalypse (Foreman 1986, p. 2) and the demise of industrialized civilization (Abbey 1986, p. 22).

Whereas political environmental groups such as the Sierra Club attempt to preserve biodiversity through lobbying and legislation, Earth First! prefers techniques of "direct action" pioneered by Greenpeace (Scarce 2006, pp. 47–48). The goal of direct action is twofold. First is to draw public attention to environmental problems through media stunts in order to bolster the efforts of mainstream environmental organizations. Earth First!'s initial foray into public relations was the memorable "cracking" of Glen Canyon Dam (Scarce 2006, pp. 57–58).

Second, Earth First! seeks to physically impede development. The most common strategy is nonviolent civil disobedience such as personally blocking bulldozers. Much more controversial is sabotage, principal to the establishment of Earth First! but rejected by Greenpeace (Scarce 2006, p. 54). One known instance of Earth First! sabotage was the targeting of a power line tower in Arizona (Robbins 1989). Though violent, sabotage is not terrorism. Terrorism aims at mutilation and murder; sabotage, in the spirit of English activist Ned Ludd (Sale 1999), is designed to destroy the technological infrastructure of industrial economy (Abbey 1983, p. 94).

Cofounder Dave Foreman traces the necessity of direct action back to the formation of the U.S political economy and the near absolute control of industrialists on environmental policy. Foreman contrasts the visions of Alexander Hamilton, who advocated an economy built on industry, and Thomas Jefferson, who advocated an economy built on agriculture. According to Foreman, the Hamiltonian vision triumphed, with the U.S. government essentially becoming an organ for the promotion of business (Lee 1995, p. 5) making normal legal and political means insufficient for the end of wilderness preservation.

For Foreman biodiversity is the summum bonum (greatest good). Economic activities that threaten biodiversity must be forestalled. Earth First! claims that in this mainstream environmentalism has failed through capitulation and concession (Foreman 1983, pp. 95–96). In an industrial economy, destruction of industrial infrastructure is more effective than negotiation. Laws protect property, making sabotage intrinsically illegal. In contrast to "reform" environmentalism, which operates within normal legal paradigms (Manes 1990, pp. 45–65), sabotage, as illegal, is "radical" (Scarce 2006, p. 5).

Sabotage for ecological ends—"ecotage" or "ecosabotage"—is the use of the tools of industry against itself (Foreman 1981). This method, also known as "monkeywrenching," was famously sketched by Edward Abbey in novel form (1985 [1975]). In the enigmatic relationship between Abbey, who clearly enjoyed the role of rhetorician provocateur, and Earth First!, art imitated actuality, and actuality art. Of *The Monkey Wrench Gang,* Abbey wrote: "This book, though fictional in form, is based strictly on historical fact. Everything in it is real or actually happened. And it all began just one year from today" (1985, frontispiece). Foreman (1993, frontispiece) makes a similar jocose disclaimer in his practical field guide to ecotage in spite of the book's apparent intent to foment the collapse of the Hamiltonian economy.

Foreman diagnosed philosophical rumination leading to political impotence (1983). Given the preference for action over thought, the exact ecological axiology in the Earth First! platform is vague, a conglomeration of biocentric egalitarianism (Foreman 1995 [1980], p. 2), ecocentric holism (Wolke 1983, p. 3), and pantheism (Taylor 1991). The strongest of these themes is ecocentrism. The loci of moral consideration are ecological wholes, and given the negative human impact on the biosphere, *Homo sapiens* are of disvalue (Foreman 1991, p. 26).

Themes of antihumanism in Earth First! became explicit in the mid-1980s. Associate journal editor Christopher Manes (1986) argued that technology exacerbates overpopulation by staving off death and therefore the practice of medicine ought to be discontinued. Most contentiously, Manes (1987) asserted that the biosphere would benefit from a substantial decline in human population, and acquired immune deficiency syndrome (AIDS) might provide a welcome palliative.

Members of Earth First! Protest the Timber Industry. *Earth First! is an environmental activist group that distinguishes itself by utilizing direct action, nonviolent civil disobedience, and sometimes ecotage as techniques. Here members protest logging of old-growth or "ancient" forests in the Pacific Northwest. Some, including Murray Bookchin, have criticized the group's ideology as being antihumanist.* **STEPHEN FERRY/LIAISON/GETTY IMAGES.**

Predictably, this argument and others like it provoked the wrath of social justice thinkers and drew the battle lines of a barbed exchange between Foreman and Murray Bookchin (Chase 1991). Bookchin argued that ecocentrism leads to unconscionable misanthropy (1988, p. 25). Earth First!ers treat humanity as one undifferentiated overpopulating mass, missing the fact that ecological problems are not the result of human existence per se but rather the differential consumption of resources between socioeconomic classes (Chase 1991, p. 57). Bookchin's critique suggests Foreman has tended to focus categorically on the impact of humans on nonhuman nature in terms of industrialization and overpopulation. This overlooks the relationships of individuals to each other within unjust social structures (such as patriarchy and class hierarchy) and how these inequities translate into the human devastation of ecological systems.

This external debate mirrored an internal debate and precipitated an eventual rupture in the ranks of Earth First! (Lee 1995, pp. 115–127). Demographically, this schism occurred between the original founding faction—the "rednecks"—predominately from the desert southwest, and younger members—the "hippies"—predominately from northern California and Oregon.

Generally, while the founding faction applauded ecotage, the second generation favored civil disobedience. For the latter, environmental justice requires social change, and ecotage merely generates antagonism. Judi Bari publicly renounced tree spiking, the iconic hallmark of Earth First! ecotage, in an effort to forge alliances between loggers and environmentalists and win public support (Lee 1995, p. 134).

Ecotage works best when decentralized. In this sense, first-generation Earth First!ers departed from their fundamental premise the moment they gave themselves a name. Nevertheless, the project of initiating social change is amenable to, and benefits from, efficient systematic organization. This ideological difference gave the social change faction an inherent institutional advantage. By the late 1980s these dynamics played out and the social justice faction gained majority control. Foreman departed in 1990 (Lee 1995, pp. 139–140) and, perhaps ironically,

went on to serve on the Sierra Club's Executive Committee from 1995 to 1996 (Sierra Club 2007).

Earth First! has succeeded remarkably in expanding the range of debate about environmental issues. It has achieved its objective of making mainstream environmentalism seem moderate and hence more widely palatable. Any assessment of Earth First! must look beyond the group itself to the ripple effect it has had on the totality of political ecology.

EARTH SUMMIT

The United Nations Conference on Environment and Development (UNCED), popularly known as the Earth Summit, was convened in Rio de Janeiro, Brazil in June 1992 in the hopes of securing a number of environmentally responsible international agreements. The conference brought together the largest number of world leaders that had ever been assembled: 118 heads of state and government and delegations from 178 nations. There were 7,000 diplomats and their staff. As Thomas Kamm wrote in the *Wall Street Journal*, this "mother of all summits" was "the biggest gathering of world leaders ever held" (1992, p. A1). Through media coverage from the 7,000 journalists who were present, UNCED gained world attention for major environmental issues. The chief official for UNCED was Maurice Strong, a Canadian businessman and environmentalist.

THE CONFERENCE AND ITS PUBLICATIONS

Parallel to the official summit was a Global Forum. Here, by one count, there were 3,738 nongovernmental organizations (NGOs) from 153 countries that had something to say about the environment, and about 30,000 participants in total. The Global Forum featured hundreds of displays in outdoor booths and had hundreds of speakers, including many celebrities.

The conference produced the *Rio Declaration* (United Nations Conference on Environment and Development 1992b), a short statement of principles on environment and development. It also produced *Agenda 21* (United Nations Conference on Environment and Development 1992a), at over 500 pages long perhaps the most complex and comprehensive international document ever attempted. Initially, there was hope for four international conventions—(1) Forests, (2) Biotechnology, (3) Biodiversity, and (4) Climate—though only the latter two survived the negotiating process, both in greatly weakened form. The principal stumbling blocks on biodiversity and biotechnology conventions revolved around access to genetic resources and technology transfer.

UNCED did adopt a more schematic statement of principles for the sustainable management of forests.

A widely read preparatory study, *Our Common Future* (World Commission on Environment and Development 1987), commonly called the Brundtland Report after its chair, Norwegian Prime Minister Gro Harlem Brundtland, set the tone for much of the debate. The study opened with a memorable aphorism: "The Earth is one but the world is not." On the one home planet, with its plural and often divisive peoples and their national interests, the principal focus must be on sustainable development. "Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (World Commission on Environment and Development 1987, pp. 27, 43). That statement set future generations on the horizon of the present but also opened up questions of distributive justice in the present time, whether current patterns of wealth and poverty would contribute toward sustaining such a future.

UNCED and the Global Forum turned out, to the surprise of some, to be a global morality play, where the developing nations could gain equal hearing with the developed nations. "The summit must establish a whole new basis for relations between rich and poor, North and South, including a concerted attack on poverty as a central priority for the 21st century" (Maurice Strong, quoted in Allen, 1992, p. A8). At both UNCED and the Global Forum, much concern was expressed about the North, the rich, American and European lifestyles, the G-7 nations, and paternalistic do-gooders. The event became almost a guilt trip, with, at the same time, many world leaders inclined to pin responsibility on someone else and to duck strong measures that could hurt them economically or politically.

One lesson from Rio is the excruciating difficulty of getting past the political barriers facing any attempt at a concerted international effort to achieve reform that is in every human being's long-term interest but runs contrary to many countries' short-term priorities. National sovereignties tended to constrain the effectiveness of the conference when it sought to protect the global commons. Concern was ample, but cooperation was elusive because nation-states defended the interests of their citizens, and this cast nation against nation, and often the developed nations against the developing nations. The question of responsibility to Earth was addressed only subsequently, when it was discussed at all. More frequently, the developing countries were demanding what they claimed to be their rights and the developed countries were defending what they claimed to be theirs.

A VISION FOR THE FUTURE

Nevertheless, UNCED produced memorable visions of responsibilities to life on Earth. Boutros Boutros-Ghali, speaking as the United Nations secretary-general, closed the Earth Summit: "The Spirit of Rio must create a new mode of civic conduct. It is not enough for man to love his neighbour; he must also learn to love his world" (Boutros-Ghali 1992a, p. 1). "We must now conclude an ethical and political contract with nature, with this Earth to which we owe our very existence and which gives us life" (Boutros-Ghali, 1992b, vol. IV, pp. 66–69). Such an environmental ethic enlarges its vision from a social contract to a natural contract between one planet and many peoples in search of an urgent world vision. The summit was a watershed because two principles of international order were solidified: an equitable international economic order and sustainable development with requisite protection of the environment.

The United Nations (UN) set up a Commission on Sustainable Development (CSD) for effective follow-up. In 1997 at the New York headquarters, the UN General Assembly held a five-year review of progress on Earth Summit, commonly called Rio+5. The assembly found uneven progress, with widening inequities in income and continued environmental deterioration. The World Summit on Sustainable Development (called Earth Summit 2002) was held, after ten years, in Johannesburg, South Africa, in 2002; it was boycotted by the United States. The UN simultaneously sponsored an intensive analysis, the *Millennium Ecosystem Assessment,* and a statement of millennium development goals.

Holmes Rolston III

ECOCRITICISM

If our personal lifestyles and the public policies of our governments are dictated by systems of values, then what shifts in values might guide us toward patterns of behavior that would be less detrimental to environmental health and social justice than the activities of the currently dominant model of global capitalism? What is the ideal relationship between the individual human mind and the rest of the world, or between human society in general and the rest of the world? How does language rhetorically function in environmental contexts? And what kinds of artistic expression—in literature, film, visual art, music, and even dance and television—might prompt people to attend more deeply to these questions, might guide us toward imaginative solutions of our most serious social and environmental problems?

When scholars ask themselves questions like these as they read, teach, and comment on literary texts and other works of art, they are practicing what scholars since the early 1990s have come to call ecocriticism, short for *ecological literary criticism*. The actual term *ecocriticism* was first used by William Rueckert in "Literature and Ecology: An Experiment in Ecocriticism" (1996 [1978]). Later Cheryll Glotfelty defined *ecocriticism* as "the study of the relationship between literature and the physical environment" (1996, p. xviii). Glotfelty's definition seeks to go beyond the narrowly anthropocentric scope of most literary scholarship, which has traditionally emphasized interactions among human beings, relationships between humans and their own constructs, and during recent centuries the interior psychological lives of human characters.

In various publications Scott Slovic defined the field more broadly:

> It is the study of explicitly environmental texts by way of any scholarly approach or, conversely, the scrutiny of ecological implications and human-nature relations in any literary text, even texts that seem, at first glance, oblivious of the non-human world. In other words, any conceivable style of scholarship becomes a form of ecocriticism if it is applied to certain kinds of literary works; and, on the other hand, not a single literary work anywhere utterly defies ecocritical interpretation, is off-limits to green reading. (1999, p. 1102)

Slovic's understanding of the field emphasizes the porousness of ecocriticism: the idea that any standard mode of textual and cultural analysis in contemporary literary studies—from formalism to gender studies to cultural materialism—can be practiced from a green perspective.

The practical dimension of the field is reflected in Greg Garrard's approach in *Ecocriticism*: "Ecocriticism makes it possible to analyse critically the tropes brought into play in environmental debate, and, more tentatively, to predict which will have a desired effect on a specific audience at a given historical juncture" (2004, p. 14). Of the many definitions of the field proposed in recent years, the most profound may be David Mazel's flippant yet poignant assertion that ecocriticism is the examination of literature "as if the earth mattered" (2001, p. 1).

So does the environment, the Earth on which we live, matter? Even to teachers and scholars of literature? Even the most postmodern, urban, petroleum-loving, animal-hating individuals would have to admit that they breath air, drink water, and in myriad ways depend on the world for survival, while also affecting the world through resource use and the by-products of consumption. Because the condition of Earth is intrinsically important to all beings living on the planet, the decrease and outright destruction of the biosphere ought to be of concern to all thoughtful people, including scholars working in the humanities. It is no accident that the self-conscious practice of ecocritical scholarship began shortly after the emergence of the modern environmental movement in the 1960s. Ecocriticism enables literary scholars and scholars in neighboring disciplines to assert the relevance of their work to many of the world's most pressing contemporary issues.

Despite suspicion toward Western-style ecocriticism, the discipline quickly gained footholds in scholarly communities throughout the world. Initial resistance occasionally occurred because the field seemed to be relatively new and untested, sometimes because the theoretical apparatus of ecocriticism appeared less elaborate and sophisticated than that of other branches of contemporary humanities scholarship, and at other times because of an innate uncertainty about the social/political aims of Western environmentalism. As South Korean ecocritic Dooho Shin put it, "Without taking into consideration the political and social conditions of Korean society and

its South-North divided situation, ecocriticism will be dismissed as just one of those foreign ideas that the First World foregrounds and pushes onto less powerful countries to keep them under economic and political control" (1999, p. 127).

In many parts of the world today, one encounters the concern that Western environmentalism, including ecocritical literary scholarship, is simply a new form of colonialism. The answer to this concern may be to encourage countries across the globe to pursue their own versions of environmental protection and social justice, not merely to mimic or absorb approaches practiced in the West. As Shin proceeds to state in the previously cited essay,

> Implications of ecocriticism in Korea can also be found in the movement of the re-appreciation of traditional Korean and, more broadly, Asian religious thinking, culture, and literature. Blaming Western culture for many of the root causes of the current world-wide environmental catastrophe, scholars from both West and East began to turn to Eastern religious traditions as an alternative ecological solution, because, unlike the West's tendency to materialize nature, Eastern traditions value the harmony between nature and humans. (p. 127)

There is much to be gained from sharing culture in every direction. Quite possibly, some of the most wholesome and inspiring ideas about the relationship between humans and the rest of nature to be found in American environmental literature—works by David Abram, Peter Matthiessen, and Gary Snyder, among others—originated in Daoist, Confucian, and Buddhist philosophies from various parts of Asia. But it is also possible that the sense of contemporary urgency that we find in the environmental movements throughout the world—from Ishimure Michiko's stories of Minamata disease in southern Japan to Homero and Betty Aridjis's literary efforts on behalf of gray whales off the coast of Mexico—may have its source in the European and American tradition of social activism, spurred perhaps by the extreme environmental destruction caused by Western consumer cultures.

As various scholars have stated over the years, ecocriticism is not so much a specific critical methodology as a movement, a broader perspective toward the enterprise of literary scholarship and toward the meaning of human society on this planet. As Lawrence Buell stated, "The environmental turn in literary studies is best understood, then, less as a monolith than as a concourse of discrepant practices" (2005, p. 11). The cross-disciplinary influences on ecocriticism bring together ideas and vocabularies from the social and natural sciences to foster a deeper appreciation of the environmental implications of literary texts.

In today's society one of the most basic roles of environmental writers and their scholarly commentators is simply to redirect our attention to the world beyond human construction—to make us pay more attention to ourselves and to nature. This emphasis on consciousness raising often considers the psychological processes by which humans contemplate their relationships to place and other living organisms, employing the terminologies of ecopsychology, cognitive psychology, and sometimes the philosophical ideas expressed in such works as Anna L. Peterson's *Being Human: Ethics, Environment, and Our Place in the World* (2001). Other common ecocritical perspectives focus on the significance of gender in determining and explaining human attitudes and behaviors toward each other and toward the natural world. The natural and engineering sciences—from evolutionary biology to concepts of prediction and computer modeling—have provided useful theoretical scaffolding for ecocritical studies.

The 2002 publication of *The Environmental Justice Reader*, edited by Joni Adamson, Rachel Stein, and Mei Mei Evans, formalized the work that many scholars had been pursing for years in the effort to show how environmental problems are often fundamentally linked to social problems and social injustice. As T. V. Reed put it in his contribution to that collection, environmental justice ecocriticism asks such questions as,

> How can literature and criticism further efforts of the environmental justice movement to bring attention to ways in which environmental degradation and hazards unequally affect poor people and people of color? . . . How can issues like toxic waste, incinerators, lead poisoning, uranium mining and tailings, and other environmental health issues, be brought forth more fully in literature and criticism? . . . To what extent and in what ways have other ecocritical schools been ethnocentric and insensitive to race and class? (2002, p. 149)

Subsequent volumes, such as the collection *Caribbean Literature and the Environment* (DeLoughrey et al. 2005), have demonstrated that environmental justice is the most suitable lens through which to appreciate the complex intertwining of social and ecological history in some parts of the world, especially where the impact of colonial brutality has been most destructive and where the legacy of colonialism continues to affect how people and the land are treated. Meanwhile, other scholars, especially moved by human mistreatment of other animal species, argue that until humans can learn to respect the subjectivity and intelligence, the mere right to life, of organisms other than ourselves, we cannot be fully humane in our treatment of each other. Particularly

eloquent studies of how literature can guide us toward this expansion of ethical thought and action include Randy Malamud's *Poetic Animals and Animal Souls*, in which he calls for a new "ecocritical aesthetic ethic": "seeing animals without hurting them; seeing them in *their* differences; teaching about animals; advocating respect for them; and finally *knowing* them, richly but also incompletely" (2003, p. 45).

Finally, some of the important contributions to ecocriticism have been studies not of literature per se, but of artistic media that closely parallel literary expression. These studies serve as demonstrations that film, visual art, and music probe our experience of the natural world and compel audiences to contemplate important social change in an effort to overcome environmental destruction. Major ecocritical examinations of film include Jhan Hochman's *Green Cultural Studies* (1998), David Ingram's *Green Screen* (2000), and Scott MacDonald's *The Garden in the Machine* (2001). Works such as Simon Schama's *Landscape and Memory* (1996) and David Rothenberg's *Sudden Music* (2001) extend ecocritical analysis into the realms of visual art and music/natural sound, respectively.

In this disparate and energetic field of humanities research, what is there to hold the discipline together, to provide a center of gravity, a common focus of attention? Several theorists of ecocriticism, less patient with the pluralism of the field than their predecessors, have suggested that ecocriticism, in its purest and most potent form, must address the moral urgency of the environmental degradation of the planet. For instance, the Puerto Rican scholar Camilo Gomides writes that ecocriticism, for him, is "the field of enquiry that analyzes and promotes works of art which raise moral questions about human interactions with nature, while also motivating audiences to live within a limit that will be binding over generations" (2006, p. 16). Ecocritics working in all branches of the field take heart in the activist zeal that motivates the more extreme and militant practitioners, even if most scholars, like the artists they study, operate in a more celebratory, less overtly political, vein.

Using their preferred term *ecoliterature*, the Chinese ecocritics Wang Nuo and Zhang Bigui have offered a prognosis for the future of the field—both the literature itself and the scholarly examination of this literature. They write that the field of ecoliterature will prosper so long as the ecological crisis is with us, and that the field will decline only when it achieves its purpose of a "reliable, sustainable, and secured environment" (2006, p. 10). Unfortunately, we are not close to achieving this dream of a stable, secure, healthy environment. Hence, the field of ecocriticism and the artistic texts it examines will likely become increasingly important during the coming decades. If this work manages to gain some traction in the realm of public policy and in the daily lifestyles of people in consumerist, polluting societies around the world, there is a slight chance we might avert, or at least slow down, the collapse of the ecosystems that we rely upon for our very lives. And it is in pursuit of this goal that ecocritics toil.

ECOLOGICAL FEMINISM

Ecological feminism is the confluence of feminist and environmentalist strains of thought. Its main claim is that "nature" (or the natural environment) is a feminist issue. Something is a feminist issue when understanding it helps one understand something about the social and economic status of women. Equal rights, comparable pay for comparable work, and day-care centers are feminist issues because understanding them sheds light on the subordination of (many) women. Sexism, racism, classism, heterosexism, ethnocentrism, and colonialism are also feminist issues because understanding them helps one understand the subordination of (many) women. Likewise, deforestation, desertification, and water pollution are feminist issues because understanding them helps one understand both the subordination of (many) women.

Defining ecological feminism more precisely in the context of environmental ethics and environmental philosophy is not that easy. There are five contributing factors that make defining ecological feminism (or "ecofeminism" as it is often called) difficult. The first is that just as there is not one feminism, there is not one ecological feminism. Historically, the variety of different feminisms (e.g., liberal, Marist, radical/cultural, social/socialist feminisms) gave rise to a variety of different ecological feminisms. A second factor is that the varieties of ecological feminism that emerged in the 1980s and continued through the 1990s often were a response to two competing environmental ethics: deep ecology and social ecology. Separating off the basic claims of ecological feminism from the positions they criticized poses its own challenges. A third factor is that some ecological feminisms emerged as differing accounts of how the separation of the human from the nonhuman world happened and ways the separation disproportionately and adversely effected women and children. For example, Greta Gaard and Lori Gruen define ecological feminism in this way, offering six explanations of the ways the separation occurred: scientific; religious; psychological; economic; human evolutionary development; and the mistreatment of animals and women (Gaard and Gruen 2005). Such accounts, however, do not define ecological feminism as an environmental ethic or environmental philosophy, because none of the six explanations is distinctly philosophical and the set of six parameters of human-nonhuman separation might exclude some noncontroversial ecological feminisms. Fourth, ecological feminism has become a scholarly topic in nearly every academic discipline and many interdisciplinary programs, producing positions that do not easily fit within disciplinary boundaries, emphases and methodologies. Fifth, taxonomies of ecological feminisms in terms of alleged women-other Others-nature connections (Warren 2000) often mistakenly suggest that these connections are stable, static or fixed; that suggestion misrepresents both differences and commonalities among distinct ecological feminisms. (The word *Other* is often capitalized by feminists to refer to any description or characterization of beings [human and nonhuman animals], "natural objects" [such as forests, watersheds], and nature itself as mere objects that do not have or deserve moral consideration [or, are not morally considerable]. This status of an Other is in contradistinction, and often opposition, to those "others" who regard themselves, or are regarded by the dominant group or tradition, as subjects who have or deserve moral consideration. For many ecofeminists, the "Other" refers to those deemed inferior by 'ratio-normative, hetero-normative, white male human being, who, by contrast, historically or currently accept and assimilate themselves to the dominant norm.) The sixth and last factor is implied by the other five: There is simply no one, unified notion of ecological feminism. Instead, there are clusters of positions and efforts that are related as much by family resemblances as by common perspectives, analyses and agendas.

Mindful of all its diversity, what is a minimal-condition characterization of ecological feminism? First, all ecological feminisms are explicitly both feminist and environmentalist, despite very real differences among them regarding their understandings of feminism and environmentalism, women and nature, oppression and liberation (Cuomo 1998). Second, ecological feminism posits a variety of connections between the domination of women (and other Others) and the domination of "nature." Beyond that, self-identified ecological feminists seem to share three additional convictions: (1) ecological-feminist insights concerning women-other Others-nature connections should be a part of any adequate environmental ethic or environmental philosophy; (2) ecological

feminism's critique of the gender-exclusive nature of leading positions in environmental ethics and environmental philosophy comes with the responsibility of engaging in practices intended to help dismantle the unjustified systems of human domination; (3) a commitment to ecological feminism involves creative problem-solving in developing life-affirming, environmentally and socially sustainable, biologically and culturally diverse practices, policies, lifestyles, and communities of choice.

Even though one can so characterize ecological feminism (especially as a philosophical position), it is quite a different matter whether, in contemporary patriarchal and naturist culture, one can live anything like an ecological feminist lifestyle or practice the commitments of ecological feminism in one's personal and professional lives. That is neither a defect of ecological feminism nor a defect of human will. Ecofeminists see this as the current reality of what is and is not possible in a society that is institutionally structured by "isms of domination," that lacks the infrastructure to make it possible to live an ecologically responsible lifestyle or to always act in accordance with one's feminist commitments. In addition, ecological feminism is not a fixed position or event; it is a way of thinking and set of practices in transition, a social movement in-process. Ecological feminism is about the gendered journey to continually seek out and expose (objectionable) male-bias wherever and whenever it occurs in feminism, environmentalism, environmental ethics and environmental philosophy. Recognition of the in-process nature of ecological feminist theorizing, practice, and grassroots activism contributes to its health, growth and sustainability, as well as its potential to join in solidarity with other social movements—such as the environmental justice movement, the civil rights movement, the peace movement—that (unlike ecofeminism) may or may not have gender as the starting point or primary category of analysis.

LINKS BETWEEN ENVIRONMENTAL AND FEMINIST ISSUES

Connections among environmental and feminist issues are well documented in two (of many) principal ways—empirical and linguistic—about which a brief account follows (Warren 1987). For empirical connections, consider women's gendered role responsibilities in much of the "South" (countries in the "developing" world or the less developed tropical and subtropical regions of the world in both the Northern and Southern hemispheres) regarding trees and forests. In India forests are inextricably connected to rural and household economies managed by women. As managers of forests, collectors of firewood, and heads of subsistence domestic economies, Indian women are thus the primary victims of forest resource depletion (Fortmann and Rocheleau 1985). Trees provide such essential elements necessary to the maintenance of women-headed households as food, fuel, fodder, products for the home (including building materials, household utensils, gardens, dyes, medicines), and products that generate income on local markets. As trees become scarce, women must walk farther for fuelwood and other forest resources and carry it without the help of animals or vehicles. Moreover, as a result of World Bank projects designed to solve tree shortages by creating monoculture tree plantations (typically eucalyptus or teak), rural men increasingly seek employment in towns and cities, leaving women to carry out both men's former jobs and their own time- and labor-intensive tasks of collecting and processing forest products on degraded soils.

The impact on Southern women of fuelwood scarcity is serious. The United Nations reports, "Rough estimates of the proportion of rural women affected by fuelwood scarcity—based on estimates . . . of the percentage of household energy provided by fuelwood—are 60 percent in 32 African countries, nearly 80 percent in 18 Asian countries, and nearly 40 percent in 14 Latin American and Caribbean countries" (United Nations 1995). These empirical data link feminist and environmentalist issues by showing how women's responsibilities for collecting firewood, maintaining domestic households, and managing forests is significantly, directly and disproportionately affected by tree shortages and loss of indigenous, multispecies forests (Warren 2000).

Environmental issues and feminist issues are also linguistically and conceptually linked. The twentieth-century Austrian philosopher Ludwig Wittgenstein (1889–1951) argued that the language one uses mirrors one's view of oneself and one's world. Language thereby plays a crucial role in concept formation. Women routinely are described in pejorative animal terms: Women are dogs, cats, catty, pussycats, bitches, beavers, old bats, cheetahs, vixens, serpents, pets, dumb bunnies, cows, foxes, chicks, old hens, old crows, queen bees, hare-brains and bird-brains, elephants, and whales, and go to hen parties. Women cackle, henpeck their husbands, and become old biddies (old hens no longer sexually attractive or able to reproduce) (Dunayer 1995). Animalizing women in a patriarchal and naturist culture in which animals are seen as inferior to humans reinforces and authorizes women's inferior status.

Similarly, language that feminizes nature in a patriarchal culture, in which women are viewed as subordinate and inferior, reinforces and authorizes the domination of nature. Mother Nature (not Father Nature) is raped, mastered, controlled, conquered, and mined. Her secrets (not his) are penetrated, and her womb (men do not have

one) is put into the service of the man of science (not woman of science, or simply scientist). Fertile (not potent) soil is tilled, and land that lies fallow is useless or barren, like a woman unable to conceive a child. In these cases, the exploitation of nature and animals is justified by feminizing (not masculinizing) them; the exploitation of women is justified by naturalizing or animalizing (not humanizing) them. As Carol Adams argues in *The Sexual Politics of Meat,* language that feminizes nature and naturalizes women describes, reflects, and perpetuates unjustified patriarchal domination by failing to see the extent to which the dominations of women and nature, especially of nonhuman animals, are culturally analogous and not simply metaphorically analogous (Adams 1990; Warren 2000).

HOW ECOLOGICAL FEMINISM EPISTEMOLOGICALLY AND CONCEPTUALLY LINKS ENVIRONMENTAL ISSUES AND FEMINIST ISSUES

The preceding section illustrated the sort of empirical and linguistic connections that link feminist and environmental issues in ways that substantiate key claims of ecological feminism. But to establish ecological feminism as an environmental ethic and environmental philosophy, one must show that these links are grounded in deeper philosophical connections as well. How does one do this? There are three ways. The first identifies the male-gender bias of epistemological assumptions underlying these empirical and linguistic connections, which, unless questioned, perpetuate inaccurate, male-biased understandings of environmental issues concerning women, trees and forests. The second describes the conceptual framework that provides the theoretical basis for ecological feminism's linking of feminist and environmentalist issues. The third demonstrates how male-biased concepts, dualisms, and distinctions provide the argumentative justification for recognizing ecological feminism as an environmental ethic and environmental philosophy.

Consider examples of each of these three ways to link empirical, linguistic and conceptual links to philosophical connections. The first—identifying epistemological assumptions—may be illustrated by a long-standing assumption of orthodox forestry: "the outsider knows best": It is the detached, impartial, objective, graduate-degreed scientist who is the presumed expert ("knower") solving tree shortage problems. The World Bank funded these experts to plant and oversee monospecies eucalyptus plantations in northern India. But the empirical data on women and trees in northern India, as in much of the South, shows this assumption to be false: It is "the insider" (i.e., the local women most inside the culture)—who have the vital responsibilities regarding trees and forest management; it is they who have the requisite *indigenous technical knowledge* to know what is needed to restore indigenous forests and to solve the problem of tree shortages and deforestation. Their knowledge is not the "justified true belief" of an impartial independent, detached, objective observer, idealized in mainstream epistemology and philosophy of science. What they know is gained through their daily, concrete, felt, lived, partial, attached, involved, relational experience as primary users of the forest (Fortmann and Fairfax 1985). It is more akin to biologist Donna Haraway's epistemological view that knowledge is "situated"; situated knowledge is always given relative to a particular set of observations, beliefs, values, attitudes, or assumptions (Haraway 1988). The empirical data on women in Northern India as the "expert knowers" about trees is substantiated by a separate study of women in a Sierra Leone village: Women were able to identify thirty-one products from nearby bushes and trees while men could identify only eight (Hoskins 1982). Women's firsthand, experiential, gender-generated knowledge about multiple kinds and uses of local trees was neither available to local men nor Western ("outsider") foresters. The outsider does not necessarily know best.

A second assumption of commercial Western forestry is that activities that fall outside the boundaries of commercial fiber production are less important, because it does not register in econometrics. Yet these activities are precisely those that women engage in daily. Conceptually, this standard economics "invisibility" of what women do accounts for the mistaken assumption that management and production policies of orthodox forestry are not male gender-biased.

A third assumption of orthodox Western forestry concerns efficiency. Usually it assumes that it is better to have large-scale production using a small number of species than small-scale, community-based forestry using a wide variety of species. But the Chipko Movement (initially a movement of twenty-four women from northern India who hugged trees to prevent them from being felled by commercial loggers) challenges this assumption. Small-scale production reflects local priorities, involves multiple uses of many species of trees, is responsive to the social reality of women's importance in agriculture and forest production, and maintains the livelihood and well-being of women and children.

The second way ecological feminism links feminist and environmental issues is through the apparatus of an oppressive (especially patriarchal) conceptual framework. A conceptual framework is a learned set of basic beliefs, values, attitudes, and assumptions that shape and reflect how one views oneself and one's world. It functions as a

lens through which one perceives reality; it is socially constructed by such factors as sex/gender, race/ethnicity, class, age, affectional orientation, marital status, religion, nationality, colonial influences, and culture.

Some conceptual frameworks are oppressive. An oppressive conceptual framework functions to explain, maintain, and "justify" relationships of (unjustifiable) domination and subordination. When an oppressive conceptual framework is patriarchal, it functions to "justify" or legitimate the subordination of women by men.

There are five features of an oppressive (and patriarchal) conceptual framework (Warren 2000). First, an oppressive conceptual framework (OCF) involves value-hierarchical or Up-Down thinking—thinking that attributes greater value to that which is "Up" (e.g., wealthy white men) than to that which is "Down" (poor white women) (Gray 1981). It does so typically by citing some property that the Ups have and the Downs lack (or lack in the proper amount or respect)—such as reason or rationality. The claim then is that the Ups are justified in being Ups by virtue of that property. Second, an OCF contains descriptions of reality in terms of mutually exclusive, oppositional (not complementary) value dualisms (e.g., reason/emotion; culture/nature; mind/body; objective/subjective). These dualisms (disjunctions) are expressed through "either-or" thinking and language that places higher value (status, prestige) on that disjunct that historically is associated with male-gender identified traits. For example, Western philosophy historically has privileged reason over emotion, culture over nature, mind over body, objectivity over subjectivity. It also has associated (stereotypical) male-gender identified traits with the privileged disjunct—reason, culture, mind and objectivity, and women with the inferior or lower status disjunct—emotion, nature, body, and subjectivity. So the first and second features of OCFs are mutually reinforcing. They support the view that Ups are superior to Downs by virtue of their reason/rationality (not emotion) being in culture (not nature), having minds (not bodies) and being capable of objectivity (not mere subjectivity).

Third, in OCFs Ups have power and privilege—for example, to mobilize resources for self-determined ends—that systematically advantage them over Downs. Fourth, in systems of domination that assign power and privilege to those born male (white, upper-class) over those born female (of color, poor), the power and privilege of Ups is unearned, undeserved, and unmerited.

The fifth and philosophically most important characteristic of an oppressive (and patriarchal) conceptual framework is that it sanctions a "logic of domination." This is the moral premise that superiority justifies subordination. A logic of domination is the moral stamp of approval that "justifies" the domination of women, other Others and nature. This justification turns on the premise that reason (rationality) is the property that Ups have and Downs lack or, at least, lack to the requisite extent.

The five features of an oppressive, patriarchal conceptual framework provide the third way ecological feminism conceptually links feminist and environmental issues. All five of these time-honored features of mainstream ("canonical") Western philosophy are critiqued by ecological feminists. Ecofeminist philosophers Karen J. Warren (1992) and Val Plumwood (1993) critique the Western notion of reason as part of a male gender-biased dualism—reason/emotion—that creates a false ontological divide between humans and other beings, elevating humans into culture and out of nature. Plumwood adds that reason thereby provides a faulty conception of an atomistic, abstract individual self "hyperseparated from nature" in a way that makes impossible the notion of a relational, ecological self—a mainstay of much ecological feminist theorizing. This mainstay claim is that the self is not an isolated, immaterial Cartesian ego, soul or psyche in a physical body (lampooned as "the ghost in the machine"); rather, it is constituted by its relationships with others—just as in ecology the characteristics of various species are constituted by their relationships with other species and the abiotic environment.

Ecofeminist philosopher Chris Cuomo also criticizes dualistic thinking as male-biased, false dichotomies "construed in order to maintain a power structure and a false conception of essential reality" (1998). Because dualisms are construed in systems of binary opposition, they often become the bases of systems of domination and subordination; in fact, "many dualisms are based on a scientific view of the world that favors the most simple explanations consistent with the previous findings of science over more complex explanations that call given models into question" (1998). Theories and positions that presuppose such dualisms contradict feminist commitments to deconstructing oppressive systems and creating genuinely liberating systems and intentional communities.

ECOLOGICAL FEMINISM AND AN ETHIC OF CARE

The historical development of ecological feminism since the early 1970s reflects the variety of tradition-based positions in environmental ethics. For example, Peter Singer's utilitarian-based "animal liberation" and Tom Regan's animal-rights-based position were theoretical resources for early ecofeminist positions in defense of animals based on traditional rights theory (Adams 1990; Brown 2004; Kheel 1985; Gaard 1993; Gruen 1996), as were alternative theoretical positions based on Mill's utilitarianism (Donner 1997), and Immanuel Kant's ethics of duty (Wilson 1997). As feminist ethicists began developing an "ethic of

care," based on the work of Carol Gilligan (1980), so did ecofeminist ethicists (Curtin 1996; Warren 2000). Care functions as a primary, essential, moral ingredient of an ecofeminist ethic (see "justice versus care debate," below). The different ethical starting points of ecological feminism provide different accounts and recommendations about who and what is valuable, what sort of value nonhuman nature has, and what empirical aspects of life are ethically significant. Cuomo's ecological feminist ethics values "the flourishing of all living beings and communities" (Cuomo 1998). Her point of departure presupposes a conception of human well-being, grounded in a feminist conception of the self and the view that nonhuman beings and communities have value. Unlike other environmental ethics, Cuomo's offers notions of moral agency and moral considerability that are fluid (not static, unchanging, sets of essences or essential properties); moral agency is compromised and shifts by such factors as historical and material location, oppression, marginalization.

Warren (1990) has identified nine key features of an ecological-feminist ethic:

1. Ethical theory is conceived as theory-in-process that will change over time (illustrated through the metaphor of theorizing as quilting).
2. Nothing is part of an ecofeminist ethic that consciously, deliberately, or knowingly promotes sexism, racism, classism, naturism, or any other "ism of social domination."
3. An ecofeminist ethic is a contextualist ethic—one that sees ethical discourse and practice as emerging from the "voices" of entities located in different historical circumstances; an ecofeminist ethic often functions as a kind of narrative about humans, human-human relationships, and human-nonhuman animal or nature relationships.
4. These features of a contextualized ethic that often provides a sort of narrative, is a shift from a traditional, canonical ethic that is monist and focuses on absolute rights and rules to a pluralist focus on a variety of relevant values (rights, utility, duty, care), principles (including reformed principles of traditional normative ethics), narrative constructions and forms of intelligence (centralizing the role of "emotional intelligence" operating in concert with rational intelligence, as indicated below). It provides "a highly contextual attempt" (Cheney 1987 p. 143). For ecofeminist ethicists, how a moral agent is in relationship to another is of central significance. That is, it is not simply the nature of the agent or "other," or the ascription of rights, duties, and rules that apply to the agent that constitutes an ethic; the ethical nature of the relationship itself must be taken into consideration as well.
5. An ecofeminist ethic is an inclusive ethic that grows out of and reflects the diversity of perspectives of women and other Others, particularly those who disproportionately experience the harmful destruction of nonhuman nature (often poor women or communities of color in the North as well as the South. An ecofeminist ethic presupposes and maintains difference between humans and nonhuman animals and nature while also recognizing commonalities among these groups. Ecofeminist philosophy recognizes that humans, as ecological selves, are both members of an ecological community (in some respects) and different from other members of that community (in other respects). Accordingly, the attention of ecofeminist ethics to relationships and community is not an erasure of difference but a respectful acknowledgment of it.
6. Furthermore, an ecofeminist ethic makes no attempt to provide an "objective" point of view, since it assumes that in contemporary culture there really is no such point of view. This does not relegate ethics to relativism however. It acknowledges, for example, that, as a feminist ethic, if is gender-biased, but claims that this is a better bias (more inclusive and therefore less partial) bias than a male-gendered bias or biases that exclude the voices of the dominated.
7. An ecofeminist ethic provides a central place for values typically unnoticed, underplayed, or misrepresented in traditional ethics (e.g., values of care, love, friendship, and appropriate trust). It need not do this at the exclusion of considerations of rights, rules, or principles. There may be many contexts in which talk of rights or of utility is useful and appropriate; but the concept of care, for example, is not reducible to traditional theories of rights, rules, or principles; indeed Gilligan originally formulated the ethics of care as a feminist alternative to ethics of rights, rules, and principles.
8. An ecofeminist ethic involves a reconception of what it is to be human and to engage in ethical decision making, because it rejects as either meaningless or currently untenable, any gender-neutral description of humans, ethics, and ethical decision making.
9. An ecofeminist ethic acknowledges what psychologists and neuroscientists (see Goleman 1995) identify as "emotional intelligence," adopting their evidence that the ability to empathize and care is necessary for ethics, ethical reasoning and ethical decision making.

Some ecological feminists have focused on the "justice versus care" debate, both as Gilligan first articulated it and as it has been developed by feminist philosophers since. The justice perspective assesses moral conduct in terms of basic rights, rules or principles. A moral agent is viewed as a rational, detached, disinterested, impartial, independent being. The justice-oriented ethical framework is essentially hierarchical or pyramidal, where the "authority" of a right, rule, or principle is given from the top of a hierarchy of rights, rules, and principles. In contrast, the care perspective assesses moral conduct in terms of such values as intimacy, empathy, friendship, and appropriate trust. Selves are conceived "ecologically" as relational, partial, attached, interdependent, and historically situated. Morality is a matter of values, virtues, and vices, which are not unpacked in hierarchically ordered, ahistorical principles of justice.

An ethic of care offers six types of criticisms of an ethic of justice:

1. An ethic of justice is based on a faulty conception of selves as atomistic individuals, rather than as socially constructed, relational, selves that are themselves historically situated, geographically located, ecological beings (like organisms that are adapted to a niche in the "biotic community") and whose "nature" is not determined by any transcendental "essential properties";
2. It preserves a mistaken or limited concept of morality as fundamentally a matter of absolute and universal rights, rules, and principles;
3. It assumes that moral conflict resolution is always about adjudicating competing interests, rights, or rules in a hierarchical, adversarial, winner-loser ("zero-sum") way;
4. It fails to appreciate the extent to which other values, particularly values of care, enter into actual decision-making of actual women (and others) confronted with genuinely morally conflictual situations;
5. It misrepresents morality as non-ambiguous, simplified, and abstract, when most of us experience morality as ambiguous, complex, and concrete;
6. Its methodology tends to reproduce the status quo, entrenching existing power- and authority relations by methodologically concealing those relations.

The scholarly literature on an ethic of care is extensive. Ecological feminist ethics that appeal to care agree with the six main criticisms care ethicists make of "the justice perspective." However, ecological feminisms that utilize notions of care in fundamental ways do not necessarily adopt an "ethic of care." That is because they do not locate the moral significance of care in a separate ethic, which (allegedly) contrasts or competes with, or is integrated with, an ethic of justice. Locating care in this way only serves to perpetuate the traditional adversarial and hierarchical approach to ethical monism. Instead, the moral significance of care is understood as contributing to ethics in at least four ways:

1. It makes the ability to care central to motivating ethical conduct, reasoning ethically, and making ethical decisions;
2. It assesses the appropriateness of an ethical decision in a given context partly by how caring the resulting practices are;
3. It makes care a moral emotion and locates ethics in human psychology.
4. It provides a non-question begging answer to the question "Why care?" The answer: One cannot reason morally, be motivated to act morally, choose to act morally, or value certain practices as moral and others as immoral or amoral unless one cares.

THE "DEEP ECOLOGY/ ECOFEMINISM DEBATE"

In 1973 Norwegian philosopher Arne Naess wrote a seminal article, "The Shallow and the Deep, Long-Range Ecology Movement," in which he used the term "deep" to refer to the development of a new, challenging, profound ecological consciousness, in contrast to a "shallow" focus on more conventional, apolitical issues like resource depletion, pollution, and recycling, While no attempt is made here to engage the debate, in part because most ecofeminisms have moved beyond the debate, some of the points of contention in the ecofeminism/Deep Ecology debate are summarized.

Deep Ecology, like ecofeminism, is not one unified movement. Although the Deep Ecology "platform" consists of eight planks, there are four basic claims of Deep Ecology:

1. Deep Ecology is contrasted with "reform environmentalism" (shallow ecology);
2. Deep Ecology endorses "biocentric egalitarianism—in principle," the position that all living things have an "equal right to live and blossom" as entities with "inherent" or "intrinsic" value;
3. Deep Ecologists are critical of animal ethics as not a true liberation of nature but only of sentient life forms within nature;
4. According to the Deep Ecology principle of Self-realization, humans are not discontinuous with nature. The human self (*jiva* in ancient Hindu

thought) is only fully realized when it identifies with the larger cosmos—the Self (*Atman/Brahman*).

"The Deep Ecology-Ecofeminism Debate" that began in the early 1980s focused on five main questions: First, is the root environmental problem anthropocentrism (human-centeredness), an assumption of Deep Ecology, or androcentrism (male-centeredness)? Second, is deep ecological practice, particularly EarthFirst!, an expression of gender, race, class, and geographical privilege? Third, does Deep Ecology presuppose a masculinist psychology? Fourth, is the Deep-Ecological platform male-gender biased? (also a question not addressed here). Fifth, are the principles of biocentric egalitarianism-in principle and Self-realization problematic from an ecofeminist point of view?

Ecological feminists have provided different answers to these questions. Ariel Salleh (1984, 1993) argues that androcentrism, not anthropocentrism, is the source of the worldview that posited a firm ontological divide between culture and nature. She holds that the notion of Self-realization is an objectionably abstract, transcendental view of becoming one with nature, with no recognition of women's lived experience of being in both culture and nature. In her view the goal of biocentric egalitarianism-in principle cannot be achieved without attending to sexism, racism, classism, and the complex "interlocking issues, economic and ideological." For these reasons, she continues to be an opponent of Deep Ecology.

Other ecofeminists (Cheney 1987, Cuomo 1994, Doubiago 1987, Hallen 1999, Kheel 1990, Plumwood 1993, Sessions 1996, Slicer 1995, Sturgeon 1993, and Warren 1999) have offered clusters of similar criticisms. In varying ways, they claim that Deep Ecologists do not adequately do any of the following: engage sufficiently with feminism; acknowledge different versions of ecological feminism; adequately integrate theories of gender, race and class oppression with that of the undifferentiated, indiscriminate human domination of nature; recognize the male-gender bias in their positions; conceptualize ecological feminism as a separate position from Deep Ecology; appreciate that dualisms are the main ideological strategy of patriarchal domination**;** politicize identification with nature; recognize that the Deep Ecologist's notion of the Self is masculinist, all encompassing, totalizing and detached from social and political realities, problematically transcendent and indistinguishable from nature; adequately critique the rationalist tradition or appreciate the value of the personal, embodied, productive and reproductive self; and show sensitivity to the notion of wilderness as having indigenous inhabitants.

Many Deep Ecologists criticize different versions of ecological feminism (Fox 1998, Naess 1999, Tobias 1983). The more common criticisms are that ecofeminism: falsely essentializes women as better nurturers and "closer to nature than men"; loses focus on the natural world in its preoccupation with social justice issues; reinforces harmful and apolitical gender stereotypes of "mother earth"; tends to privilege white women's experience of the world and fails to see forces in addition to patriarchy that contribute to unjustified dominations of human groups and nature.

Since the early 1990s many versions of ecofeminism have been developed that are not, or are far less, susceptible to Deep Ecology's criticisms. During the same period, however, Deep Ecology did not develop into a main stage player in environmental ethics and philosophy—as was expected. though Its main influence now is in various forms of environmental activism, from Earth First!ers, who are also on the wane, to conservation biologists who are in ascendency.

ECOLOGICAL FEMINISM AND ESSENTIALISM

Sherry Ortner's 1974 essay "Is Female to Male As Nature Is to Culture?" asks whether women are closer to nature than men. Ecofeminists who answer "yes" are vilified by other ecofeminists as biological determinists, conceptual essentialists or, to use the language of Victoria Davion "ecofeminine" rather than "ecofeminist" (Davion 1994). Some ecofeminist philosophers have argued that the question is malformed, since it presupposes the legitimacy of the false "culture verses nature" dualism. Ecofeminist philosophers also have argued that both "women" and "nature" are socially constructed concepts for which there is no set of essential properties or characteristics about members of either category. This means that there is no meaningful understanding of women *simpliciter.* Every woman's identity is socially constructed by such factors as race/ethnicity, socioeconomic status, affectional/sexual orientation, geographic and material location, age, and marital status. Furthermore, the category *women* is destabilized by the different roles and positions women occupy as mothers, daughters, wives, partners, lovers, workers, sexual and materially embodied beings. Accordingly, it is neither possible nor desirable to seek an essence shared by all women—what one would have to do to take seriously Ortner's question or engage with deep ecologists who criticize those (early) select ecofeminists who seem to say "yes."

Note that saying "nature" and "women" are socially constructed concepts does not mean that no references to, or generalizations about, women are possible. A rejection of conceptual essentialism (the view that there are some properties that apply, for example, to all and only women) is compatible with endorsement of strategic uses of "women" in order to make defensible generalizations about women "on the average"—such as that women grow at least half of the world's food in Africa (they

produce almost 90 percent). Well-placed, strategic claims about women, including claims about differences among women in connection with disproportional effects of environmental degradation on the health and livelihood of different groups of women, are necessary to any feminist or ecofeminist analysis. The main point is that a strategic use of the concepts "women" and "gender"—so-called "strategic essentialism"—does not imply or accept a conceptually essentialist notion of either. Gendered perspectives will continue to permit some useful generalizations: those that pass what Warren calls "the 4 R test" will continue to be theoretically and strategically important. "The 4 R test" specifies that the samples which are the basis of generalizations must be *r*andom, *r*epresentative, the *r*ight sample size, and *r*eplicable (or, *r*epeatable).

CONCLUSION

Ecological feminism is a cluster of theoretical perspectives, not a monolithic philosophy. It also is a social movement that offers novel solutions to contemporary environmental and feminist issues. Nearly every academic discipline now harbors a body of ecofeminist scholarship within that discipline. The commitment of ecological feminism is to develop strategic explanations and conceptual analyses of interconnected environmental and feminist issues that generate creative, healthy and sustainable relationships among us all with each other and with the earth.

ECOLOGICAL RESTORATION

The term *ecological restoration,* which often is used interchangeably with *restoration ecology,* refers to the science and social practice of re-creating ecosystems that have been damaged or destroyed by human activity or natural events. Ecological restorationists have attempted to recreate a wide variety of ecosystems, including tall-grass prairies, oak savannas, wetlands, forests, streams, rivers, and coral reefs. These projects can range from small-scale urban park reclamations, such as ongoing restorations in urban parks in New York and Chicago, to huge wetland mitigation projects encompassing hundreds of thousands of acres, such as the $8 billion project to restore the everglades ecosystem in Florida. Also included in ecological restoration are attempts to reintroduce species, principally to save those which are endangered, and the removal of exotic species thought to be a threat to native biodiversity.

ACADEMIC BACKGROUND AND FIELD PRACTICE

As a scientific practice restoration ecology has its background primarily in academic disciplines such as field botany, conservation biology, landscape ecology, and adaptive ecosystem management. As an exercise in environmental-design practice most restoration in the field is orchestrated by landscape architects and environmental engineers. However, a range of other academic disciplines, including philosophy, have been attracted to restoration both as an object of study and as an opportunity to apply their ideas on the ground (Gobster and Hull 2000). Some of the first tall-grass prairie restorations in the United States were initiated by Aldo Leopold at the University of Wisconsin Arboretum and on his own land on the Wisconsin River (Meine 1988).

Environmental philosophers attracted to restoration initially focused principally on the issue of whether a restored ecosystem could be an adequate substitute for the original ecosystem it was emulating and, as part of that inquiry, whether restored ecosystems were really natural or instead humanly produced artifacts. The most influential and widely discussed work by environmental philosophers on this topic is that of Robert Elliot (1982, 1997) and Eric Katz (1996, 1997, 2002, 2007a and b),

Wetland Restoration, West Virginia, 2005. *In addition to re-creating a wide variety of ecosystems, ecological restorationists attempt to reintroduce species and remove exotic species thought to be a threat to native biodiversity.* **PHOTO BY TODD HARLESS/U.S. FISH AND WILDLIFE SERVICE.**

both of whom argued that ecological restorations do not produce natural entities and that restorations may harm naturally evolved systems, especially if one considers those ecosystems a subject worthy of moral consideration in their own right.

THE THEORIES OF ELLIOT AND KATZ

The initial concerns of Elliot and Katz were based on their objections to the claims of some professional restorationists and, for Elliot, some corporations that suggested that a restored environment could replicate the value of the original environment it was replacing. Elliot began an article on restoration titled ''Faking Nature'' by identifying an Australian corporation that claimed that it should be allowed to mine ore from a pristine environment on the grounds that it could restore that environment fully at a later time. Elliot called that view the restoration thesis and stated that it consists of the claim that ''the destruction of what has value [in nature] is compensated for by the later creation (re-creation) of something of equal value'' (Elliot 1982, p. 82). Elliot rejected the restoration thesis by using an analogy based on the relationship between original and replicated works of art. Just as we would not value a replication of a work of art as much as we would value the original we wouldn't value a replicated bit of nature as much as we would the original thing. What gives value to a work of art, for Elliot, is its origins (who produced it, at what time, and in which artistic milieu and its respective importance in that milieu); equally, what in part gives value to nature is its origins, most importantly the fact that it is not human-made. In light of their anthropogenic origins, restorations are not natural entities if one understands nature as having non-human origins.

Elliot supplemented that general claim through a series of thought experiments that show how a person who placed high value on wilderness could find fault with a series of humanly produced simulacra, including a restored environment modeled on a naturally occurring wilderness. That argument is expanded and given a stronger philosophical foundation through the development of a subjectivist account of intrinsic value in Elliot's 1997 book, which also was titled *Faking Nature*.

Katz went much further than Elliot in making a case against restored environments. He used a similar distinction between the natural and the nonnatural—specifically between the natural and the artifactual—as a starting point. For Katz it is not just that ecological restorations are artifacts but that they are artifacts whose existence demonstrates human hubris (people presume the ability to replicate and replace natural environments and therefore may be inclined to destroy as much as they want of such environments on the assumption that they can recreate them) and exemplifies a form of domination over the natural world by imposing people's will on it. People restore nature to the form they want it to take, make it perform the functions they want it to perform, and in doing so constrain natural systems from evolving as they would without human interference. In this view restored ecosystems are an embodiment of everything that is wrong with anthropocentrism. Katz makes the point that "the practice of ecological restoration can only represent a misguided faith in the hegemony and infallibility of the human power to control the natural world" (Katz 1996, p. 222).

REACTIONS TO KATZ AND ELLIOT

The initial concern of many other environmental ethicists who added to the literature on restoration was to respond to what might be called the Elliot-Katz view (Gunn 1991, Scherer 1995, Throop 1997, Lo 1999, Light 2000). Those responses took the form of general criticisms of the distinction between the natural and the nonnatural (the nature-culture dualism) in those accounts (Gunn, Scherer, and Lo), questions about the propriety of Elliot's analogy between the value of nature and the value of art (Gunn), and criticisms of the potential lack of appreciation in the Elliot-Katz literature for specific restoration practices with a particular focus on the necessity of removing exotic species of flora and fauna to maintain biological diversity and ecosystem integrity and health (Throop and Light).

In addition, many restorationists wrote about the kinds of issues raised in the Elliot-Katz literature, responding in large part to the publication of a version of Katz's 1992 influential paper on restoration "The Big Lie: Human Restoration of Nature" (reprinted in Katz 1996) in one of the two main journals in the field of restoration ecology, *Ecological Restoration,* then called *Restoration and Management Notes*. In large measure the responses took the form of claims that restorationists could avoid the concern that restorations are not natural by strictly prescribing that ecological restorations would have to reproduce as closely as possible the exact ecosystems that had existed at the same locale in an identified natural state. Although that answer does not address the ontological claims in the Elliot-Katz view, it began what has become known as the authenticity debate among restorationists.

Discussion of the original propositions advanced by Elliot and Katz has continued (Vogel 2003). However, in the first decade of the twenty-first century the philosophical debate on that topic went beyond the criticisms raised by Elliot and Katz. On the one hand, earlier philosophical focus on restoration has led to increased critical questions about the conceptual foundations of restoration without entailing a wholesale rejection of restoration as an environmental practice. On the other hand, some of those who have rejected the criticisms of Elliot and Katz have gone on to make a positive case for the moral or social value of ecological restoration.

CONTEMPORARY ISSUES

The issues discussed above can be divided into three categories: defining what restoration is (something that has plagued the Society for Ecological Restoration [SER], the principal international organization of restorationists and those studying restoration), distinguishing between native and exotic species (which in part drives the activity of restorationists who define the practice in part around the removal of exotic species and the maintenance of native biodiversity), and determining the period to which people should endeavor to restore a place, with attention to the specific question of whether the goal should be pre-Columbian or presettlement. None of these issues could be considered settled, but each has been the subject of interesting work. Eric Higgs (2003) contributed important work on the first and third topics in his scholarly publications on the distinction between restorations and good restorations and as a president of SER. Mark Woods and Paul Moriarty (2001) argued that the second issue should be resolved through a defensible set of distinctions concerning what makes an exotic species exotic, and Mark Sagoff (2000) encouraged abandonment of the distinction. Numerous philosophers have weighed in on the issue of the alleged naturalness of the pre-Columbian ecosystem as part of a general criticism of the idea of wilderness (Callicott 1995).

Among those who have made positive cases for restoration that have been discussed and criticized are

Wildflowers at American Camp, Washington. *The American Camp prairie, located in the San Juan Islands National and Historical Park, underwent an extensive retoration beginning in the early 2000s. The area is one of the last surviving natural prairies in the region. Without such a restoration, park officials belive that encroaching nonnative plants would overcome native ones, and over time the prairie would become completely forested.* **PHOTO BY MIKE VOURI.**

Higgs, William Jordan (2003), and Andrew Light (2000, 2002). Higgs (2003) combined an understanding of the philosophical questions at the heart of restoration with field experience in the design of restorations. In one important respect, Higgs fully embraced the cultural aspects of the practice, arguing that the reference ecosystems for restorations of necessity have cultural components insofar as humans have evolved a variety of modes of interaction with different places that have shaped their coevolution. A well-designed restoration not only contributes to the ecological integrity of a site but also helps improve the human relationship with particular places. Jordan (2003), one of the founders of the modern science of restoration, argued that the practice of restoration not only can improve people's relationship with the natural world but also overcome the ''existential shame'' that humans have in relation to the natural world insofar as their existence relies on and is maintained by the destruction of nature. Light (2002) argued that the positive value of restoration lies in its ability to provide opportunities for direct public participation in environmental management and thus serve as a foundation for building ecological citizenship.

New critical work on these figures and others has led to a reassessment of the original arguments by Elliot and Katz as well as potential new directions in the moral dimensions of restoration practice (Katz 2007a, 2007b, Throop and Purdom 2006). A new subfield of restoration appears to be emerging in response to climate change. This subfield focuses on the necessity of designing so-called novel ecosystems by constructing ecosystems in places where they have never been before as a way of adapting to global climate change. The development of this field is sure to spark further philosophical debate.

ECOLOGY

This entry contains the following:

I. OVERVIEW

The distinctive subject matter of the science of ecology was first identified by the English naturalist Charles Darwin (1809–1882). He recognized that the struggle for existence that was the engine behind natural selection was, although extremely complicated, amenable to scientific investigation. Darwin did not give a name to this distinctive study; it was the German biologist Ernst Haeckel (1834–1919) who first christened this area of scientific inquiry as ecology in 1866.

Neither Darwin nor Haeckel did much by way of direct investigation of these processes; the latter part of the nineteenth century, however, did see a number of biologists actively investigating "conditions of existence" of various kinds of organisms. For the most part these early studies focused on the interactions between organisms and the physical conditions of their environment. In aquatic environments, for example, much effort was devoted to the impact of factors such as pH and salinity on the fates of organisms. The tendency in these early studies was to focus on individual species. It was plant ecologists who took the lead in moving inquiry in the

direction of the patterns and mechanisms of organization among communities of organisms.

The beginning of the twentieth century saw the introduction of the first widely influential theoretical perspective in ecology: the superorganism view of the community introduced by the American plant ecologist Frederic Clements (1874–1945). Two decades later the English zoologist Charles Elton (1900–1991) provided a comprehensive theory from the perspective of animal ecology. Although the superorganism ideas of Clements have been largely superseded, the theoretical approach of Elton, which focused on the factors that limit community membership, has remained influential. In 1935 the English botanist Arthur Tansley (1871–1955) introduced the ecosystem concept into ecology; a decade later, following seminal contribution by American ecologist Raymond Lindeman (1942), a robust research program of ecosystem studies was underway. By the middle of the twentieth century, ecology was moving forward as a coherent scientific discipline with its familiar hierarchy of individual, population, community, and ecosystem ecology in place.

The hierarchy of levels of organization of ecological phenomena provide natural topical partitions. At the basic level is the Darwinian struggle for existence that each organism must wage. One level up is the aggregation of individual organisms into populations. Populations themselves come together to form communities, and communities exist in a physicochemical context that is shaped by climatic, geological, and other physical processes—the level of the ecosystem.

APPLIED ECOLOGY AND ACADEMIC ECOLOGY

There is an important difference between applied ecology and academic ecology. Applied ecology is concerned primarily with the conservation and management of natural resources. In the United States both the federal government and all the states have a division of government directed toward this end. This governmental body is typically further subdivided into programs in fisheries, wildlife, and forestry. The applied ecologists that populate these programs usually receive their training from academic programs in the relevant fields. Academic ecology focuses on scientific understanding for its own sake, pursuing research programs for the ecological insights they reveal, irrespective of any potential practical utility.

The American ecologist and forester Aldo Leopold (1887–1948), one of the seminal figures in the early history of applied ecology, neither made nor exemplified such a distinction. Nevertheless, these two traditions of ecological inquiry have developed along independent trajectories, with little interaction even though management activities represent a form of experimentation that could, if properly integrated, inform the more academic side of the discipline (Norton 2005).

Although the development of applied ecology owes much to the natural-resource management tradition, its goals are much broader, and the horizons of its practitioners extend well beyond the various governmental agencies. The vibrant field of conservation biology—concerned primarily with protecting the planet's biological diversity—involves a significant degree of application of ecological ideas. Applied ecologists are also concerned with issues such as ecological restoration, integrated pest management, and a host of other land-use concerns.

INDIVIDUAL ECOLOGY

Much of the ecology that takes the form of natural history focuses on the ways in which individual organisms of a species interact with their environment. In part the fascination of Leopold's *A Sand County Almanac* (1966 [1949]) stems from his excursions into the processes whereby various individual organisms in a habitat are both shaped by and give shape to the land. He contributed to a venerable natural history tradition in ecology that focuses on the various life-history patterns and requirements of organisms. For example, the Wisconsin Department of Natural Resources publishes a brief pamphlet titled "The Ecology of the Black Crappie." The black crappie is a fish species of some recreational significance in the state. The pamphlet details various features of the life history of the species: its habitat requirements, the water temperature that induces spawning, and major predators and prey. This is ecology at the level of the natural history of the species. Although not very glamorous, this kind of inquiry is significant in the overall development of ecological understanding. As G. E. Hutchinson once said of Robert MacArthur (1930–1972), perhaps the most influential theoretical ecologist in the history of the discipline, "MacArthur really knew his warblers" (1957, p. 427).

Not all individual-level ecology is natural history, however. There is a significant theoretical movement that seeks to ground ecological phenomena in processes that take place at the level of individual organisms (Grimm and Railsback 2005). These individual-based models have the virtue, when they work, of providing a more mechanistic understanding of emergent population phenomena. Furthermore, because the responses of organisms to their environments are usually adaptive (i.e., they are responses to the selection pressures the environment imposes), individual-based modeling supplies a framework for understanding the Darwinian idea that the ecological struggle for existence is the engine of natural selection.

Aldo Leopold in Rio Gavilan, Mexico, 1938. *Aldo Leopold to this day remains one of the best-known figures of applied ecology. The field of ecology, which began with Darwin's scientific study of individual species, has now branched out into several more specific research areas, including population ecology, community ecology, and ecosystem ecology.* **COURTESY OF THE ALDO LEOPOLD FOUNDATION ARCHIVES.**

The natural history of individual species is ethically and philosophically significant in at least three related ways. First, sound natural history is a prerequisite for the development of accurate population models for individual species. Because responsible environmental decision making often depends on a thorough understanding of the demographics of particular populations, natural history is important. Second, natural history can enhance aesthetic appreciation. Often people's aesthetic dispositions exert a strong influence on their land-use decisions and policy preferences. Yet there is significant controversy among theorists about the aesthetic appreciation of the natural world (Carlson and Lintott 2008). One of the more prominent, Leopold-influenced views is that ecological understanding paves the way for aesthetic appreciation of the natural world in much the same way that ''art appreciation'' enhances the capacity for the aesthetic appreciation of artistic creations. Third, Leopold once said that his objective in his wildlife ecology class was to teach his students how to ''read the land'' (1966 [1949], p. 336). By this he meant the capacity to bring together a deep understanding of natural history and the powers of observation to make inferences about the environmental history of a site. Reading the land in this way is important because it enhances aesthetic insight and serves as a prerequisite for the kind of husbandry that Leopold regarded as the core of sound conservation.

The ecology of individual-based modeling is primarily a proposal for a distinctive research program in ecology—an alternative way to do population ecology. As such, its significance for environmental philosophy remains uncertain. There is one area of immediate relevance, however. Individual-based modeling is a type of simulation modeling, and its potential is a function of recent advances in computing technology. Analytic modeling, the traditional approach of ecological theories such as competition theory, involves writing equations that will describe the behavior of the system. Simulation modeling involves specifying the interactions between individuals and then studying the time-evolution of the system via computer simulation. Conservation biologists often do not know how to write the dynamic equations needed to model certain populations. They are better able to specify the parameters of individual interaction. Thus individual-based modeling has the potential to make significant practical contributions in this domain (Sarkar 2005).

POPULATION ECOLOGY

The core of ecological inquiry is at the level of the population. The most widely accepted definition of *ecology* is that provided by Charles J. Krebs in his influential textbook, *Ecology: The Experimental Analysis of Distribution and Abundance* (1978). Krebs defines ecology as the study of the distribution and abundance of populations. Population ecology has been preeminent since at least the beginning of the twentieth century. There have been fundamental and long-running controversies, such as the extent to which populations in nature are governed by density-dependent factors or by density-independent factors such as the weather and whether organismic interactions, especially competition, are more important than the interactions between organisms and their physical conditions of life. Nevertheless, the population has remained the central focus of ecological inquiry.

Population ecology is relevant to environmental ethics and philosophy in a number of ways. One central area of relevance concerns efforts to understand and influence the population biology of economically significant and endangered species. Many of the activities of government-based natural-resource programs focus mainly on the population dynamics of specific species, although there is an increasing emphasis on community-level restoration efforts and emerging trends toward ecosystem management. Single-species management is also an important focus of conservation biology. Keystone species (e.g., the American alligator) are species that influence the population biology of many other species in an assemblage. Flagship species (e.g., the panda) are usually charismatic megafauna that may not be ecologically influential but have the capacity to capture the public imagination and can thus serve as a rallying point for preservation efforts. Umbrella species (e.g., the spotted owl) are species that have such extensive habitat requirements that managing for their persistence promotes, as a side effect, the preservation of numerous other species. As the examples indicate, conservation biologists have directed their efforts at species in all three categories. Management at the single-species population level, although politically popular, is controversial, and many conservation biologists argue that resources are better deployed at the level of ecosystem management (Simberloff 1998).

The controversies surrounding the prevalence in nature of density-dependent population regulation and the importance of competition are also relevant at a more conceptual level. Those who urge the dominance of competition-mediated regulation are committed to what might be called the balance-of-nature paradigm (Cooper 2003). Some argue that those on the other side portray an ecology of chaos or radical historical contingency (Worster 1993; Kingsland 1995). Some scholars argue, however, that this conclusion mischaracterizes certain novel theoretical approaches—such as chaos theory (Solé and Bascompte 2006) and/or certain macroecological perspectives on the relevance of biogeographical history (Ricklefs and Schluter 1993)—as the mainstream issues of population ecology. These balance-of-nature themes have oscillated in and out of favor for more than a century, but the debate has not been about order versus chaos, or even about repeatable mechanisms versus historical contingency. It has been about the nature of the order that population phenomena exhibit and the kinds of mechanisms responsible for it. These debates about the balance of nature have complicated philosophical discussions about when and where it might be appropriate for humans to simply get out of the way and let nature take its course.

COMMUNITY ECOLOGY

The next level up in the organizational hierarchy, the community, has also been a prolific source of controversy. Perhaps the most ambitious approach to community ecology was the superorganism view of Frederic Clements (1905). One of the most famous debates in the history of ecology was between the Clementsian perspective and the "individualistic hypothesis" of H. A. Gleason (1926). In Gleason's view community boundaries are largely indeterminate, with notable exceptions such as ponds and other ecological situations in which there is a relatively sharp demarcation between habitat types. The debates continued largely unresolved until, in the middle of the twentieth century, the work of Robert Whittaker (1975), John Curtis (1959), and their students settled the matter,

at least to the satisfaction of most of their contemporaries. This research revealed that most communities do not possess discrete boundaries. Populations of different kinds of organisms respond to environmental gradients such as average annual rainfall in an individualistic way.

The revelation that communities lack the kind of distinct boundaries found, for example, in organisms challenged the superorganism view. Nevertheless, there were alternative approaches to community organization that were more resilient. Charles Elton's (1927) way of thinking about communities in terms of available niches has remained influential. As recounted in Sharon Kingsland's history (1995), this Eltonian idea of limited membership was elaborated in the 1960s and 1970s by influential ecologists such as G. E. Hutchinson and Robert MacArthur in terms of competition for resources. At its zenith this research program posited community-level assembly rules that governed the composition of ecological communities. These purported assembly rules pertained mostly to the ways in which community membership is dictated by competition for limited resources and the limits to similarity in resource use among coexisting species. Although the search for assembly rules has continued (Weiher and Keddy 1999), they have been proved hard to pin down. This competition-based approach to community organization is not central to contemporary community ecology. Nevertheless, the search for community-level organizational structure continues, although shorn of its heavy emphasis on competition. It remains a potential organizing principle even though ecologists have turned to other ideas such as complex adaptive systems theory.

The feasibility of identifying ecological communities as an independent level of causal organization hinges on where communities stand along three important dimensions (Sterelny 2001). The first we have already seen: the idea of boundedness. If communities have causally salient properties, then they must have discrete boundaries. A second dimension is internal organization—organizing mechanisms that give communities an internal structure that is analogous to that of organisms. Organisms have cohesion and integration because they are subject to the organizing forces of natural selection; they respond as unitary entities to natural selection as an organizing mechanism, and selection is the reason that they have many of the properties that they do. Finally, the causally salient community-level properties must be identified. Certainly ecological communities exist in the sense that it is possible to observe community types such as a beech-maple forest or a temperate rain forest. For the community to exist as an independent level of causal organization, however, some of these community-level properties—what philosophers would call emergent properties—must play a causal role in shaping ecological phenomena. Scientists do not know how the various kinds of ecological communities will be placed along these three dimensions; it is possible that different kinds of communities will end up in different places. In the meantime, much of the work that proceeds under the label of community ecology is a kind of multispecies population ecology. Two or three (sometimes more) interacting populations are analyzed for their population-level effects on one another. The interactions modeled include competition, predator-prey relations, mutualism, and parasitism. Daniel Simberloff call this "traditional community ecology." (2004, p. 787).

The relevance of traditional community ecology to environmental problem solving has been a matter of controversy. J. H. Lawton (1999) argues that it has been a disappointment and that the focus should be on the lower level of population ecology and from there should ascend to macroecology. Simberloff (2004) disagrees, arguing that there are clear success stories in which traditional community ecology has contributed to the achievement of environmental goals (e.g., efforts to rescue the red-cockaded woodpecker from extinction). Both authors agree that traditional community ecology is destined to be a largely local, system-specific enterprise (Shrader-Frechette and McCoy 1993). Given the small likelihood that broad, community-invariant generalizations will emerge, the most promising alternative lies in investigating the mechanisms of multispecies assemblages.

The local, idiosyncratic nature of community organization is yet another sign that the more holistic aspirations of some community ecologists are problematic, which has implications for environmental ethics and philosophy. A prominent strain in environmental ethics, tracing its roots back to Leopold, holds that communities will emerge as the kind of holistic entities to which one may properly attribute intrinsic value and thus moral standing (Callicott 1999). The state of community-level inquiry at the beginning of the twenty-first century appears to cast some doubt on this enterprise. It may turn out that the current picture of ecological communities is mistaken or that the attribution of intrinsic value does not require such holism. There are resources within ecology, such as complex adaptive systems theory (Solé and Bascompte 2006), that provide grounds for arguing the former; and there are resources within environmental philosophy, such as an appeal to ecological integrity understood in terms of coevolutionary relationships (Karr 2000) for arguing the latter as well.

MACROECOLOGY

The 1930s has been called the golden age of population ecology (Scudo and Ziegler 1978). Perhaps the 1960s was the golden age of community ecology, with its

themes of niche and of limiting similarity. That decade yielded another important theoretical development: the equilibrium theory of island biogeography developed by Robert MacArthur and Edward O. Wilson (1967). The theory explained the number of species on islands as an equilibrium between extinction and colonization, with these two processes themselves depending on the size of the island and the distance from the mainland, respectively. This new theoretical approach represented an expansion of the scale of ecological inquiry both in space and time. Accompanying this shift in scale was a shift in methodology away from a more reductionist, often experiment-based, and mechanistic understanding of the dynamics of populations toward the discovery of broader-scale statistical patterns and correlations. This approach has emerged as the field of macroecology (Brown 1995).

Macroecology differs from more traditional approaches to community ecology in two fundamental ways. The first difference, already mentioned, pertains to scale and the kinds of generalizations pursued. Macroecologists are usually concerned with regional patterns of species abundance and biodiversity and with how those patterns change over long periods. The other significant feature of macroecology is its interdisciplinary nature. As Brown puts it, "[M]acroecology explores the domain where ecology, biogeography, paleobiology, and macroevolution come together and thus has the potential to forge synthetic links among these disciplines" (Brown 1995, p. 19).

Macroecology offers a number of distinct advantages for tackling environmental issues. First, by expanding the scale of inquiry in both space and time, it opens up the possibility of recognizing patterns and processes that might not be apparent from a more mechanistic and reductionist perspective. Second, as already indicated, traditional community studies usually require significant investments of both cognitive and economic resources. Uncovering and quantifying the mechanisms of interaction among a group of populations is often a significant challenge. Furthermore, the local relevance of the results means that, for large-scale processes, the efforts will have to be replicated across a range of situations. Macroecology can, at times, deliver a level of understanding relevant to policy deliberations without such massive investments of time, money, and energy. For example, K. A. McDonald and J. H. Brown were able to generate a prediction about extinctions among small terrestrial mammals living on mountaintops in the Great Basin of western North America that would be expected with a three-degree Celsius increase in global temperature. They based the prediction mainly on three variables: (1) data on the expected elevation shifts in montaine forest that would accompany such change in average global temperature; (2) information on current mammalian distributions at these sites; and (3) the species/area relationships of island biogeography. As Brown points out, tackling this problem with the methods of traditional community ecology would have required dozens of time-consuming studies of individual communities.

ECOSYSTEM ECOLOGY

The next level in the organizational hierarchy of ecology—beyond the individual, population, and community—is the ecosystem. The term *ecosystem* was introduced in 1935 by Tansley. He proposed the term as an alternative to the Clementsian concept *superorganism*, which was, in his view, causing significant confusion within the discipline. He intended the term to refer not just to the particular complex of organisms occurring at a site (the organismic community) but also to the physical environment. Tansley's ecosystem concept received its first detailed empirical development at the hands of Lindeman. His "trophic-dynamic concept" (1942) put flesh on the idea of an ecosystem by focusing on structural elements and the functional relationships among them. Structurally ecosystems are divided into trophic levels, each with its own function: Primary producers (plants) capture solar energy and turn it into biomass; herbivores consume the plants; and first-level carnivores consume the herbivores. Decomposers represent the trophic level responsible for disassembling the organic material into its constituent parts, thus recycling crucial elements such as nitrogen within the system. Lindeman's unique contribution was in quantifying these relationships.

In the wake of Lindeman's pioneering work, ecosystem studies have developed into a distinctive field of scientific inquiry (Golley 1992; Hagen 1993). Some (e.g., Schlesinger 1997) argue that it is a distinctive discipline in its own right: biogeochemistry. Others see it as one of two fundamental perspectives within ecology, the ecosystem perspective focusing on temporally extended processes (such as primary production of biomass) and functions (such as nutrient cycling), and the population-community perspective focusing on spatially extended entities and the ways in which they form groups and interact. Population/community ecology emphasizes patterns of distribution, the abundance of organisms, and the mechanisms responsible for these patterns. Ecosystem ecology conducts its business in the language of physics and chemistry. Although there have been numerous calls for a unified ecology (e.g., Allen and Hoekstra 1992), these two approaches analyze the natural world from two distinct points of view.

Although full-blown unification may not be likely, there have been numerous successful efforts at integrating the two perspectives. Moving from organisms to ecosystem

processes leads toward research that suggests that biodiversity can have a stabilizing effect on ecosystem productivity (Tilman 1999). In the other direction a large body of evidence indicates the various ways in which ecosystem processes impose constraints on the population biology of organisms (Sterner and Elster 2002).

Another subfield, landscape ecology, strongly resembles macroecology (Turner 1989). Like macroecology it focuses on ecological processes at broader scales, especially spatial scales. Landscape ecology, however, is also more likely to incorporate both organismic and ecosystem perspectives into a single study (Holling 1992). It thus provides further opportunities for bringing together the organismic and ecosystem perspectives.

Ecosystem ecology has influenced environmental ethics and philosophy in at least three important ways: First, the ecosystem perspective encourages the use of the evaluative concept of ecosystem health. Although the issue has been controversial, there appears to be an emerging consensus that it makes sense to conceive of ecosystem health in terms of the sustainable delivery of ecosystem goods and services (Daily 1997, Callicott and Mumford 1997). Ecosystems provide the resource inputs for various economic activities. They also provide other less readily apparent but no less valuable services, including the purification of air and water, pollination of crops, stabilization of climate, mitigation of floods and droughts, and maintenance of biodiversity. Radical changes in ecosystem structure and disruptions of ecosystem function can interrupt this flow of goods and services. In healthy ecosystems these structural and functional elements remain intact.

It is also possible to think of ecosystem health in a less instrumental way. Although there are reasons to doubt whether ecological communities can sustain attributions of intrinsic value, ecosystems may fare better. A number of environmental ethicists, sometimes called ecosystem holists, have argued for the moral standing of ecosystems. Holmes Rolston, for example, talks about "duties to ecosystems" on the basis of their "systemic" value—their status as natural systems that both create and sustain biodiversity at the species level (1991). Other environmental ethicists, such as Laura Westra (1994) and Eric Katz (1997), see in ecosystems a capacity for self-realization that commands moral respect.

Ecosystem ecology introduces the important practical perspective of ecosystem management into environmental decision making. Ecosystem management directly addresses the issue of sustainable delivery of ecosystem goods and services. Although it has its controversial elements, as Simberloff (1998) points out, ecosystem management has several attractive qualities. By focusing on entire systems, it is better able to cope with ecological complexity. Key elements that might be ignored by a more reductionist approach are implicitly included. Also, many environmental issues are scale-dependent; the ecosystem approach makes it easier to calibrate to the appropriate scale. Finally, ecosystem level approaches more readily accommodate the incorporation of the most ecologically influential species on the planet: humans.

II. COMMUNITY ECOLOGY

The fundamental idea behind community ecology in the modern sense was expressed by the nineteenth-century English naturalist Charles Darwin (1809–1882) in his image of the entangled bank:

> When we look at the plants and bushes clothing an entangled bank, we are tempted to attribute their proportional numbers and kinds to what we call chance. But how false a view this is! Everyone has heard that when an American forest is cut down, a very different vegetation springs up; but it has been observed that the trees now growing on the ancient Indian mounds, in the Southern United States, display the same beautiful diversity and proportion of kinds as in the surrounding virgin forests. What a struggle between the several kinds of trees must here have gone on during the long centuries, each annually scattering its seeds by the thousand; what war between insect and insect—between insects, snails, and other animals with birds and beasts of prey—all striving to increase, and all feeding on each other or on the trees or on their seeds and seedlings, or on the other plants which first clothed the ground and thus checked the growth of the trees! Throw up a handful of feathers, and all must fall to the ground according to definite laws; but how simple is this problem compared to the action and reaction of the innumerable plants and animals which have determined, in the course of

> centuries, the proportional numbers and kinds of trees now growing on the old Indian ruins! (Darwin 1962 [1859], p. 86)

This remarkable passage is testimony to the daunting complexity of ecological systems. It also reveals a vision of ecological communities as deeply ordered. According to the Darwinian image, if one cuts down the forest something vastly different appears in its place. But if one waits long enough, as with the Indian mounds, the forces responsible for this order will reassert themselves, and the community will return to its original state. But what are these forces? And is this tendency toward community reassembly true of all ecological communities, or are the forest of the American South a special case? The historical approaches to community ecology can be sorted in terms of the answers they seek to give to these questions.

THE SEARCH FOR COMMUNITY-LEVEL ORGANIZATION

The skeptical answer to these questions draws a distinction between two kinds of factors that might influence population behavior. Darwin placed a great deal of emphasis on the interactions among organisms (what ecologists call *synecology*). There is, however, a long tradition of ecological thought that views the interactions between organisms and the physical or abiotic conditions of life as the most important influence on the fates of organisms (what ecologists call *autecology*). The synecologist emphasizes the degree to which the entangled bank is shaped by biological interactions among organisms. The autecolgist emphasizes the impact of abiotic factors like the weather. Each perspective recognizes that both kinds of processes are at work; however, each emphasizes one type over the other—the type that it believes to be doing most of the work. It appears that inclinations on this issue correlate with the kinds of organisms studied. For example, ecologists who study birds tend to focus on synecological factors, whereas insect specialists often emphasize autecological influences. Their shared insight is that different kinds of processes are likely to be at work in shaping the demographies of different kinds of organisms. This is clearly an empirical question that can only be settled by understanding population behavior. That ecologists have been so determined to take a position on this issue before all the evidence is in attests to the importance of background knowledge—what the philosopher Thomas Kuhn might call the power of paradigm (1962).

One skeptical response should now be clear. For autecologists such as Andrewartha and Birch (1954), there is not much to be done in community ecology if it is about studying the population interactions that shape the entangled bank. Autecology, however, does not entail skepticism about the second Darwinian question: whether the southern forests are the exception or the rule. It might be that the unique species mix and relative abundances of the southern forest—the community type—are determined by pervasive physical factors such as the climate. This was the view of Frederic Clements (1905). But Clements had an additional idea: Communities experience their environments in much the same way in which individual organisms do. On this view ecological communities are a kind of superorganism to which scientists can apply the same kind of developmental analysis they apply to organisms. For Clements the community is a natural kind (a search for natural kinds seeks to classify things in terms of their causal influence) that is itself part of the causal structure of the biological world.

This appeal to communities as natural kinds brings forth the second skeptical objection. The skeptic worries that the cohesiveness of the southern forest, and most of the other community-types in Clements's typology, is illusory. As early as the 1880s, before ecology was even recognized as a discipline, European plant ecologists were debating this issue. The Danish botanist Eugenius Warming (1841–1924) urged a focus on the individual (1895); the German botanist Oscar Drude (1852–1933) championed a community-level perspective that Clements himself regarded as among his intellectual precursors (1890). Perhaps the most famous clash was between Clements and H. A. Gleason (1926). Gleason propounded what he called the "individualistic hypothesis," the view that congeries of populations do not come packaged with cohesive and coextensive boundaries but are spread out along environmental gradients, such as soil moisture. Only in special circumstances, such as the edge of a pond, do we find relatively crisp edges between community types. Here again an empirical question is being treated more like a presupposition.

The question of community cohesion was finally tackled empirically beginning in the 1950s with the work of the Cornell ecologist Robert Whittaker (1975), John Curtis's (1959) team at the University of Wisconsin, and others. The evidence suggests that, like so much else in ecology, there is an element of truth to both sides of the debate. Certainly communities come in kinds. There is such a thing as the long-leaf/loblolly pine biome type—just the kind of thing that Darwin had in mind. Furthermore, the Clementsian idea of succession terminating in a distinct community type (i.e., the process that led, for Darwin, from the clearing of the Indian mounds to the reestablishment of the "virgin forest"—what Clements would call the climax community) has a solid hold on the ecological canon. When the details are supplied, however, ecological communities usually lack the

cohesiveness and uniformity that would be required of a Clementsian superorganism.

Another possibility is that communities cannot be individuated as distinct natural kinds by mapping the distributions of individual organisms. But it does not follow that there are no community-level processes giving structure to the entangled bank. In a very influential book, *Animal Ecology*, Charles Elton (1927) developed a view of community organization that he thought might hold for all communities. He observed that all biotic communities exhibit a trophic pyramid of numbers: Plants, at the base of the food web, must be much more numerous than the herbivorous animals that feed upon them; but those herbivorous animals must be much more numerous than the omnivorous and carnivorous animals that feed upon them; and at the apex of the food web are the large carnivores that are very few in number. Further, constraints such as the limit to food-chain lengths shape the available niches in a community, and the available niche structure of the community limits the number of organisms that can coexist. Inspired by central figures such as G. Evelyn Hutchinson (1957) and Robert MacArthur (1972), Elton's program was elaborated by others into a pluralistic theoretical ecology, with features such as niche theory, the theory of limiting similarity, and island biogeography (Morin 1999).

These efforts to locate a kind of universal community structure have been met with skepticism (Strong et al. 1984). Like Clementsian succession, thinking in terms of the niche, the partitioning resources, and competitive exclusion (Gause 1934) has remained useful to most ecologists; but the idea that the ecological community is itself an independent level of causal structure has proved more difficult to defend.

THE EVOLUTION OF COMMUNITY ECOLOGY

Although none of these efforts to establish an independent level of community organization above the population level has really taken hold, community ecology is nonetheless a well-established domain of ecological inquiry. It has emerged in two distinct forms. One takes its cue from the Darwinian vision of the entangled bank—a vision in which synecological interactions among populations play the major role. These biotic interactions—competition, predation, and mutualism—have long been the focus of ecological study. This study of population interaction is itself a kind of community ecology, focusing not on entire communities but on component populations, typically only of two or three species at a time. Such an approach predominates in influential texts on community ecology (Morin 1999). The views of Hutchinson (1957) and MacArthur (1972) on community ecology have been influential as well. In an important book, James Brown describes the situation: "My colleagues who call themselves ecologists are virtually all reductionists. . . . On the other hand, my colleagues who call themselves biogeographers, paleobiologists, and macroevolutionists tend to be holists. They use inductive, nonmanipulative methods to study whole systems or emergent characteristics of large, complicated assemblages of many species distributed over geographic spatial scales and evolutionary time scales" (Brown 1995, p. xi). Much of the spirit and some of the letter (e.g., the theory of island biogeography) of this earlier vision is embodied in this higher-level study of ecological systems—what Brown calls macroecology.

There is a significant relationship between community ecology and the two related fields of ecosystem ecology and landscape ecology. In 1935 Arthur Tansley introduced the concept of the ecosystem—essentially the organismic or biotic community viewed in conjunction with its physical surroundings. Some ecologists, most notably Eugene Odum (1953) and Howard Odum, saw in the ecosystem that elusive higher level of causal organization that has been the holy grail of community ecology. Not surprisingly, this outlook has engendered controversy, and the holistic vision of the Odums remains the minority view.

Ecosystem ecology, however, has emerged as a distinct and robust field. It might be best to call it biogeochemistry because its defining feature is the analysis of ecological systems in physicochemical terms. The emergence of this new field has resulted in efforts to unify ecology, to embed the ecosystemic and organismic perspectives within a single conceptual framework (Allen and Hoekstra 1992). A complete unification seems unlikely, however, because one field uses the language of physics and chemistry and the other the language of organisms and populations. Nevertheless, there is a natural synergy between the two fields, and the development of studies at the interface between them has been a growth area in ecology (Tilman 1999).

One significant trend in ecology since the mid-1980s has been an increasing focus on matters of scale—especially spatial scale. In the case of the community ecology of interacting populations, this trend has led to the emergence of metapopulation ecology (the recognition that many populations are themselves composed of interacting subpopulations) and even a metacommunity approach that recognizes spatial structure among communities (Holyoak et al. 2005). At a more holistic level this focus on spatial structure, and especially spatial heterogeneity, has led to the emergence of landscape ecology (Turner 1989), which is concerned with the influence of spatial heterogeneity on biotic and abiotic processes. This variant is usually more focused on applied questions (such as the ecological consequences of human impacts) than are

its sister disciplines of population/community ecology and biogeochemistry. It bears close affinities to both, however, and much of the work in landscape ecology lies at the interface with these two fields.

COMMUNITY ECOLOGY AND ENVIRONMENTAL ETHICS

Community ecology relates to environmental ethics and environmental philosophy mainly in two areas: (1) pragmatic issues that pertain to environmental decision making and (2) conceptual issues that relate to the formulation of moral obligations to the natural world.

Sound environmental policy formulation and decision making require a sound understanding of how ecological systems work. Community ecology, especially those studies that focus on the population consequences of multispecies interactions, has played an important role in enlightening policy decisions. For example, Robert Paine (1966), through his seminal work on marine intertidal communities, demonstrated that removal of a species can have dramatic effects on an ecological community. In a classic experiment Paine showed that the removal of a predatory starfish enabled a competitively superior barnacle to dominate the community, thereby significantly reducing biodiversity. This simple and elegant experiment clearly demonstrated the magnitude of the impact of such a disappearance. Peter Karieva and Si Levin (2003) detail the importance of species to ecological processes; Simberloff (2004) describes the birth of a new field: invasion biology. This style of community ecology, which examines the population interactions of multispecies assemblies, is a key element in the development of effective environmental policy.

Another style of community ecology—macroecology—has also made important contributions to sound environmental decision making. Island biogeography was, perhaps, the first ecological theory to be applied systematically to biodiversity conservation. The macroecological perspective has also been useful in understanding how populations differ in their vulnerability to extinction, identifying regions of maximal biodiversity, and providing a perspective on the spread of introduced species as a consequence of human activities.

Beginning with the seminal work of Aldo Leopold (1966 [1949]), environmental ethicists have been tempted by the idea that ecological communities have a moral standing in their own right. Leopold's famous formulation of his land ethic calibrates the rightness or wrongness of an action in terms of its impact on the stability, integrity, and beauty of the biotic community. Leopold was heavily influenced by the holistic Eltonian view of community organization. Whether he was committed to the extension of moral standing to ecological communities has been a matter of significant controversy, but such efforts have proceeded apace, in the claimed recognition of human membership in the ecological community (Callicott 1999) or the idea of community self-realization (Katz 1997, Westra 1994), notwithstanding persisting skeptical counterclaims regarding the boundedness, cohesion, and self-organizing capacities of communities.

Given these skeptical challenges, some environmental ethicists with holistic, extensionist sympathies have turned their attention away from ecological communities and toward ecosystems as the entities of higher moral significance (Callicott 1999, Golley 1993, Rolston 1991). These scholars argue that, given the structural and functional characteristics of ecosystems, they are better suited to ascriptions of moral standing, with ecological integrity as the normative ideal. Ecological communities have integrity in this sense when the various kinds of organisms that coexist at a site share an evolutionary history. According to James Karr (2000), a community's ecological integrity has been compromised if it has undergone significant anthropogenic species extinctions and introductions. If communities lack sharp boundaries, then a shared evolutionary history obtains mainly at the population level. This outlook may not attain the degree of integrity that some ecosystem holists had hoped for, but for some thinkers it remains a workable criterion for valuing communities that are evolutionarily intact.

III. ECOSYSTEMS

The *ecosystem* is a basic unit of ecological research and ecological management. One scholar has even defined the whole science of ecology as "the study of the structure and function of ecosystems" (Odum 1962, p. 108; Odum 1964). Ecosystems are commonly used as baseline criteria of conservation and environmental protection, as expressed in various kinds of "ecosystem approaches" in conservation and natural-resource management, most notably in the Millennium Ecosystem Assessment (Millennium Ecosystem Assessment 2005; see also CBD 2008).

The term *ecosystem* was coined as a scientific way of encompassing the groups of interacting plants and animals, which were previously designated metaphorically as "communities" or even "superorganisms." Despite its scientific origins, *ecosystem* has become a buzzword, indiscriminately applied to many things that people associate with ecology. In the scientific sense of the term, an ecosystem is a unit composed of an assemblage of organisms together with its inorganic (waters, minerals) environment (Krebs 1985, Likens 1992). To this basic definition of *ecosystem* a multitude of other meanings have accrued, even within scientific ecology. That multitude of meanings—and philosophical problems to which it gives rise—is of more than merely academic interest: It has implications for conservation policy and environmental ethics as well.

HISTORY AND CURRENT USAGE

The term *ecosystem* was coined by the eminent British plant ecologist Arthur Tansley in 1935. He took sides in a long-standing debate about the nature of the plant "community" and its extension, the "biotic community," which is composed of animals as well as plants. He argued against the use of the term *superorganisms* to characterize groups of interacting plants and animals, viewing it as a kind of reification. This "reified" view had been expressed most ardently by the leading American plant ecologist of the early twentieth century, Frederic Clements, who conceived of interacting groups of plants and animals as "an organism" that "arises, grows, matures and dies" (Clements 1916, p. 3). In contrast, Clements's most prominent opponent, Henry Allan Gleason, considered the (plant) community as "not an organism, scarcely even a vegetational unit, but merely a *coincidence,*" its structure

originating from the "environmental sorting" of individual organisms and their specific migration patterns within a site (1926, p. 16; emphasis in original). Tansley, calling the community a "quasi-organism" (1935, p. 289), traveled a road in between these two extremes. He argued that biotic communities (or biomes) were not the fundamental units of nature. Instead, he proposed that

> the whole *system* (in the sense of physics), including not only the organism-complex but also the complex of physical factors forming what we call the environment of the biome—the habitat factors in the widest sense.... It is the systems so formed which, from the point of view of the ecologist, are the basic units of nature on the face of the earth.... These *ecosystems,* as we may call them, are of the most various kinds and sizes. They form one category of the multitudinous physical systems of the universe, which range from the universe as a whole down to the atom. (Tansley 1935, p. 299; emphasis in original)

Tansley thus placed living and nonliving elements on the same level: a system, in the sense in which that term is used in physics. This definition of the term *ecosystem* was not the first to express the idea that groups of organisms (communities) and their environments were closely interrelated "systems" (compare the *holocoen* concept of Karl Friederichs 1927 and other concepts described in Jax 1998). Nor were its details, in particular Tansley's emphasis on the epistemological status of the concept (about which more shortly), retained in later definitions and applications.

If ecosystems, comprising biotic and abiotic elements, are the "basic units of nature," just *what* are they? For Tansley an important part of the answer was that they were abstractions, mental isolates formed according to the purpose of the (particular) investigation:

> The whole method of science....is to isolate systems mentally for the purpose of study, so that the series of *isolates* we make become the actual objects of our study, whether the isolate be a solar system, a planet, a climatic region, a plant or animal community, an individual organism, an organic molecule or an atom.... The isolation is partly artificial, but it is the only possible way we can proceed. (Tansley 1935, p. 299)

Note, however, that Tansley did not consider ecosystems to be mere abstractions, as he remarks in a footnote: "The mental isolates we make are by no means all coincident with physical systems, though many of them are, and the ecosystems among them" (Tansley 1935, p. 300).

Tansley's approach avoided reification of the concept and at the same time allowed a very broad use. For many later investigators, however, ecosystems had more specific properties (e.g. self-regulation and information networks—see, e.g., Odum 1969, Patten and Odum 1981, Jørgensen et al. 1992). It is often not clear, however, whether these are really meant as definitions in a strict sense—as criteria that have to be fulfilled to attribute the term *ecosystem* to some physical object—or if these were just derived (or postulated) properties of units defined by much simpler criteria such as topographical boundaries (Jax 2006).

Nowhere in his defining paper did Tansley mention the word *energy.* In a subsequent paper, "The Trophic-Dynamic Aspect of Ecology," Raymond Lindeman (1942) employed Tansley's ecosystem concept in his study of the flow of energy through an aquatic community—Cedar Bog Lake in Minnesota. He calculated the amount of solar energy falling on the pond's surface and then measured the amount converted by photosynthesis to chemical energy by the pond's plants; he then calculated how much of that energy herbivores converted to their own biomass and so on up the food chain to the top carnivores in the ecosystem. Just as Tansley had added the inorganic or abiotic components to plants and animals (the biota), so Lindeman added a major force that drives the dynamics of ecosystems: energy.

This historical development led to an understanding within the scientific community of ecosystem ecology as dealing with energy flow and nutrient cycling (Evans 1956, Likens 1992). This predominant view resulted from the first implementations of the concept under the influence of G. Evelyn Hutchinson. In addition to the work of Hutchinson's student Raymond Lindeman (1942), also that of another of his students, Howard T. Odum (1951) was a major figure for developing and popularizing this approach (Taylor 1988, Hagen 1992, Golley 1993, and Jax 1998, 2006).

Ecosystem ecology is sometimes described as a process-functional approach to ecology as opposed to a population-community approach, which emphasizes the biological components (O'Neill et al. 1986, Vogt et al. 1997). Some of the key terms used in describing ecosystems in the process-functional approach are *energy budgets*, *trophic levels* (or slightly more refined functional groupings of organisms), *flows* and/or *cycles* of various chemical elements, and *information networks*. From this perspective the components (plants and animals) are important to the extent that they are moments in ecological processes within ecosystems. Their specific identities as this or that species are less important than the roles they perform in channeling energy and information and cycling materials.

On the one hand this focus on flows of energy and cycles of matter has led to a less ambiguous and mathematically

more tractable definition of *ecosystem*; on the other hand it has eclipsed alternative views and risks omitting important aspects of natural objects, especially the specificity of particular species. This problem is especially important in connection with ecosystem management and conservation. Ecosystem research of this kind became so specialized that many ecologists felt a need to reconcile ecosystem research with other approaches to ecology, especially those emphasizing particular populations and species (Allen and Hoekstra 1992, Jones and Lawton 1995).

VARIOUS DEFINITIONS OF THE CONCEPT OF THE ECOSYSTEM

Notwithstanding the typically narrow use of *ecosystem* in process-functional ecology, controversies and methodological ambiguities persist. Both in the older and in later literature the reader has to be careful to extract the intended meaning, which is often merely implicit.

Obtaining a precise definition means posing and answering several key questions (Jax et al. 1998). One important question, for example, is whether ecosystems are defined by topographical boundaries (that is, by criteria that are visible in space) or by functional boundaries (by process relations among the elements of the system). A topographical definition of an ecosystem is often determined by the boundaries of a watershed, which might be useful in the study of the movement of a pollutant. A functional definition might be determined by the home range of a population of bats, an approach that might be useful in the study of the pollination of plants, the control of noxious insects, or the spread of a disease like rabies. The methodological problem is that functional boundaries or those determined by concrete topographical criteria often do not coincide. There is no simple way to infer one from the other.

Definitions also differ in the degree and kind of internal relatedness involved in constituting an ecosystem. At one extreme the parts of an ecosystem need not display any interrelations at all—they qualify as an ecosystem merely as happenstance assemblages of organisms (just ''coincidences,'' as Gleason argued). At the other extreme an object is called an ecosystem only if the parts of that unit give rise to self-regulation, equilibrium states, and relative functional autonomy in relation to other units of the same type (Jørgensen et al. 1992). Between these two extreme views ecosystems are characterized as displaying clearly defined relationships between the various parts but not necessarily with equilibrium or self-regulation. Such differences in definitions can even lead to contradictory assessments about which material systems should be called ecosystems.

An ecosystem cannot simply be ''found.'' Different definitions delimit different parts of the world as an ''ecosystem'' (Ahl and Allen 1996, Jax et al. 1998). Hence what qualifies as an ecosystem is not fixed in external reality but varies with the research questions posed and even the social implications assumed (Pickett and Cadenasso 2002, Jax 2006). The implementation of the concept of the ecosystem is thus far from simple.

Beyond such technical definitions the term *ecosystem* is frequently used in a generic manner that connotes more a perspective or general heuristic idea than a clearly delineated object in nature. The generic definition is the ''basic definition'' of *ecosystem* given in the introduction of this article. Although narrow, technical definitions are required for theoretical generalizations and for implementing the ecosystem concept in the field, the generic definition, which emphasizes the interrelatedness of natural phenomena, helps to describe and structure modes of ecological research (Jax 2006). In a similar way Pickett and Cadenasso describe the use of the ecosystem concept as ''meaning, model, and metaphor'' (2002, p. 1). The first dimension (''meaning'') comes close to the generic use of *ecosystem*, the second (''model'') comes close to the technical definitions, and the third (''metaphor'') describes an informal and symbolic use of *ecosystem*, mainly in a management or policy context. This variation in usage corresponds to the observation that the *ecosystem,* in contemporary ''ecosystem management,'' functions as both object and perspective, the latter describing a kind of policy or philosophical approach that extends beyond the empirical realm of the hard sciences and into the interpretive realm of the social sciences.

ECOSYSTEMS, CONSERVATION, AND ETHICS

The ecosystem concept has become an essential part of many normative concepts in conservation (Callicott et al. 1999). In the last two decades of the twentieth century, conservation efforts increasingly shifted from single species and populations to the conservation of whole ecosystems (Walker 1995, Christensen et al. 1996). This latter, more comprehensive, approach raises questions about the moral status of ecosystems (Cahen 1988, Salthe 1989) and poses the risk of conflicts between competing targets of conservation.

Various definitions of ecosystems put different aspects of the material world in the foreground or the background. In some extreme process-functional definitions of *ecosystem*, species populations become completely interchangeable and ''invisible'' because only their functional roles are relevant (O'Neill 1976, Mclntosh 1981). Thus the protection of the whole ecosystem (as understood in a process-functional sense) is no guarantee of the protection of specific species populations; they could, in theory, be replaced by others with no loss whatever to the ecosystem as a whole.

Hence, with implicit differences in the definition of *ecosystem,* the targets of protection can vary widely. Some of these definitions are compatible with species protection, whereas others are not. The notion of protecting "ecosystem functioning" and "ecosystem services" (as a preconditions for human well-being), especially since applied in the Millennium Ecosystem Assessment, has become a prominent point of international discussion. The idea that ecosystem processes and "services" depend on specific actors to perform them in specific places can help to bring the issue of biological diversity (as a precondition for sustained ecosystem functioning) into the awareness of a broader public.

Nevertheless, scientific, philosophical, and ethical questions persist: Just how much does the identity of the species performing a functional role in an ecosystem matter for the successful discharge of the ecosystem process and/or service? Can one species be substituted for another without a significant impairment of ecosystem processes and services? The protection of ecosystem services and the preservation of a specific biodiversity are distinct tasks that can dovetail only if the conservation of species is deemed to be important. From a nonteleological evolutionary point of view, is it metaphysical nonsense to impute any function or role at all to a population of organisms? Earthworms, for example, are not designed to aerate soil and decompose detritus; they are naturally selected to burrow through soil, digest dead organic matter, and make more earthworms. From the very beginning ecosystems were conceived to be as much theoretical as natural objects. Are ecosystems and all their purported functional processes mere figments of the ecologists' imagination? Should an ecosystem approach to conservation serve only utilitarian purposes (protecting those parts of nature that are useful to humans)? Or is it also compatible with other approaches of environmental ethics—those that advocate protecting nature (or parts of nature) for its own sake?

The selection of an appropriate definition of *ecosystem* for management purposes depends on values, decisions, and societal choices (Jax and Rozzi 2004). The demands of such choices raise the need for interdisciplinary work and participatory, transparent, and democratic forms of decision making. Ecosystem management is not a matter of science alone.

IV. DIVERSITY-STABILITY HYPOTHESIS

The idea that biological diversity enhances ecological stability has inspired a huge body of scientific research. It has also played an important role in environmental ethics, especially in Aldo Leopold's land ethic. According to Leopold, biodiversity is essential for "a food chain aimed to harmonize the wild and the tame in the joint interest of stability, productivity, and beauty" (1949, p. 199). Potential links between diversity and stability have helped to spur conservation efforts.

Nevertheless, ecologists have at times shown what Samuel McNaughton called a "marked instability of attitudes regarding diversity-stability relationships." He attributed this to a "low diversity of empirical tests of the hypothesis" (1977, p. 523). In this respect scientists are now in a much better position to assess the diversity-stability hypothesis (henceforth merely "the hypothesis"), with more than forty direct experimental trials on the books and more in progress. But another reason for changing attitudes has been that stability is a multivocal concept, and evidence suggests that not all types of it vary positively with biodiversity. Thus, the plausibility of the hypothesis has varied as different kinds of ecological stability have come into vogue.

Three interrelated trajectories have been discernible in the years since World War II. First, scientists' confidence in the hypothesis plummeted in the early 1970s; but then it steadily rose again, beginning in the mid-1990s. Two other trends help to explain this recovery: Emphasis has shifted from the stability of individual populations to that of entire communities or ecosystems, and ecologists have come to focus on forms of stability that are both empirically measurable and theoretically tractable.

In the 1950s, three of the twentieth century's most influential ecologists argued that the hypothesis was plausible enough to warrant further study (Odum 1953, MacArthur 1955, Elton 1958). They reasoned that if a given species preys on several others, its population size will fluctuate less in response to environmental variations affecting one of its prey than it would if the species in question ate fewer prey species. Similarly, if a species has many predators, its population will vary less in response to exogenous changes in one predator's population size. As empirical support for these ideas, Eugene Odum and Charles Elton cited the dramatic oscillations experienced by many populations in the Arctic but not in the far more species-rich tropics; they further noted the tendency for pest populations to undergo more frequent and severe "outbreaks" in simplified agricultural systems than in complex natural systems. Although MacArthur's paper was more conceptual than empirical, he also conceived the hypothesis in terms of population stability.

The few empirical studies of diversity-stability relations conducted in the 1960s and early 1970s yielded a confusing mix of positive, negative, and ambiguous results (Goodman 1975). But the coup de grâce came from a purely theoretical exercise, on the basis of which May claimed that "simple mathematical models with many species are *in general* less stable than the corresponding simple mathematical models with few species" (1973, p. 49; italics added). This is not actually a general theoretical result, since it depends on *particular* and, indeed, quite debatable assumptions about whether and how certain other variables (e.g., the number and strength of interactions between species pairs) change as the number of species increases (McCann 2000). Nevertheless, the idea that diversity destabilizes ecological systems quickly became a "new paradigm" despite a continued dearth of empirical tests of the hypothesis (Loreau et al. 2002).

Direct experimental tests finally got under way in the mid-1990s as preliminary evidence came to light that, when it comes to diversity-stability relations, the whole may not be predictable from a knowledge of the parts. (In "direct" experiments of this kind, the number of species is manipulated independently of other independent variables, such as soil fertility.) In some grasslands where diversity *decreases* the stability of individual plant populations, it nevertheless *increases* the stability of the ecosystem as a whole. This is because in the more diverse ecosystems upsurges in some populations are more often offset by declines in others (Tilman et al. 2006).

Along the way to this discovery, a key conceptual stumbling block was overcome: the mathematically convenient but empirically inapplicable definitions of *stability* used by May and many others. Such definitions often assume infinitely small perturbations of population size from equilibriums that most actual populations never reach, among other potential problems (Mikkelson 1997). Ecologists eventually settled on two empirically meaningful types of stability amid the great majority of direct experimental tests of the hypothesis: resistance to invasion by new species and temporal stability—the mean value of a variable (usually biomass or productivity) divided by its standard deviation, both calculated over time. The latter measure respects the pre-1970s emphasis on variability and can be applied to entire ecosystems as well as to component populations; moreover, it can be explored through a broad range of theoretical tools (Lehman and Tilman 2000).

The upshot of the direct experimental tests performed so far is that diversity does indeed enhance both invasion resistance and the temporal stability of ecosystem biomass or productivity (Ives and Carpenter 2007). Although these authors did not review direct experimental tests of the diversity-*population*-stability hypothesis, it seems that the evidence about it is more mixed (Romanuk et al. 2006). One possibility is that Odum, MacArthur, and Elton were right about the positive effects of prey and predator diversity on population stability. But they did not take into account the point that having numerous prey and predator species allows numerous competitor species to also "fit" into the ecosystem (Chase and Leibold 2003). If competitor diversity, in turn, has negative effects on population stability, then the overall diversity-population-stability relationship may depend upon a highly contingent balance between the effects of diversity at these different trophic levels.

To sum up, then, a period of relatively unconstrained theorizing led most ecologists to reject the diversity-stability hypothesis by the 1980s. A much more experimentally driven research program, along with a shift in focus from population to ecosystem stability, then led to the rehabilitation of the hypothesis, starting in the mid-1990s. There is reason to hope that knowledge of diversity-stability relations will help in mitigating contemporary human-induced mass extinctions. As this knowledge improves, however, it is important to keep in mind that effects of diversity on stability and other aspects of ecosystem function are only some of the many reasons—among them moral, intellectual, and aesthetic—for protecting and promoting the variety of life on earth. As Elton put it, "conserving the variety of nature" is also simply "a right relation between man and living things" (1958, p. 145).

V. DISEQUILIBRIUM ECOLOGY

Since its foundation as a discipline, ecology has been dominated by an equilibrium view of nature. According to the historian Frank Egerton, the idea of "balance of nature" is present in most "primitive" cosmologies and is inherent in humans' ancestral worldviews. In ancient Greek philosophy, together with the concepts of the "great chain of being" and the "microcosm-macrocosm analogy," the balance of nature remained a fundamental if untested assumption of natural history (1973, 1993).

These assumptions, inherited from an equilibrium worldview, were incorporated without questioning or testing into the most influential ecological theories of the twentieth century, ranging from populations and communities to ecosystems. Examples include the idea of "climax" as the steady-state endpoint of plant succession theory (Clements 1916); W. C. Allee's (1949) notion of balanced animal communities; "the equilibrium theory of island biogeography," which predicts the number of species on oceanic islands as a balance between immigration and extinction (MacArthur and Wilson 1967); and Eugene Odum's (1969) "strategy of ecosystem development," which postulated that all ecological systems progress toward homeostasis. Based on studies on vertebrate and invertebrate social animals, the University of Chicago professors Allee, A. E. Emerson, O. Park, T. Park, and K. P. Schmidt, in their influential book *Principles of Animal Ecology* (1949), concluded that

> the community maintains a certain balance, establishes a biotic border, and has a certain unity paralleling the dynamic equilibrium and organization of other living systems. Natural selection operates upon the whole interspecies system, resulting in a slow evolution of adaptive integration and balance. Division of labor, integration, and homeostasis characterize the organism and supraorganismic intraspecies population. The interspecies system has also evolved these characteristics of the organism and may thus be called an ecological supraorganism. (p. 728)

According to these authors, the theory of evolution by natural selection, pioneered by the English naturalist Charles Darwin (1809–1882), provided a mechanism that, through interspecific interactions and evolutionary processes, gave rise to equilibrium at supraorganismic levels, which is analogous to the process of "homeostasis" at the individual level.

Accordingly, twentieth-century ecologists retroactively imparted greater heuristic power to the eighteenth-century century notion of the economy of nature as pioneered by the Swedish botanist, zoologist, and physician Carl Linnaeus (1707–1778). Both Linnaeus and Allee (1949) held that there is an essential analogy between the organs in an animal and the species in a community. In turn, Linnaeus based his *Oeconomia Naturae* notion on the work of seventeenth-century naturalists and theologians and on ancient Greek natural philosophers. The creation myth in Plato's *Timaeus* affirms that the creator made the world as "one visible animal comprehending within itself all other animals of a kindred nature" (30 c-d). Plato's dialogues have had a pervasive influence in European and North American thought, integrating the microcosm-macrocosm analogy with the image of the parts of an animal body as a representation of the different parts of the universe; Plato held that the diversity of species of living beings are the organs of a supraorganismic being and that the universe as a whole is a super superorganismic being.

Such ancient organismic perspectives influenced Linnaeus, who in turn influenced nineteenth-century biologists and thinkers concerned with "organic wholeness" (Jax 1998). In the early twentieth century the German ecologist Karl Friederichs affirmed, "In the same way in that the world is a dynamic system, which actively persists in a delicate state of equilibrium by means of self-regulation, this is also valid for naturally delimited parts of the biosphere (e.g., pond, fen, beach . . .)" (Jax 1998, p. 117).

Friederichs coined the term *holocoen* to refer to "a forest, a lake, a fen"—perceivable habitats that exist as delimited living systems within a nested hierarchy of nature.

Friederichs's view contrasts sharply with that of Arthur Tanlsey (1935), who understood an ecosystem as an operational distinction made by scientists. Charles Elton (1930) was even more radical in his criticism of the organismic and equilibrium views of nature when he affirmed,

> "The balance of nature" does not exist, and perhaps never has existed. The numbers of wild animals are constantly varying to a greater or less extent, and the variations are usually irregular in period and always irregular in amplitude. Each variation in the numbers of one species causes direct and indirect repercussions on the numbers of others, and since many of the latter are themselves independently varying in numbers, the resultant confusion is remarkable. (p. 17)

With the work of Tansley, Elton, and others in the mid-twentieth century, the assumptions of natural equilibrium and balance of nature came under critical scrutiny. H. G. Andrewartha and L. C. Birch (1954) rejected the idea that density-dependent factors (endogenous

factors within the ecological system) alone controlled populations in ecological communities. They emphasized, instead, the importance of allogenous disturbances (external factors such as volcanic eruptions, flooding and hurricanes) as drivers of population fluctuations.

The alternative tenets of equilibrium vs. disequilibrium ecology have implications not only for the scientific understanding of nonhuman nature but also for the relations that human societies establish with their environments. From the perspective of public understanding, equilibrium views that draw on the traditional metaphor of "the balance of nature" have had profound implications for the broad application of ecological theories to resource-management and conservation issues (Botkin 1990, Wu and Loucks 1995).

RELATED CONCEPTS

Related to the idea of natural equilibrium are the notions of "stability" and "resilience" that have been ubiquitous in community ecology during the twentieth century (Wu and Loucks 1995). Stability is a condition that enables the system to tolerate or resist external perturbation without significant structural and functional change. Resilience is the ability of the ecological system to return to its previous equilibrium state after a disturbance. Both notions have proved to be problematic when empirically tested in diverse aquatic and terrestrial environments (Wu and Loucks 1995).

In the last quarter of the twentieth century, equilibrium-centered theories were gradually supplanted by alternative conceptions stemming from the increasing awareness that frequent disruptive events (or disturbances) on both land and in water lead to the reorganization of ecosystems in often-unexpected directions (Simberloff 1980, Pickett and White 1985). Under this new probabilistic understanding, equilibrium or stable conditions are viewed as special transient cases or as consequences of applying a narrow spatial or temporal gauge in examining large-scale ecosystem dynamics (Wu and Loucks 1995). Nonequilibrium models and empirical studies of fire and pest-outbreak effects on biotic communities, on the other hand, have increasingly demonstrated the existence of multiple equilibriums and have emphasized the role of stochastic and probabilistic processes in ecological systems (Simberloff 1980).

PARADIGM SHIFT: RESULTS AND PROSPECTS

The turn from equilibrium to disequilibrium conceptions of ecological systems since the late 1970s has been considered by many (Simberloff 1980; Pickett et al. 1992, 2007; Wu and Loucks 1995) as a "paradigm shift" in the science of ecology. *Paradigm* here connotes the constellation of concepts, ideas, and approaches shared by a working community of scientists (Kuhn 1962). This paradigm shift questions, on empirical grounds, the previous tenets of ecological theory (i.e., equilibrium assumptions) and obliges a rethinking of the application of theory to environmental problems such as the design of nature reserves (Pickett et al 1992), the management of wild populations, and the perception of disturbance regimes (Botkin 1990). It also calls into question the traditional view of humans as agents of the destruction and/or restitution of natural "harmony" and "balance" and urges us to reformulate the goals of biological conservation and ecological restoration practices.

According to Pickett and his coauthors (1992), the old equilibrium paradigm of ecology, embodied in the traditional metaphor of "the balance of nature," was replaced in the late twentieth century by a nonequilibrium view, best expressed in the new metaphor "the flux of nature." Such metaphors are essential elements in the understanding of scientific theories and are closely linked to cultural worldviews. Implicit in the old metaphor are (a) the closed character of ecological systems; (b) the predominantly autogenic origin of ecosystem structure and function determined by species and genetic diversity, life histories, biomass accumulation, and other internal biological and physical properties; and (c) the existence of a predictable condition (in the sense of Odum's homeostasis), often called the climax state, that is resistant to occasional external disturbances (Pickett et al. 1992). In turn, the new metaphor, representing the nonequilibrium concept of ecological systems, denotes (a) the open nature of most ecosystems; and (b) their dependence on both exogenous forces (such as fire, climate change, or pollution) and autogenic forces (such as species life histories). A high frequency of disturbances relative to the life spans of the organisms in the local community may drive the system to (c) multiple possible endpoints, theoretically possible stable states notwithstanding. In the nonequilibrium view, a metaequilibrium is possible on a broad spatial scale that examines the collective dynamics of multiple patches in the landscape, although single patches are constantly changing.

The paradigm shift in ecology (from equilibrium to disequilibrium concepts and theories) brings a philosophical turn to the notion of disturbances as destructive or catastrophic forces, usually disrupting the orderly trajectory of ecological systems toward homeostasis. Disturbances are sudden events altering ecosystem or community structure and processes, destroying biomass and releasing resources for the survivors or newcomers (Pickett and White 1985). Ecological studies have demonstrated that "disturbance regimes" can be an intrinsic component of the ecological system under study, depending on the selection of spatial and temporal scales. Under this

perspective apparently destructive forces such as wildfire become necessary for an ecosystem to sustain its characteristic species composition, structure, and productivity (Botkin 1990). Exclusion of fire from such ecosystems through preventive management impoverishes their performance in the long term because of losses of species and changes in structure that drive the system to a state that diverges markedly from its historical patterns. Repeated disturbances such as volcanism and landslides that recur over several millennia maintain the characteristic age structure and species composition of many Andean *Nothofagus* forests in southern South America (Veblen et al. 1996). Hence disturbances can foster conditions (e.g., open patches, resource hot spots) that facilitate the regeneration of species and increase local species richness.

An important corollary of this view of disturbance as a driving force for patch dynamics is the realization that such perturbations can be integrated into the definition of ecosystem insofar as they are seen as products of the interaction between the system's structure and exogenous physical factors. Several examples show how the onset and effect of disturbances can be modulated by species traits and the structure of a community (Pickett and White 1985). For instance, the rates at which trees fall in a forest canopy depend on individual tree longevity and species composition, which in turn influence species diversity and tree regeneration (Johnson and Miyanishi 2007). Species composition and ecosystem structure and processes hinge on a continuous interplay of both endogenous and exogenous forces that lead to multiple possible end points. This perspective challenges the idea that "there is only one point at which balance occurs, and that balance is normally static," thereby affirming Aldo Leopold's (1939) insights into the flux and diversity that inhere in an equilibrium.

VI. PATCH DYNAMICS

The history of the concept of patch dynamics can be traced back to the classic work of A. S. Watt (1947), who described the dynamic mosaic structure of vegetation, with patches constantly dying and regenerating in different areas of the landscape. In a variety of plant communities, including peat lands, grasslands, and forests, Watt analyzed temporal succession of pioneer, building, mature, and degeneration phases. Watt emphasized that

there are frequent departures from unidirectional, ordered sequences and that the spatial mosaic of patches can be interpreted in terms of their temporal relations: "The community consists of patches, each of limited area, and differentiated by floristic composition, age of dominant species and by habitat" (Watt 1947, p. 16). This view of the community as a dynamic mosaic of patches differing in a succession of ages has become known as "the pattern and process hypothesis," which emphasizes the relations between structure and function (Wu and Loucks 1995). The term *patch* refers to a discrete unit of space differing in nature and appearance from the surrounding landscape (Wiens 1976). Patches may be identified at different spatial scales, from an island surrounded by ocean or a tract of forest surrounded by pastures to a tree-fall gap in the forest canopy to an aggregate of barnacles on a rock of the intertidal zone. In landscape ecology (Forman and Godron 1986) patches are the basic functional units of the landscape. Usually the area of habitat surrounding a recognizable patch type is termed the ecological "matrix," although a matrix may itself comprise different patches (Pickett et al. 2000).

Patches differ in area, shape, structure, species composition, duration, structural complexity, and boundary characteristics. Some patches may be sharply bounded (e.g., a lake, a remnant woodlot within a cultivated area); in other cases boundaries may be diffuse (e.g., the transition from steppe to forest). Patches may differ greatly from the species composition and abundance in the surrounding matrix, or the differences may be subtle. Patch shapes may be regular, approaching Euclidian geometric figures such as a circle or square, or they may be irregularly shaped, which demand the use of fractal geometry.

MECHANISMS OF PATCH FORMATION

Patches are originated by a variety of physical and biological mechanisms, including patch creation and habitat fragmentation by humans. Physical mechanisms of patch origination in unmanipulated landscapes include disturbances such as lightning-caused fires, tree windfalls, hurricanes, droughts, floods, landslides, volcanic eruptions, earthquakes, and climate change. There is a striking example of remnant patches caused by climate change along the Pacific margin of southern South America, where fog-dependent rain-forest patches on the summits of the coastal hills of semiarid Chile (annual rainfall below 150 millimeters) became segregated from their main temperate latitudinal range by more than 1,000 kilometers because of incremental aridization during the Quaternary (Núñez-Avila and Armesto 2006). On a smaller scale, the north-facing and south-facing slopes—sometimes separated by just a few meters—of the coastal and Andean mountains of central Chile also exhibit contrasting patches characterized by differences of temperature, solar radiation, and humidity. This physical microheterogeneity, in turn, generates sharp differences in plant composition, flowering periods, pollinator ensembles, and genetic differentiation among populations of the same species (Armesto and Martínez 1978; Rozzi et al. 1997).

Biological mechanisms of patch origination include animal effects (e.g., burrowing activities, building of dams, defoliation of trees, trampling, and wallowing) plant effects (e.g, allelopathy, accumulation of organic matter, shading effects), resource distribution (e.g., soil types, large fruit crops, nutrients under bird perches), aggregation patterns (e.g., marine mammal congregations, limited seed dispersal, vegetative propagation), and migratory routes and dispersal patterns (e.g., bipolar distribution of plant species found in subarctic and subantarctic regions because of seed dispersal by migratory birds and similar climatic conditions). Human creation of patches include historical land use change, such as the creation of bodies of waters through the building of dams or open land by the clear-cutting of forests; introduction of exotic animal and plant species involving monocultures for husbandry or crops; gardening and planting seeds in cultivated patches such as the "islands" of palms planted in Amazonian savannas by indigenous peoples; and the creation of barriers to dispersal of animals and plants, such as those imposed by highways, channels, fences, or the application of pesticides or herbicides.

PATCHINESS

Patch mosaics of a given landscape can be described in terms of patch composition (patch types and their relative abundances), the spatial configuration of patches, and the connectivity among patches. Connectivity can be a function of both the nature of boundaries (the transition between patches and the surrounding matrix) and the permeability of the matrix to the transit of organisms moving between patches. Patch connectivity is a critical yardstick for biodiversity conservation and is thus an important source of information for conservation policy at the landscape scale because of the negative effects of isolation on mating probabilities (Sieving et al. 2000; Díaz et al. 2006), population sizes and gene flow, and the facilitation or impeding of the movement of exotic invasive species or pests (Fahrig 2003).

The descriptive parameters and scale of patchiness are both organism-dependent because different species have varying capacities for filtering heterogeneity in a given environment (Wiens 1976). Accordingly, patchiness varies

for organisms with different degrees of mobility (e.g., immobile plants vs. mobile animals), physiological tolerance of environmental stress (e.g., mammals vs. frogs, because the latter have higher skin permeability, making them more dependent on moisture), life-history characteristics (e.g., bamboo species with single mass flowering events vs. oak trees with annually recurrent flowering events), and perception mechanisms (e.g., bumble bees that can see ultraviolet wavelengths but not red colors vs. hummingbirds than cannot see ultraviolet wavelengths but can see red, a flower color for which they have a preference). In many cases it will be necessary for ecologists and conservation policy makers to adjust the scale of observations to the heterogeneity perceived by the target organism and the ecological processes under study or under adaptive management.

Patchiness can change as a consequence of patch dynamics. Patch dynamics are the result of the simultaneous operation of various physical, biological, and human patch-generating mechanisms (Pickett et al. 2000). How do patches and ecological systems persist in the presence of destabilizing forces? In the traditional ecological view of disturbances, a clearly exogenous factor occurs at a single time—creates a ''patch'' with abrupt or clearly defined boundaries—and increases the resources available for new growth through decreased biological use, increased decomposition, or both (Pickett and White 1985). Nevertheless, disturbances can be caused not only by exogenous factors (originating from outside the ecosystem) but also by endogenous factors (originating from within the ecosystem) such as synchronous aging of cohorts of trees or insect outbreaks. In practice exogenous and endogenous factors interact. For example, insect infestation of trees increases vulnerability to windfall, and, in turn, windfall might facilitate insect infestation.

The term *disturbance regime* is used to characterize the spatial scale and temporal patterns of exogenous and endogenous disturbances and the subsequent response and recovery of ecosystems. Patchiness within a landscape reflects the types of disturbance and their frequencies and magnitudes; landscape elements of topography, substrate conditions and organisms, and resource base available to organisms; and life histories and assimilative capacities of species present or potentially available to colonize a disturbed site (Forman and Godron 1986). Disturbances vary in magnitude, depending on the intensity and severity of the disrupting event. The eruption of Mount St. Helens in 1980, the Yellowstone fires of 1988, and Hurricane Hugo in 1989 are examples of intensive and large scale disturbances that captured public attention (Turner et al. 1997). Both large- and small-scale disturbances operate simultaneously and generate, within a landscape, mosaics with patches of varying size, species composition, and age structure (Pickett and Thompson 1978). For example, in forest ecosystems small-scale disturbances such as falling trees usually favor shade-tolerant plant species, whereas larger-scale disturbances such as landslides favor shade-intolerant plant species.

In ecological systems stability has been characterized mainly through four properties (Wu and Loucks 1995):

1. resistance (capacity of a system to resist an external perturbation),
2. resilience (rapidity with which a system returns to a previous equilibrium after a perturbation),
3. persistence (ability of a system to remain within defined limits despite perturbations),
4. and invariability or constancy (uniformity of system properties over a given period).

Resistance and resilience presuppose an equilibrium from which the ecosystem may depart or to which it may return. Persistence and invariability, however, do not necessarily imply equilibrium. Nonequilibrium models emphasize openness, transient dynamics, and stochastic processes of ecosystems. In 1987 ecologist Zev Naveh contrasted the static notion of homeostasis (maintenance of a static structure), by introducing the concept of homeorhesis (Wu and Loucks 1995, p. 444). Under a homeorhetic perspective, resilience can be understood in nonequilibrial terms: After a perturbation systems may return to their original trajectory or rate of change rather that to equilibrium.

Patches can vary at different temporal and spatial scales in the same landscape (Wu and Loucks 1995) because of disturbance, species interactions, and propagation modes. Consequently, understanding and modeling patch dynamics in a given landscape and making decisions about resource management and conservation policy require a recognition of the diverse causes and mechanisms of patchiness in various spatial and temporal scales.

ANTHROPOGENIC PATCHINESS

Spatial patterns and temporal heterogeneity created by humans are often qualitatively and quantitatively different from unmanipulated ecological heterogeneity. Landscapes are rarely homogeneous, but human monopolization of the landscape for urban settlement, farming, or forestry can greatly reduce heterogeneity and alter ecosystem and landscape patchiness. The drivers of ecological change will produce new configurations and compositions of patches that will affect organisms over a spectrum of scales, generating novel spatial patterns and trajectories of change. Landscape contexts can strongly influence local ecosystems; the consideration by environmental policy makers of spatial and temporal heterogeneity, which are constantly

changing as the products of natural and anthropogenic patch dynamics, is necessary to support biodiversity, maintain ecological and evolutionary processes, and provide multiple ecosystem services to humans (Kolasa and Pickett 1991). The role of patchiness and patch dynamics in ecological and evolutionary processes has led to the development of metapopulation theory which examines the dispersal and isolation of individuals between patches in heterogeneous landscapes. This theory is relevant to the persistence of species in fragmented habitat patches created by human land use.

The ubiquity and persistence of the spatial legacies of past disturbances underscore the importance of the historical dimensions of natural and anthropogenic patch dynamics. Knowing that landscapes are dynamic mosaics composed of various kinds of interdependent patches, humans can no longer manage a park or reserve as a homogeneous unit (Biggs et al. 2003). Moreover, the spatial patchiness of a given landscape, whether natural or anthropogenic, must be maintained in order to conserve biodiversity. This approach has been called the "minimum dynamic area" concept (Pickett and Thompson 1978).

CONCLUSION

Patch-dynamic concepts offer a contemporary unifying framework for ecology, evolution, and conservation practices under a nonequilibrium view that appreciates the spatiotemporal variability of "shifting mosaics" (Wu and Loucks 1995). The patch-dynamic perspective has largely supplanted traditional succession theory (Clements 1916), which assumed an orderly, repetitive, and deterministic sequence of change tending toward equilibrium. Alternatively, vegetation dynamics can be represented by a hierarchical patch-dynamics theory (Pickett et al. 1987) that accepts multiple end points starting from the same initial condition (but varies with stochastic and probabilistic events) (Simberloff 1980) and does not require the assumption of a stable "climax" stage.

VII. PHILOSOPHY OF ECOLOGY

The philosophy of ecology, broadly understood, converges with environmental philosophy. In a narrower, more technical sense, it is a subfield of the philosophy of science. The philosophy of ecology in this sense is a branch of the philosophy of biology. It is concerned primarily with two kinds of questions: (1) epistemological questions about the manner and degree to which ecology meets the general standards of successful science, as classically specified in twentieth-century philosophy of science, and (2) foundational questions about the discipline's deep and guiding empirical presuppositions.

ARE THERE LAWS IN ECOLOGY?

There is disagreement about whether there are laws in ecology. Lev Ginzburg and Mark Colyvan argue (2004) that there are; Daniel Simberloff (2004) and Kristin Shrader-Frechette and Earl McCoy (1993) exemplify the more skeptical view. Why is this question important? From the standpoint of traditional philosophy of science, laws are important because they are prominent in scientific explanations. One of the earliest and most influential accounts of the role of laws in scientific explanation was the covering-law model developed by Carl Hempel (1965). To explain a given phenomenon on the covering-law model is to show (by deductive argument), given the laws of nature and certain initial conditions, that a phenomenon was inevitable. Thus, on Hempel's view, laws are important because without them there would be no explanation.

A significant number of ecologists, probably a majority, doubt that there are the kind of exact quantitative laws in ecology that Hempel's covering-law model of explanation presupposes; yet they do not doubt that ecology offers genuine explanations This suggests that the conventional philosophical portrait of science as necessarily involving crucial notions like law (along with the covering-law model of scientific explanation) might not capture the science of ecology. If the tail (conventional philosophy of science) wags the dog (ecology), then ecology is not a science. If it is the other way around, then conventional philosophy of science is parochial and incomplete. Thus, the question here is whether philosophers of science need to rethink what a law is.

In the early days of the philosophy of science, the guiding image of successful science was physics; thus the image of a successful law incorporated high standards of invariance. The laws of physics are not easily transgressed. John Beatty (1995), Sandra Mitchell (2000), and several other philosophers of biology have developed suggestions about how to rethink the idea of a scientific law in terms that are more applicable to biology. What these views share is a tendency to relax the standards of invariance expected of a genuine law. The laws of biology may have more exceptions than the laws of physics, but they are still laws. A natural outcome of this process is to recognize that the necessity or invariance of laws is a matter of degree—they have differing degrees of *nomic force*. A significant project in the philosophy of ecology is to apply this notion of nomic force to the generalizations of ecology. This project also gives rise to an important philosophical question: Do the generalizations of ecology have sufficient nomic force to underwrite the explanatory claims of the discipline? The answer to that question depends on how one views the explanatory claims.

EXPLANATORY VIRTUE

Philosophical theories about the nature of scientific explanation often share two deep intuitions. One concerns covering laws. As Gilbert Ryle (1949) long ago suggested, laws are a kind of inference ticket; they license the transition in belief from one set of facts to another. The second intuition is that explanation is a matter of telling the causal story. To explain a phenomenon is to elucidate the causal mechanisms responsible for that phenomenon. These two explanatory virtues are at the core of two influential theories of scientific explanation: Philip Kitcher gives prominence to the covering-law intuition in his unificationist approach, and Wesley Salmon emphasizes the importance of elucidating causal mechanisms.

Ecology appears to manifest both explanatory virtues. Some explanations in ecology are more mechanistic than others, and some generalizations license stronger inferences than others. Moreover, there is no reason to think that being good at one will mean being good at the other. In ecology it appears that just the opposite is true: The more fidelity one seeks in the description of causal mechanisms, the more likely the account developed will hold of only a restricted group of situations. Thus there appear to be two independent dimensions of explanatory success in ecology: explanation as unification and explanation as telling the causal story. Gregory Cooper (2003) develops an account that judges explanatory success to be a mixture of the two virtues.

THE BALANCE OF NATURE

What does "the balance of nature" mean? Is there such a thing? Such questions move from the epistemological to the ontological. Questions about the balance of nature concern the deepest empirical presuppositions of the discipline. Because of its foundational role, the idea of the balance of nature tends to guide inference rather than be guided by it. Thus, a belief in the balance of nature and an understanding of what that term really means must be inferred from the overall arguments that ecologists make. Cooper (2003) identifies one form that this commitment often takes: the idea that populations in

nature are regulated by density-dependent factors mediated primarily by the mechanism of intraspecific competition. A. J. Nicholson uses the metaphor of a steam engine. Competition is like the governor on the engine; if population density gets too high, it throttles down population growth, and if density is too low, it relaxes its intensity so as to induce more population growth.

When spelled out explicitly, it is clear that the balance-of-nature assumption—in this narrowly defined instance of that much broader concept in ecology—really is an empirical claim. Is it true? At the population level, whether a population is so regulated seems to depend a great deal on the kinds of organisms one examines. It is more likely to be true of birds, for example, than insects. At the community level the clearest manifestation of the balance of nature was Frederic Clements's (1905) conception of succession to climax. As the articles on disequilibrium ecology and patch dynamics amply demonstrate, succession does not terminate in a predictable climax state of equilibrium. Another kind of balance of nature was attributed to ecosystems by Eugene Odum in the middle of the twentieth century; on his view balance was purportedly manifest as a kind of cybernetic, self-organizing characteristic.

A twenty-first century manifestation of the balance-of-nature idea is the complex adaptive systems approach to communities as developed, for example, by James Drake and his colleagues (1999). Are these plausible manifestations of the balance of nature? As indicated in the previous section, there are two questions to ask of such accounts. Does it function as an effective inference ticket, taking us reliably from one set of facts to another? Does it elucidate the mechanisms behind the phenomena? When it comes to the balance of nature at the levels of community and ecosystem, a special problem emerges with the second question. To suggest that there is a balance of nature implies some sort of functionality. The homeostatic mechanisms of an organism represent the operation of balancing mechanisms in the functional sense—when dogs get too hot, they pant. But how does such functionality come to be? How do such regulatory mechanisms get established in systems? In the case of human artifacts and organisms, we know the ultimate answer. In the former, such as heating/cooling systems, they are the product of design. In the case of organisms, they are the product of natural selection. Although many biotic communities and ecosystems—for example, gardens and agroecosystems—are designed by humans, many are not. But natural selection apparently does not occur at the level of the community or the ecosystem. If not, and we are to continue to attribute functional characteristics to them, then there must be an alternative mechanism for generating functional characteristics, and it is not clear what that is for nonartificial communities and ecosystems.

LEVELS OF ORGANIZATION

If no coherent account of the origin of functional characteristics of communities and ecosystems is forthcoming, then there is reason to doubt the existence of these functional properties. Clearly we do say such things as the function of decomposers in an ecosystem is to break down organic compounds so as to facilitate the cycling of nutrients through the system. Which organisms accomplish this, or whether it is done by organisms at all, is of no real significance for the putative functionality of the system. If there are such functions as decomposition, and if they are carried out by functional components such as fungi and bacteria, then a new and independent level of biological organization beyond organisms will also necessarily exist. On the other hand, such putative functions may only be the fortuitous side effect of the independent activities of coexisting organisms, each doing what organisms do—eating, growing, reproducing. One central question of the philosophy of ecology is an ontological question: Do communities and ecosystems actually exist as transorganismic levels of biological organization, or is the functionality attributed to these systems explainable at a lower level of organization?

Although the existence of communities and ecosystems as independent levels of biological organization depends on finding the mechanisms responsible for biological function at that level, that is not the only ontological issue central to the philosophy of ecology. Two others are salient: (1) If communities and ecosystems exist as such, it seems necessary that they exhibit identifiable and nonarbitrary boundaries similar to other biological entities such as cells (which have bounding membranes) and organisms (which typically have skin, bark, or other identifiable surfaces). But communities are notoriously fuzzy, and ecosystem ecologists themselves determine the boundaries of ecosystems depending on the ecosystem processes they are investigating; ecosystems exist more in the eye of the beholder than as observer-independent units in the natural world. (2) If communities and ecosystems exist, they should be causal entities that affect other entities, including their component organisms. In the case of communities, there is some hope in this line of investigation. Niche theory in community ecology holds that species adapt to niches in communities; if this is true, then the community is causally efficacious as an entity to which species evolve adaptive characteristics. On the other hand, reductionists might counter that niches are resolvable into their organismal and abiotic components and that other species adapt to each of them severally.

Both the epistemic and ontological questions raised by ecology remain unresolved, offering much future work for philosophers of science. Although the philosophy of

science may help ecologists think more systematically about the epistemic and ontological conundrums of their field, as philosophers of science begin to take ecology seriously, the philosophy of science will be transformed.

VIII. INTEGRAL ECOLOGY

Today, experts agree that because environmental problems are very complex, the perspectives afforded by many different research methods and disciplines are needed to analyze and solve such problems. What are those perspectives, however, and how do they relate to one another? Integral ecology (IE) proposes to answer these questions. IE is a comprehensive, meta-perspectival, and postdisciplinary framework for characterizing ecological phenomena and resolving environmental problems. IE is comprehensive in that it both draws upon multiple perspectives, including those in the natural and social sciences, the arts and humanities, and also provides a theoretical scheme for showing the relations among them. IE is meta-perspectival because it unites, coordinates, and enriches knowledge generated from at least four different major perspectives and eight foundational methodologies (see below). IE is postdisciplinary by virtue of its applicability within, between, and across disciplinary boundaries. For example, IE can be applied

- within a discipline (e.g., by integrating various schools of ecology);
- as a multidisciplinary approach (e.g., by investigating ecological phenomena from several disciplines);
- as an interdisciplinary approach (e.g., by using social science methods to shed light on economic or political aspects of environmental values);
- as a transdisciplinary approach (e.g., by helping numerous approaches and their methodologies interface through a well-grounded metaframework) that transcends disciplinary boundaries.

The IE framework draws on integral theory (IT) as developed by the American philosopher Ken Wilber (2006). According to IT, there are at least four irreducible perspectives—objective, interobjective, subjective, and intersubjective—that must be consulted in an attempt to understand and to remedy environmental problems. Each of these perspectives can be studied through two major methodological families: the interior (i.e., a first-person perspective) or the exterior (i.e., a third-person perspective). The *objective* perspective examines the composition and exterior behavior of phenomena such as individual organisms, including humans, bears, salmon, and beetles. The *interobjective* perspective examines the structure and exterior behavior of collective phenomena, ranging from socioeconomic systems to ecosystems, on various spatiotemporal scales. Data generated by these third-person, objective perspectives are valuable, but they do not provide an exhaustive understanding of the problem at hand and do not provide motivation for action. Technical information alone cannot persuade people to

act. Motivation arises when people experience a given environmental problem through two additional perspectives—*subjective* and *intersubjective*. Academic and public environmental discourses only infrequently approach phenomena in terms of how they manifest themselves within these interior perspectives, including those pertaining to aesthetics, psychology, and culture.

IE labels these four irreducible perspectives as follows:

terrain of experience (subjective, first-person);

terrain of culture (intersubjective terrain constituted by first-person/second-person exchanges);

terrain of behavior (objective, third-person singular);

terrain of systems (interobjective, third-person plural).

The perspectives are irreducible because, for example, a first-person perspective cannot be reduced to a third-person perspective. When someone says, "I feel devastated as I look at this polluted stream," that person is speaking from the first-person perspective. The perspective informing my assertion cannot be simply replaced by a third-person perspective, which would take the following form: "That person over there is saying that the stream in front of him is polluted." Likewise, the cultural significance of a religious ceremony cannot be equated with the socioeconomic function that the ceremony may have. Finally, there is the assertion that animals have subjective perspectives that make possible experiences of their own, in ways that are analogous to human first-person perspectives and experiences. Individual animals, then, can be understood from one perspective as functional units in an ecosystem, but such an understanding is incomplete. Animals have experiences and cultures of their own that should be taken into account when describing them in their habitat.

In an IE context the classical definition of ecology (the study of the objectively ascertainable interrelationships between organisms and their environment) becomes the mixed-methods study of the subjective and objective aspects of organisms in relationship to their intersubjective and interobjective environments. Introducing first-person perspectives and collective (cultural) perspectives complicates matters but provides a much richer understanding of the phenomena under investigation. A wide variety of ecologists, environmentalists, urban planners, wilderness guides, and activists recognize the theoretical comprehensiveness and practical efficacy of IE.

IE also examines developmental stages in both nature and humankind; it examines how nature shows up to people operating at differing psychological and/or developmental stages. IE does not employ a new definition of ecology but rather uses an integral interpretation of the standard definitions of ecology, whereby organisms (including humans) and their environments are recognized as having interiority. This expanded definition has allowed IE researchers to identify more than 200 varieties of ecological thought (including eighty schools of ecology), ranging from acoustic ecology to zoo semiotics and occupying various positions within the four major perspectives.

In affirming the differences among, as well as the importance of, each of these major perspectives, IE avoids both gross and subtle reductionism. Gross reductionism views all reality, including first-person interiority, in terms of individual objects without interiority (experience) of any sort. Subtle reductionism interprets all things as interobjective phenomena, thus treating the "I" and "we" (interior perspectives) as components of interwoven objective systems. Subjective and intersubjective perspectives—including beliefs, values, norms, religious traditions, and ethnic self-identification—must be included in characterizations of environmental problems. Marshaling, coordinating, and assessing pertinent perspectives require *integral methodological pluralism* (IMP), which contrasts with methodological hegemony, according to which one's own perspective (e.g., one's preference for a particular school of ecology such as community ecology) is more important than any other perspective that might be brought to bear on the problem at hand (e.g., ignoring insights from other schools of ecology).

Proper utilization of IMP presupposes a high level of cognitive, moral, and psychosocial development if one is to follow its three principles of *inclusion* (consult multiple perspectives and methods impartially), *enfoldment* (prioritize the importance of findings generated from these perspectives), and *enactment* (recognize that phenomenon are disclosed to subjects through their activity of knowing it). As a result of these commitments, IE is considered to be *postmetaphysical* (i.e., it avoids postulating a priori structures by highlighting the perspectival nature of enacted reality). In other words, a particular phenomenon can show itself—and in that sense *be*—only within a perspective or world space consistent with the features of that phenomenon. For instance, ecosystems subsisted long before ecologists conceptualized them, but, in another sense, ecosystems could become manifest only when people established the cognitive world space necessary for such manifesting to occur.

After using IMP to develop a solution to a particular environmental problem, IE must communicate that solution in ways consistent with the developmental worldviews of a given audience. Extensive psychocultural research indicates that about 30–40 percent of the adult population of the United States is centered at the premodern stage (e.g., conservative Christian), 30–50 percent is centered at the modern stage (i.e., people committed to democratic

individualism and science-oriented rationality), and 10–30 percent is postmodern (e.g., environmentalists concerned with ending sociocultural hierarchy and the domination of nature) (Kempton et al 1996, Ray and Anderson 2001). IE respects individuals and organizations that adhere to the values associated with each of these worldviews and addresses them in terms consistent with how proposed solutions show up for and thus matter to them.

ECONOMIC DISCOUNTING

One of the difficulties in comparing the costs and benefits of different policies or actions involves time. Uncertainty about the future effects of actions is a problem, but the time at which a future effect is realized can be relevant to an understanding of its value. To illustrate, one can compare a prospect in which a person pays $100 today and receives $100 ten years from now with a prospect in which that person receives $100 today and pays $100 ten years from now. If one ignores the timing of the cost and the benefit, the prospects are equivalent, but the second prospect is clearly better than the first. It is better now, when one has the money to use, and it is better ten years from now. This is true whether the person wants to use the money to increase consumption now or invest it to increase consumption later. The value of money, as well as the value of commodities, is partly a function of time.

When economists evaluate different actions or policies, therefore, they apply a discount rate for time. Discounting allows them to compute a present value for costs and benefits that occur at different times that makes them comparable. A discount rate for monetized costs and benefits is similar to an interest rate. If one applies a 5 percent discount rate to an outcome that would produce $100 in benefits five years from now, its present value is $78.35. That is the amount which, if invested today at 5 percent interest, would yield $100 in five years.

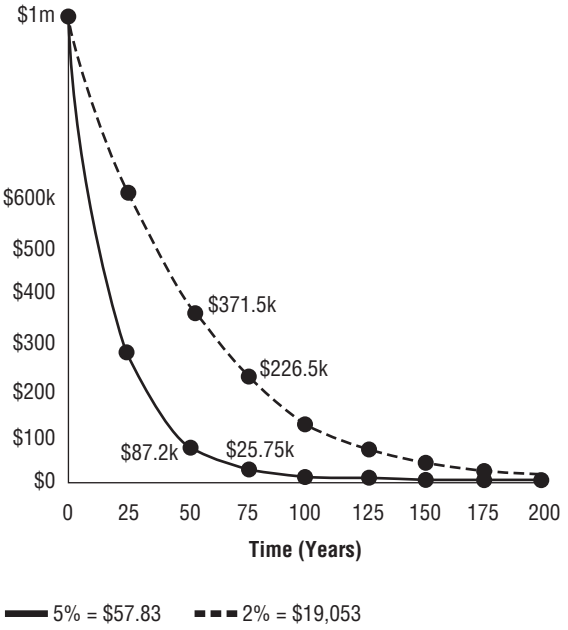
To get a sense of how much the choice of a discount rate matters, one can consider the value of $1 million in 50 years. At a discount rate of 2 percent the present value of that amount is $371,528, but at a rate of 5 percent the present value falls to $87,204. Using a 5 percent discount rate, for example, the present value of $1 million 200 years from now is only $57.83. Clearly, the choice of a discount rate for proposals with costs and benefits that extend into the distant future has significant implications (see Figure 1). One economist remarked about the impact of climate change, "It is not an exaggeration to say that the biggest uncertainty of all in the economics of climate change is the uncertainty about which interest rate to use for discounting" (Weitzman 2007, p. 705).

Analysts offer different reasons for discounting. The one described above is related to the opportunity costs of capital. Some others have to do with the benefits of consuming sooner rather than later; the uncertainties of predicting the future effects of an action or, for that matter, the uncertainty that humans will exist in the future to experience those effects; and what some call pure time preference, which states that the value of any outcome is greater if it occurs sooner rather than later. These are very different kinds of reasons, and they must be examined separately.

EFFICIENCY

The first reason involves efficiency. Money, resources, and some commodities have opportunity costs; that means that they can be consumed now or invested to produce more in the future. Discounting is a way of taking these costs into account, as the examples described above illustrate.

A different kind of efficiency argument rests on two empirical assumptions about the future. The first is that the economy will continue to grow in the future, just as it grew in the past. Economic growth means that the average wealth per person increases over time. The second assumption is that there is decreasing marginal utility of the value of resources or commodities. The first car a family purchases may lead to a large benefit; a second car will give them some additional benefit but less than the first. The



The graph shows the present value of future costs or benefits worth $1 million. The solid line shows the effect of a 5% discount rate; the dotted line shows the effect of a 2% discount rate. Notice the sensitivity to the choice of discount rates: the present value of $1 million in 50 years is about $371,500 at 2% and $87,200 at 5%. Notice also how the present value of costs and benefits in the distant future count for very little, regardless of the discount rate chosen. The present value of $1 million in 200 years is $19,053 at 2% and $57.83 at 5%.

Figure 1. CENGAGE LEARNING, GALE.

assumption of decreasing marginal utility implies that a specific amount of money will benefit a poorer person more than the same amount will benefit a richer person. The better off people become in terms of well-being, the less efficient they are in converting additional resources to further increases in well-being. Most experts accept this assumption as a general although not universal truth.

Economic growth implies that people in the future will be better off than people currently are. They will have more commodities or resources, and their level of well-being will be higher. Decreasing marginal utility implies that people living today will benefit more than people in the future from the same increments of resources or wealth. Saving for future generations thus involves a redistribution of wealth from those who are worse off to those who are better off. To maximize the value of resources, therefore, people should discount future costs and benefits. Discounting thus is justified as a way of maximizing the value of commodities or resources over time.

If it is reasonable to deny that the economy will continue to grow in the future, perhaps because global climate change will have profound negative impacts on the economy, the discount rate should be set at zero or perhaps be negative. The empirical assumptions behind efficiency arguments may be controversial, but the logic of arguments for discounting for this reason is hard to resist.

Those arguments are not based on controversial ethical assumptions; they are compatible with most ethical theories. Most theories of justice, for example, do not call for redistributing wealth from those who are worse off to those who are better off. Efficiency reasons for discounting are also compatible with utilitarianism, which focuses only on aggregate well-being and is insensitive to how well-being is distributed among individuals or groups. Efficiency reasons for discounting are intended to maximize aggregate well-being in a way that is neutral in regard to when well-being occurs. It is important to realize that these reasons for discounting future costs and benefits do not discount the well-being of people or generations as a function of time.

JUSTICE: CURRENT VERSUS FUTURE WELL-BEING

A second reason for discounting, which is ethically more significant, considers the well-being of people who will live in the future less important than the well-being of people alive today. Different arguments are given to justify this reason for discounting. One argument rejects utilitarianism and appeals to considerations of fairness. If people living in the future will be better off than people are today, then policy makers should give priority to those who live now because people today are worse off than people in the future will be. Someone who defended discounting for this reason might claim that it is unfair to impose large sacrifices on people who are worse off as a means of increasing total well-being.

To illustrate this reason for discounting, one can consider the evidence that people's activities today are causing climate change that will have profound effects that will extend for a very long time. Economists working with the best current estimates of the costs of mitigating those effects have estimated that if people do not discount the value of changes in the well-being of future generations, even if they discount for efficiency, the present generation will have to save up to 97.5 percent of its income to mitigate those costs. Partha Dasgupta concluded that this means that "the current generation in the model economy ought literally to starve itself so that future generations are able to enjoy ever increasing consumption levels" (Dasgupta 2007, p. 6). Dasgupta suggests that under the same economic assumptions discounting the well-being of future generations at a rate of 3 percent per year would

imply that the current generation should save or invest 25 percent of its net output, which is far more than people do save but might be neither unreasonable nor disruptive. Also, if people in the future are better off anyway, discounting their well-being is not unfair either.

TIME PREFERENCE

The most controversial reason for discounting is pure time preference, which most economists endorse but some have rejected. Pure time preference states that things that happen in the future are less valuable than things that happen now simply because they happen in the future. The main argument for basing a discount rate on time preference appeals to democracy or citizens' sovereignty. When most people think about their own lives or about government spending, they prefer to get benefits sooner and defer costs to a later time. Most economists believe that cost-benefit analysts should try to be ethically neutral, which they take to mean that they should base the values in their analyses on citizens' preferences or what people are willing to pay.

Critics of time preference have argued that to evaluate policies on the basis of what people happen to prefer, whatever reasons they may or may not have for their preferences, is not democratic but irresponsible because some preferences may be unjustifiable or, especially in complicated matters involving time, irrational. Thus, Roy Harrod claimed that "pure time preference [is] a polite expression for rapacity and the conquest of reason by passion" (Harrod 1948, p. 40). F. P. Ramsey dismissed time preference as "a practice which is ethically indefensible and arises merely from the weakness of the imagination" (Ramsey 1928, p. 543).

How should people think about time preference? Interpreted objectively, it means that if one compares two states of affairs, A and B, which are identical in all respects except that B occurs later than A, B has less value or counts for less than A. Interpreted this way, time preference implies that the death in 2020 of a 30-year-old is better than the death in 2010 of an otherwise identical 30-year-old. It means that the loss of 100 Union soldiers in the Battle of Gettysburg in 1863 is much worse than the loss of 100 American soldiers at Iwo Jima in 1945 simply because the American Civil War occurred much earlier than World War II. If these implications seem unjustifiable, as they do to many philosophers, people should reject time preference or find another way to interpret it.

Economists who have defended time preference on grounds other than democratic deferral to citizens' preferences typically reject the objective interpretation in favor of one that applies discounting from the temporally relative perspective of the present. Their aim is to constrain the implications of pure utilitarianism, which can require unlimited sacrifice of the present generation to produce benefits that will affect countless future generations. In this interpretation time preference does not apply to the value of events in the past, which the actions of people today cannot affect. It applies instead from a time-relative perspective to events that are in the (relative) future. The time-relative interpretation of time preference that rejects neutrality has some controversial implications. Consider an individual who applies time-relative time preference to her own interests. In deciding what to do today, she would discount the effects of her action on her well-being in the future, but she also would be aware that as time passes and she applies the same principle, the relative value of different states of affairs will change. Thus, she may make a decision that is best from her present perspective while recognizing now that it will not be best from some future perspective.

This implies a strange dissociation in an individual's judgments (Broome 1994). The analogous problem for social decisions is intergenerational conflict. When economists talk about time preference, they often make simplifying assumptions that allow them to consider generations as discrete and separate entities. In reality, however, the world always contains members of overlapping generations. If different time perspectives are appropriate for members of different generations, the interests of a 60-year-old today may lead him to discount the welfare effects of a policy that are expected to occur in thirty years, whereas the interests of a child today may suggest that those effects should not be discounted. If one does not ignore the perspectives of future generations, one must figure out a way to reconcile the inconsistencies and dissociation or reject the interpretation of time preference interpreted as temporally-relative.

UNCERTAINTY ABOUT THE FUTURE

Another reason for discounting is uncertainty about the future. If one is trying to evaluate the consequences of a policy far into the future, one may want to take into account the possibility that war or an astronomic catastrophe will bring an end to life (or human life) on earth. One may want to estimate the chances that humans will not be around to bear the costs or reap the benefits of actions today. Whatever the likelihood of extinction may be, it probably increases with time and thus may constitute another reason for discounting.

PRACTICAL EFFECTS OF CHOOSING A DISCOUNT RATE

The practical effects of choosing a discount rate may be of the highest importance. In 2007 a team of British scientists and economists published a report on the

economics of climate change. That report described the state of scientific knowledge about climate change and some actions that might be taken in response to it. The report gives a careful assessment of reasons for discounting costs and benefits over time. It accepts discounting for efficiency and for uncertainty but rejects time preference. The result is that the report uses a discount rate of about 1.4 percent per year. It concludes that the case in favor of taking strong and costly actions today to mitigate the effects of climate change is overwhelming.

These conclusions have been rejected by some American economists who insist that neutral analysts should apply a discount rate for time preference, and so the discount rate should be somewhere around 5 to 6 percent per year. Using that discount rate allows these critics to conclude that the most reasonable response to climate change that people can take now is a wait-and-see approach, hoping that it will be possible to reduce the costs by deferring them to the future. This example illustrates an important general point. When people are thinking about actions or policies that will have important consequences far into the future, the choice of a discount rate can swamp all other considerations and drive the decision.

ECONOMICS, ECOLOGICAL

Economics as a modern academic discipline focuses on the exchange of goods and services, with little attention to the effects of these activities on the natural environment. *Ecological economics,* by contrast, views the natural context as of crucial importance.

In 1988, largely under the leadership of Robert Costanza, a student of Howard T. Odum, the International Society for Ecological Economics (ISEE) was established, with Costanza as its first president. Its membership includes a few professional economists and a larger number of people in the field of public policy. Its journal began publication in 1989, with Costanza as its first editor. Costanza also established the Institute for Ecological Economics at the University of Maryland.

The ISEE has shown steady growth. In 2004 it had more than 2,400 members in nineteen countries. There were eight regional societies. It remains committed to new forms of economic thinking based on different assumptions rather than simply to the application of mainstream theory to new problems, as is the case with "environmental economics." But the latter approach is not excluded, and as more people with a mainstream education in economics join the society, the line separating the environmental and ecological approaches may fade.

MAINSTREAM ECONOMICS

Modern economics originally included land among the distinct factors of production. This view originated with the physiocrats, a school of eighteenth-century economics that held a nation's wealth came exclusively from the value of land, whether from agriculture or development. Adam Smith, however, initiated a shift toward industry. Capital and labor became the focus of attention. Land was increasingly considered as a commodity or a form of capital. Although Smith and his successors recognized that industrial production requires natural resources, they analyzed the value of these resources primarily into the capital and labor involved in making them available. Treated simply as physical givens in the natural world, natural resources all but disappeared from consideration in standard economics. The issue that was seriously debated between the mainstream of classical economists and Marxists was whether capital should be considered a

distinct factor of production or should be understood as ''congealed labor.''

The absence of the natural world from economic theory is accompanied by the presence of the implicit aim of growth. The growth in question is of human production and consumption, especially on a per capita basis. This growth is achieved by efficient organization of human labor and by replacing much of it with fossil fuels—in short, by industrialization. Economists also showed that the larger the market, the more efficient production becomes.

Many observers have noted the costs of industrialization and the enlargement of markets to nature and to human community. In *The Great Transformation* (2001 [1944]), Karl Polanyi mourned especially the widespread erosion of human community. These losses, however, did not figure into the mainstream economists' calculations of progress. They noted that far more goods and services were available to far more people than ever before. Many people in nonindustrialized societies longed to achieve the affluent lifestyle of the industrialized ones. After World War II there was wide agreement in the general public and among those charged with third world development in both the developed and the developing countries that the goal must be the economic growth of the former colonies and other countries that were not yet industrialized. This shared objective led to the globalization of the economy.

CRITICISMS OF GLOBAL CAPITALISM

Two forms of criticism of the new global economy arose. First, there was an increasing recognition especially in the seventies of the problems brought about by typical development policies. The gap between rich and poor countries grew as did the gap between the rich and the poor within both developing and developed countries. In the 1970s and 1980s the many international agreements to reduce tariffs and other obstacles to trade typically benefited only the rich.

In 1976 Susan George wrote a powerful book, *How the Other Half Dies,* that showed how rarely the third world people who were supposed to benefit from economic growth actually did so. She depicted most so-called development as exploitation.

Economists claim that most of these failures are due to distortions introduced by unequal power or poor governance rather than to inherent flaws in the policies they recommend. The breakdown of efforts to push the global market even further, beginning in the 1990s has been due primarily to the injustices built into the global trade system by the unequal power of first and third world countries. For example, farmers in third world countries, which are under pressure not to subsidize their agriculture, often cannot compete with imports from the United States and Europe, which continue to subsidize their farmers generously. Fundamental rejection of the economic theories supportive of free trade have played only a secondary role.

Second, critics have also focused attention on the importance of the natural environment. Kenneth Boulding in 1966 stimulated thinking about economics in this context by contrasting a desirable ''spaceship'' economy with the existing ''cowboy'' one. The latter, supported by mainstream economic theory, ignored the degradation of the natural environment, the exhaustion of resources, and pollution.

Mainstream economists respond that when income levels rise, nations enact laws protective of the environment, so that growth is the solution to the environmental problem. They contend that capital, in the form of technology, can replace one resource with another, so that the problem is not the shortage of resources but of capital. Technology can also reduce pollution. Mainstream economists, therefore, do not ignore nature altogether. In fact, some mainstream economists specialize in the study of natural resources. Moreover, in response to concern about environmental issues, mainstream economists have developed the new sub-discipline of environmental economics.

The views of mainstream economists on these topics merit serious attention. Desperately poor people cannot afford to consider the sustainability of their survival strategies in the way that the economically secure can. Also, technology can often replace one resource with another or curb the output of pollutants: For example, there are many proposals for replacing petroleum with more sustainable sources of energy, and automobiles are far less polluting than was once the case thanks to the use of catalytic converters.

Most of those who criticize mainstream economic thinking, and especially the reliance of political leaders upon it, are ecologically concerned persons outside the official precincts of academic economics. Recognizing the importance of economic thinking in our world and their own lack of expertise, they have appealed to economists to adjust their theories to encompass ecological concerns. Although many economists continue to resist interdisciplinary approaches, Kenneth Arrow has recognized that interdisciplinary are important. He headed a group of distinguished economists and ecologists who worked together for four years. They published their conclusions in 2004. While employing standard economic concepts and methods, they developed a measure of ''inclusive wealth'' that measures natural as well as social and financial capital. Their findings did not suggest radical changes in policy in the developed world, but they did

show that ''development'' policies in third world countries sometimes impoverish them, especially when there is too little investment in human capital.

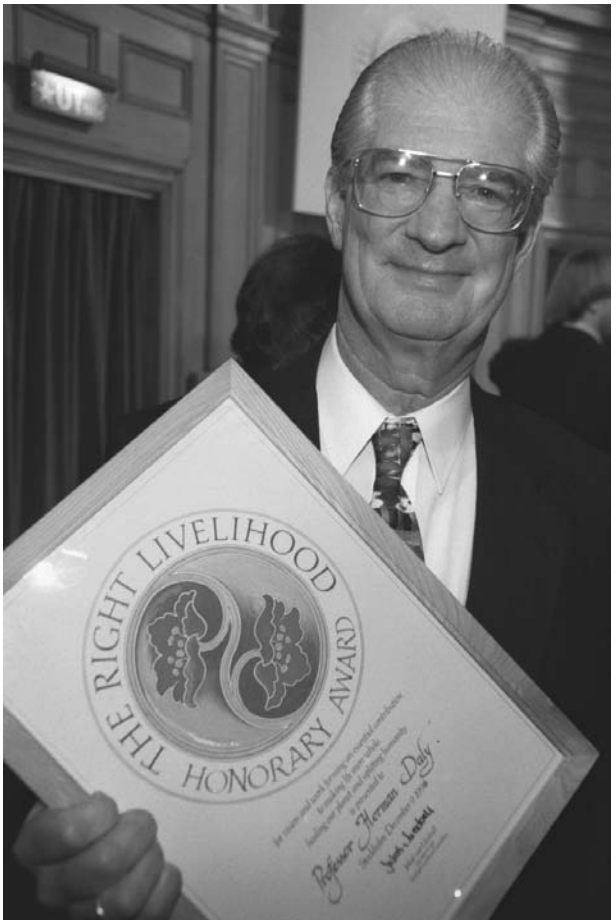
Global climate change is a particularly important test of economic thinking. President Bill Clinton sought the advice of a leading economist, William Nordhaus, who had engaged in extensive studies of the probable economic effects of global climate change in 1991. Nordhaus concluded that the loss from global climate change would amount to around 1 percent of gross domestic product. No shift from the goal of growth was indicated.

EMERGENCE OF ECOLOGICAL ECONOMICS

Despite the apparent reasonableness of the claims of these academic economists, many ecologically aware critics are not convinced of the soundness of mainstream proposals for dealing with the world's problems. Replacing what is natural with what is artificial makes for an increasingly precarious situation. For example, replacement of the natural fertility of the soil and natural defenses against insect pests with petroleum based fertilizers and insecticides, renders the future of agricultural production less secure. Similarly, increasing production by hybridizing grains renders farming more dependent on increasingly scarce water and petroleum and in greater danger from blight. In the view of these critics, the theories of academic economists ignore the complex interconnections among things, proposing to solve each problem separately. Further, the critics think that organizing the world for the sake of increasing human production and consumption is the problem, not the solution. They see the typical responses of economists as expressing a narrow and fragmented worldview.

The most important proposal for a different approach to these issues came from the ecologist Howard T. Odum. He proposed studying both ecosystems and human society in terms of energy flows and analyzing economic issues in this context in *Environment, Power, and Society* (1971). Some of his students have been leading founders of the discipline of ecological economics. In the same year the economist Nicholas Georgescu-Roegen, published a fundamental challenge to the ideal of limitless growth, *The Entropy Law and the Economic Process* (1971). He called attention to the increase in entropy that always results from the human use of resources.

The economist who has taken the natural context of the human economy most seriously is Herman Daly (1977). Assuming the correctness of Georgescu-Roegen's points, he has argued that organizing the world for undifferentiated growth leads to fundamentally unsustainable consequences. He argues that, although there are forms of growth that are thoroughly sustainable, such as the arts, an endless increase of production from farms and factories is not possible, and the effort to sustain it has devastating consequences.



The Alternative Nobel Prize. *Professor Herman Daly, of the University of Maryland, holds his Right Livelihood Award, which he received December 9th, 1996, in Stockholm Sweden. Daly is known for his work in ecological economics, a field that studies the exchange of goods and services in a natural environment.* **AP IMAGES.**

Daly points out that one of the founders of modern economics, John Stuart Mill, upheld the goal of a stationary-state economy. This idea presupposed ample production but not continuing increases beyond that point. The real goal should be to meet human needs without endless growth. For mainstream economists this proposal was so radical that Daly was no longer viewed as a serious economist. He was excluded from ''the guild,'' but he became the primary founder of ecological economics as a distinct discipline.

Because growth economics controls university departments of economics, the first task of ecological economists was to create an alternative constituency. Daly has excelled

at promoting convincing ways of looking at the economy. For example, he describes the human economy as a subset within the larger natural economy. This view posits an inclusive economy composed of both natural and artificial capital; artificial capital grows at the expense of natural capital and thus cannot grow forever.

In standard economics texts the economy is depicted as a circular flow of income and expenditure between households and firms. By shifting attention to the larger context, Daly encourages us to view industrial production in terms of "throughput"—that is, the natural resources that go into it and the human creations that emerge from it. In this process entropy increases, and an endless increase of entropy cannot be a desirable goal for humanity. Rather, the goal should be meeting human needs with a minimum of throughput.

In 1989 Daly and John B. Cobb Jr. coauthored *For the Common Good.* They analyzed the assumptions underlying mainstream economics and proposed alternative assumptions that seem more realistic to them. The book emphasizes the contrast between the self-enclosed *Homo economicus* of standard economics and "person-in-community." In the former model individuals are understood to relate only through contracts and exchange. According to the proposed alternative model, relations with other human beings and the wider environment are constitutive of human existence. On this view economics should aim at the improvement of both human communities and the wider ecological system. By ignoring the most important human relationships, the authors argue, mainstream economics encourages practices that have destroyed thousands of human communities and degraded the biosphere.

MEASURING ECONOMIC PROGRESS

Mainstream economics promotes increasing throughput. Its standard measure of progress is the gross domestic product (GDP), which measures market activity rather than economic well-being. Economists assume enough of a connection between markets and well-being to justify continuing use of GDP as their chief yardstick of economic health. Ecological economists, however, dispute the connection. Redefining Progress, a public-policy think tank dedicated to promoting sustainable economic approaches, issues an annual report based on its genuine progress indicator (GPI), which shows that sustainable economic well-being has actually declined in the United States as the GDP has risen (2008). Results are similar in other developed countries.

The GPI and similar measures in other countries mostly use the same indices as those that mainstream economists employ. But they include household work and leisure as contributions to economic well-being, and they subtract "defensive expenditures," those that increase as market activity increases. The cost of armies, police, courts, prisons, and hospitals all add to the GDP but not to GPI.

Studies of self-evaluated happiness by mainstream sociologists and psychologists have shown that, beyond a certain threshold, happiness does not increase with income. Some ecological economists conclude that the goal of the economy should be to increase happiness rather than income or wealth. Hence, they call for fundamentally different ways of evaluating the economy. Mark Anielski has done extensive work on alternative indices (2007).

Another influential approach that focuses on sustainability has emerged from the work of William Rees, Mathis Wackernagel, and Phil Testamale. In 1995 they published *Our Ecological Footprint: Reducing Human Impact on the Earth.* They examine the area from which a city or a nation must draw in order to meet its demands for resources. This analysis yields a vivid image of the unsustainability of contemporary urban society. It highlights the problem of population growth as well, which Daly treats under the heading of "carrying capacity."

CONCLUSION

Although ecological economics today is not read in graduate departments of economics, it is affecting the thinking of a broader public. In public policy discussions it is beginning to play a small role. As concern about environmental issues such as global climate change increases, ecological economics is likely to grow in importance.

ECONOMICS, ENVIRONMENTAL

Environmental economics applies the theories and methods of economics to problems in environmental policy and management. Viewed from one perspective, economics may be understood as a descriptive science that aims to model and predict the behavior of economic systems (Robbins 1932). More broadly, however, environmental economics builds on the normative principles of welfare economics, an approach developed by Pigou (1920), Samuelson (1954), and others in the early to mid-twentieth century. Environmental economists seek both to predict the effects of policy decisions and to design optimal policies that reflect individual and social values. In this sense, environmental economics is closely linked to the field of applied ethics.

THE THEORETICAL BACKGROUND

Modern economic theory emphasizes a behavioral model in which human beings are assumed to be well-informed and rational. The rationality assumption is grounded in the nineteenth-century utilitarianism of Jeremy Bentham (1789) and John Stuart Mill (1863). The idea is that people derive utility from the consumption of market goods and services plus an inclusive array of nonmarket amenities that contribute to the good life. Utility may be understood in terms of happiness, well-being, or the satisfaction of preferences. In principle, the emphasis on preferences leaves open the prospect that people might rationally make choices that sacrifice their own happiness based on motives of altruism and/or the promotion of moral goods such as environmental conservation.

In an ideal world characterized by rational behavior, perfect information, complete markets, and perfect competition, economic theory suggests that voluntary exchange between economic actors would give rise to an *economically efficient* outcome in which potential gains from trade are exhausted. In technical terms, a resource allocation is economically efficient if there is no available alternative that is preferred by at least one member of society and that leaves no individual or group worse off. This theoretical finding formalizes Adam Smith's (1776) concept of the "invisible hand," in which the market mechanism both maximizes the total value of goods and services produced in an economy and guides those goods and services to their highest-valued uses in the absence of central planning or government regulation.

As emphasized early on by Pigou (1920), however, environmental problems have central characteristics that depart from the ideals of an efficient, competitive market. In particular, there is typically no market in which people can buy goods such as clean air, biodiversity conservation, and climate stabilization. Using formal economic reasoning, Pigou showed how the existence of *externalities* can lead to inefficient resource allocation and a need for corrective public policies.

An externality exists when an action taken by one party imposes costs (or confers benefits) on third parties in the absence of consent or compensation. The pollutants emitted by a coal-burning power plant, for example, inflict environmental harms on thousands, millions, or even billions of people through their effects on ecological systems and human health. Because the owners of the power plant do not bear these costs, they have an economic incentive to ignore these effects in making business decisions. This incentive prevails even when the private costs of pollution control are less than the monetary value of the associated environmental benefits. In principle, this means that both the polluter and the victims would benefit if pollutant emissions were cut and the victims compensated the polluter for any foregone profits. The absence of a functioning market, however, rules out this possibility.

Ronald Coase (1960) reasoned that the existence of externalities provides opportunities for the victims and beneficiaries of environmental degradation to negotiate contracts that efficiently balance the interests of each party in the absence of policy intervention. Coase's argument, however, is based on the assumption of minimal transaction costs—the cost of gathering information and negotiating and enforcing contracts. In the real world, environmental externalities persist because environmental problems involve large numbers of parties whose actions are too costly to coordinate through private negotiations. Stated somewhat differently, environmental resources

generate widely shared benefits to many members of society. Although market goods can be efficiently allocated by competitive markets, goods that provide shared benefits must typically be provided through collective action. One example is a legislative process that establishes regulations that balance the costs and benefits of pollution control to promote collective welfare.

Pigou (1920) argued that the social costs of environmental degradation could be internalized through the use of corrective taxes. In the Pigouvian framework, polluters pay a fee on each unit of pollution that is set equal to the marginal cost that pollution imposes on society. Marginal cost is defined as the incremental damage that would be caused by increasing pollution by one additional unit, measured in monetary units. In intuitive terms, Pigouvian taxes place a price on environmental degradation, thereby providing incentives for polluters to cut pollutant emissions. From an ethical perspective Pigouvian taxes have two key properties. First, they result in an economically efficient level of pollution that maximizes total net benefits to society, including both environmental benefits and the costs of pollution control. Second, they ensure that the public is compensated for the use of environmental resources. In this sense Pigouvian taxes are linked to the Public Trust Doctrine, which holds that certain types of natural resources (such as clean air) are the shared property of all members of society.

PRACTICAL ISSUES

Although appealing from a theoretical perspective, Pigouvian taxes are relatively uncommon in practice. Instead, governments typically address environmental externalities by implementing technology-based standards or tradable emissions permits that cap pollutant emissions at a specified level. In political terms, pollution taxes are often opposed by polluters because they require polluters to both bear the costs of pollution control and pay the government a per-unit fee on each residual unit of pollution. In societies where polluting industries exert significant political influence, this reduces the political feasibility of the Pigouvian approach (Nelson 1987).

Economists are often critical of technology-based standards that require the use of systems such as catalytic converters in cars in order to achieve environmental objectives. This view is supported by the argument that market mechanisms and incentives provide polluters with the flexibility to reduce pollution at the lowest possible cost. In this perspective, requiring a coal-burning power plant to install expensive pollution-control equipment (such as "scrubbers") would be inefficient if emissions could be cut at a lower cost through a switch from high- to low-sulfur fuel.

This line of reasoning rests on the assumption that economic actors are well-informed and rational. Although this is a workable hypothesis in some decision-making contexts, there are cases in which imperfect information and/or bounded rationality impedes the adoption of least-cost pollution abatement technologies. Engineering studies, for example, find that energy use and (by extension) energy-related pollutant emissions could be reduced significantly through the full adoption of energy-efficient technologies that are cost-effective at prevailing market prices (IPCC 2001). The existence of such market failures provides a rationale for the direct regulation of automobile fuel economy and the technical efficiency of energy-using equipment, provided that such regulations target the adoption of technologies that provide overall cost savings to businesses and consumers.

COST-BENEFIT ANALYSIS

Cost-benefit analysis plays a central role in environmental economics because designing environmental policies to maximize net monetary benefits results in an economically efficient outcome. In the 1930s economists such as Nicholas Kaldor (1939) and John Hicks (1939) reasoned that maximizing net monetary benefits was equivalent to maximizing social welfare. This argument, however, has been subjected to rigorous critiques (Persky 2001).

One critique is based on the observation that (in most applications) cost-benefit analysis attaches equal weight to net monetary benefits that accrue to each member of society. Since the time of John Stuart Mill (1863), however, utilitarian theorists have argued that the utility a person derives from incremental monetary gains and losses is a decreasing function of his or her income. Based on this premise, Mill called for the redistribution of income from the rich to the poor. In the context of environmental policy, utilitarianism might justify actions that imposed costs on affluent members of society while conferring benefits on the poor and/or disadvantaged, even if the net monetary benefits associated with this action were negative. Although it is fair to identify cost-benefit analysis as a consequentialist approach to social choice, it is consistent with utilitarianism only if prevailing public policies ensure an optimal distribution of welfare between members of society.

Cost-benefit analysis is, however, useful in identifying potential improvements in economic efficiency. If net benefits (defined as benefits minus costs) are positive, then the winners from a proposed action could compensate the losers so that all members of society were made better off. If compensation were actually paid, then the action in question would lead to an unambiguous increase in social utility. In addition, the payment of compensation would ensure the voluntary agreement and fair treatment of those bearing the costs of actions aimed at benefiting society as a whole. As such, cost-benefit analysis can be linked

instrumentally to both utilitarian and rights-based ethical theories of policy evaluation. The method is useful as a means to identify potential gains from trade and to gauge the incidence of costs and benefits between stakeholders.

NONMARKET VALUATION TECHNIQUES

Environmental economics focuses closely on the value of nonmarket goods and services. Accordingly, nonmarket valuation techniques play a central role in this field (Pearce 1993). So-called "revealed-preference" methods infer the value of environmental quality from people's observed behavior in markets. One example is the hedonic pricing method, which measures willingness to pay for environmental amenities based on the statistical correlation between environmental variables (such as air quality) and housing prices. A second approach is the travel cost method, in which the value of an outdoor recreation site such as a park, wilderness area, or scenic locale is inferred from the expenses people incur in visiting the site.

A third revealed-preference method employs data from labor markets to estimate the monetary value that people attach to health and safety risks. This approach builds on the observation that, all else being equal, workers in high-risk occupations are paid higher wages than people in safer jobs requiring similar skills and effort. Current estimates suggest that workers receive between $1 to $10 million in extra pay for each on-the-job fatality (Robinson 2007). Such estimates provide one way to balance the costs and benefits of health risks in the evaluation of environmental policies. On the other hand, assigning a monetary value to human life is in tension with the moral judgment that the taking of life is fundamentally wrong. Attempts to resolve this paradox have focused on whether health risks are accepted freely by the affected persons or whether they are imposed involuntarily by third parties (Shrader-Frechette 1991). The imposition of involuntary risks can conflict with the notion that people have a right to self-determination in the absence of coercion by others.

In contrast with revealed preference methods, so-called "stated-preference" techniques measure environmental benefits using modern survey and interview methods. These include contingent valuation, in which respondents directly answer survey questions about their willingness to pay for nonmarket goods. Choice modeling—in which respondents are asked to evaluate tradeoffs between hypothetical choice options—also falls in this category. Proponents argue that stated-preference methods are the only way to assign a monetary value to nonuse goods—things such as biodiversity conservation that people value even though the good in question seems remote from their personal experience (Mitchell and Carson 1989). Critics charge that stated-preference methods seek to reduce moral values concerning duties to nature or toward future generations into the language of commercial exchange, thereby committing a category mistake (Sagoff 2004).

LONG-TERM ENVIRONMENTAL ISSUES

Long-term environmental issues such as biodiversity conservation and climate stabilization pose special challenges to environmental economics. In standard cost-benefit analysis, net monetary benefits that accrue in the future are discounted (i.e., receive less weight) relative to the present. Discounting is based on the fact that people demand a positive return on investment in their observed economic behavior. From this some economists reason that investments in environmental quality are justified only if they generate returns equivalent to those available in financial markets. In the United States the federal government employs a standard 7-percent discount rate in the evaluation of most proposed regulations (Office of Management and Budget 1992). A 7-percent discount rate, however, implies that no more than $1.15 should be spent today to avert $1,000 in environmental damages that would occur just one century into the future. Because this approach implies that little or no weight is attached to the interests of future generations, discounting techniques have been sharply criticized by philosophers (Parfit 1984).

To address this concern environmental economists have extended their framework to operationalize the concept of "sustainable development" as set forth by the World Commission on Environment and Development (1987). Under one interpretation an economy is "sustainable" if it ensures that the welfare of a typical member of society is maintained from each generation to the next (Pezzey 1992). Given this definition, environmental economists have explored how forecasting and accounting methods can be used to gauge the impacts of current choices on future well-being.

A second approach views "sustainability" in terms of maintaining the effective freedoms or life opportunities available to future generations (Page 1983). This approach attaches importance to the conservation of environmental resources unless resource depletion would confer greater benefits on future generations. It rests on the moral premise that the environment is the joint property of present and future generations and that present decision makers have no right to impose uncompensated costs on posterity.

Viewed narrowly, the policy prescriptions advanced by environmental economists can conflict with the insights provided by environmental ethics if maximizing net monetary benefits is taken as a sufficient definition of

social optimality. Environmental economics, however, is a flexible field of inquiry with deep ties to theoretical and applied ethics. Viewed broadly, environmental economics has contributed richly to debates over the design and evaluation of environmental policies and institutions.

ECONOMISM

The term *economism* refers to the view that problems of social policy, particularly environmental policy, can best be understood as economic problems, and that solutions to them are best justified in economic terms. A century ago, this approach applied intuitively to public investments in large-scale projects such as dams. In the United States, the River and Harbor Act of 1938 required a board of engineers to weigh the commercial benefits, such as irrigation and hydroelectric power, of any water project against its costs, for example, in labor and materials. Hence, major water projects, such as flood-control projects that the Corps of Engineers undertook early in the twentieth century, gave rise to cost-benefit analysis. In this initial stage, cost-benefit analysis appealed to the same commonsense ideas of profit and loss as would characterize a child's lemonade stand. The price the project receives for its products (lemonade) should at least equal the prices it pays for input (labor, lemons, sugar, etc.). This approach to cost-benefit analysis, which still offers a defense against pork-barrel projects, served as "an administrative device owing nothing to economic theory," as one commentator has written (Hammond 1960, p. 3).

THE ETHICAL BASIS OF ENVIRONMENTAL LAW

The 1970s saw an outpouring of environmental legislation, such as the Clean Air Act and the Endangered Species Act. These statutes had less to do with providing goods than with protecting rights, in particular, the rights of persons and property to be free of the coercion or trespass implicit in pollution. For this purpose, economic analysis—the measuring of social costs and benefits—seemed less relevant. Society tried to find its conscience on matters affecting public safety and health, which is quite different from making a profit, that is, balancing benefits and costs.

The Occupational Safety and Health Act of 1970, for example, orders the secretary of labor to set, for hazardous pollutants, standards "that most adequately assure, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health

or functional capacity even if such employee has regular exposure to the hazard dealt with by such standard for the period of his working life.'' This requires industries to treat workers and their safety as ends in themselves, rather than as merely means to maximizing profit, efficiency, or any other economic objective.

Similarly, the Endangered Species Act requires federal departments and agencies to ''insure that actions authorized, funded, or carried out by them do not jeopardize the continued existence'' of any endangered species. This statute, among others (wilderness acts, for example), seeks to institute a public sense of duty toward preserving spiritually, aesthetically, or ecologically important aspects of nature. Insofar as environmental and other decisions respond to moral, aesthetic, and other judgments made as a community—often through deliberative political and legal processes—they cannot be assimilated to the subjective preferences that represent personal wants as distinct from community obligations or objectives. Insofar as environmental statutes serve ethical, aesthetic, and cultural goals rather than primarily economic purposes, ''the cornerstones of federal environmental policy in the United States explicitly prohibited the weighing of benefits against costs in the setting of environmental standards,'' as two economists pointed out (Cropper and Oates 1992, p. 675).

Eight major federal pollution-control statutes enacted between 1969 and 1978 created a quandary for society. These statutes in general treated hazardous pollution as a social evil to be minimized, not as a diseconomy to be optimized; as a trespass to be enjoined against, not as a cost to be offset by benefits. In other words, these statutes recognized pollution as a form of coercion, that is, as a moral problem, rather than as a bad side effect or external (involuntary) cost passed on to society, that is, as an economic problem. If someone throws trash in your yard (or deposits toxic substances through the air or water into your body), you may demand that the offense cease, even if it can be justified by some economic argument. To regard pollution as an assault or trespass is to treat it as a moral wrong, not as a market failure. Yet even if pollution is a moral wrong, it is also to some extent a necessary evil, since an economy cannot function without causing some emissions or effluents. If society prohibited pollution regardless of the economic costs of controlling pollution, it could bring the economy to a screeching halt, and this might be the worst outcome for everyone.

Even if (contrary to the view of economism) pollution is in principle not an economic but an ethical problem, many methods may legitimately be used to bring costs into consideration in environmental regulation. According to one well-known principle, the law may overlook risks that are so small they are hardly detectable. Governmental agencies such as Environmental Protection Agency generally regard as de minimis (so minimal as to be not worthy of consideration) a one in a million increased risk of a bad outcome to a person exposed to a hazard over a seventy-year lifetime in a large population.

German Police Enforcing Environment Checks. *Several German cities introduced environment zones in January 2008, requiring cars to display stickers to confirm that they meet particle emission standards. In February, vehicles without these stickers were fined 40 euros. Some economists believe a measure called "Willingness to Pay" can be used to create and enforce environmental standards.* **SEAN GALLUP/GETTY IMAGES.**

A second way to consider costs is to use a benchmark amount, say $6 million, to test different regulations to see if they require society to spend more or less than that amount for each statistical life saved or death avoided. If a set of regulations entail significant cost differences, these have to be defended by some moral argument or reason. Such defenses are often possible, since some risks are more odious to society than others. A benchmark figure, a sort of average number, may be necessary to make sure cost differences can be explained. A cost-effective approach secures the greatest public safety and health possible for the sacrifice of resources.

Third, in many industries, initial gains to the environment are inexpensive, but eventually the cost of controlling an incremental unit of pollution increases. At some given state of technology, one can often find an inflection point or knee of the curve—a point at which the cost of controlling the next or marginal unit of pollution rapidly increases, and returns to the environment rapidly diminish per dollar spent. A morally acceptable approach (for example, through cap-and-trade markets for pollution allowances) continually encourages or prods industry to improve its processes and technologies so as to move the knee of the curve—the point at which control costs may become asymptotic—ever farther out along the pollution-control axis. To the extent

that the government, through incentives and threats, can move industry to invent environment-friendly technology, it can assure environmental progress while allowing, at a given stage of technology, the minimum amount of pollution necessary for economic growth.

THE ECONOMIC RATIONALE FOR ENVIRONMENTAL LAW

Many economists would assert that environmental problems are essentially not ethical but economic, and therefore that these methods of bringing costs into consideration may fail to achieve what they regard as the goal of environmental regulation. The goal of environmental protection, as these economists understand it, is not based on moral principles about person and property rights or on aesthetic or spiritual concerns about protecting the natural world. Instead, the goal of environmental regulation should be understood in terms of economic concepts such as utility, net benefit, "being well off," efficiency, and welfare—all of which are defined as theoretical constructs within economic theory. Environmental problems, on this view, are problems of maximizing net utility, welfare, or benefit, as economists explain or seek to explain these terms.

Stokey and Zeckhauser, for example, assert, "Individual welfare is all that counts in making policy choices" (1978, p. 262). Freeman concurs: "Society should make changes . . . only if the results are worth more in terms of individuals' welfare than what is given up by diverting resources and inputs from other uses" (1993, p. 6). In a widely used textbook, Goodstein states, "Economic analysts are concerned with human welfare or well-being. From the economic perspective, the environment should be protected for the material benefit of humanity and not for strictly moral or ethical reasons" (1999, p. 24).

To understand the current theory of cost-benefit analysis, which epitomizes economism, we need to examine the concept of welfare to which it appeals, including equivalent concepts such as well-being, utility, being well off, value, and benefit. All these concepts are measured by willingness to pay (WTP) and are defined as whatever WTP measures. Pearce observes, "Economic value is measured in terms of willingness to pay" (1998, p. 221). Goodstein writes, "One can measure the benefits of environmental improvements simply by determining people's willingness to pay. . . . An alternative approach would be to ask an individual their minimum willingness to accept (WTA) compensation in exchange for degradation in environmental quality" (1999, pp. 88–89). Another text says, "Benefits are the sums of the maximum amounts that people would be willing to pay to gain outcomes that they view as desirable" (Boardman, Greenberg, Vining, and Weimer 1996, p. 76).

IS WTP NORMATIVE?

To understand cost-benefit analysis in its current highly theorized form, one must first ask whether it has a normative basis, whether it prescribes what we ought to do. How do economists justify the relation they posit between WTP and normative-sounding concepts such as welfare? Is WTP a measure of value of a kind one can understand, or is it simply a measure of itself and of concepts that it defines and that serve as no more than proxies or stand-ins for it (concepts such as well-being and the rest)? In other words, does WTP correlate with any goal, such as perceived happiness, that makes sense, or is it simply a crochet of economic theory. No one has measured benefit (or welfare) separately from WTP to show that an empirical correlation holds between them. If welfare, along with proxy terms such as economic value, refers to WTP, then WTP has no normative significance but correlates only with itself.

Second, even if we suppose that WTP has a normative aspect, can it be measured? Is WTP any more observable than the utility that it is supposed to define? People pay market prices for the things they want, but these prices reflect the minimum people have to pay for some good, not the maximum they would be willing to pay for it if they had to. Can economists tell how much less of a good a person would buy—or more a person would pay—in the hypothetical case of a price spike? Let us consider these questions.

The first thing to understand about welfare or well-being as economists use these terms is that it has no known or explicable relation to human happiness or satisfaction as these ideas are commonly understood. As Richard Posner has written, the "most important thing to bear in mind about the concept of value [in the economist's sense] is that it is based on what people are willing to pay for something rather than the happiness they would derive from having it" (1981, p. 60). In fact, if one takes income as a surrogate measure for WTP (because the greater one's income, the more one can pay) and if one takes reported happiness as a measure of welfare, then one finds scores of studies that show that once basic needs are met, WTP does not correlate with welfare in the sense of contentment or happiness. Possibly the most often shown result of social-science research is that money (and therefore WTP) does not buy happiness.

Welfare economists often try to connect WTP with benefit by suggesting that people choose and are willing to pay for goods that they believe will benefit them. Empirical research consistently shows, however, that in many choices (particularly those concerning social policy) people are motivated by moral commitments, aesthetic judgments, and political convictions, not by their expectations about how a policy or outcome will affect them or

add to their well-being. Even in the mind of the individual, WTP may have nothing to do with expected benefit. Kenneth Arrow has written, "The individual orders all social states by whatever standards he deems relevant" (1963, p. 17).

Amartya Sen has discussed "the reasons that may lead a person to have different goals from what she sees as her own welfare, or to choose behavior and conduct that go beyond pursuing her own goals." In such cases, "a person's choice behavior may be constrained or influenced by . . . rules of conduct (for reasons that Immanuel Kant and Adam Smith described so well)." "One way of defining commitment," Sen writes, "is in terms of a person choosing an act that he believes will yield a lower level of personal welfare to him than an alternative that is also available to him" (2005, pp. 5–6).

If people favor, prefer, and are willing to pay for things for disinterested reasons—ethical, religious, political—what is the relation between WTP and welfare? It is clear that economists use value terms, such as *benefit* and *welfare*, for their normative connotations, but WTP is the whole story. To say that WTP measures value (benefit, welfare, and the rest) is only to say that WTP measures itself, because it defines all these terms. People are willing to pay for those goods for which they are willing to pay. But what makes this tautology relevant, indeed basic, to environmental or social policy?

To be sure, people should be free to try to satisfy their own preferences in open and fair markets and other institutions as long as they respect the same freedom of others. To be sure, public policy should help with and support certain kinds of preferences, such as those for basic needs (because of a theory of justice), security (because of any political theory), and merit goods (goods that the government thinks the public ought to value, such as the sciences, the arts, historical monuments, and the magnificent aspects of the natural world). The basic premise of cost-benefit analysis asserts, however, that environmental and other social policy should be based on the satisfaction of preference—any and every preference—weighed by WTP, and WTP should be taken as it comes. Insofar as WTP is arbitrary—insofar it has nothing to do with what society has a good reason to provide or individuals have a good reason to want—why should WTP be the basis of social policy? Economists have no answer. They cannot justify the assumption that preference satisfaction per se, measured by aggregate WTP, is a good thing.

CAN WTP BE MEASURED?

Economists define *value* in terms of the maximum amount people are willing to pay for a good, not the minimum amount they can get it for. One can see why. People pay the lowest prices they can conveniently find for consumer goods, no matter how much they need them. For example, even if you are desperate to fill up your tank, you will go to the cheapest gas station within reach. Competition among suppliers tends to drive prices down to costs. The price of a medicine, to give another example, has more to do with its patent than its efficacy. If price varied with benefit, then the government could never approve inexpensive drugs, nor could doctors prescribe them, because they could not be effective.

When economists seek to measure maximum WTP, especially for environmental goods with which people may not be familiar, they encounter many fascinating technical and methodological problems. These have been the subject of much research. To show that they can measure maximum WTP, especially for goods that may not be familiar, investigators working independently should be able obtain roughly the same results. Replication is vindication. So far, there is no evidence to suggest that different teams of economists would independently arrive at anything like the same WTP measurements for a given environmental good. For example, in a legal dispute concerning emissions from a power plant, two teams of economists paid by opposing sides tried to assess WTP for visibility in the Grand Canyon. The resulting estimates differed by an order of magnitude (Deck 1997, pp. 267–301).

ECOSABOTAGE

In the mid-1980s, Dave Foreman, one of the founders of the Earth First! movement, published a manual for radical environmental activists with clear instructions on how to spike trees, sabotage construction equipment, destroy power lines, and remove signs posted along snowmobile trails. Here is one illustrative passage under the heading of "condo trashing":

> The following method has been suggested for use against environmentally objectionable construction projects such as condominiums and shopping centers. . . . After the concrete slab foundation is poured, the connections for the plumbing (especially sewer) are exposed. Usually these connections are covered by duct tape to prevent foreign objects from being accidentally dropped down the pipes. Should someone remove the duct tape and deliberately put foreign materials into the pipes, and then replace the duct tape, the results are interesting. The material put in the pipes should be designed to cause a permanent stoppage (e.g., concrete or epoxy). (Foreman and Hayward 1993, p. 190)

This environmentally motivated property destruction is sometimes called *monkeywrenching*, and sometimes *ecosabotage* (or just *ecotage*). The term *monkeywrenching* comes from Edward Abbey's 1975 novel, *The Monkey Wrench Gang*. The main characters in that book carry out a campaign of ecosabotage in the southwestern United States: They set fire to billboards, disable construction equipment, and pull up survey stakes.

Since the early 1980s, ecosabotage has been associated with Earth First!, an activist movement based on the philosophical/religious outlook of deep ecology. Within Earth First!, however, there has been considerable disagreement about tactics, with some members at times calling for ecosabotage, and others favoring more moderate approaches. Since the 1990s, a number of acts of ecosabotage have also been carried out by activists identifying with groups such as the Animal Liberation Front (ALF) and the Earth Liberation Front (ELF), resulting in millions of dollars in damage. The attacks have included arson at a ski resort in Vail, Colorado in 1998, and the destruction of SUVs at a car dealership in West Covina, California in 2003. The U.S. government regards the ELF and ALF as domestic terrorist groups. For discussion of the history of these groups, see Bron Taylor's 2005 article "Earth First! And the Earth First Liberation Front."

Proponents of monkeywrenching stress that they take great care not to injure or kill anyone, and that this distinguishes their activities from more familiar kinds of terrorism. Instead, they target property, with the aim of making it prohibitively expensive for humans to despoil the natural environment. In other words, they see property destruction as a way to counteract the perverse economic incentives that lead to environmental destruction.

Some authors (Martin 1990; Welchman 2001; Hettinger 2001) have compared monkeywrenching to civil disobedience. One problem with the comparison, as these authors note, is that monkeywrenchers operate clandestinely and anonymously while seeking to avoid capture by the authorities. By contrast, activists who take their inspiration from Socrates, Henry David Thoreau, Mohandas Gandhi, and Martin Luther King Jr. advocate open and public violation of laws that they take to be unjust or immoral, without any attempt to evade the consequences of doing so. Jennifer Welchman (2001), however, defends a more expansive conception of civil disobedience that could encompass some forms of ecosabotage.

ETHICAL ARGUMENTS

Common sense moral thought suggests that destroying someone else's property is prima facie wrong, and those who recommend ecosabotage need to do the work of justifying such activity. The arguments in favor of ecosabotage fall roughly into two families: (i) *consequentialist* arguments, which appeal to the good environmental consequences of such actions, and (ii) *ecodefense* arguments, which appeal to a right of self-defense (or a right to assist other victims of an attack).

The consequentialist line of argument faces a number of obstacles:

1. One problem is that acts of ecosabotage may have a number of costs in addition to the damage done to property. For example, they may have a negative impact on the general public's perception of the environmental movement, thus making it more difficult to protect the environment using more conventional means. They may erode people's respect for the law, or for other people's property rights. They may provide encouragement to others (for example, abortion clinic bombers) who wish to use similar tactics to promote different causes. These bad consequences may be difficult to estimate, but they should figure in the overall cost/benefit analysis. (See, however, Young 2001 for some responses to these concerns.)
2. Would-be ecosaboteurs need to give some reason to think that ecosabotage is better than the alternative tactics (including, and perhaps especially, traditional civil disobedience).
3. The amount of property damage done needs to be proportional. Would-be ecosaboteurs need to be able to show that they have not destroyed property excessively—that is, that they have not done more damage than is necessary to create a sufficiently strong disincentive for individuals and corporations engaged in environmentally destructive activities.
4. Finally, one might think that the only way to address the problems just mentioned is to do a detailed cost/benefit analysis. But proponents of ecosabotage must somehow accomplish this without revealing themselves or their plans to the authorities (Turner 2006).

Suspicious Fire in Woodinville, Washington, 2008. *Firefighters douse water on houses in this Seattle suburb, where four multi-million dollar homes were set aflame. An official at the scene reported finding a sign with the initials ELF, the initialism of environmental group Earth Liberation Front. The ELF is one of a number of activist groups reported to employ ecosabotage methods to protect the environment.* **AP IMAGES.**

In one important 2001 article on the ethics of ecosabotage, Thomas Young suggests that the success of the consequentialist approach may depend on which version of consequentialism one endorses. He argues that *rational preference utilitarianism* is the moral theory that is likeliest to provide justification for particular acts of ecosabotage. This theory differs from other versions of consequentialism in two ways: First, it takes into account the desires and preferences of sentient nonhuman animals; second, it does not include irrational human preferences (such as, say, the desire to sell or to purchase a Hummer) in the calculation of costs and benefits.

As it happens, proponents of ecosabotage seldom try to justify their activities by appeal to consequentialist arguments. More common is the *ecodefense* argument, which appeals to the idea that environmental activists have a right to come to the defense of non-human nature. There are several versions of this argument. The ''unjust war'' version proceeds from the assumption that the human species is waging a war of conquest against nonhuman nature. According to this picture, nonhuman nature is an innocent victim of unjustified human aggression, and activists are entitled to render assistance by making it more expensive for other humans to prosecute this war (see Turner 2005 for more discussion of this argument). The ''home invasion'' version begins with the idea that the wilderness is our home, and that wilderness is under attack by individuals and corporations. Just as we are entitled to defend our homes against intruders, activists are entitled to defend wilderness from economic development. The ''self-defense'' version is closely associated with deep ecology's idea that fulfillment requires one to identify with (or become one with) nonhuman nature. If activists come to identify with a natural area, they may reason that ecosabotage is literally a form of self-defense, or a defense of that with which they have become one. Finally, there is the ''biocentric'' version, which appeals to the idea (endorsed by some biocentrists, especially deep ecologists) that every living thing has ''an equal right to live and blossom.'' On this version of the argument, the ecosaboteur is simply defending the rights of plants and nonhuman animals.

The ecodefense arguments have the merit of tapping into some widely shared intuitions about the right of self-defense, and about the right to intervene on behalf of innocent victims. Derek Turner (2006) argues that they also have the defect of proving too much—that is, that they would sanction destruction of other people's property in cases in which any reasonable person (including the most enthusiastic ecosaboteur) would think that we ought to respect one another's property. Philosophers have only begun to look seriously at the connections between these arguments and biocentric and ecocentric environmental thought.

THE "TERRORISM" LABEL

Whether ecosabotage should be considered a form of domestic terrorism is a controversial question to which philosophers have given scant attention. The question has important legal ramifications. For instance, in one highly publicized case, *United States v. Thurston* (2007), Federal District Court Judge Ann Aiken applied "terrorism enhancements" to the sentences of several ecosaboteurs who had pleaded guilty to a number of crimes committed between 1996 and 2001. The question also has ethical ramifications, since virtually everyone agrees that terrorism (however it is defined) is a prima facie moral evil. Ecosabotage is an important test case for philosophers wishing to clarify the concept of terrorism. To date, most of the discussion of terrorism in journals dedicated to moral and political philosophy has proceeded without much regard for questions about environmentally motivated actions.

Those who think that ecosabotage is not a form of terrorism often cite the following considerations:

1. Proponents of monkeywrenching have insisted all along that their efforts target property only, and that activists should take care to avoid killing and injuring persons. This seems like a significant departure from standard cases of terrorism (for a helpful characterization of standard cases, see Sheffler 2006). Indeed, the actual track record of Earth First!, and even the ELF and ALF, is consistent with this stated intent to avoid injuring or killing anyone.
2. There are also strong parallels between the activities of ecosaboteurs and other historical cases that no one would regard as instances of terrorism, such as the Underground Railroad or the Boston Tea Party. Both of these actions were illegal; both were undertaken clandestinely; and both had the effect of depriving other people of their property.
3. Perhaps the only clear-cut example of an ecoterrorist that one can point to today is Theodore Kaczynski, known as the Unabomber. Although Kaczynski seems to have shared some of the antitechnology views of those on the left wing of the environmental movement in the United States, there are important differences between his actions and those of ecosaboteurs. For example, Kaczynski targeted people rather than property. (For discussion of Kaczynski's relationship to the radical environmental movement, see Taylor 1998.) One concern is that applying the term *ecoterrorism* to the activities of monkeywrenchers could create the mistaken impression that they are no different, morally speaking, than the Unabomber.
4. One related worry is that if we are too liberal in applying the term *terrorism,* we will no longer be able to use that term to capture what is distinctively bad about actions such as the September 11, 2001, attacks, or the 1995 Oklahoma City bombing.

Alternatively those who do think that ecosabotage is a form of terrorism can point to undeniable structural similarities between the activities of some ecosaboteurs and those of more traditional terrorists. For example, the ELF activists who destroyed several buildings and ski lifts at a ski resort in Vail, Colorado, in 1998, subsequently issued a statement saying, "For your safety and convenience, we strongly advise skiers to choose other destinations" (cited in Taylor 1998). This is a clear case of using threats to modify people's behavior. What's more, some might think that the terrorism label captures an important moral difference. Consider the following two cases. In the first, some apolitical pranksters destroy an SUV at a car dealership. In the second, environmental activists commit exactly the same crime, but they spraypaint the letters *ELF* at the scene and issue a communiqué advising car dealers not to sell SUVs. Some people who have the intuition that the second case involves a more serious crime than the first, even though the damage done to property is exactly the same, might wish to use the word *terrorism* to capture what is worse about the second case. The difference is that the second case involves property damage plus a threat, whereas the first case involves property damage alone.

The question about whether to apply the terrorism label is complicated by the fact that the term *ecosabotage* can refer to a wide range of illegal activities. Many of these activities (such as pulling up survey stakes) will almost certainly not qualify as terrorism. Discussions of whether to apply the terrorism label tend to focus on the more extreme forms of ecosabotage, especially arson. Finally, it is important to bear in mind the current historical context. The U.S. government regards itself as being involved in an open-ended war on terror; one of many things at stake in this discussion is whether certain environmental activists ought to be considered enemies in that war.

ECOSYSTEM HEALTH

Ecosystem health is an instance of the extension of the concept of health beyond its core reference to the optimal state of living organisms. In addition to healthy ecosystems people often speak of healthy economies or a healthy body politic. Health sometimes is called a "thick descriptor" because it integrates a scientifically measurable state or condition with a positive value judgment. In the case of human health a body temperature of 98.6 degrees Fahrenheit and a pulse rate between 60 and 70 beats per minute are healthy, and to be healthy is good. Similarly, the concept of ecosystem health enables conservationists to evaluate, at once scientifically and ethically, the states or conditions of ecosystems.

ORIGINS OF THE CONCEPT

The attempt to articulate the concept of a "healthy" nature was popularized by Aldo Leopold with his notion of land health. Leopold argued on behalf of the preservation of wilderness for the last thirty years of his life, but his arguments changed over the course of those years. In the 1920s his arguments for designated wilderness areas were based on their value as recreational assets. However, in 1941, in his essay "Wilderness as Land Laboratory," Leopold argued that wilderness should be preserved as a measure or "base-datum for . . . land-health" (Nelson/Callicott 2008, p. 93). Evoking the Ancient Greek word *autopoeisis* (literally self-making, more loosely self-renewing), Leopold defined land health as the ability of the land to maintain the capacity for "self-renewal." Some have suggested that Leopold's famous summary moral maxim—"A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise" (Leopold 1949, p. 224–225)—should be read as a call to preserve the health of ecosystems. A close analysis of Leopold's use of the term *beauty* elsewhere in his writings indicates that he used the word to refer to land health. Healthy ecosystems are beautiful ecosystems.

The precedent for this type of argument for wilderness preservation goes back to the early 1930s or even the late 1910s. In a 1916 essay titled "Animal Life as an Asset of National Parks," the ecologists Joseph Grinnell and Tracy Storer went beyond the typical recreation arguments for the preservation of so-called protected areas. Although they seem to be interested mainly in preservation as a means to provide important areas of "scientific research," they at least hint at the object of that research: They refer to untoward human impact as a kind of "disfigurement" (Nelson/Callicott 2008, p. 24) of nature and suggest that in these places there still exists a "finely adjusted balance" (Nelson/Callicott 2008, p. 8) that scientists might study and come to understand. Although Grinnell and Storer never explicitly suggested that protected areas provide a standard of land or ecosystem health, their colleagues in the 1930s did. George Wright saw those areas as a source for healthy wildlife populations.

Ecologists such as Victor Shelford argued for the preservation of certain areas that would "serve among other things to show what natural fluctuations in abundance are like" (Nelson/Callicott 2008, p. 92). Those early twentieth-century ecologists used the terms *natural* and *normal* to mean both a descriptive state of affairs and a positively valuable condition without expressly employing the term *health* and apparently were arguing in favor of the preservation of certain land types (Nelson and Callicott 2008). Early twentieth-century ecology was dominated by the superorganismic paradigm propounded by Frederic E. Clements, who conceived of what later came to be called ecosystems as third-order organisms: Just as multicelled organisms evolved from closely associated single-celled organisms, superorganisms evolved from closely associated multicelled organisms. Because ecosystems were conceived

literally as organisms of the third kind, to think of them in terms of health was not far-fetched.

The superorganismic paradigm no longer dominates ecology. Hence, one must ask whether ecosystems sensibly can be said to be autopoeitic or healthy (or even natural or normal). If they can, what does this imply for human obligations toward ecosystems and for conservation?

Contemporary philosophical issues surrounding the concept of ecosystem health are of two varieties: metaphysical and ethical. First, the two main, and intertwined, metaphysical questions concern the form of the existence of ecosystems. In what way do ecosystems exist: as merely socially constructed and therefore metaphorical entities or as mind-independent and therefore genuine or real entities? In what way is it possible to press the notion of health onto an ecosystem? Are ecosystems healthy in the same way an economy can be said to be healthy (i.e., metaphorically) or in the same way an individual human organism can be said to be healthy (i.e., literally)?

Second, environmental philosophers and ethicists, as well as conservationists, are interested in the notion of ecosystem health for a number of reasons. The concept apparently combines scientific/descriptive elements and evaluative/normative elements. That is, as was noted above, health is both an objective state of a specific entity and a condition that is positively valuable and implies an obligation to act in ways that maintain that state or condition. Hence, interest in ecosystem health is premised on the assumption that if humans can determine what an ecosystem is and determine that an ecosystem can be healthy or unhealthy, along with what its state of health is, they have established a set of obligations to maintain healthy ecosystems.

CRITICISMS

Critics of ecosystem health attack it on both metaphysical and ethical grounds. Some believe that the category ecosystem has no independent reality beyond that created for it by humans and that the notion of ecosystem health therefore is an ontological, ethical, and conservation nonstarter. If ecosystems are a scientific artifact, a useful fiction of ecology constructed by ecologists to isolate parts of nature artificially for scientific study, the notion of health can apply to them in only a metaphorical way. Some of these constructivists believe that health still can serve as an object of environmental management strategies, whereas others do not. Finally, some believe that ecosystems exist in a robust, mind-independent fashion, that they have a good of their own, and that humans can make sense of the notion of ecosystem health in the same way they can make sense of human health.

In their 1993 book *Method in Ecology: Strategies for Conservation,* Kristin Shrader-Frechette and Earl McCoy summarize this dilemma:

> Some researchers have argued that one can measure biotic health by means of factors such as the ability of ecosystems to recover their equilibria after a disturbance; their not losing sensitive species; or their resistance to disease. . . . Using such factors as indicators of health, however, presupposes accounts of equilibrium or stability that are question-begging and unconfirmed. Ecology has no clear, unambiguous norms for when a community is normal or healthy and, as a consequence, positing a goal for ecological practice is quite difficult. (Shrader-Frechette and McCoy 1993, p. 102)

ECOSYSTEM HEALTH AS A GOAL FOR CONSERVATION

Despite the fact that it is a controversial notion, ecosystem health might be viewed as a worthy goal for conservation. First, many environmental thinkers who comment on the application of health to ecological entities such as ecosystems note that in addition to health describing a purported objective state of affairs, health also comes with a positive value connotation. Thus, there is the assumption that healthy ecosystems are worthy of preservation and unhealthy ones are worthy of restoration. Second, an ecosystem (or watershed, or species, or Leopold's land) is perhaps a more tangible conservation unit than is something such as nature or the biosphere. Therefore, conservation might be more precisely focused than it would be if the preservation of nature were its goal. Third, since it might be possible to describe both a wilderness ecosystem and an agricultural ecosystem as healthy or unhealthy, ecosystem health might provide a way to account for the good of a variety of environments—from the natural to the seminatural. This would allow conservation to avoid charges of elitism and misanthropy. Finally, conservation efforts focused on ecosystem health might facilitate the confluence of anthropocentric environmental efforts such as sustainability and nonanthropocentric or ecocentric efforts such as wilderness preservation. The current natural resource management scheme of ecosystem management may be seen as a direct reaction to the assumption that ecosystems exist in a tangible fashion and that they count morally, although proponents of ecosystem management do not always articulate it in this way.

Apart from the advantages the concept of ecosystem health may offer conservation, it remains to be seen whether that concept can withstand philosophical scrutiny. Philosophers vary widely on whether ecosystems have the necessary qualities such as "a good of their own" that would make sense of the idea of ecosystem health. In her 2004

essay "Ecosystem Health" the philosopher Katie McShane concluded that "ecosystems *are* the kind of thing that can be healthy or unhealthy in a fully literal sense" (p. 245), and in his 1995 essay "The Value of Ecosystem Health," the philosopher J. Baird Callicott argued that "ecosystems may not be so well integrated that they can be thought to form mature, persistent superorganisms . . . the concept of ecosystem health is at best a metaphor, since 'health' may be predicated literally only of organisms" (Holland 1995, p. 347).

The International Society for Ecosystem Health (ISEH) was formed in 1994 to "engage scholars from a variety of fields to transcend the natural, social, and health sciences . . . [and] to encourage the understanding of the critical linkages between human activity, ecological change and health." The society published the journal *Ecosystem Health* from 1998 to 2001 and hosted a number of major international conferences. David J. Rapport, a leading figure in the field, served as both president of the ISEH and editor-in-chief of the journal *Ecosystem Health*.

ECOTAGE AND ECOTERRORISM

The terms *environmental terrorism*, *ecotage*, and *ecoterrorism* have generated intense controversies—about both their meaning and their ethical implications. Debates over these terms have been an important part of the ferment in environmental philosophy since it emerged as a distinct field of study in the early 1970s.

ENVIRONMENTAL TERRORISM

Environmental terrorism, as the term is usually understood, involves causing serious damage to the ecosystems upon which a group of people depends. The term can also apply to an attempt by a state or corporation to damage some natural resource for political or economic reasons: for example, the Iraqi dictator Saddam Hussein setting oil fields on fire during the first Gulf War in 1990. Because of this political undertone, some claim that environmental terrorism is primarily an activity of either nation-states or organized terrorist groups, such as Al-Qaeda.

Others use the term to describe the behavior of corporations that, through negligence or maliciously indifferent behavior, destroy or damage ecosystems and all who depend upon them. One example often cited by environmental activists is a case in Nigeria where Royal Dutch Shell Oil Company purchased mineral rights to land occupied by the indigenous Ogoni people, subsequently heavily polluting their lands and suppressing dissent. The company allegedly supported the 1995 execution, at the hands of Nigeria's military, of one of the most charismatic of their opponents, Ken Saro-Wiwa, after a widely condemned, irregular tribunal convened by the Nigerian government.

ECOTAGE (MONKEYWRENCHING)

Ecotage is a term that combines the words *sabotage* and *ecology* to capture the idea of extralegal property destruction or sabotage committed in an effort to protect nature. It is often deployed by radical environmentalists who consider all species to be intrinsically valuable (and/or the earth to be sacred in some way) and believe that humans have precipitated an environmental crisis so grave that civil disobedience

Kuwaiti Oil Fields Set Ablaze. *During the Persian Gulf War (1990–1991), Iraqi dictator Saddam Hussein employed a method of environmental terrorism, or ecotage, by setting oil fields on fire. The aftereffects of this act were vastly destructive: More than 500,000 tons of air pollution was created, and 460 million gallons of oil contaminated the Persian Gulf. Because this was one of the first large-scale efforts of ecoterrorism, many today still think of such acts as tied to large-scale terrorist organizations.*

and even sabotage are morally permissible—if not obligatory—tactics in arresting the destruction of nature.

A synonym for *ecotage* is *monkey wrenching*. This term was coined by the writer Edward Abbey in his (in)famous 1975 novel *The Monkey Wrench Gang*, which portrayed a group of angry but spirited environmentalists cutting down billboards, destroying bulldozers, and contemplating the liberation of the dammed Colorado River—by the use of dynamite to breach Glen Canyon dam.

Although the novel was fictitious, it drew on real-life sabotage campaigns, dating back to the 1950s, when activists cut down unsightly billboards and desurveyed (removed survey stakes from) development sites and otherwise sought to thwart urban sprawl and the destruction of wilderness. Abbey himself participated in some of these activities, including efforts to prevent Peabody Coal (later renamed Peabody Energy) from mining Black Mesa, an area in New Mexico considered sacred by many American Indians and environmentalists. Abbey and many of his comrades found a part of their rationale for extralegal action in anarchist philosophy; they considered nation-states illegitimate, in part because they promote plutocratic and oligarchic interests and the exploitation of nature.

The Monkey Wrench Gang inspired the formation, in 1980, of Earth First!. This group soon began publishing the *Earth First! Journal,* publicly promoting tactics such as tree spiking, road blockading and spiking, the toppling of power lines, and the destruction of bulldozers and logging equipment. Three years earlier, in 1977, the Earth Force Society (which became the Sea Shepherd Conservation Society in 1981) had been founded by one of the original founders of Greenpeace, Paul Watson. Watson left Greenpeace when some of its members orchestrated his removal from the board, claiming he had become too aggressive in his tactics. The initial Sea Shepherd campaigns included ramming whaling ships, intervening to prevent the clubbing of baby seals, and the cutting of drift nets to prevent dolphin deaths, actions that were later labeled by the Federal Bureau of Investigation in the United States as

the first cases of ecoterrorism. Watson has steadfastly defended his tactics, arguing that rather than breaking the law, he is enforcing international environmental laws that nation-states fail to enforce.

The tactics pioneered by Sea Shepherd and Earth First! activists were criticized as violent or counterproductive even by some of those sympathetic to these new forms of environmental militancy. For example, Pete Dustrud, the first editor of *Earth First! Journal*, resigned in 1982 when Dave Foreman, one of the cofounders of Earth First! and its most charismatic and influential leader, insisted on promoting tactics in the journal that Dustrud considered violent. Dustrud especially took exception to an article explaining how to spike roads with metal to deflate tires and thereby delay pursuers of those engaged in acts of ecotage.

In 1982, Gary Snyder, the anarchistic Buddhist-animist writer who contributed significantly to the bioregional and Deep Ecology movements, criticized what he considered to be Foreman's romantic naiveté about violence and the state. In a letter to Foreman, Snyder prophetically warned that in all likelihood, ''Earth First! is already well-infiltrated,'' and argued that sabotage would only provide ''the excuse the government needs to begin to crack down.'' (Snyder 1982, pp. 2–3). Shortly afterward, Eugene Hargrove, the founding editor of *Environmental Ethics*, criticized what he considered to be the new movement's penchant for violence, labeling it terrorism. This critique led to rejoinders from Foreman and Michael Martin in the pages of *Environmental Ethics,* and from many activists in radical environmental publications, including by Christopher Manes in *Green Rage* (1991). Later, Bron Taylor argued that the term *terrorism* rarely was an apt description and that some extralegal tactics could, in certain cases, be justifiable (1997, 1998).

ECOTERRORISM

From the early 1980s *terrorism* or *ecoterrorism* was the preferred term of denunciation favored by movement adversaries, including law-enforcement authorities and partisans of extractive enterprises. Ron Arnold became the best-known nongovernmental figure making accusations, serving as a spokesperson for the so-called ''Wise Use Movement.''

Foreman famously rejected the label ''ecoterrorist'' in a 1989 *60 Minutes* interview that was conducted soon after he had been arrested, with four others, for involvement in a plot to topple electrical power-line towers carrying electricity from a nuclear power plant in Arizona to nearby cities. (Foreman and the others eventually were convicted of one or more charges; all but Foreman served jail or prison sentences. The longest sentences were more than three to six years, while two others were sentenced to about a year each.) Foreman stated during this interview that, to him, terrorism was the harpoon blowing up in a whale or the chainsaw ripping through an ancient tree, and that although monkeywrenching might precipitate fear, it was a nonviolent and justifiable tactic given the magnitude of the human assault on nature.

Unfortunately for the movement, on the same program, Darryl Cherney, an activist involved with the Earth First! campaign to save California's remaining redwood biome, reinforced the growing public perception of the movement as terrorist. Earning the ire of many of his comrades, he claimed that if he knew he had a fatal disease, he would blow up the Maxxam corporate headquarters building after it shut down for the night. Maxxam owned a Northern California logging company that Earth First! activists were battling. Shortly after the *60 Minutes* interview was aired, in May 1990, Cherney was the passenger in a car with Redwood forest activist Judi Bari when a bomb went off directly under her seat. The incident, which occurred in Oakland, California, permanently injured Bari. Bari and Cherney were soon charged with possession of an explosive device and labeled terrorists by the authorities, confirming in the minds of many that they and the movement they were involved with was terrorist. The bombing set back significantly the Earth First! campaign to save some of the last unlogged redwood groves. Many years later the Oakland Police and FBI settled a lawsuit by these activists claiming they had been slandered and their civil rights violated. Movement activists took this as a vindication and as a refutation of the terrorism charge, and some alleged as well that the authorities were behind the bombing and were the true ecoterrorists (illustrating how the label remains in use in multiple and contradictory ways in environmental politics).

Politicians and officials of the U.S. government have repeatedly labeled as terrorists those who engage in ecotage; one FBI official testifying before Congress in 2002 suggested that special interest terrorists, like those in the Earth and Animal Liberation Fronts, had become among the most significant domestic terrorism threats. Such allegations began early in the 1980s in response to the emergence of the concerted use of ecotage to prevent deforestation and other environmentally destructive practices. Critics who labeled ecotage ''ecoterrorism'' initially focused especially on tree spiking, a practice that seeks to prevent logging by driving metal or ceramic spikes into standing trees in order to make it more costly to harvest and mill them. They claimed that the practice either had caused injury to loggers or mill workers or that it could cause injuries or even death. There certainly were risks to workers, although they were overestimated by the critics of the practice and underestimated by its advocates. Tree fellers face little risk largely because they must cut the tree low to the ground (a fact learned from a contract logger

and lobbyist who is ardently opposed to tree spiking), and tree-spiking instructions emphasize that spikes should be placed chest-high or higher to prevent such injuries (as urged by Dave Foreman in *Ecodefense*). There is greater risk to mill workers, for a saw blade can shear into shrapnel when it hits a spike. Although safety regulations require mill workers to be behind barriers to prevent injury during milling, sometimes they are not. Some advocates of the practice are unaware of or callous to such risks, whereas others argue that risking injuries is morally permissible because environmental decline must be arrested and social-change movements always involve risks to both activists and their adversaries, even when nonviolence is a governing commitment. Defenders of the practice also note that no one has yet to be injured by a spike placed in a tree that has been traced to an environmentalist cause; this argument rarely acknowledges that the longer tree spiking is practiced, the more likely it is that injuries to workers will result.

The accusation of terrorism, however, gained new ground (1) after the invention of the term the Earth Liberation Front (by Earth First! activists in the United Kingdom in 1992) as a trope for those willing to engage in even more radical acts of ecotage than most Earth First! activists had countenanced, especially arson; (2) as a core of Earth Liberation Front activists fused their more ecocentric views with those of animal-liberationist activists, who had shown greater willingness to risk or intend violence or provoke fear as a tactic; and (3) as radical environmentalism assumed an even more overtly anarchist and self-consciously revolutionary posture than the movement had in the 1980s.

"Green anarchy" and "anarchoprimitivism" came to guide the revolutionary ideology of the radical environmentalists most willing to deploy arson and other tactics that could cause injuries or death among adversaries and bystanders. Some of the activists who considered themselves partisans of such movements discussed whether it might be time to take up arms or use explosives. Some even expressed affinity or sympathy with Theodore Kaczynski, also known as the Unabomber, a reclusive mathematician and anarchist who believed that technology erodes freedom and that technological societies should therefore be destroyed; Kaczynski's method for bringing this about was the attempt to maim, kill, or destroy as many technologists as he could. Kaczynski, who killed three and injured another twenty-three people during a bombing campaign conducted from the late 1970s to the mid-1990s, came to identify with the most anarchistic elements within the radical environmental movement. After his apprehension, conviction, and incarceration (arrested in 1996, he pled guilty in 1998 to avoid the death penalty and received a life sentence), he communicated with a number of radical environmentalists, including the anarchoprimitivist writer John Zerzan. Some anarchists defended Kaczynski, including writers for *Green Anarchy*, which published an interview with him.

The intensification of resistance to the war against "Mother Earth," which is how such activists often frame their task, included major acts of arson that began in the mid-1990s and continued into the twenty-first century. These acts precipitated the revision of federal law to make the suppression of these movements easier. The definition of "domestic terrorism" does not require, for example, intent to kill or maim. It requires, rather, only that such terrorism involve crimes occurring primarily in the United States that are "dangerous to human life" and that seek to "intimidate or coerce a civilian population; to influence the policy of a government by intimidation or coercion; or to affect the conduct of a government by mass destruction, assassination, or kidnapping" (Title 18, of United States Code, section 2331[5]). This broad definition allows prosecutors to seek terrorism charges (or enhancements at sentencing) and thus to seek life imprisonment of activists who engage in many acts of ecotage such as arson. This in turn makes it easier to secure the cooperation of suspects.

A good example of the radical environmentalists willing to use arson and other destructive tactics are a group of nineteen activists who, operating primarily under the Earth Liberation Front banner (some of the actions also were claimed in the name of the Animal Liberation Front), were implicated in a string of fires at corporations, research facilities, automobile dealerships, and corrals, where captured wild horses were awaiting slaughter. Their activities, scattered across the western United States, included an October 1998 fire at a lodge that was under construction at a Vail, Colorado, ski resort; the blaze resulted in $12 million in damage to facilities and millions of additional dollars in lost revenue. This case serves as one example of the arsonists' strategy: They hoped to force the resort to reverse its decision to expand into an area considered by wildlife biologists to be critical habitat for the elusive and endangered lynx.

In early December 2005 federal authorities arrested seven of the nineteen who would eventually be implicated through their investigation, dubbed "Operation Backfire." One of the first arrested was William C. Rodgers, whom authorities considered the leader of the Vail arson and one of the principal leaders of the group. Aware that his crimes were considered terrorist acts by the U.S. government and that he was facing life in prison, Rodgers wrote these words shortly before committing suicide in an Arizona jail:

> Certain human cultures have been waging war against the Earth for millennia. I chose to fight on the side of bears, mountain lions, skunks, bats,

> saguaros, cliff rose and all things wild. I am just the most recent casualty in that war. But tonight I have made a jail break—I am returning home, to the Earth, to the place of my origins. (Bernton 2006)

By 2008 fourteen of the remaining apprehended defendants had been convicted of one or more charges levied against them in Federal Court, with most drawing sentences of three to eight years. Four remained fugitives and only four of those prosecuted refused to testify against their comrades. Despite these prosecutions and convictions, ELF actions have continued in the United States and Canada; more than a dozen ELF activists face prison or have already been jailed for similar acts.

This history suggests that, however vilified by anti-environmental partisans, politicians, and law-enforcement officials, and criticized by a wide variety of other members of the public, including many environmentalists and environmental philosophers, ecotage is now likely to remain a long-term feature of contemporary environmental politics, despite the controversies that rage about the ethics of the movement's tactics. Much of this debate will persist between those who believe nature has intrinsic or inherent value and those who take a more anthropocentric and pragmatic approach to environmental ethics (although many who believe that nature has such value do not condone ecotage). Controversies will continue to swirl about whether environmental degradation is so severe that extreme tactics are necessary and justifiable.

Such debates ought not to turn on exaggerated assertions about the motives of those engaged in ecotage. With the possible exception of Theodore Kaczynski (depending on whether one considers his motivations to be environmentalist, anarchist and antitechnological, or both), and another incident when it appeared that an environmentally motivated saboteur may have returned a security guard's gunfire at a saw mill (no one was injured), in more than twenty-five years there have been no cases where environmental activists have sought to kill or maim anyone. Despite the fears that the movement will grow more violent, even developing weapons of mass death, there is little evidence for such fears based on the record and the avowed intentions of the activists. Nevertheless, the ecotage does risk causing death or great harm to humans (especially to first responders after arson attacks) and to other living things.

A small number of radical environmentalists refrain from intentional violence not because of moral scruples but because they do not think the time is ripe for it. For some, the only reason violence is not undertaken is fear of apprehension, the power of the state, a belief that it would be counterproductive to movement building to deploy such tactics, and/or a belief that the revolutionary moment is simply not yet at hand. Given the risk that some psychologically disturbed individual could be drawn to radical environmental movements, the possibility remains that an unambiguously terrorist individual or group could emerge from this movement. It is also possible that their business or governmental adversaries could promote such excesses through infiltrators to discredit their causes or environmentalism in general, or even frame these movements in terrorist crimes. Many radical environmentalists believe both have already occurred.

Perhaps the likelihood of the emergence of environmental terrorism will increase in proportion to the desperation that often has accompanied the collapse of ecological and social systems. It is even more likely that partisans in environmental conflicts will pursue their ecopolitical objectives while framing the actions of their adversaries as violent and terrorist, and their own as permissible and beneficent.

ECOTHEOLOGY

Ecological theology and religious environmental ethics have roots in the late 1960s, though earlier signs of this perspective may be found in the writings of some theologians. One of the first stirrings of an ecotheological perspective appeared in the work of Joseph Sittler in the mid-1950s and early 1960s. A Lutheran pastor and professor of systematic theology at the University of Chicago, Sittler lamented Christian theology's lack of engagement with earthly concerns and its tendency to value nature on utilitarian grounds, if at all. Sittler called attention to, and presented a Biblical basis for, the inseparability of the spiritual from the material. His early call to resacralize the material—the body as well as the natural world generally—is a prominent theme in contemporary ecotheology.

The spark that ignited ecotheology came not from within Christian theology but from a historian of technology, Lynn White Jr. In 1967, in an essay titled "The Historical Roots of Our Ecologic Crisis," White pointed to Christianity (or more broadly, the Judeo-Christian tradition) as the world's most anthropocentric religion, and as a primary source of our modern environmental crisis. White claimed that a central dogma in Christianity had gradually displaced ancient pagan worldviews that understood spirits as inhabiting and animating the natural world. This dogma, White charged, consists of a dualistic worldview that separates spirit from matter and devalues the latter; an assumption that nature is a mere backdrop and temporary stage for the real drama of humans, who, created in the divine image, ultimately leave this world to return to their true home with God; and a divine mandate for humans to exploit nature for their own ends.

White did not hold Christianity solely responsible for promoting negative views of nature. He maintained that science and technology, as expressions of the Judeo-Christian worldview, supported a widespread belief that human mastery of nature is synonymous with progress. White contrasted this worldview with Asian perspectives, which lack the fundamental spirit/matter dualism of Christianity and a linear notion of time presupposing an endpoint to the existence of the physical world. He did not recommend abandoning the Judeo-Christian tradition. Rather, he suggested Saint Francis of Assisi, protector of animals, as the patron saint of an alternative, yet authentic, greener form of Christianity.

EARLY ECOTHEOLOGY

The body of ecotheological work that grew up in response to such critiques encompasses a variety of distinct forms and approaches. Many theologians take issue with White's interpretation of the term *dominion* as human domination of nature, and interpret it, rather, to mean responsible stewardship, not despotism. In 1970 the evangelical Francis Schaeffer published *Pollution and the Death of Man*, which rejected White's interpretation of dominion but warned against a pantheistic and potentially idolatrous form of Christianity that would confuse nature with God. The degree to which God may be seen as coextensive with nature remains somewhat controversial in ecotheology. Some argue for a less transcendent deity, envisioning God as more interconnected and interactive with the natural realm and natural processes than the traditional Christian God. Indeed, the Christian belief in the incarnation—God taking bodily form in Jesus—illustrates the profound interpenetration of the spiritual and physical in Christianity. Some theologians have highlighted this core event to stress Christianity's nondualistic elements and to demonstrate the value the tradition confers on the physical. The Protestant theologian Sallie McFague, for example, suggested new metaphors for thinking about God in *Metaphorical Theology* (1982) and *Models of God* (1987). She urged Christians to imagine the world as

God's body, a physical extension of God's being that suffers along with creation and is vulnerable to human-inflicted harms. The traditional model of God as an otherworldly, kingly figure, McFague argued, contributes not only to devaluing nature but also to Christians feeling like aliens on earth.

PROCESS THEOLOGY

Following the philosopher Alfred North Whitehead, process theologians such as John Cobb also posit a deity who interacts with and is affected by natural processes. They affirm, in contrast to omnipotent and transcendent conceptions of God, a deity whose actions in the world are persuasive but not coercive. That is, God lures creation forward, allowing it to develop along diverse and novel lines but never forcing it into particular, preordained directions. In this account, all entities are seen as potentially capable of experience and creative response. The path that evolution takes results from the combined activity of God and the self-willed activity of individual organisms. One implication for environmental ethics is that all entities have some degree of value, by virtue of their capacities for rich experience and subjecthood. Similarly, in McFague's account, envisioning the earth as God's body suggests that all beings in nature have intrinsic value.

ECOFEMINISM AND ECOTHEOLOGY

Ecofeminists stress parallels between human oppression of nature and powerful males' oppression of certain classes of humans, most notably women and minorities. As McFague argues, models of God as a distant, male lord or monarch contribute to the oppression of both women and nature. Along with other Christian ecofeminists, McFague wishes to redirect the healing, saving ministry of Jesus toward this world. Salvation is not about humans fleeing this world for eternal life elsewhere. Rather, salvation refers to the life and death of the earth as a whole, here and now. In *Gaia and God* (1992) the Catholic and ecumenical theologian Rosemary Radford Ruether also urges a retrieval of environmentally positive, but neglected or forgotten, strands within the Christian tradition that can counter an earth-fleeing spirituality. She argues that deeply rooted Christian conceptions of sin that link it to human mortality and a corrupted creation, and the association of goodness with immaterial, immortal life, are not wholly tenable. Biblical and historical materials support different interpretations of sin and evil—interpretations that make valuing the body and the created world consistent with Christianity and render Christianity a less woman-blaming and more egalitarian tradition.

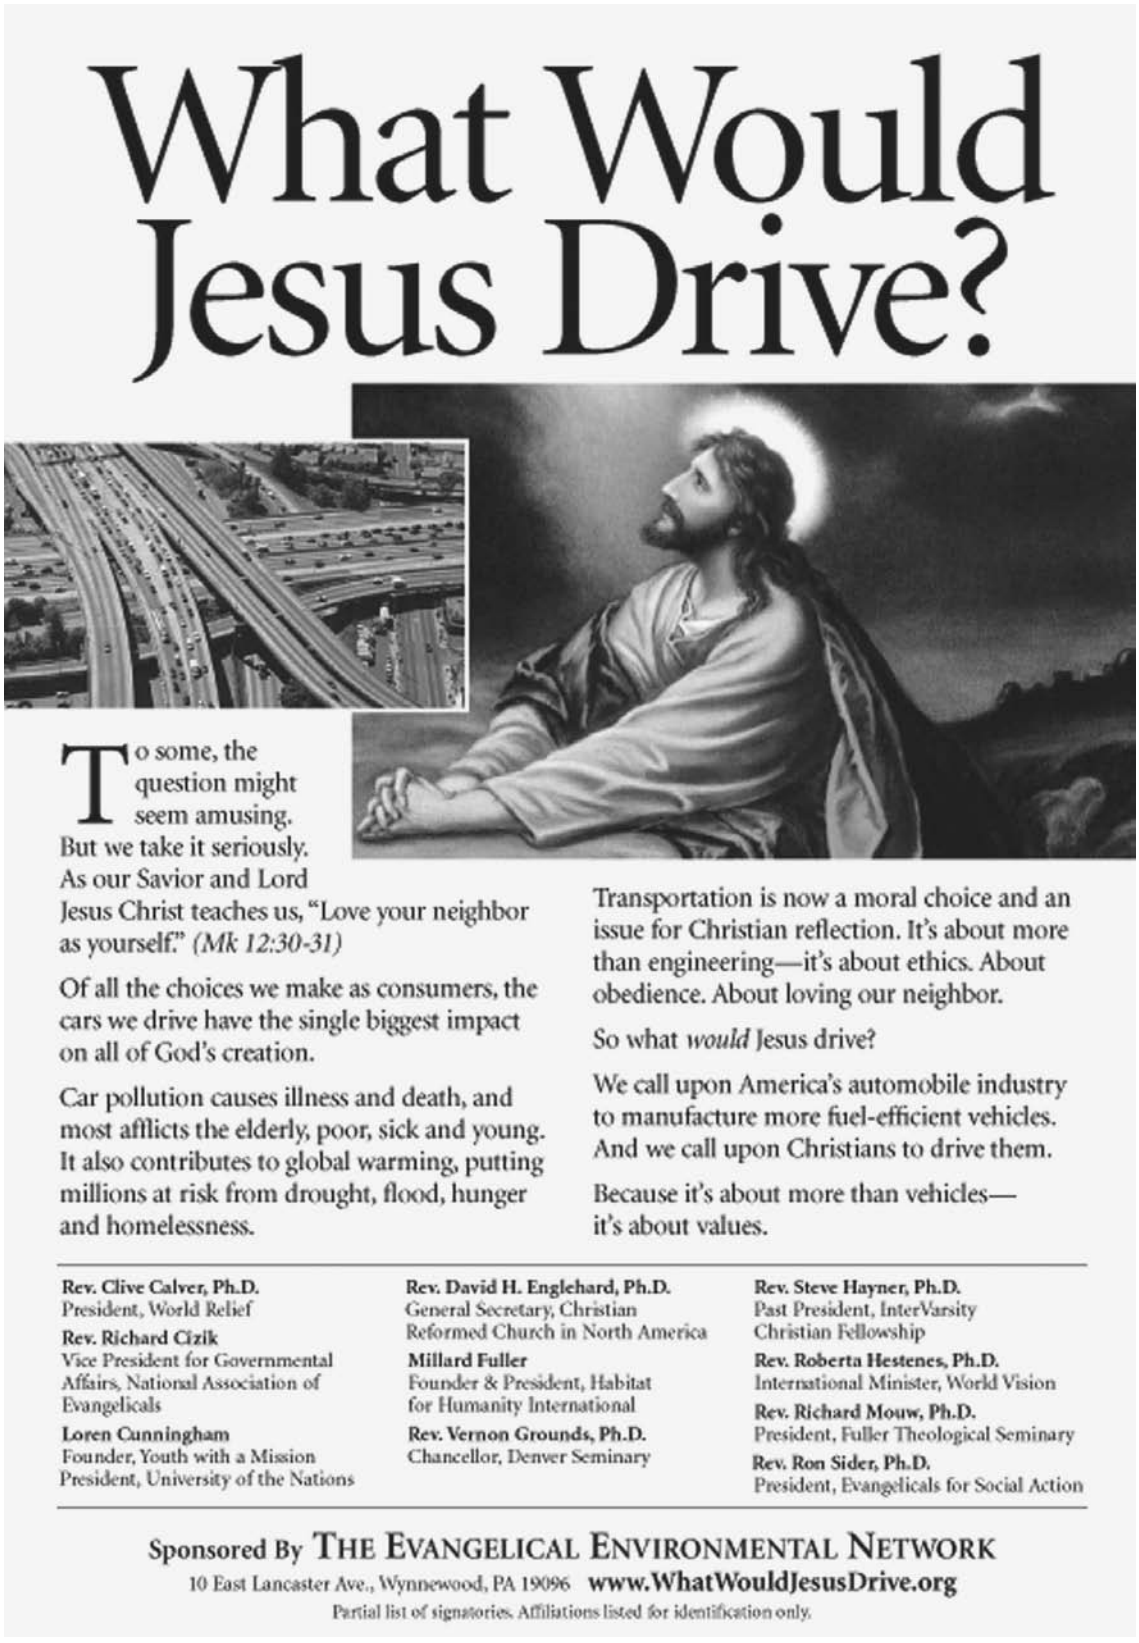
LIBERATION THEOLOGY AND ECOTHEOLOGY

Ecofeminist and process approaches further resonate with a strain of liberation theology extended to the earth and its nonhuman inhabitants. Liberation theology, which emerged among Roman Catholic Clergy in Latin America in the 1960s, interprets the ethic of Jesus to be solidarity with the oppressed and preference for the poor. Popularized by Gustavo Gutiérrez's *Theology of Liberation* (1973 [1971]), the movement endeavored to translate Christian teaching into practice to address the concrete struggles of certain groups against oppression. Combining the gospel of Jesus with Marxist perspectives, liberation theology interprets and applies scripture to economic, political, and social realities that contribute to oppression and discrimination. For ecotheology, this means understanding the environmental crisis, a crisis produced largely by white elites in capitalist countries, as an extreme form of oppression of impoverished creatures, both human and nonhuman. Since the foundation of Christian ethics is care and concern for the suffering and oppressed neighbor, it seems plausible that we include among our neighbors the many life-forms with whom we share the planet. Leonardo Boff, for example, understands both Christianity and ecology as indicating that relationships and interdependence are central in community. In *Ecology and Liberation* (1995), Boff applied this expanded form of liberation theology to all life, extending the preference for the poor to all beings and situating human communities within a larger ecological community.

Some ecotheologians interpret liberation as freedom not only from oppressive social and economic structures but also from oppressive modes of Western thought, including modern scientific enquiry. Charles Birch and John Cobb (1990) call for the liberation of all life from objectifying conceptions and categories stemming from and perpetuated by science. Scientific investigation, they allege, treats living beings as mere objects or machines, rather than as subjects. Such green critiques of science often combine elements of process thought, feminist criticism, and liberation theology. As an alternative to objectifying models, many ecotheologians offer what they call an ecological model, which embraces radical relationality, interconnectedness, and an updated, or postmodern, form of scientific inquiry.

SCIENCE AND ECOTHEOLOGY

Clearly, science plays a complex role in shaping and supporting ecotheological ethics. In *The Death of Nature* (1980) Carolyn Merchant has devoted sustained attention to the argument that modern science—science since the scientific revolution of the sixteenth and seventeenth



Evangelical Environmental Network Ad Campaign. *This print advertisement from the Evangelical Environmental Network plays on the popular initialism "WWJD" (What Would Jesus Do), in order to encourage Christians to drive more environmentally friendly vehicles rather than sport-utility vehicles.* **PHOTO BY THE EVANGELICAL ENVIRONMENTAL NETWORK/GETTY IMAGES.**

centuries—has promoted ecologically disastrous models of nature that perceive matter as essentially inert and valueless. Merchant particularly pointed the finger at mechanistic models of nature and aggressively masculinist attitudes toward nonhuman life perpetuated by René Descartes and Francis Bacon. Ecotheologians have also been influenced by works such as Fritjof Capra's *The Tao of Physics* (1975) and *The Turning Point* (1982), which discern parallels between physics, particularly quantum theory, and Eastern mysticism. Capra maintained that adopting a holistic framework that dispenses with subject/object and fact/value dichotomies is not only better for the natural world but consistent with cutting-edge science.

Such ambivalence toward science often pervades ecotheology. On the one hand, much of ecotheology has not fully integrated aspects of evolutionary theory into its environmental ethic. For example, a focus on healing and liberating animal subjects from suffering and oppression seems out of place alongside a frank recognition of predation and other harsh processes in nature that necessarily operate at a physical cost to some, especially weakened or sick individuals. On the other hand, many ecotheologians have enthusiastically and uncritically embraced postmodern physics, which entails appreciation of extreme interrelatedness and continuity among all entities and the potential subjecthood of all.

REINTERPRETING AND RETAINING TRADITION

In keeping with White's critique, many ecotheologians reinterpret the Christian tradition in ways that implicitly or explicitly generate parallels with less dualistic traditions, such as Buddhism and Hinduism. But to what extent is White's account of the Christian tradition a crude or unfair caricature? Have ecotheologians conceded too much to White? It is doubtful that any strand within Christianity consistently holds to a radically transcendent deity and wholly devalued earthly realm. That said, however, much of ecotheology grew out of Protestantism, perhaps because it is Protestant Christianity that bears at least some similarities to the worldview assailed by critics such as White. Features of Christianity such as the centrality of scripture and an intimate connection between religious worldviews and the rise of technology and capitalism appeared to implicate Protestantism in particular. The environmental crisis seemed to some to be a crisis brought about by Protestantism, and it was Protestant theologians who led the response.

But not all of these responses involve radical reinterpretation of traditional symbols and beliefs. Michael Northcott, an ordained Episcopal priest and ecotheologian, understands concepts such as covenant and natural law as supporting human moral obligations to nature, as well as the existence of a moral order within natural patterns and processes themselves. Northcott, in *A Moral Climate* (2007), was also one of the first ecotheologians to address climate change as a moral issue that can and ought to be addressed within a traditional theological framework. In this endeavor, his work finds support among some conservative Christians. Some evangelical groups have enthusiastically embraced the environmental agenda. Foremost in these efforts is Calvin DeWitt, who promotes a strenuous form of earth stewardship rooted in understanding humans as created in the image of God. DeWitt helped to found the Evangelical Environmental Network, which promotes a form of "creation care" modeled on the example of Jesus and based on Biblical teachings. Evangelicals remain wary of pantheism and idolization of creation, holding firmly to a transcendent God who is intimately involved with, but wholly other than, creation. The Evangelical Environmental Network has become a significant political and ethical voice on issues such as climate change and global environmental justice. Their much publicized educational campaign against sport utility vehicles (SUVs) titled "What Would Jesus Drive?" points to the relevance of Jesus's ministry to lifestyle choices that negatively impact life on earth.

Calls for global justice and sustainable lifestyles emanate from Catholic circles as well. Thomas Berry, whose work (2006) was strongly influenced by the French Jesuit priest Pierre Teilhard de Chardin, has garnered worldwide attention. Berry considers himself a "geologian," that is, one who studies the history of the earth and its processes. His language often departs from traditional theological language, but it bears definite marks of a spiritual movement. Berry urges an "enchanted" reading of cosmogenesis—a resacralization of the scientific narratives that recount the birth and evolutionary unfolding of the cosmos. Combining earth spirituality and reverence for life with knowledge of evolutionary processes and cosmology, Berry presents a "New Story" as our common creation myth. The New Story is intended to replace our modern, destructive myths of progress and enchantment with technology with a myth that is more energizing and enriching. Berry hopes thereby to effect a dramatic change in worldview, inspiring ways of life that are more sustainable and conducive to social justice. Humans, as a uniquely self-reflective and complexly conscious species, have a special role in the evolutionary process, an obligation to guide and safeguard its unfolding.

THEORY AND PRACTICE

On the whole, the extension of Christian theology and ethics to nature and nonhuman life has proven fruitful as a way of connecting Christianity with environmental concerns. But to what extent can practical Christian ethics, and

particularly the healing ministry of Jesus, be made compatible with biological notions of suffering and death as integral to the evolutionary process? These approaches raise the question of whether differences between humans and animals ought to be respected even while we regard animals and other forms of life as deserving moral consideration. As Michael Northcott has observed, ecotheology has a tendency to homogenize all life-forms and their moral claims to a degree that is unhelpful in terms of practical application. Imperatives to respect an alleged equal intrinsic value of all life-forms render real-world decision-making extremely difficult, if not impossible. How can all these claims be met without fundamentally altering the character of the natural world and the relationships that constitute it? Conversely, approaches that value capacities for rich experience and complex sentience may give ethical priority to organisms that share humanlike capacities without sufficient regard to the ecological context and evolutionary role played by less sentient or even nonsentient species. Too often ecotheological ethics seems inordinately concerned with the needs and the value of individual organisms at the expense of collective entities such as species and ecosystems. Because many of these ethical approaches grew out of paradigms initially directed toward human suffering and injustice, they may be ill suited to nature's realities. In this context, some ecophilosophers and ecotheologians, most notably Holmes Rolston (1988), have argued for different ethical duties toward human culture and domesticated life-forms on the one hand and native or wild species on the other. Rolston views natural suffering as an inherent and useful feature of evolutionary processes, not as an evil to be redressed by human ethics. Values inhere in and are generated by evolutionary processes themselves. But more work is needed to bring Christian environmental ethics and evolutionary, ecological science into meaningful dialogue.

BROAD IMPLICATIONS OF ECOTHEOLOGY

Ecotheology has the potential to have a significant impact on theology more broadly construed. Many of the questions raised by ecotheologians have profound significance for Christian theology as a whole: How is God to be defined; what are the core divine attributes? How does God relate to nature? How central is scripture to Christian ethics? Can Christianity remain Christ-centered without being overtly human-centered? How much can Christianity shift its focus to this world without losing its distinctiveness? There are no simple answers to these questions, and the answers given by some ecotheologians might be perceived as far too radical, or simply too abstract, for many practicing Christians. While ecotheology and religious environmental ethics now have a strong presence in academic departments and university course offerings, it is not clear how much impact this work has on Christian congregations or the public at large. However, a number of academic ecotheologians, such as Mary Evelyn Tucker and John Grim, who helped found the international and interreligious Forum on Religion and Ecology, are devoted to spreading the message outside the academy and around the globe. Grass-roots religious environmentalism and increasing activism even within evangelical and conservative circles may help bridge the gaps between the academic study of the religion-environment intersection and the behavior and beliefs of average Christians.

ECOTOURISM

Ecotourism is a relatively small sector of tourism, accounting for only 2 to 4 percent of international travel. It has aroused interest because it represents an attractive alternative to mass tourism that has transformed the social and ecological conditions of destinations throughout the world, but it also has stimulated controversy because many feel that it has not lived up to its potential as a more environmentally responsible form of travel. Ecotourism is a type of tourism that is founded primarily on a specific interest in the natural history of a region. It has been defined as "a sustainable, non-invasive form of nature-based tourism that focuses primarily on learning about nature first-hand, and which is ethically managed to be low-impact, non-consumptive, and locally oriented (control, benefits, and scale). It typically occurs in natural areas, and should contribute to the conservation of such areas" (Fennell 2007, p. 24).

Its core variables of sustainability, ethical planning and development, education, and a focus on community development and conservation make ecotourism different from the more broadly based but closely related nature-based tourism. Nature-based tourism, which includes an array of consumptive activities (e.g., hunting and fishing) as well as less consumptive activities (e.g., boating or four-wheeling), can be defined as any form of travel for the purpose of enjoying undeveloped natural areas or wildlife (Björk 2007).

ORIGINS

Ecotourism emerged from the ecodevelopment literature of the 1970s and was based on harmonization of social and ecological objectives, wise management of the environment, and the just treatment of individuals and communities. In the second half of the 1980s those ideas were crystallized as sustainable development (SD), a model for structural change within society. SD quickly entered the tourism lexicon, with a growing market of travelers who were dissatisfied with the mass tourism industry that by the 1980s had had an adverse effect on many of the most beautiful and sensitive regions of the world, harming communities and the natural world. Ecotourism as an alternative to mass tourism was designed to ensure that tourism policies no longer would concentrate on economic and technical necessities but would emphasize the demand for an unspoiled environment, the needs of local people, and the elimination of outside influences (e.g., external stakeholders) on decision-making powers.

Although the term was coined in the mid-1980s, *ecotourism* has actually been with us for much longer (e.g. the American Museum of Natural History has conducted natural history tours since 1953). Some of the popular destinations for ecotourism include protected areas in Costa Rica such as the Monteverde Cloud Forest Reserve, the Galapagos Islands of Ecuador, Iguaçu Falls, the Amazon basin, the Patagonian region of Argentina and Chile, Antarctica, hill tribe trekking in Southeast Asia, Ayers Rock and the Great Barrier Reef in Australia, the Milford Track in New Zealand, the Serengeti Plain, Kruger National Park in South Africa, and polar bear watching in Churchill, Canada. Ecotourism has thrived in all environments, including rain forests, mountain regions, polar areas, islands and coasts, deserts and grasslands, and marine regions. Practices in these and other ecotourism destinations include the watching of specific animal groups such as cetaceans, birds, and bears.

ANTHROPOCENTRIC AND ECOCENTRIC TOURISM

Many ecotourists desire a more "shallow," or anthropocentric, ecotourism experience; this can be characterized as a business-as-usual attitude toward the natural world in which nature is seen as a resource to be exploited to maximize human benefits, management decisions are based on utilitarian reasoning, and sustainability is viewed from a weak or very weak perspective. Far fewer ecotourists prefer a "deep," or ecocentric, ecotourism experience characterized by intrinsic value, small-scale development, community identity, community participation, and the notion that materialism for its own sake is wrong (Acott, LaTrobe, and Howard 1998). The shallow approach has been criticized for valuing nature and natural resources far less than its counterpart, in which more consumptive practices have been included within ecotourism. For example, moose hunting in Sweden has been referred to as ecotourism when certain cultural and social aspects are taken into consideration (e.g. sustainable harvests). In other cases, billfishing (sport fishing for marlin and sailfish) has been referred to as ecotourism because it directs economic assistance to the local community and has economic advantages over other uses.

Theorists argue that such activities cannot be ecotourism because of (1) the intention to catch the animal (ecotourism should be about minimum disturbance in all cases); (2) the pain and stress that result from catching

Monteverde Cloud Forest Reserve, Costa Rica. *A man stand on a hanging bridge overlooking the rain forest in the Monteverde Cloud Forest Reserve, one of the most popular destinations for ecotourism vacations. The premise of ecotourism is to provide a more environmentally responsible form of travel. It is differentiated from nature-based tourism because of its emphasis on sustainability, ethical planning and development, education, and community development and conservation.* **JERRY DRIENDL/THE IMAGE BANK/ GETTY IMAGES.**

the animal; (3) consumptiveness (catch-and-release practices may be viewed as consumptive); and (4) values, such that ecotourists have a different set of values in relation to sport and the intrinsic and extrinsic motivations surrounding participation in those activities. It follows that the treatment of animals cannot be based on healthy populations (i.e., it is acceptable to catch animals because of the healthy state of the population) but that respect must be shown to the individuals that constitute those populations (Fennell 2000).

The development and use of weak ecotourism definitions thus has opened the door to a great deal of misrepresentation and the prospect of anthropocentric values superseding ecocentric ones. The rationale for including activities such as hunting and fishing under the ecotourism umbrella is not clear. One hypothesis is that the ecotourism label offers those activities social acceptability in the face of declining participation. Accordingly, the best way to increase participation is to make an activity more socially acceptable through normative measures related to sustainability and ethics (i.e., catch and release or contributions of meat, skins, bones, and ivory to local people for commercial reasons).

RESPONSIBLE TOURISM

One way to ensure that ecotourism lives up to its reputation as a more ecocentric form of tourism is through the emerging concept of responsible tourism, which emphasizes the fair distribution of benefits to local people and the safeguarding of the natural world. Responsible tourism is not a form of tourism but rather a way of practicing tourism. Taking a Kierkegaardian view of responsibility, this means having ecotourism stakeholders exercise the will to move beyond a focus on the aesthetic realm of life (the focus on the bodily, temporal, finite, and necessary) through an effort to know the self better by searching for the authentic self in reaching for a higher ethical existence (Fennell 2008). It is a lack of understanding of the self, Søren Kierkegaard would argue, that predisposes people

to acts of irresponsibility (a lack of appreciation of others or other things that leads to impacts, in the tourism vernacular).

By demonstrating a willingness to choose for nature and for others, people can step outside of instrumental rationality—the crowd or horde mentality—in which actions are deemed worthy as a function of what Heidegger termed the calculative mind-set: People value nature and the world in general on a functional level on the basis of efficiency, productivity, technology, and short term cost-benefit calculations. However, by first understanding themselves—not only their internal conflicts but also how they as individuals fit into the complex web of life—people may be able to respond to the needs of others. Collectively, this emerging ecotourism community of responsible individuals may begin to agitate against dominant instrumental values and codes of practice in making the prevailing social order of tourism more responsive to entities they should protect instead of exploit.

EHRLICH, PAUL
1932–

Paul R. Ehrlich was born in Philadelphia on May 29, 1932. His pioneering research contributions and public outreach have made him one of the world's best-known public scientists, opening and informing discussion of environmental values and policy. As the author of *The Population Bomb* (1968), he brought world demographics to the forefront of environmental discourse. In addition to overpopulation, he has publicly addressed overconsumption and human migration; racial, gender, and economic equity; the ecological effects of nuclear war; and the importance of ecosystem services to humanity. With his spouse Anne and colleague John Holdren, in the 1970s he produced a series of classic books and research papers (culminating in the text *Ecoscience* [1977]) that shaped the entire area of environmental science and policy.

Ehrlich's involvement with ethical issues began in the mid-1950s, when he and H. Ralph Barr led a successful effort to desegregate the restaurants of Lawrence, Kansas (where Ehrlich was a graduate student). In the course of analyzing the role of population growth in environmental deterioration, he was led to consider a complex of ethical issues, many of which remain contentious: Is it ethical for a rich person to have more than one or two children, in view of the pressure that consumption by those children is likely to place on human life-support systems? How should the welfare of future generations be considered in such calculations? Do individuals have a right to have as many children as they want, or are social considerations (including the fate of those children) a more important consideration? Under what circumstances can a woman ethically have an abortion? What are the responsibilities of rich nations to help poor nations develop and preserve their natural capital, a fundamental basis of human well-being? How should blame for carbon dioxide emissions be apportioned? Does a nation such as the United States have the right to invade an oil-rich country to gain access to oil to support what Ehrlich considered environmentally disastrous overconsumption?

Often in collaboration with Anne and other colleagues (especially economists), Ehrlich brought these and many other ethical and scientific issues to the general public in some 40 books (such as *The End of Affluence* [1974], *The Population Explosion* [1990], *The Stork and the Plow* [1995], *Human Natures* [2000], *Wild Solutions* [2001], and *One with Nineveh* [2004]), over 900 articles, and numerous public appearances (hundreds of lectures and thousands of radio and TV shows, including 20 appearances on Johnny Carson's *Tonight Show*).

Ehrlich's best-known scientific work was his founding (with Peter H. Raven) of the field of coevolution. Ehrlich and Peter H. Raven's classic paper on coevolution (1965), possibly the most significant research at the interface of ecology and evolution since Darwin's *Origin of Species*, spawned dozens of books and thousands of articles. This area of research is important to issues concerning the preservation of biodiversity, since biologists now look to ways to conserve not just species but also coevolving sets of species.

Ehrlich's nearly fifty-year long investigations of the structure, dynamics, genetics, ecology, food-plant coevolution, and conservation of Checkerspot and other

butterflies—as summarized in *On the Wings of Checkerspots* (2004; edited with Ilkka Hanski)—has become a paradigm of using a model system to understand the basic functioning of natural systems. Partly based on these studies, Ehrlich and several colleagues founded the now exploding discipline of conservation biology. These are only part of Ehrlich's scientific contributions. His work has ranged widely: from the procedures and philosophy of taxonomy, the evolution of DDT resistance in fruit flies, and the behavior and ecology of birds and reef fishes, to the effects of crowding in human populations. His most recent area of research has been into the mechanisms of human cultural evolution, especially the evolution of norms and ethics.

Ehrlich has increasingly claimed that the major scholarly input on environmental issues should switch from the domains of natural sciences to social sciences and philosophy. He has stated that more than enough is known about the science of the human predicament to start taking ethically appropriate actions; the problem lies in getting those actions taken. In support of that view, he and former Stanford University President Donald Kennedy urged that a millennium assessment of human behavior be undertaken to see if the necessary cultural changes could be initiated.

For his efforts, Ehrlich has received numerous awards and honors, including the Crafoord Prize of the Royal Swedish Academy, an explicit substitute for the Nobel Prize in areas where the latter is not offered.

EMERSON, RALPH WALDO

1803–1882

Ralph Waldo Emerson was born in Boston, Massachusetts, on May 25, 1803, and educated at Harvard College and Harvard Divinity School. In 1832 he resigned his ministerial pulpit, having lost faith in Christian doctrine and being eager to pursue a career as a writer instead. After his move to Concord, Massachusetts, in 1835 and with the publication of *Nature* in 1836, Emerson emerged as a central figure in the American Transcendentalist movement.

Emerson's transcendentalism enabled him to pursue a spiritual life despite his distaste for Christian orthodoxy and his religious skepticism, the latter encouraged by modern science. He sought to confirm his intuitions about the vital relationship of the spirit to nature by reading the work of Romantic poets like William Wordsworth and exploring the idealist philosophical tradition culminating in the work of Immanuel Kant. However, Emerson knew Kant's work largely at second hand and was never a systematic student of philosophy, much less a systematic philosopher. Nor was he ever a disciplined natural historian, despite his lifelong enthusiasm for plants, birds, and unspoiled landscapes.

Emerson's lack of interest in philosophy as a system (as a search for valid premises, a painstaking justification of belief, and the like) is evident in his essays, especially in the seemingly carefree way in which he contradicts himself. However, this self-contradiction is arguably both a weakness and strength of his work. According to Emerson, "A foolish consistency is the hobgoblin of little minds, adored by little statesmen and philosophers and divines" (2003 [1841], p. 265). Those looking to *Nature* for a vision of the earth that may lead them to greater environmental awareness, for example, will find some statements dismaying and others inspirational. His idealism leads Emerson to suggest that nature, which is impermanent and mutable, is less real than ideas, which are eternal. He calls nature a "great apparition," "the vehicle of thought," "the symbol of spirit," and "an appendix to the soul" (1983 [1844], pp. 7, 20, 37). All this would

seem to hobble environmental thinking from the outset, as would the statements that nature is "made to serve" (1983 [1844], p. 28) and that "all the facts in natural history taken by themselves, have no value, but are barren, like a single sex" (1983 [1844], p. 21). Statements like these have led some critics to dismiss Emerson as a booster of American expansion and enterprise, and as an idealist of an objectionable kind—one who dismisses the natural world as merely phenomenal and illusory.

However, Emerson also writes in *Nature* that he has "no hostility to nature, but a child's love to it. I expand and live in the warm day like corn and melons" (1983 [1844], p. 38). And his later essays (on a wide variety of topics) are punctuated by similar evocations of the delight he took in sensual, earthly life. There thus seems to be a fault line running through Emerson's thinking on the subject of nature, one perhaps best explained by his willingness, despite his distrust of criticism, to think critically and therefore negatively about all subjects, including his own pet themes. Supporting this suggestion is Emerson's statement in his 1844 essay "Nature" that one can "hardly speak directly" of nature, especially landscape, "without excess." He adds, "It is as easy to broach in mixed companies what is called 'the subject of religion,'" and suggests that nature worship, unchecked by doubt and unguided by the critical faculty, results in false "euphuism" or purple prose (1983 [1844], p. 545).

In view of the paradoxical character of the thoughts expressed in his essays, Emerson seems to be a writer who does not think contradictorily but instead thinks deliberately *through* (or *about*) contradictions. This does not mean, however, that he tries to resolve them. In 1844, again in "Nature," he raises the skeptic's question "Are we tickled trout, and fools of nature?" (1983 [1844], p. 553), only to answer it, once again, in idealist terms. "The world," he concludes, "is mind precipitated" (1983 [1844], p. 555). So it is unsurprising that opinion of Emerson's place in the history of American environmental thought is evenly divided, some readers believing his philosophical idealism ultimately disqualifies him as an environmental thinker, and others taking delight in the tensions and apparent contradictions of his writing and arguing that his heart was, after all, in the right place.

It should be noted that Emerson served as a mentor to Henry David Thoreau, author of *Walden* (1855), taking long daily walks with him in the woods of Concord and encouraging him to write about the natural world. Emerson's essays also inspired John Muir, founder of the Sierra Club. However, Emerson came to feel that Thoreau had frittered his life away in the study of natural history. Ironically, Emerson himself was something of a disappointment to Muir when they met on a camping trip in California in 1871, as his enthusiasm for wilderness was no match for Muir's own. Hence, Emerson's contributions, both direct and indirect, to the development of American thought about nature, while indubitable, remain debatable.

ENDANGERED SPECIES ACT

The Endangered Species Act (ESA) is widely regarded as the United States' strongest environmental statute. It has been both touted and condemned as "the pit bull of environmental law." The act dates from the foundational period of modern environmental law in the United States—a time when the National Environmental Policy Act, the Clean Air and Clean Water Acts, and the Marine Mammals Protection Act were all adopted, and when a

new cabinet-level department, the Environmental Protection Agency, was created to safeguard nature.

The period can be dated from February 1965, when President Lyndon Johnson sent a lengthy message to Congress urging it to join him in forging a ''new conservation.'' Technology and growth, he wrote, ''have a darker side'' that imposes a responsibility to preserve and restore ''the beauty of our country'' as a means of conserving ''not just man's welfare but the dignity of man's spirit'' (Johnson 1966, pp. 155–156).

The following year Congress enacted the first endangered species act, the Endangered Species Preservation Act of 1966. The statute's first section echoed Johnson's message: ''One of the unfortunate consequences of growth and development in the United States has been the extermination of . . . native species.'' Despite Congress's assertion that the purpose of the act was ''to provide a program for the conservation, protection, restoration, and propagation'' of species ''threatened with extinction'' (sec. 1(a)), the Endangered Species Preservation Act established at best a very modest program of habitat acquisition. Three years later Congress amended and renamed the act the Endangered Species Conservation Act. This more comprehensive but still limited act regulated foreign commerce in species listed by the secretary of the interior as ''threatened with worldwide extinction'' (sec. 3).

A broad consensus quickly developed that the Endangered Species Conservation Act was also inadequate to the task at hand. In his 1972 environmental message, President Richard Nixon wrote that federal law ''simply does not provide the kind of management tools needed to act early enough to save vanishing species''; he proposed that legislation be enacted that ''would permit protective measures to be undertaken before a species is so depleted that restoration is impossible'' (1972, pp. 223–224). Representative John Dingell offered a similar analysis when he introduced the bill that became the Endangered Species Act of 1973: ''The existing laws are sound, as far as they go, but later events have shown that they do not go far enough'' (1973, pp. 162–163). The new statute again echoed Johnson's language: ''Various species of fish, wildlife, and plants . . . have been rendered extinct as a consequence of economic growth and development untempered by adequate concern and conservation'' (ESA, sec. 2(a)(1)). Despite its current status as a lightening rod, the Endangered Species Act was among the least controversial bills enacted by Congress in 1973. The Senate passed the legislation without a dissenting vote, and the House of Representatives adopted it by an overwhelming vote of 355 to 4.

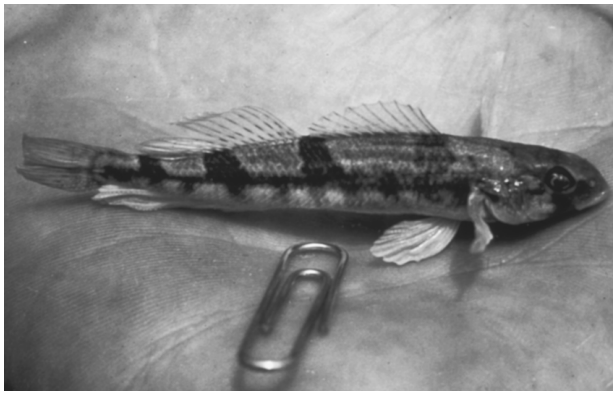
The values underlying this consensus—that preservation and restoration are a responsibility that the current generation has to the future because what is at risk is irreplaceable—are captured in an analogy from the *House of Representatives Report* on the bill:

> A certain humility, and a sense of urgency seem indicated. . . . One might analogize the case to one in which one copy of all the books ever printed were gathered together in one huge building. The position in which we find ourselves today is that of custodians of this building, and our choice is between exercising our responsibilities and ignoring them. If these theoretical custodians were to permit a madman to enter, build a bonfire and throw in at random any volume he selected, one might with justification suggest that others be found, or at least that they be censored and told to be more careful in the future. So it is with mankind. Like it or not, we are our brothers' keepers, and we are also keepers of the rest of the house. (1973, pp. 4–5)

CONTENT

The 1973 act mandated two types of actions to preserve and restore species: risk assessment and risk management. The federal fish and wildlife agencies charged with implementing the act (either the Fish and Wildlife Service in the Department of the Interior or the National Marine Fisheries Service of the National Oceanic and Atmospheric Administration in the Department of Commerce) are directed to assess the risk of extinction that a species faces by evaluating whether it is ''endangered'' (that is, ''in danger of extinction throughout all or a significant portion of its range'' [ESA, sec. 3(6)]) or ''threatened'' (that is, ''likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range'' [ESA, sec. 3(20)]). If the agency concludes that the species is either endangered or threatened, it is listed—an action that triggers the act's risk-management actions. Actions of this second type are either extinction-prevention or recovery actions.

Extinction-prevention actions prohibit activities that threaten the continued existence of listed species. Section 7 requires any federal agency that proposes an action (including funding or permitting private action) to consult with the relevant federal wildlife agency to ''insure that [the] action . . . is not likely to jeopardize the continued existence'' of the species or ''result in the destruction or adverse modification'' of the species' critical habitat (ESA, sec. 7(a)(2)). Section 9 prohibits any person (broadly defined to include governmental and business entities [ESA, sec. 3(13)]) from taking (broadly defined to include harassing and harming [ESA, sec. 3(19)]) or engaging in commerce involving an endangered species (ESA, sec. 9(a)(1)). Section 11 contains civil and criminal penalties applicable to violations of these prohibitions.



Snail Darter. *The fish, declared an endangered species in 1975, became an icon for the effects of the Endangered Species Act. The discovery of the Snail Darter interrupted an expensive Tennessee dam project, and the decision to classify the fish as endangered was finally decided in the Supreme Court, remaining one of the earliest and most important environmental law cases. The Snail Darter's classification was later reduced to a threatened species.* **U.S. FISH AND WILDLIFE SERVICE.**

The second group of risk-management actions comprise recovery actions. This group was largely ignored in the 1973 act, arguably because the drafters believed that extinction-prevention actions would suffice to preserve and restore at-risk species. The only recovery action mandated in the act was the obligation of all federal agencies to "utilize their authorities in furtherance of the purposes of this Act by carrying out programs for the conservation of [listed] species" (ESA, sec. 7(a)(1)).

The drafters of the statute thus envisioned a linear process: When a species is determined to be sufficiently at risk of extinction, it is listed as either threatened or endangered. After listing, the species is protected from actions that jeopardize its existence. With this protection, the species rebounds because threats have been removed, and it can then be delisted. Implementation of the act over the past thirty-plus years has demonstrated that preservation and restoration of at-risk species is far more complicated.

IMPLEMENTATION AND AMENDMENTS

Implementation of the act—the political and institutional interactions of Congress, the agencies charged with its administration, the courts, and the competing public interests—have also complicated the initial clarity of the statute's values. The *first* Endangered Species Act of 1973, the one just outlined, was a remarkably rare legislative creature. Eschewing the normal balancing of interests, Congress enacted a "prohibitive policy" (Yaffee 1982) that reflected a simple ethical conclusion: The preservation of other species is a moral imperative that takes precedence over other societal goals. The breadth of the Endangered Species Act and its moral force set it apart from other wildlife conservation statutes, and turned the snail darter into the urban myth of the little fish that stopped the big dam. In *Tennessee Valley Authority v. Hill*, the Supreme Court held that Congress meant what it said:

> One would be hard pressed to find a statutory provision whose terms were any plainer than those in section 7 of the Endangered Species Act. Its very words affirmatively command all federal agencies "to *insure* that actions *authorized, funded,* or *carried out* by them do not *jeopardize* the continued existence" of an endangered species or "*result* in the destruction or modification of habitat of such species . . ." (p. 173).

"This language," the court concluded, "admits of no exception."

The broad, bipartisan consensus on the importance of environmental protection that produced the Endangered Species Act began to crumble in the late 1970s—a victim of the growing mistrust of government and its solutions that began with the Vietnam War and was heightened by Watergate, of the systemic economic changes caused by the war's inflation and the oil embargo of the Organization of the Petroleum Exporting Countries, and of the growing attacks on environmental protection by industry-funded groups such as the Sagebrush Rebellion. *Tennessee Valley Authority v. Hill*, decided in 1978, fed into these developments, and the Endangered Species Act suddenly became the statute that was going to shut the country down, or so its opponents branded it.

The Supreme Court's decision presented Congress with a dilemma: Endangered species were a powerful political symbol, but public-works projects are central to congressional politics. There were three positions in the ensuing congressional debates. The sponsors of the bill eventually adopted—Senators Howard Baker (Rep., Tennessee), John Culver (Dem., Iowa), Jennings Randolph (Dem., West Virginia), and Malcolm Wallop (Rep., Wyoming)—argued that increased flexibility was needed. Although "in the vast majority of cases" the existing process had been successful in resolving conflicts between preservation and development, there were situations, they argued, "in which a Federal activity, if it is to achieve its stated purpose, simply cannot avoid a direct impact to a species or its critical habitat." There thus was a need for a mechanism to resolve these uncommon, unresolvable conflicts. Their bill established a cabinet-level Endangered Species Committee (the "God Squad") empowered to exempt agency actions from the act's prohibitions.

There were two groups of opponents to this proposal: those who felt that the amendments did not go far enough and those who thought no changes were needed. The advocates of fundamental change supported an amendment offered by Senators John Stennis (Dem., Mississippi), Jake Garn (Rep., Utah), James Eastland (Dem., Mississippi), Orrin Hatch (Rep., Utah), Paul Laxalt (Rep., Nevada), Milton Young (Rep., North Dakota), Carl Curtis (Rep., Nebraska), and Barry Goldwater (Rep., Arizona) that would remove the act's categorical prohibition by authorizing the agency proposing the harmful action to balance the competing interests. These senators rejected the Endangered Species Act's fundamental policy that all species of plants and animals were entitled to protection, and their rhetoric disparaged "useless," "esoteric," and "insignificant" species. Quoting Genesis, Senator William Scott (Rep., Virginia) argued, "People should have dominion over fish, wildlife, and plants. Only where the lower species are of benefit to mankind are they important." These senators believed that ultimately a utilitarian calculus was the appropriate measure for resolving all conflicts, that "considerations of convenience and comfort . . . should take precedence" over the preservation of species. Their amendment was rejected by a vote of 76 to 22.

Although it is common to speak of the Endangered Species Act of 1973, the act has been changed substantially since its enactment. The 1978 amendments created the *second* Endangered Species Act of 1973. In addition to adding the God Squad, Congress also amended the listing process—or, more accurately, burdened it—by substantially increasing its procedural complexity and also specifying that listings not completed within two years were to be withdrawn. The consultation procedures were also substantially expanded (and complicated). The slightly more than 100 words in the original section became the first subsection of a new section that expanded to fill nearly eight pages in *Statutes at Large*.

Congress also amended the risk-management side of the act by adding a requirement that the appropriate wildlife agency develop a recovery plan for listed species. This requirement reflected the emerging understanding that recovery requires more than simply removing threats. It also requires restoration of the conditions a species needs to thrive.

The 1978 amendments focused largely on procedure. What had been a relatively simple statute was transformed into a procedurally complex one. Courts are required to defer to substantive decisions of agencies, the principle of judicial deference. As one court put it, "In this case, . . . a federal judge sitting in Washington, D.C., is asked to speculate on whether there are any grizzly bears in a portion of Montana and whether holes drilled into a mountainside will frighten those bears away. That is not a task judges are equipped to perform, and, in any event, it is not a task they should perform" (*Cabinet Mountain Wilderness v. Peterson*, pp. 1190–1191). Judicial deference does not, however, extend to agency decision-making procedures. As a result, procedural complexity increases the likelihood that the agency's decision will be reversed for a procedural misstep. By modifying its procedures, Congress restructured the act without modifying its substantive standards. In the process, the statute's original prohibitive stringency was substantially softened. The most significant changes to the act were produced by the 1982 amendments, which resulted in the *third* Endangered Species Act of 1973. The dominant concern in 1982 was discretion. The detailed, time-consuming procedures added in 1978, particularly when coupled with the Reagan administration's (1981–1989) emphasis on economics, especially cost-benefit analyses, had effectively stalled listings. As a result of the two-year time limit imposed in 1978, the Fish and Wildlife Service withdrew proposals to list 1,876 species in December 1982. Moreover, the fact that James Watt, Reagan's secretary of the interior, was openly hostile to preservation of endangered species (Snow 1996) was a concern for Congress. In response, Congress moved in more than one direction.

First, the 1982 amendments restricted the secretary's discretion by specifying that the listing determination was to be made "solely on the basis of the best scientific . . . data available" (ESA, sec. 4(b)(1)(A)); economics are not to be considered in determining whether a species is biologically at risk. Section 4 was also amended to restructure the listing procedure into a three-step process, with specific deadlines for each step. These steps were intended to get the secretary back in the business of listing species.

Second, Congress also added new provisions that relaxed the strictness of the substantive requirements. Most significantly, the act was amended to permit "incidental take" of listed species. For actions requiring consultation under section 7 (actions that have some federal involvement, such as issuing permits), Congress added a provision authorizing the wildlife agencies to include an "incidental take statement" that permitted the take of listed species as long as the action would not jeopardize the species' continued existence (ESA, sec. 7(b)(4)). Under section 10, Congress also established an incidental-take-permit process that authorized the issuance of permits if the secretary found that the take would not "appreciably reduce the likelihood of the survival and recovery of the species in the wild" (ESA, sec. 10(a)(2)(B)(iv)). These provisions effectively authorize the killing of endangered species if the killer has a permit (Ruhl 1999). This is an all too common legislative tool. The Clean Water Act, for example, makes it illegal to discharge a pollutant into a body of water—unless the discharger has a permit to do so.

Since 1982 Congress has played a more limited role in the evolution of the Endangered Species Act. In 1988,

The Mexican Wolf (*el Lobo*). *The species, endemic to northern Mexico and the southwestern United States, was declared endangered in 1976 following a period of intense eradication by hunters and trappers. Efforts have since been made to reintroduce the Mexican wolf to the wild.* PHOTO BY JIM CLARK/U.S. FISH AND WILDLIFE SERVICE.

for example, it amended the act by expanding the provisions on recovery planning and adding a section on candidate species. Yet the most significant congressional actions have been those least likely to attract attention. Congress has slowly starved the wildlife agencies by denying them funding to fulfill their statutory obligations (Miller et al. 2002).

With Congress unable to muster majorities to amend the act since 1988, actions by the wildlife agencies have been the primary source of change. The *fourth* Endangered Species Act of 1973 was a result of the Clinton administration's (1993–2001) response to Republican congressional victories in 1994 and the hostility to the act reflected in several bills that would have fundamentally reduced protection for at-risk species. Secretary of the Interior Bruce Babbitt sought to "save" the Endangered Species Act through a series of "incentive-based strategies to try and reconcile endangered species conservation with economic development" (Berry 1998). The centerpiece of this initiative was a series of permits created to provide private landowners with assurances that the Fish and Wildlife Service would impose no additional restrictions on the landowner—the no-surprises policy. Although the permits—Habitat Conservation Plans, Candidate Conservation Agreements, and Safe Harbor Agreements—varied in detail, they were intended to make the Endangered Species Act more developer-friendly by balancing two competing goals: flexibility (to adapt to changing biological circumstances and new information) and certainty (to allow the permittee to make economic decisions). Of course, certainty for developers comes at some expense in preservation and restoration.

During the George W. Bush administration (2001–2009), formal administrative modifications of the act gave way to refusal to implement the act except when forced to do so by court order. For example, fewer species have been listed in the nearly eight years of that administration than the average annual listing during the George H. W. Bush administration (1989–1993) (Eilperin 2008). The agency has also been forced to relist species (including wolves and bald eagles) that it had delisted (see, for example, *National Wildlife Federation v. Norton* and *Defenders of Wildlife v. Norton*).

ASSESSMENT

This, then, has been the evolution of endangered-species preservation since 1966. The act has been buffeted by forty-plus years of politics. At this point, what values remain? Most fundamentally, the act is a statement that our species has an obligation to consider the impact of our actions on the other species with whom we share this planet. However, this statement no longer "admits of no exception" (*Tennessee Valley Authority v. Hill*). It has been qualified and limited. It has also been quietly desiccated by Congress's failure to fund, by administrative willingness accommodate habitat destruction, and by judicial deference to administrative expertise. Yet something still remains of Johnson's original goal of preserving and restoring nature as a means to enhancing the "dignity of man's spirit" (Johnson 1966, p. 156)—the noble statement that our species has an obligation to limit its impact on nature.

ENERGY

An enormous release of energy, the Big Bang, is credited with beginning the universe as we know it some 14 billion years ago. The general trend of energy since then has been toward dispersal, which increases the condition known as entropy. Because energy can perform work only when it is concentrated, complete entropy (uniform energy levels throughout the universe) would entail complete stasis.

Usable energy on the earth derives mostly from the sun, in which the nuclei of hydrogen are fused to form helium. In addition, energy also comes from nuclear fission, ocean tides, and the molten core and mantle of the earth, which is still dispersing energy, sustained by the decay of radioactive elements, after more than 4 billion years of the earth's cooling.

Life on the earth depends on energy and delays the process of entropy. Living organisms use the energy of the sun and of the earth's core to create large molecules, whose energy can be released later through oxidation. The sun's radiant energy is converted to chemical energy through the process of plant photosynthesis.

The pioneer ecologist Aldo Leopold compared an ecosystem to a fountain of energy. At the bottom of the fountain, green plants capture the energy of the sun through photosynthesis. All animals get their energy ultimately from these green plants, some animals eating plants directly, others consuming the energy of plants indirectly by eating animals. Fungi get their energy by breaking up the complex organic molecules of dead organisms. The biological material produced in these ways is called biomass. Unoxidized biomass can become stored over millions of years with its chemical energy intact. Such stored forms of biomass are fossil fuels and include coal, oil, and natural gas.

HISTORY OF HUMAN CONSUMPTION OF ENERGY

At the dawn of human existence, the only energy people controlled was from the food they consumed. Early in the course of human evolution—no one knows exactly when—people domesticated fire to warm themselves, cook their food, and enhance their hunting and gathering. About 10,000 years ago, people began dramatically to increase their access to energy by developing agriculture, a human intervention in ecosystems designed to promote the growth of plants suitable for human consumption. Some 7,000 years ago, people began using draft animals, thereby controlling the energy those animals had available through their food intake. People started obtaining energy from flowing water about 3,000 years ago, when watermills came into use. In 1185 the first practical windmill was used.

Water power depends largely on the sun's energy to evaporate water and move water vapor to higher elevations, where it condenses and falls as water. The sun generates wind through differentials in temperature and air pressure. In addition to the sun's energy, the earth's rotation affects prevailing winds. The attraction of the moon, combined with the earth's rotation, produces moving water in the form of ocean tides.

The stage was set for widespread use of coal, a fossil fuel, when the first practical steam engine was developed and then improved in 1698 and 1721. The first sustained production of electricity took place in 1831. Electricity is a form of energy but not a source of energy. It can be produced from such sources as moving water, fossil fuels, sunlight, and nuclear fission. The first controlled nuclear fission took place in 1942.

By the early twenty-first century, the main sources of nonfood energy being used by human beings were the fossil fuels—coal, oil, and natural gas—as well as hydropower and nuclear power. All of these were used to generate electricity, but oil was used primarily for transportation, and natural gas largely for heating, although its role in electricity generation is increasing. In 2005 humanity used nearly 70 BBOEs (billion barrels of oil or equivalents), about half of it in oil.

ENERGY CONCERNS OF THE EARLY TWENTY-FIRST CENTURY

Energy concerns of the early twenty-first century are about diminished supplies and the environmental disruption

Coal Basin near Wright, Wyoming, 2003. *Huge trucks loaded with coal from the Black Thunder Mine can carry from 240 to 360 tons. Unlike other natural resources, coal remains abundant. It has been used to create synthetic gasoline, and can also be converted to electricity.* **AP IMAGES.**

and pollution that result from obtaining and using these supplies. The most immediate worry about diminishing supplies concerns petroleum, since there is good evidence that, regardless of whether environmentally controversial drilling in Alaska and other locations is allowed, annual worldwide production will peak in the first two decades of the twenty-first century. Annual production of natural gas is expected to peak two to five decades later. The enormous reliance of industrial countries on these two fossil fuels and their dramatically increased use in China, India, and some other developing countries raise fears of economically crippling shortages as annual supplies remain steady or decline while demand continues to increase. The result could be economic depression or international violence.

Coal and uranium (the main fuel in the nuclear generation of electricity) remain abundant, although most uranium ore may be of such poor quality that it would require more energy to mine and refine than it would produce. Resource optimists, often called cornucopians, believe human ingenuity will forestall shortages as increasingly clever methods of discovery and extraction make new supplies available. For example, coal has been used to create synthetic gasoline, and oil may become available through extraction from tar sands in Venezuela and Canada, which are said to contain 3,000 BBOEs of oil. Pessimists about oil claim that producing synfuels is horribly polluting and too expensive to be economical. Even worse is extracting oil from tar sands, which has been compared to separating tar from sand after they have been mixed in a sandbox.

Apart from considerations of supply, using coal and tar sands is controversial owing to additional concerns about pollution, especially the release of carbon dioxide, which contributes to global climate change. Burying or chemically sequestering the carbon dioxide released when coal is burned to generate electricity may be possible in

the near future. Currently, coal in coal-fired electricity-generating plants is pulverized before being burned. If it is gasified instead, it may be possible to bury or chemically sequester the carbon dioxide so that it never enters the atmosphere.

Nuclear power has never been commercially viable without huge government subsidies. In addition, mining uranium releases unhealthy radiation; nuclear power plants are potential terrorist targets; reprocessing the products of fission risks the proliferation of nuclear weapons; and nuclear waste threatens future generations.

The prospects for additional power from falling water are poor because most sites suitable for hydropower are already being exploited and many unwanted environmental problems result from interrupting a river's flow. These include the erosion of deltas, the silting up of lakes, the spread of disease, and the interruption of fish migrations.

Because problems of supply and/or environmental degradation attend the use of power sources dominant at the beginning of the twenty-first century—coal, petroleum, natural gas, falling water, and nuclear fission—environmentalists propose two different but complementary strategies: increased efficiency to reduce demand and commercial development of more earth-friendly sources.

With continuing efforts to improve automotive gas mileage, replace automobile use with public transportation, install compact fluorescent light bulbs, insulate houses better, and require more efficiency in household appliances and air conditioners, efficiency had increased in most developed countries by the beginning of the twenty-first century, and less energy was consumed per unit of gross domestic product. For additional energy savings, electricity-generating plants can be located close to industrial and residential consumers of heating and air conditioning so that waste heat from electrical generation can be used for heating and air conditioning. Such trigeneration can more than double efficiency.

Because society bears much of the cost of current energy use—costs associated, for example, with illnesses produced by pollution, environmental dislocations caused by global climate change, and military interventions needed to secure petroleum supplies—considerable public effort and expense to increase efficiency are warranted by cost-benefit analysis. These include mandating higher efficiency standards and giving tax credits for trigeneration and for installation of energy-saving devices.

The same cost-benefit considerations warrant government support for more earth-friendly sources of energy. Many ideas and projects are aimed at producing electricity. For example, electricity generation by wind turbines increased worldwide by 29 percent per year around the turn of the twenty-first century. In 2005 Germany produced 6 percent of its electricity in this way. Government support of this technology in the United States and elsewhere includes tax credits for installation of wind turbines and mandates for net metering. Under net-metering mandates, electric utilities buy wind-turbine-generated electricity or credit the electric account of wind-turbine owners to the extent that their wind turbines supply power to the electricity grid.

Environmental controversies regarding wind turbines center on two matters. One is concern that turbines, like tall buildings, interfere with bird migrations. The other is the aesthetic objection to the introduction of turbines in beautiful landscapes and seascapes. The turbines can be 300 feet or more in height and visible from afar.

SOLAR ENERGY

Wind is an indirect form of solar energy because, as the sun heats the atmosphere more at the earth's equator and less at the poles, convection currents are created in the air. Direct solar energy also has much potential. Every forty-five minutes, the energy reaching the earth from the sun equals humanity's total annual use of power. Solar energy has long been used in warm climates to heat water in residential homes; about 40 million homes are thus served worldwide. Solar energy can also be used for home heating. South-facing houses in cool climates can be designed to capture sunlight through windows in winter and, with appropriate overhangs, to avoid direct sunlight in summer when the sun is higher—designs that can meet some heating and cooling needs. This is passive solar heating. The most efficient active solar-heating systems use sunlight to heat water or another liquid, which is then piped through a slab floor that stores and radiates the heat. Such water- and space-heating systems seldom meet all heating requirements.

Solar energy as well is used to generate electricity. One method heats water on an industrial scale to make steam, which turns an electrical turbine. Mirrors concentrate the sun's energy on a tower that contains the water. In addition, through the photovoltaic process, sunlight directly generates electricity when it falls on certain types of silicon chips. This source of power is already widely used in small electronic devices, such as calculators and watches, as well as in extraterrestrial exploration, including the International Space Station. But it can seldom provide all the electricity needs of a home, because sunshine is intermittent and battery storage devices are expensive. As with electricity generated by wind turbines, photovoltaic energy is most helpful and cost-effective when integrated into the electricity grid through net metering. This eliminates the problem of electricity storage. Electricity generated by wind and sun is still more expensive for consumers than that generated by coal-powered plants

because the latter are not required to internalize the costs of (pay for) all the negative environmental impacts that the former avoid. It is unknown which would be more expensive if each system had to pay for all its true costs.

A more visionary project uses the sun's energy to separate hydrogen from oxygen in water in the process of electrolysis. This could be done on an enormous scale in sun-rich areas, such as the American Southwest. The resulting hydrogen could be piped around the country using a distribution system already in place for piping natural gas. Where needed to produce electricity, this hydrogen could be combined again with oxygen—burned, in a word—with water being the only waste product. Electric power generated in this manner could be used for all purposes, including transportation when hydrogen fuel cells are improved.

ENERGY FROM BIOMASS

Energy from biomass (not including fossil fuels) can be environmentally friendly because it is carbon-neutral: The carbon released by burning biomass is equal to that absorbed by plant growth to produce the biomass. However, biomass can never entirely replace other sources of energy, because the world's annual energy consumption already equals 22 percent of worldwide annual plant growth. Still, biomass can contribute to meeting the world's energy needs and currently supplies 3 percent of U.S. energy use, surpassing hydropower.

Much biomass is used for heating. Wood stoves made of iron or masonry are increasingly efficient and clean burning. Biomass is also used to generate electricity. Agricultural waste, wood chips, wood pellets, and switchgrass (a hardy perennial grass) can be used to generate electricity, as can methane, also a greenhouse gas, which must in any case be drawn out of landfills to avoid explosions and reduce the risk of global climate change.

Biomass is used to make liquid fuels, primarily to replace gasoline and diesel fuel, which are currently made from petroleum. The gasoline substitute, ethanol, is a form of alcohol that can be made from several plants, including sugar cane and corn. In the United States, 95 percent of ethanol is made from corn. The major benefit to Americans is reduced reliance on foreign sources of oil. The other benefit, as with biomass generally, is reduced *net* emissions of carbon dioxide. But because the methods of corn cultivation in the United States are energy-intensive, neither reduction is enormous. On average, it takes 1 BTU (British thermal unit) of oil to produce 1.3 BTUs of ethanol. The net reduction in carbon dioxide emissions is about fifteen percent, and is negative when coal is used, instead of natural gas, to refine ethanol from corn. Sugar cane is a more efficient source crop for ethanol because it contains more calories per acre and, as a perennial grass, requires less plowing.

Bio-Diesel Bus. *One of the most immediate energy concerns of the twenty-first century involves the diminished supply and negative environmental effects of petroleum. Bio-diesel is an alternative energy fuel made from biomass, usually made from soybeans or canola.* **NPS PHOTO.**

Environmental problems associated with ethanol include soil erosion and pollution from fertilizers, herbicides, and pesticides used in American corn production. These problems are likely to increase as land currently out of production to conserve topsoil is planted in corn. In addition, greater production of ethanol will cause increases in the price of corn, which in turn will increase the price of dairy products and meat. Subsidies for corn-based ethanol (51 cents per gallon in the United States in 2007) may not be justified as cost-effective. Sugar-cane ethanol promotes destruction of rainforests, as sugar cane displaces forests.

More promising is cellulosic ethanol, made from plants, including grass, that people cannot eat because of their high cellulose content. Enzymes break down the cellulose. Although not yet produced on a commercial scale, such ethanol could be made from switchgrass and other perennials, as well as from the waste products of corn and other food crops. This would improve agricultural efficiency, avoid increases in the price of food, and encourage maintenance of perennials, which build soils. Such ethanol is more expensive because it requires additional ingredients and a more complex process.

Biodiesel is the other main liquid fuel made from biomass. In the United States, biodiesel is made primarily from soybeans, but it can be produced more efficiently from canola (rapeseed). The same issues concerning planting marginal land and increasing the price of food arise with biodiesel as with ethanol. Producing the required oil from algae, still experimental, may solve these problems.

In no case can such fuels replace petroleum, because the earth's capacity for producing the required crops is limited in comparison to current and projected uses of

petroleum. In transportation, it will eventually be necessary to replace much liquid fuel with electricity.

Although falling water offers little promise for increased power generation, sea water may hold such promise. Ocean waves are produced by wind, and wind by solar radiation. Electricity can be generated from waves by tubular structures with joints. The joints move with the wave action, pumping oil through an electric generator. More promising is the use of submerged turbines moved by ocean water as tides come in and go out. This would be a form of gravitational energy because the tides are caused by the gravitational influence of the moon on the earth's oceans. Such turbines would pose none of the avian or aesthetic issues that attend wind turbines. However, the durability of submerged turbines, their effect on marine life, and the cost of the resulting electricity are uncertain.

GEOTHERMAL ENERGY

Geothermal energy is energy from the earth's interior. High-temperature geothermal energy comes from areas where molten matter appears near the earth's surface, such as areas prone to volcanic action. Such heat can be used for direct heating, as in Reykjavik, Iceland, and Boise, Idaho, or it can be used to produce steam, which then generates electricity. The main limitation is the scarcity of places where molten rock is accessible.

Low-temperature geothermal devices take advantage of the relatively constant temperature, between 45 and 60 degrees in most places, of the top fifteen feet of the earth's crust. In the United States, for example, homes can be heated and cooled by burying pipes in the ground next to the home, using a liquid in the pipes to transfer the ground's energy to the home, and using a heat exchanger for heating or air-conditioning as needed. The energy needed to pump the exchange liquid and run the heat exchanger is far less than would be required to heat or cool the home conventionally.

Except for the visionary idea of generating hydrogen directly from sunlight in sun-drenched parts of the earth and piping it to where it is needed, no single energy source or technology promises to provide all the energy people are likely to want in the future. Energy sources and technologies will probably change quickly and often throughout most of the twenty-first century.

ENVIRONMENTAL ACTIVISM

Environmental activism takes many forms, including engaging in different types of direct action, signing petitions, writing letters, attending meetings, and contacting political representatives and officials. This activism usually is peaceful, conventional, and noncontroversial, although its targets often suggest that it is illegitimate or the product of malign motives. Nevertheless, such actions fall within the range of normal politics in liberal democracies. However, liberal democracies have become more participatory, and the limits of what is accepted as normal have been extended, especially since the 1960s. Thus, the signing of petitions, which once was considered, like the writing of letters to newspapers, an activity of cranks, has become almost as common as voting in national elections. What used to be seen as a dichotomy between the conventional and the unconventional has come to be recognized as a continuum from the orderly and highly institutionalized to the disorderly and uninstitutionalized.

TRADITIONAL ORGANIZATIONS AND NEW ACTIVISM

Just as the variety of forms of political action commonly engaged in by mass publics in democratic societies has increased, the repertoires of environmental activists have broadened. The advent of a new wave of activist environmental organizations in the 1970s—notably Friends of the Earth and Greenpeace—brought new forms of symbolic direct action to public notice. These often spectacular protests were designed to attract the attention of the mass media and thus, by arousing mass public opinion, put pressure on corporations and governments to remedy environmental ills. Those protests at first were viewed negatively by older conservation-oriented organizations, especially those which had consultative or lobbying relationships with governments and state agencies. However, the seriousness of the new activists and their success in drawing attention to the issues they selected influenced older organizations, some of which began to engage with them and attempt more actively to mobilize their

supporters. As campaigning successes and rising public support conferred legitimacy on the newcomers, the older organizations' fears of losing their established status and access to decision makers were overtaken in some cases by their fear of losing public support. Thus, campaign coalitions uniting the older conservationists and the new environmental activists became more common.

The new environmental organizations attempted to work at the national and transnational levels, but at the local level environmental activism usually was left to its own devices. The extent to which national environmental organizations neglected local activists varied from country to country and from one organization to another. In the United States mainstream conservation- or wilderness-focused organizations such as the Sierra Club resisted broadening their agendas to embrace recurrent and increasing concerns with issues of pollution and hazardous waste, particularly in urban environments. As a result local environmental activists began to fashion an environmental justice (EJ) movement that largely was disconnected from the historical issues of environmental protection and was organized into networks of autonomous local groups without a national bureaucracy. In Europe, where landscapes were so demonstrably the products of human activity that wilderness issues were marginal, broad environmental movements developed to embrace protection of the environmental interests of human populations as well as the preservation and conservation of species and cultural landscapes. Because the ambit of such groups was more encompassing, it was easier in Europe for forms of activism associated with one environmental issue to be adapted to the service of another than was the case in the United States.

Most environmental activism is at the institutionalized end of the activist continuum, but the focus of political and scholarly attention has been on strategic and ethical issues surrounding action at the disorderly and uninstitutionalized end of the spectrum. However, there are ethical dilemmas involved even in strictly legal, conventional, and institutionalized action. Such action may be slow or ineffective in addressing urgent and compelling grievances and may allow the perpetuation and exacerbation of environmental degradation beyond the point where redress is possible. It would be unethical for people who know or believe this to be the case to confine their activities to the slow deliveries of conventional action. The urgency of environmental concerns thus drives many activists to consider less conventional forms of activity, even disorderly actions that in extreme circumstances may transgress norms of nonviolence.

DIRECT ACTION

Forms of direct action that range from boycotts, blockades, and site occupations to more confrontational and sometimes actually or potentially violent actions such as sabotage of facilities and machinery have become more common. Although they are condemned by their targets and by the policing authorities, they often attract public sympathy. Thus, in Britain and France majorities of the public approve of the actions of those who uproot or otherwise destroy genetically modified (GM) crops, the police have been reluctant to act against them, and the courts often have not convicted those who commit them. Public sympathy with and tolerance of direct action, especially when it is associated with environmental issues, has been increasing.

However, in all the countries for which there is systematic evidence the overwhelming majority of environmental protests are nonviolent and nonconfrontational. Despite the media's reporting bias toward spectacular and violent events, during the ten years between 1988 and 1997 violence figured in fewer than 10 percent of the environmental protests reported in leading newspapers in eight Western European countries (Rootes 2007). This is not surprising in light of the fact that the ethics that underpin environmentalism are fundamentally pacific: care for the earth and consideration for the well-being of living things, including humankind. Even dark green activists, who are prone to assert the ecological equality of all living things, are not antihuman so much as critical of what they perceive as the arrogance and careless self-interest that lead humans to subjugate the rest of nature to their own ends.

Their most controversial actions, including ecotage and monkeywrenching—such as the destruction of environmentally offensive buildings in wilderness areas or machinery used in logging, land clearing, or construction and the spiking of trees in logging areas—usually are not designed to cause harm to people but are expressions of protests at and attempts to impede the destruction of the natural environment. Thus, activists associated with Earth First! have insisted on the fundamental nonviolence of their actions and carefully train activists to minimize the likelihood of harm to themselves and others.

The rare occasions on which people who call themselves or have been called environmentalists have deliberately taken actually or potentially violent action against other people almost always have involved the actions of campaigners for animal welfare or animal rights. However, although some animal rights activists may identify themselves as green and in some European countries are accepted as such by those primarily concerned with more unambiguously environmental issues, in the English-speaking world animal rights activists generally are not regarded by environmentalists as part of the environmental movement.

MONKEY WRENCHING

Environmental activism takes a variety of forms. Extreme activist groups such as Earth First! use *monkey wrenching,* a term that refers to blockading roads, sinking ships, bombing power stations, tree sitting, and engaging in other forms of ecotage: the illegal sabotage of industrial development efforts that are seen as damaging to the environment.

RELATED TERMS

Monkey wrenching often is equated with ecoterrorism and civil disobedience; the former association is preferred by its critics, and the latter by its advocates. The Federal Bureau of Investigation (FBI) defines terrorism as "the unlawful use of force or violence against persons or property to intimidate or coerce a government, the civilian population, or any segment thereof, in furtherance of political or social objectives" (*Code of Federal Regulations*). This definition, with its inclusion of violence against property, has been used to justify the application of the term *ecoterrorism* to monkey wrenching tactics. Advocates of monkey wrenching see it as an appropriate form of civil disobedience. In their view nonviolent civil disobedient protest—including the Boston Tea Party, the Underground Railroad, and the civil rights movement—has long been used to foster social change.

ORIGINS AND HISTORY

The phrase "to throw a monkey wrench in the machinery" dates to 1918. Among several books that popularized the term, probably the most influential was Edward Abbey's *The Monkey Wrench Gang* (1975). That 1975 novel traced the travels of four ecologically minded misfits through the Southwestern U.S. as they vandalized bulldozers and destroyed bridges in the cause of environmental protection. Abbey's book both coined the term *monkey wrenching* and inspired the foundation of Earth First! with its motto "No Compromise in Defense of Mother Earth." In *Ecodefense: A Field Guide To Monkeywrenching* (1993) the coeditor Dave Foreman wrote: "Monkeywrenching is nonviolent resistance to the destruction of natural diversity. It is aimed at inanimate machines and tools that are destroying life. Care is always taken to minimize any possible threat to people, including the monkeywrenchers themselves" (Foreman and Haywood 1993, p. 9).

ETHICAL JUSTIFICATIONS

According to advocates of monkeywrenching, the goal of terrorism is always political. Monkey wrenching, they argue, is used to protect the environment. Further, advocates invoke the perspective of deep ecology, which places the protection of nature above that of humankind. From this perspective, the earth is under assault and monkeywrenching is morally required as self-defense on its part.

CRITICISMS

To its critics monkey wrenching is vandalism, potentially life-threatening, illegal, and better termed ecoterrorism. Critics focus on the more dangerous forms, some of which have been denounced by movement leaders. Those critics argue that whatever the motivation, common monkeywrenching tactics such as tree spiking, arson, and the damaging of machines and equipment are illegal and can result in injury or death.

In congressional testimony in 2002 by James Jarboe, chief of the Domestic Terrorism Section of the FBI's Counterterrorism Division, it was estimated that over the previous six years two groups associated with monkey wrenching, the Animal Liberation Front (ALF) and the Earth Liberation Front (ELF), had committed more than 600 criminal acts in the United States, resulting in damages of more than $43 million. In response to such testimony an Animal Rights and Ecological Terrorism Act has been proposed that creates penalties for persons encouraging, financing, assisting, or engaging in acts of animal and ecological terrorism.

The label *ecoterrorist* often is applied to environmental activists who rarely employ tactics that are in any way violent or threaten physical harm to people or other living things but not to corporations and their agents whose careless or deliberate actions in pursuit of profit damage the health and sometimes threaten the survival of individuals and whole communities. Environmental terrorism might be seen as a fair description of the actions of those who wilfully pollute the air and water on which lives depend and who overtly and covertly act to suppress the protests of their victims. That has been the experience of many of those who complain of environmental injustice or environmental racism as they struggle to survive while living close to hazardous waste deposits whose existence sometimes is denied by those who created them or authorized their creation or downwind of emissions plumes from factories or waste incinerators whose toxic content often is known only to those who control them. Some environmental activists, including Chico Mendes, have been murdered by those whose environmentally exploitative interests they opposed.

NONVIOLENT DIRECT ACTION

The ethic that informs the more radical forms of environmental activism is that of nonviolent direct action (NVDA). Below are several points of significance about environmental NVDA.

Environmental NVDA Is a Matter of Principle Environmentalists protest against the violence done to the environment and to people unable to defend themselves. Nonviolence is thus the form of action consistent with the fundamental philosophical principles that inform environmentalism.

Environmental NVDA Is a Pragmatic Strategy Recognizing the difficulty of achieving practical objectives by any other means while retaining widespread public support, environmentalists work to maximize their gains within the existing system rather than adopting the riskier strategy of radically and violently challenging it. This strategy is more attractive in circumstances in which the environmental movement is organizationally relatively strong and has a large measure of public support than in circumstances in which it is organizationally weak and has only moderate support and thus is unable to anticipate gains as a result of its efforts within the existing system.

Environmental NVDA Is a Defensive Tactic Recognizing their weakness in the face of more powerful forces, especially when confronted by the power of the state at a time when the threat of terrorism has justified increased surveillance and extraordinary preemptive and punitive measures, environmentalists strive to avoid being labeled as ecoterrorists and so being subjected to restrictions similar to those imposed on groups suspected of involvement with political violence. Because of the presence among their opponents of people and organizations that seek pretexts to stigmatize them, environmentalists are concerned with preserving their legitimacy and latitude for maneuver. Even before 9/11 and the war on terror, environmentalists emphasized the nonviolence of their actions as they attempted to avoid guilt by association with animal rights activists, a minority of whom had employed violent tactics and as a result generally were considered extremists. In some countries court-imposed restrictions and newly restrictive public order legislation reduced the margin of latitude for any but unambiguously legal forms of action.

Nonviolence is also a reflection of the identity of environmentalists. Environmentalists are often herbivores rather than carnivores (often literally, as the frequent association of environmentalism with vegetarianism attests) who are averse to physical struggle and favor the congeniality of communitarian utopias. Their nonviolence might be interpreted as a lack of courage, but it is more often a product of distaste for violence. This, however, puts them at a disadvantage in an age in which political and public policy games are played hard and neither noninstrumental reason nor principle is valued by those who hold political power and dominate public agendas.

NVDA goes well beyond the avoidance of violence and conflict. Civil disobedience, which originally was an individual act of defiance of authority, was turned by Mohandas Gandhi into a tactic of mass resistance and later was adopted widely by civil rights, peace, and environmental activists. In that context one of the hallmarks of environmental activism since the 1970s has been the increasing employment of tactics of manufactured vulnerability that expose activists to the risk of injury to emphasize the disjunction between power and principle. Those risks are largely calculated and managed, especially in the actions mounted by professionalized protest organizations such as Greenpeace. Greenpeace protesters who scale incinerator or power station stacks to unfurl banners highlighting pollution are trained climbers who use state-of-the-art safety equipment.

Environmental activists and activist organizations are affected by the dilemmas that confront all challengers of the status quo, forced to choose between strategic effectiveness and the mobilization of supporters and between tactical effectiveness and participatory democratic principles. Many of the differences between environmental movement organizations and groups stem from their responses to those dilemmas. Thus, Sea Shepherd split

from Greenpeace because its founders believed that more radical action was required, and in Britain Greenpeace UK emerged from Friends of the Earth, which had been founded by people unimpressed by the strategies of older nature conservation organizations. Activists such as those who gather beneath the banners of Earth First! or Reclaim the Streets are so fundamentally committed to radical democratic principles that they refuse formal organization altogether, even though this may limit the effectiveness of their actions. Friends of the Earth International has expended much energy on the maintenance of a non-hierarchical organization of autonomous partners, probably at the expense of the effectiveness of its campaigns. Greenpeace, by contrast, is organized more like a corporation than a participatory democracy in order to maximize its efficiency and effectiveness.

NEW FORMS OF ENVIRONMENTAL ACTIVISM: THE INTERNET

New forms of activism have developed alongside new communication media. Thus, in addition to enabling nearly instant mass petitions, the transnational mobilization of protests—physical or virtual—and rarer tactics such as netstrikes on the servers of parties, governments, or corporations that are identified as the perpetrators of environmental ills, the Internet has fostered the development of consumer boycotts. Web sites and e-mail listservs increasingly are used to protest against oil and coal corporations that finance movements against environmental reform and banks that finance environmentally damaging projects. Insofar as many of these consumer actions are individual rather than directly collective, their increasing use has led some to worry about the future of environmental activism. Even the ease that the Internet confers on the organization of protests carries with it the risk that people with little or no previous experience of activism will be drawn individually to protests by Internet appeals but will not be involved in the sustained collective activism by which environmental organizations are built.

ENVIRONMENTAL AESTHETICS

Environmental aesthetics, a subfield of both aesthetics and environmental philosophy, emerged in the late 1960s and has steadily grown in importance since then. Although discussions of the aesthetics of nature have had a place in philosophy for a much longer time, twentieth-century environmental movements provided the context and conditions within which the discipline of aesthetics began to recognize problems connected to the aesthetic value of the environment and its role in weighing environmental issues.

Environmental aesthetics brings philosophical attention to issues in aesthetics as they relate to environments, natural objects within environments, and natural phenomena and processes (as opposed to artworks). The field has attended mainly to natural environments, but its scope has gradually widened to include mixed environments: those that have been modified or influenced by humans, such as gardens, as well as the human environments of everyday life, such as aspects of the built environment.

HISTORY

The genealogy of environmental aesthetics is traceable to at least three different areas: philosophical discussions of aesthetic appreciation of nature, theoretical and practical discussions of landscape design and landscape tastes (including romantic literature and poetry), and early conservation thought and nature writing. Although significant *philosophical* discussions of aesthetics of nature emerged only in the eighteenth century, the aesthetic appreciation of nature and

landscape would probably have played an important role across cultures throughout human history.

Philosophical Aesthetics Although philosophers such as Plato, Aristotle, and Aquinas were concerned with the relation of beauty and the arts, the inception of the modern discipline of aesthetics is usually traced back to philosophical and literary discussions conducted in the early 1700s by figures such as Anthony Ashley Cooper (Lord Shaftesbury) (1801–1885), Joseph Addison (1672–1719), and Alexander Gottlieb Baumgarten (1714–1762). Treatises by these philosophers widened the scope of aesthetics in important ways. They theorized about nature as an object of aesthetic experience and appreciation in its own right, in contrast to earlier discussions, which gave little attention to nature apart from its representation in the arts. At the same time they widened the categories of aesthetic value beyond the beautiful to include the sublime and the picturesque, which created new contexts within which to discuss nature. Many scholars point to a "subjective turn" in aesthetic theory. Attention turned from understanding beauty as an objective quality to grasping the relationship between the aesthetic object and the appreciator; hence the character of aesthetic experience and appreciation became more important.

Before the eighteenth century, at least in North America and Europe and probably in other cultures as well, wild nature was often feared rather than appreciated for aesthetic qualities such as beauty or sublimity. It was more common to appreciate humanly modified nature or nature as represented through art, music, and literature. Gardens have held an important place in history since ancient times, but, as Marjorie Hope Nicolson has shown in *Mountain Gloom and Mountain Glory* (1959), wilderness and the rugged, great mountains of the world were not formally aesthetically appreciated until, roughly, the late seventeenth century, when many well-to-do travelers took part in the Grand Tour, a new form of tourism that included the great mountains of Europe (and to some extent eastern North America). The Grand Tour is often referred to in the literature as a form of nature connoisseurship that reflected philosophical discussions of the time, and it provided an important impetus for the appreciation of the beautiful and the sublime in practice. This change in landscape tastes opened up a greater potential for valuing wild nature.

Philosophers in the eighteenth century argued that disinterested pleasure lay at the root of the appreciation of aesthetic qualities such as the beautiful and sublime in nature; the concept of "disinterestedness" migrated from moral philosophy into aesthetics. It was Immanuel Kant (1724–1804) who conferred enduring importance on this concept through his analysis of aesthetic judgments in the *Critique of the Power of Judgment* (1790). In his work the term *disinterestedness* pertains to aesthetic experience and valuing that are noninstrumental, directed at the perceptual qualities of an object apart from any personal or utilitarian interests of the perceiver. Some more recent theories in environmental aesthetics recognize the importance of this concept, whereas others object that disinterested appreciation distances the appreciator and blocks full engagement with environments.

Kant's aesthetic theory is especially important to the history of environmental aesthetics because it makes nature the paradigm of aesthetic experience and judgment. More than other writers of his time, Kant privileges nature over art, and interpretations of his aesthetic theory show that the aesthetic appreciation of nature was more significant—even more edifying morally—to human life than the appreciation of the arts. For Kant this superiority of nature applies to both the beautiful and sublime. His theory of the beautiful, like others of the period, argues that beauty is associated with delightful, pleasing perceptual qualities and tranquil contemplation, whereas the sublime is associated with a "negative pleasure" of feeling overwhelmed by the massive, powerful, and seemingly infinite qualities of natural objects and phenomena such as towering cliffs, raging seas, and vast deserts. An experience of the sublime, which Kant believed arises only in the contemplation of nature, induces feelings of human insignificance in the face of natural forces; yet, at the same time, we recognize our place as free, moral, and rational beings in the world.

Kant's ideas influenced romanticism and the "nature worship" expressed through the literature, poetry, music, and visual arts of the nineteenth century. The poetry of William Wordsworth (1770–1850) is especially notable for showing vividly how a deep aesthetic engagement with nature can shape and invigorate human imagination and lived experience. John Ruskin (1819–1900), the artist and art critic, holds a key place in postromantic thought for his criticisms of classical landscape painters, who, he argued, lacked a true understanding of nature. Many scholars and critics admire the aesthetic, scientific, and spiritual sensitivity shown for nature in his major work *Modern Painters* (1873).

Romanticism's reverence for nature influenced writers and artistic movements in nineteenth-century North America, including the transcendentalists and the Hudson River school of landscape painters. These figures lie outside of philosophical aesthetics, but they become relevant to discussions of conservation that arise in the history of environmental aesthetics.

Despite the strong interest in nature in romanticism and its offshoots, the philosophical concern with the aesthetics of nature tailed off in the nineteenth century as the philosophy of art gained a foothold. This trend was precipitated by Georg Wilhelm Friedrich Hegel's

Sutherland, Scottish Highlands. *A wilder landscape with a range of aesthetic qualities: roughness, rockiness, and striking shapes. Early appreciation of the aesthetics of nature focused on the Picturesque, a theory of landscape painting.* **PHOTO BY DAVE MOLLAH. COURTESY OF EMILY BRADY.**

(1770–1831) influential insistence on the primacy of art over nature. For Hegel nature's aesthetic value is realized only when fashioned by the human spirit through the production of art. His ideas signalled a gradual move away from a conception of art as a representation of nature and toward art as the expression of the human imagination.

The move away from nature was also evident in developments in the art world as the influence of romanticism waned; art moved toward expression and abstraction rather than representational or naturalistic depictions of the world. Twentieth-century avant garde movements provided still greater inspiration for philosophers to devote their attention to art rather than nature. In the face of Marcel Duchamp's (1887–1968) *Fountain* (the provocative dadaist artwork that consisted of a urinal turned upside down), and other works that charged past the traditional boundaries of art, philosophy was presented with a formidable challenge: redefining art.

Landscape Theory and Practice Alongside philosophical work on aesthetics of nature, there have been important movements in theory and practice related to landscape that indicate appreciation of nature in one form or another. These movements have raised problems and issues now taken up in contemporary debates in environmental aesthetics.

Interest in nature through classical landscape paintings was brought into the real-world context of gardens and landscape design through theories of the picturesque. The picturesque was developed mainly by William Gilpin (1724–1804), Sir Uvedale Price (1747–1829), and Richard Payne Knight (1750–1824) in the mid-to-late eighteenth century. The movement prized qualities associated with landscape gardening and the paintings of Claude Lorrain (1600–1682) and Salvator Rosa (1615–1673).

The picturesque is sometimes linked to Humphry Repton (1752–1818), who was critical of Lancelot "Capability" Brown's (1716–1783) grand designs for the great manor houses of England, which involved moving earth and trees to create classical landscapes with extensive prospects across lawns, lakes, and constructed

features such as classical temples. Its enthusiasts were keen to mark out a new aesthetic category lying somewhere between the beautiful and the sublime. Among the aesthetic qualities prized by proponents of the picturesque were roughness, sudden variation, mystery, irregularity, and weathering.

Although the picturesque spurred interest in a greater range of natural qualities than previous theories, it has been criticized for promoting an appreciation of nature only as it appears through the lens of art. The theory originated in the idea that the nature lover most deeply apprehends the beauty of landscapes by looking at them in paintings: standing back and beholding the design, forms, and colors of the picture. Connoisseurs of the picturesque in the eighteenth century used a special device through which they viewed natural landscapes: the "Claude Glass," a tinted convex mirror that framed and reflected the view, transforming it into something like a miniature painting (in the manner of Claude Lorrain). Gilpin was among the theorists who believed that art improves upon nature—hence the grand designs of picturesque gardens and the use of the Claude Glass. Theories of the picturesque—and the "scenery model" of aesthetic appreciation of nature they engendered—presented aesthetic and moral challenges to the pioneers of environmental aesthetics as the field emerged in the 1960s.

Conservation The influence of the picturesque was confined mostly to Western Europe, notwithstanding its undeniable impact on landscape practices and tastes in North America, most notably in the work of the great American landscape architect Frederick Law Olmsted (1822–1903). In North America attitudes toward nature in theoretical discussions, the arts, and in practice leaned much more toward a wilderness aesthetic that influenced the ethos of the conservation movement that developed in the United States in the late nineteenth century.

The transcendentalist aesthetic of Henry David Thoreau (1817–1862) was steeped in a reverence for wilderness; his major work, *Walden* (1854), recounts his experiment of living close to nature at Walden Pond. The growing receptivity to untamed landscapes crested in the wilderness worship of transcendentalism, which was a compound of aesthetic and philosophical notions that echoed the spirit of romanticism. Transcendentalists shared the romantic revulsion at the dehumanizing effects of technology and urban civilization; they prized wild nature as a source of spiritual regeneration, a messenger of profound moral truths. The wilderness paintings of Thomas Cole (1801–1848) and Frederick Church (1826–1900) (both Hudson River School artists) depict mountain and river landscapes with little or no human presence. Their canvases dramatically express the wild, sublime, and divine forces of nature.

This wilderness aesthetic is central to the environmental awareness conveyed in John Muir's (1838–1914) classic essay, "A Near View of the High Sierra" (1894). Muir's exploration of the Sierra Nevada mountain range reflects both his deep interest in natural history and his aesthetic and spiritual values. In contrast to the visual artists he meets on his journey, Muir appreciates nature not merely as an aesthete savoring distant scenery as an object but as an engaged environmentalist, an intimate participant in the beauty and sublimity of the mountains who understands them from within. This environmental aesthetic also found expression in the work of the great conservationist and forerunner of environmental ethics Aldo Leopold (1887–1948). In *A Sand County Almanac* (1949) he combines ecological knowledge with aesthetic sensitivity in evoking environments from the typically beautiful to the "unscenic." Leopold's "land ethic" is, perhaps, the first conservationist philosophy that joins ethical and aesthetic concerns in valuing environments.

Another key aesthetic theme running through conservation and nature writing is the idea that all of the natural world is beautiful, that nature untouched by humans is inherently good and aesthetically edifying. The thesis of "positive aesthetics," as articulated by Allen Carlson (2000), is traceable to figures such as John Constable (1776–1837), John Ruskin, George Marsh (1801–1882), William Morris (1834–1896), and John Muir. This outlook, although not without its critics, is a key component of contemporary environmental aesthetics.

CONTEMPORARY DEBATES

Discussions in philosophical aesthetics, landscape theory and practice, and early conservation literature together form the historical foundation of environmental aesthetics. After Hegel aesthetics evolved into the philosophy of art. Apart from some interesting attempts to extend aesthetics beyond art by analytic aestheticians such as Frank Sibley in the 1950s, philosophers focused on art to the exclusion of natural environments. Ronald Hepburn's seminal 1966 article, "Contemporary Aesthetics and the Neglect of Natural Beauty"—widely viewed as marking the emergence of environmental aesthetics as a distinct field—asks why aestheticians should be less interested in natural beauty and the environment than in art. Hepburn sets out to develop an understanding of what an aesthetic appreciation of natural beauty might look like, thus posing a key issue: How does an aesthetic appreciation of nature differ from an appreciation of artworks? This question leads to others: What is distinctive about environments as compared to artworks? What guides aesthetic appreciation of nature in the absence of art history, knowledge of artistic intention, and the conventions that govern the judgment of artworks?

Hepburn's main task is to show the novel perspectives opened up by an aesthetic grasp of nature. Natural aesthetic appreciation can center on discrete objects viewed up close or as part of a scene; more typically, however, the observer is immersed in environments—for example, walking through a forest or standing in the middle of a plain. Hepburn argues that nature, unlike traditional works of art, affords the observer more freedom to explore the range of qualities that are possible in a truly environmental experience. It is not just the position of the observer that is different; environments are not framed or bounded in the way that many forms of art are. These distinctive features of immersion in the environment offer opportunities for an aesthetic experience that draws on a broader range of senses than is commonly used in responding to artworks.

Hepburn's starting point is a comparison of art and nature, whereas Arnold Berleant, another important contemporary environmental aesthetician, argues that aesthetics ought to use the environment rather than art as its starting point and main context. In *The Aesthetics of Environment* (1992) and other works, Berleant argues that aesthetic experience begins with the environment (both natural and humanly modified environments) and extends to art. Berleant is critical of the traditional aesthetic virtue of "disinterestedness"; for him this approach distances the subject from aesthetic object. In its place he reconceives the aesthetic response as an "aesthetics of engagement" that collapses the dichotomy between subject and object through participation in the environment.

These ideas emphasize important distinctions between environmental aesthetics and the philosophy of art. They also signify an important move away from the "scenery model" that dominated earlier nature aesthetics. Many writers have argued that scenic appreciation is narrow, static, and two-dimensional, ignoring the richness of three-dimensional environmental qualities that envelop the observer in dynamic and shifting milieus with the variations of the time of day, tides, weather conditions, and seasons. These critics fault the scenery model for prizing conventionally beautiful landscapes over environments traditionally viewed as "unscenic," such as marshlands, even though the latter may have great aesthetic value (Saito 1998b, Callicott 1983, Carlson 2000). On ethical grounds some have argued that the scenery model's roots in the picturesque make it anthropocentric, viewing nature as if it were a work of art rather as an organic, living, evolving environment.

Cognitive and Noncognitive Theories Environmental aesthetics seeks to understand what makes an environment *natural* rather than something produced by human intentions and actions. In art, experience is shaped by qualities such as harmony, style, and form. Aesthetic judgments consider such qualities in gauging the success or failure of an artwork. Hepburn and others have noted that the freedom of natural environments distinguishes them from works of art, but how does this difference alter experience and judgment?

Answers to this question fall into two camps: *cognitivism* and *noncognitivism*. These terms reflect the role of knowledge in theories of the aesthetic appreciation of the environment. Cognitivists argue that ecology, geology, and other natural sciences structure and guide "appropriate" aesthetic reactions—that is, those that are not shallow or superficial. They advance a standard for determining correct and incorrect aesthetic judgments. Carlson's "natural environmental model," developed in a series influential of papers beginning in the 1970s and culminating in his collected essays (published in 2000), has served as a foil for the many noncognitivists who have written critiques of it. Some cognitivists—as well as noncognitivists—attend to modified as well as natural environments

Carlson seeks the most suitable framework for valuing natural environments as natural. Just as an informed evaluation of art objects relies on an investigation of the categories of art history, so, Carlson argues, by analogy an aesthetic grasp of the environment ought to mine the knowledge provided by the natural sciences. Science, he contends, aids in the discovery of aesthetic qualities and deepens appreciation, and without it we are unlikely to make aesthetic judgments that are *true*. Carlson uses the example of a whale: If viewed under the category of "fish," it might appear awkward and clumsy, but regarded under the correct category of "mammal," it is likely to appear to be magnificent and graceful.

Carlson claims that a reliance on scientific knowledge not only enlightens aesthetic perceptions of nature but also endows them with a measure of objectivity. Leavening aesthetic perceptions with scientific knowledge helps to ensure that judgments are not arbitrary or subjective. This last point, Carlson believes, is especially important in incorporating aesthetic value into environmental decision-making and policy, processes that are often criticized for a reliance on unreliable, individualistic criteria.

Other cognitivists share Carlson's emphasis on the essential role of knowledge in natural aesthetics. Marcia Muelder Eaton, Holmes Rolston, and Glenn Parsons all agree that the natural sciences provide the most reliable framework for appreciation, although they elaborate their positions in different ways. Rolston and Parsons have developed approaches to positive aesthetics, which Carlson makes a central feature of his cognitivist account. Parts of nature that might otherwise seem ugly—such as a rotting animal carcass, for example—can be regarded as beautiful if viewed as a necessary component of a healthy ecosystem.

Noncognitive theories are more diverse, but they push the more subjective aspects of aesthetic experience to the forefront, often giving a backseat to scientific knowledge. Noncognitivists emphasize common features of the aesthetic response to the environment: for example, multisensory engagement, imagination, and emotion. Their typically pluralistic conception of knowledge includes folklore and other "nonscientific" modes of understanding. These positions grew largely out of objections to Carlson's approach. These critics argue that, by making science a necessary condition of aesthetic appreciation, cognitivism (especially the natural environmental model) unreasonably restricts the range of aesthetic perceptions and judgments. On this view the problem stems from according legitimacy to only one epistemological framework—one grounded in scientific knowledge—and thereby stigmatizing nonscientific modes of apprehension because they presumably impose human values onto nature.

Berleant's aesthetics of engagement, which stresses sensory immersion, active participation, and embodied appreciation, is perhaps the longest-standing noncognitivist approach. He takes to task the subject-object dualism he detects at the root of Kant's account and the scenery and natural environmental models. Other noncognitivist approaches emphasize one component of appreciation or combine them. Through a robust account of emotions and their appropriateness, Noël Carroll's "arousal model" (1993) seeks to show that emotional responses can play a legitimate role in the aesthetic appreciation of nature. One of Carroll's aims is to include the subjective side of experience in ways that meet some common objections, such as the problem of sentimentalizing nature and the claim that our emotional responses are not communicable. The role of emotion meets a standard of objectivity, he argues, insofar as it can be shown to be sharable and not wayward or arbitrary.

Emily Brady's "integrated aesthetic" (2003) gives a prominent role to various forms of imaginative engagement, but it also integrates other components of the aesthetic response, including the senses, emotion, disinterestedness, and a pluralistic approach to knowledge. For example, imaginative engagement can involve both visualizing and taking conceptual leaps that open up new ways of perceiving natural objects. In contemplating the smoothness of a sea pebble, one might visualize the relentless surging of the ocean as it has shaped the pebble into its worn form. One might also imagine how it looked before it became so smooth, and this image might contribute to one's wonder and delight in it. Hepburn's theory (1996, 2001) gives a major role to the "metaphysical imagination"—discovery through aesthetic encounters with nature.

These approaches trace some of their roots back to Kant's aesthetic theory, which places imagination rather than knowledge at the center of aesthetic experience. Kant's influence is evident in the work of another important noncognitivist, Malcolm Budd (2002), who embraces aspects of Kant's aesthetic theory, supplementing it with new work from environmental aesthetics, especially the idea of appreciating nature as nature.

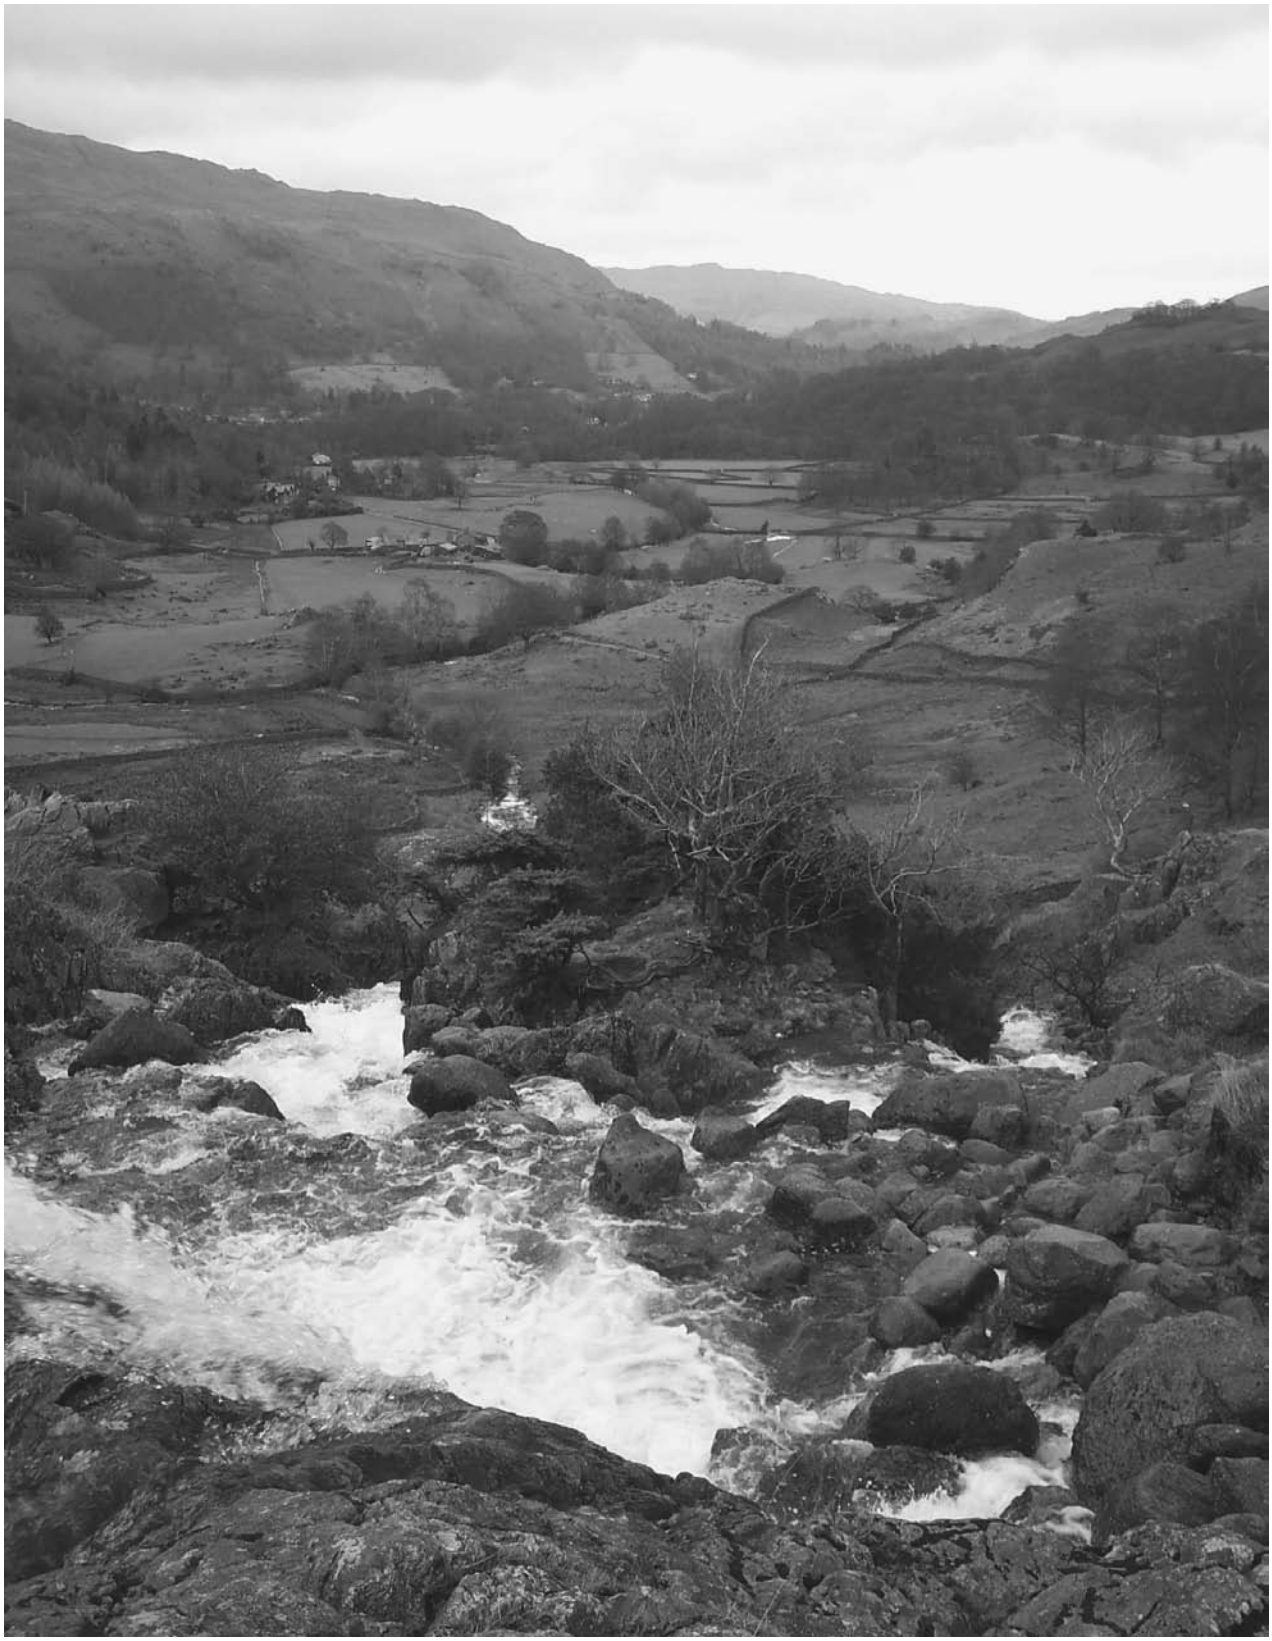
Yuriko Saito's work lies somewhere between cognitivism and noncognitivism. She supports the role of science but challenges its centrality, arguing for a plurality of appreciative frameworks, including other forms of knowledge such as folklore. On her account aesthetic appreciation can be enriched by a range of sources, but it must begin and end with the sensuous surface of aesthetic objects and environments. Saito emphasizes the importance of valuing a range of environments, from the beautiful to the "unscenic" to the everyday (2008). Saito's ideas are informed by Japanese aesthetics, which values such qualities as imperfection, transience, change, and the effects of weathering. Thomas Heyd's approach to environmental aesthetics stresses the relationship between environments and humans and the range of cultural resources they employ. Like Saito, he is interested in exploring a variety of environments, many of which occupy the middle range between wild nature and the urban (see Heyd 2007).

As environmental aesthetics has grown, it expanded its purview from natural environments to the modified environments of gardens (Ross 1998, Cooper 2006), environmental and land art (Brady 2007), and everyday environments (Light and Smith 2005, Saito 2008, Berleant and Carlson 2004). Given the prominence of nonhuman animals in environmental ethics, this topic was oddly neglected until it was addressed by Parsons (2007), who discusses aesthetic value in relation to animals.

AESTHETICS, ETHICS, AND ENVIRONMENT

Most environmental aestheticians consider their principal disciplinary home to be aesthetics rather than environmental ethics. Likewise, environmental ethicists tend to consider theirs to be ethics. Both orientations, however, are acutely aware of the productive and salutary overlaps and intersections between aesthetic and ethical value. For instance, Eugene Hargrove (1989) bases his approach to environmental ethics on the significance of the aesthetic valuing of nature.

In a 1998 article, "Appreciating Nature on Its Own Terms," Saito argues that natural aesthetics should incorporate a moral dimension that regards nature as nature and not merely as a work of art, a scene, or a cultural product (unless, of course, the environment in question is a humanly modified landscape). Hepburn, Eaton, and



Easedale, English Lake District. *A rural landscape shaped by natural forms and agricultural practices. Prior to the eighteenth century, in Western nations, such as those in North America and Europe, nature and the wild was often feared rather than appreciated for its aesthetic aspects.* **PHOTO BY EMILY BRADY.**

others also underline the importance of avoiding distorting, trivializing, and sentimentalizing aesthetic appreciation. Cognitivists claim to avoid such distortion by their reliance on scientific knowledge, whereas noncognitivists try to find various ways to strike a balance between overly serious and trivial appreciation (Hepburn 2001).

In response to worries about the potential distorting power of imagination, Brady shows how its activity can work appropriately, focused on the aesthetic phenomenon in question. She identifies relevant imaginative activity as that which is closely tied to perceptual qualities of the object, and this is bolstered by a disinterested standpoint where attention is directed to the aesthetic object rather than self-indulgent flights of fancy (Brady 2003, Moore 2008).

In an important article, "Icebreakers: Environmentalism and Natural Aesthetics" (1994), Stan Godlovitch takes the importance of appreciating nature on its own terms a step further, arguing for an "acentric" aesthetics that esteems nature as something mysterious and indefinable rather than as something culturally appropriated or determined by human imagination or science. This approach attempts to subordinate human frameworks as much as possible, thereby allowing nature to be valued, as much as possible, as nature.

Environmental philosophers such as Rolston, Hargrove, J. Baird Callicott, Ned Hettinger, and Sheila Lintott have explored more deeply the intersection of aesthetics and ethics. They agree that ecological understanding can enable us to move beyond shallow and biased aesthetic valuing and that environmental education is important in both our moral and aesthetic lives. But this approach suggests that aesthetics and ethics come together only to promote a responsibility for well-informed aesthetic appreciation. The connection has been taken a step further in the view that aesthetic valuing may support a moral attitude toward nature (see Hargrove 1989). Aesthetic attention to nature, from the delicate qualities of an everyday buttercup to the rich diversity of a rainforest, has long been recognized as a way into valuing nature that is immediate, compelling, and pleasurable. The democratic opportunities of aesthetic experience, from young to old and across cultures, may help to encourage people to care for the environment. As Brady (2003) and Lintott (2006) have pointed out, however, aesthetic valuing alone may be an insufficient foundation for environmental ethics in the absence of other concepts such as justice.

Environmental aesthetics has had and will continue to have significance for environmental disciplines and practices. A principal aim of environmental aesthetics is to seek a philosophically informed understanding of aesthetic value and judgment. To this end there is strong agreement that aesthetic value is noninstrumental and therefore distinct from other instrumental environmental pleasures such as recreation. Criticisms of the scenery model have underscored the extent to which aesthetic valuing reaches beyond mere visual enjoyment to encompass a broad range of experiences—knowledge, emotion, imagination, and all the senses. This view presents a "thicker" concept of the aesthetic experience of landscape, which, in much empirical work on the topic, has been limited to aspects that can be objectified or quantified (e.g., visual or scenic value), thus leaving out key qualitative aspects of valuing nature. A thicker concept of aesthetic value can also address criticisms of aesthetic judgment as merely subjective or relativistic (i.e., the idea that "beauty is in the eye of the beholder"). A more nuanced conception of aesthetic value may then come to have a more important role in environmental policy than it currently holds. For instance, the selection of areas to clean up (e.g., Superfund sites) can be made in part on aesthetic grounds. Also, given the surge in proposals for wind farms, with their promise of delivering green energy, a richer understanding of aesthetic appreciation and value can provide an informed way to judge the impact of these projects on the landscape (Briggle 2005, Saito 2004).

ENVIRONMENTAL ART

Environmental art, also called eco-art, is a diverse international movement that encompasses a broad variety of art forms, especially sculpture, installations, and performance art. It can be art that incorporates natural phenomena or events, such as Mount Rushmore, aeolian harps that generate sound when wind passes through them, and the Earthquake Rose that was created by a pendulum tracing in sand. Environmental art that uses natural phenomena is often large in scale, such as Robert Smithson's *Spiral Jetty,* constructed in 1970 on Great Salt Lake, Utah, and Christo and Jeanne-Claude's pioneering work wrapping islands and trees as well as their more recent *The Gates* in Central Park in New York. In its broadest use the term *environmental art* can refer to art that depicts environmental phenomena, though that kind of art is technically called nature art.

Environmental art goes beyond nature art: Ansel Adams's photography is eco-art not just because of its subject-matter but because of its symbolic function in the North American environmental movement. Although

The Gates, Christo and Jeanne-Claude, 2005. *Art and nature intermingle in the urban setting of New York's Central Park. The installation's full title is "The Gates, Central Park, New York, 1979–2005," after the years in which the artist couple conceived of the idea and attempted to bring their design into existence. The Gates consisted of thousands of steel "gates" with orange fabric.* **PHOTO BY EMILY BRADY.**

environmental art often is done in contexts that traditionally are recognized as nature or ecosystems, it also can use built environments. In guerrilla gardening, for example, artists reclaim deteriorated urban spaces and demonstrate citizens' ability to take responsibility for shared environments.

SOCIAL AND POLITICAL ASPECTS

Although Christo and Jeanne-Claude have always claimed that their art is purely aesthetic and lacks deeper significance, environmental art often has a social or political function. It can be educational for schoolchildren, the public, and policymakers. It increases ecological literacy, stimulates awareness of environmental damage and harm, provides remedial models, and raises consciousness. Environmental art also can be problematic from the point of view of environmental ethics and social justice. The faces of four U.S. presidents carved into rock on Mount Rushmore may be regarded as a defacement of a beautiful natural geologic feature. That sculpture certainly was an affront to the Lakota, who named it *Six Grandfathers* (for their most powerful spiritual beings). One also might wonder about the environmental impact of Christo and Jeanne-Claude's wrapping of whole islands in fabric.

At its most radical, eco-art is a revolutionary strategy for making nonviolent political statements and critiquing environmental issues. The Raging Grannies, for example, are ''interveners'' who use humor to teach about environmental problems without overwhelming audience members. The function of environmental art as a force for social change arose from its formative influences in the 1960s. Joseph Beuys, a controversial German artist and environmental campaigner, believed strongly in the revolutionary and healing potential of art. His ''social sculpture,'' in which society itself is considered a malleable work of art, generally is understood as the origin of the movement. Sculpture remains an important form in eco-art, as in Lynne Hull's trans-species installations that aim at habitat enhancement for wildlife and eco-atonement for human ecological impact. Eco-art also has conceptual roots in the work of the American artist Allan Kaprow,

whose Happenings challenged the distinction between art and life and initiated performance art. The British artist Stephen Willats's "behavioural art" undermined the authority of artist, critic, and tradition through participatory projects operating outside institutions in the audience's everyday life, such as the West London Social Resource Project (1974).

The pioneers of environmental art include Newton and Helen Mayer Harrison, American artists whose work since the 1970s in watershed restoration, agriculture, forestry, and urban renewal has influenced policy in the United States and Europe. Hans Haacke's Rhinewater Purification Plant (1972) exposed the role of a sewage plant in degrading a river by pumping its murky discharge, which met government standards, through an additional filtration system. Using the resulting water in the museum's garden was an innovative instance of graywater reclamation. Similarly, Flowforms, developed by a sculptor, a mathematician, and a hydrologist, showed the inner potential for movement of water and remediated water for use in, among other things, swimming pools and beer making. Tim Collins and Reiko Goto's 3 Rivers 2nd Nature Project in Pennsylvania questions whether artists can and should create social change by affecting the ways in which public policy and private capital define ecosystems and urban spaces. Thus, environmental art is useful for informing policymakers on matters of public interest and connecting scientists with communities affected by their work.

Traditionally, art has been understood in terms of the artist's intention, the relationship between form and matter, and aesthetic (sensory) presentation of conceptual content. Environmental art has these features but also complicates traditional debates about the nature of art by challenging them. For example, although Marcel Duchamp's urinal raised the question whether removing something from its functional context and placing it in an institution creates art and René Magritte's *Ceci n'est pas une pipe* challenged the representational function of art by drawing attention to its ontological rupture of instrumentalism, environmental art makes these tensions moot. Thriving independently of institutions and galleries and instead functioning in lived contexts, environmental art is both representational and functional. It is often collaborative or participatory, blurring the line between artist and audience. For example, Daniel Dancer's ZeroCircles Project raised awareness of and objections to the crisis in U.S. forests: Participants used found materials to create a circle symbolizing healing, hope, trust, and wonder at the creative and regenerative power of nature. A reclamation project in low-income urban neighborhoods along the Los Angeles River asked local children to draw their vision of nature parks and used those drawings in project design, and mothers and children decorated fences with the artwork. These are examples of the practical role of environmental art in community greening and reclamation.

AESTHETIC ASPECTS

Eco-art can consist in a lone artist expressing private inspiration but more often involves the artist and critic Suzi Gablik's concept of connective aesthetics. It joins together artists, scientists, policymakers and bureaucrats, and community members of all ages. Eco-art can be and often is aesthetically pleasing, but its treatment of devastated ecosystems and landscapes or cityscapes and polluted industrial brownlands can, like conflict art, challenge traditional conceptions of beauty. On occasion eco-art borrows directly from conflict art. For example, Wilderness Women in Black identify with the Women in Black conflict-resistance movement and use its strategies of dressing in black and holding vigils to draw attention to issues of environmental justice. Environmental art blurs distinctions between theory and artistic practice and between intellectualism and activism.

Environmental art challenges assumptions about what it means to be human. It puts into question the privileging of human being over nature that informs European and North American history. If art does not merely record history but instead opens spaces of lived meaning, environmental art in particular generates possibilities for alternative conceptualizations of nature and human being that may inspire ecologically sound practices.

ENVIRONMENTAL CITIZENSHIP

Environmental citizenship is the idea that each of us is an integral part of a larger ecosystem and that our future depends on each of us embracing the challenge and acting responsibly and positively toward our environment. This idea is about making changes in our daily lives to be environmental citizens all day, every day.

River Cleanup, Wapello, Iowa. *Two men sort trash pulled from the Iowa River as part of the fourth annual Project AWARE. Volunteers for the project travel 99 miles along the Iowa and English Rivers to remove trash. Such projects are one way for individuals to participate in environmental citizenship.* **AP IMAGES.**

The idea of environmental citizenship was first developed by Environment Canada in the context of environmental education. It has been adopted by the United Nations to some degree (Barcena 1997). It is an idea similar to and compatible with environmental stewardship in the Christian, Islam, and Judaic traditions, but is not committed to or associated with any particular religious or cultural tradition.

Environmental citizenship was anticipated in some ways by Aldo Leopold in his essay, "Land Ethic," where he writes, "A land ethic changes the role of *Homo sapiens* from conqueror of the land-community to plain member and citizen of it. It implies respect for his fellow-members, and also respect for the community as such" (1949, p. 204). Here the contrast is between human domination of the environment and membership in it, along with plants, animals, and nonliving elements.

Mark Sagoff introduced citizenship into the environmental-ethics literature as part of his critique of environmental economics in *The Economy of the Earth* (1988), where he contrasts citizenship with consumerism. Sagoff shows that although environmental policy has usually been based on consumer preferences via consumer surveys, citizen preferences based, for example, on voting in referendums may produce completely different results. For example, although the members of a community as consumers may prefer certain kinds of packaging, they may reject this packaging as citizens if their community has a solid-waste-management problem. In such cases, citizen preferences in terms of democratically cast votes may override consumer preferences in terms of interpretations of consumer-survey results by economists. This distinction is similar to Bryan G. Norton's distinction between felt preferences and considered preferences in "Environmental Ethics and Weak Anthropocentrism" (1984), although Norton does not specifically use the term *citizenship*. Norton also seeks social consensus in the political arena (see *Toward Unity among Environmentalists*, 1991).

Environmental citizenship can be associated with Aristotle's ethics, since Aristotle considered ethics and politics to be two sides of the same coin, virtue ethics. For example, Leopold created the land ethic in large measure because of the unwillingness of farmers to write their own soil-conservation rules in Wisconsin in the 1930s (1949, p. 206)—a failure in citizenship. "The answer, if there is any, seems to be in a land ethic, or some other force which assigns more obligation to the private landowner" (Leopold 1949, p. 213).

Although the idea of environmental stewardship has become well established over the years among environmentalists, environmental citizenship is an alternative with more potential, especially internationally. Because stewardship is associated with three world religions—Christianity, Judaism, and Islam—it may be difficult to establish a practice of environmental stewardship in cultures where other religions are the dominant perspective. Citizenship, in contrast, is religiously neutral. In addition, stewardship may not be the best model for environmental action even within the Judeo-Christian tradition, because stewardship owes its prominence in large measure to the fact that dominion was misinterpreted as domination during translation into most European languages. Discussion of stewardship in the Bible mostly concerns examples of bad management (see Steffen 1992). Although the original conception of dominion may be a better model than stewardship, it is probably not a viable approach, owing to its negative association with domination.

Andrew Dobson in *Citizenship and the Environment* (2003) has provided the most detailed analysis of environmental citizenship. Dobson develops a postcosmopolitan conception of environmental citizenship, which he calls "ecological citizenship." This view of citizenship is global and transcends national borders, but is focused on the responsibilities of citizens in Western nations. Cosmopolitan environmental citizenship is unacceptable to Dobson because the environmental situations of people around the world are not the same. The fundamental problem is asymmetrical globalization, in which Western industrialized nations (sometimes called "the North") have a largely one-directional environmental impact on the rest of the world ("the South"). Dobson calls his view "postcosmopolitan" in recognition of this asymmetrical relationship. This asymmetry rules out a conception of citizenship that is reciprocal and contractual because people in various parts of the world are not always in an equal position to

perform reciprocal action. Thus, Dobson's citizens are supposed to act to avoid harm to others because it is the right thing to do, not simply to avoid reciprocal harm from others. Dobson employs Wackernagel and Rees's (1996) notion of an ecological footprint, the total area of the earth that supports any political geographical unit, to define the limits of harm that any given society may do. Because Dobson is concerned with asymmetrical ecological harm, he calls his position "ecological citizenship." Nonetheless, this position is anthropocentric, rather than ecocentric, since the primary object of his conception of citizenship is preventing harm to humans.

Dobson rejects both liberal citizenship (based on rights) and republican citizenship (based on duties) on the grounds that both ultimately share a contractual conception of citizenship. The basis for his ecological citizenship is responsibility, not rights or duties. Freedom too is not as fundamental as responsibility, since asymmetrical global relationships often limit one's ability to act. His focus is more on justice than dialogue and democracy. Thus, ecological citizenship involves unreciprocated and unilateral citizenship obligations, depending on one's asymmetrical ability to act.

Environmental citizenship cannot be reduced to a set of universal principles, because the obligations of individuals are asymmetrical and depend on conditions in specific cultures around the world. Likewise, it is not possible to generate a common set of virtues, since these too will be culture-specific. Nevertheless, framing environmental education in terms of environmental or ecological citizenship may avoid resistance to teaching an environmental ethics, particularly in countries where teaching ethics, values, and virtues as such is viewed with suspicion (see Hargrove 2000, 2004).

ENVIRONMENTAL CONFLICT RESOLUTION

Environmental Conflict Resolution (ECR) consists of collaborative efforts to resolve environmental, public land, or natural resource conflicts through direct negotiations and dialogue amongst the disputants. ECR usually involves government agencies working in partnership with representatives of a full range of parties who are potentially affected by an agency decision. Third party neutrals (such as mediators or facilitators) work with agencies and the parties to promote resolution of disputes through consensus.

The four key elements of ECR, then, include: (1) agencies working collaboratively with interest groups, (2) the inclusion of all affected parties (stakeholders) in structured dialogues, (3) the presence of independent, third party neutrals (mediators or facilitators) to manage the dialogue process and ensure its impartiality, and (4) the attempt to achieve consensus amongst all the stakeholders as a basis for making decisions. As such, it differs significantly from traditional processes of public decision making. Instead of agencies first developing policies based on their own professional judgment then seeking public input through public hearings, agencies work with citizens and stakeholders from the beginning to design policies or programs that meet the interests of all the parties.

THE HOPE AND PROMISE OF ECR

While public policy generates conflict in many arenas, it is in environmental policy that conflict resolution is most widely used. Conflict resolution is particularly useful in resolving environmental disputes because the environment interacts with almost everything we do as humans. We often need to protect the environment while at the same time pursuing other social goals. We want, for example, to promote productive and reliable industries,

agriculture, energy, and transportation systems while also protecting the environment from the pollution or displacement of natural resources that these activities often entail. Good environmental policy, then, does not stand on its own, but must be integrated into other fields of economic and social policy.

During the late 1960s and 1970s, with the emergence of the modern era of environmental political activism, public debate over how best to protect the environment became increasingly contentious. While fewer than 25,000 environmental lawsuits were filed in federal district courts in 1969, the number of cases had increased sixfold by the late 1970s. Traditional means of policy-making—legislation, litigation and bureaucratic decision making—often proved incapable of balancing the complex array of interests associated with environmental management.

It was in this atmosphere of intensifying conflict that ECR emerged. ECR offered a new way to draw on the collective wisdom of interested parties and professionals to design more effective and implementable environmental policy. Each party brings considerable knowledge and experience in their own field of interest, as well as an ability to assess whether policies would enhance or detract from those interests. Through open dialogue, exchange of information, and negotiation, parties challenge each other to design solutions that best meet the needs of all the parties, thereby identifying and promoting the public interest through direct participatory democracy.

EARLY PRACTICE OF ECR

Consider as an example the first recorded use of ECR. Between 1958 and 1973, environmentalists, local residents, and farmers fought over proposals to manage flooding along the Snoqualmie River in Washington. The river frequently flooded, and farmers and residents favored a proposed dam for its flood control and irrigation values. Environmentalists opposed the dam because it would induce development in the flood plain, encourage sprawl from nearby Seattle, and destroy one of the most pristine scenic and recreation areas near Seattle. In 1973, Governor Daniel Evans invited mediators to bring the disputing interest groups into dialogue with government agencies and implementing bodies. After seven months of negotiations, the parties agreed on a plan that combined a multi-purpose dam on a different fork of the river with a system of set-back levees, land use controls and floodway easements. Instead of continuing to fight over a mutually unacceptable alternative, the interested parties designed a new set of solutions that more effectively met their mutual interests.

As can be seen from this example, ECR provided a mechanism for resolving long-standing controversies among well-matched disputants who had demonstrated a capacity to block each other's preferred policy options. ECR proved to be cheaper and more efficient at resolving differences than the litigious and politically motivated strategies that predated them. Of the approximately 160 significant cases of environmental mediation that occurred by 1984, more than 75 percent reached agreement, and enthusiasm for both the processes and outcomes of mediated ECR spread widely.

TRENDS IN ECR

While early ECR efforts focused almost exclusively on resolving existing disputes, later ECR efforts became increasingly proactive. By seeking to resolve conflict before major disputes developed and stalemate ensued, these processes focused less on negotiating over specific problems and more on building broader collaborative dialogues that promote community values. Two examples will illustrate these newer forms of ECR.

Like many industrial cities, Lowell, Massachusetts, contains a large number of old industrial sites that are no longer being actively used. These sites, called brownfields, are often located adjacent to poor and working class neighborhoods, contain deteriorating industrial buildings and infrastructure, and are potentially contaminated by industrial pollutants. They are often difficult to redevelop. Yet brownfield redevelopment provides important benefits to the city and its neighborhoods by reinvigorating their economy and quality of life. The City of Lowell therefore hired facilitators to work with community residents, developers, property owners, bankers, and government agencies to develop plans for the redevelopment and reuse of these sites. By helping to bring the many parties together and encouraging a dialogue on all the issues associated with each site, the city built the collaborative teams needed to redevelop many of the properties.

As a second example, the San Francisco Estuary Project (SFEP) is a complex set of processes seeking to resolve highly contentious issues associated with water management in Northern California. The watershed feeding into the estuary covers over half of the state of California. The size of the affected area, the complexity of the issues, the diversity of the stakeholders and the number of local, state, and national agencies involved in watershed management all posed significant challenges to management of the estuary. To design a plan for managing the estuarine system, a consensus-building process was initiated and funded by the U.S. Environmental Protection Agency (EPA). The process was divided into three committees involving over 120 individuals and consisting of state and federal agencies, citizen and interest group representatives, and scientists and engineers. The agency committee was responsible for developing consensus around policy, but these participants were highly affected by both the public and technical

advisory committees. This somewhat loose network of agencies, interest groups, and scientists effectively developed a plan of action and coordinated decision making for the estuary and the rivers feeding into it for over fifteen years, managing conflict through consensus building and directly involving all the interested parties in the management process.

THE INTERNATIONAL USE OF ECR

Although ECR practices developed in the United States and Canada are being internationalized, these practices remain limited in scope in most other countries. The different political and bureaucratic cultures of these countries have proved less fertile for the adoption of formal ECR processes. European environmental activists, for example, can more directly access political decision making (through Green parties) and bureaucracies (through consultation processes) but have less capacity to challenge bureaucratic decisions through administrative and judicial review. Hence, European environmental organizations, although more effectively institutionalized and integrated into political decision making, lack many of the direct-action tools that U.S. and Canadian interest groups use to delay and block official actions. Incentives to negotiate therefore differ. Environmental conflict is managed more politically and less bureaucratically, and agency-based ECR processes are not as useful.

THE BENEFITS AND DRAWBACKS OF ECR

Since the 1970s, the practice of ECR has offered a number of significant benefits and has raised some important questions. Effective participation in ECR often requires considerable resources—in staff time, information, research, and travel—that are more readily available to corporations and government agencies than to environmental activists or community groups. By focusing attention on resolving particular issues, ECR may also promote incremental improvements while distracting environmental groups from more basic concerns. A number of environmental groups have consequently become more cautious about the potential for cooptation through dialogue.

At the same time, well-designed ECR processes can enhance the efficiency and responsiveness of decision making, provide a meaningful voice to concerned citizens, and encourage power-sharing amongst multiple agencies and interest groups. ECR can also promote collaborative analysis, producing environmental decisions that are more thoughtful, more durable, and more easily implemented. ECR retains considerable promise as a mechanism for enhancing environmental decision making under conditions of conflict.

ENVIRONMENTAL DESIGN

Environmental design, design for environment, ecodesign, green design, sustainable design, design for sustainability, cradle to cradle—all these terms refer to integration of environmental requirements in all stages of the product development process, with the aim of reducing the environmental impact of all life cycle steps and maximizing sustainability. Ecodesign ranges from the design of small objects for everyday use to the design of buildings, cities, and the physical surface of the earth. It is a growing trend in architecture, engineering, industrial design, graphic design, interior design, and fashion design.

GENESIS

Ecodesign originated during the second wave of modern environmentalism. The first wave began in 1962 with the publication of Rachel Carson's *Silent Spring* and culminated in the publication of the 1972 Club of Rome report *Limits to Growth*. First-wave environmentalists argued that exponential growth of populations and industrial activity could not continue without exhausting the resources of the planet and overloading its capacity to deal with pollution and waste. The second wave of modern environmentalism, which began with the 1987 publication of the so-called Brundtland Report, *Our Common Future*, initiated a new approach to dealing with environmental problems. The concept of sustainable development was introduced in the belief that economic development and ecological sustainability are not incompatible. "Ecological modernization" and "pollution prevention pays" were the new slogans. End-of-pipe solutions, which focus on waste disposal, gave way to systematic attention to environmental impacts in the early design stages, moving upstream in the pipe.

The first initiatives in the area of ecodesign started in the late 1980s in Europe and the United States. In the beginning of the 1990s a series of ecodesign demonstration projects in different industrial sectors was organized in the Netherlands. On the basis of experiences with those projects, an ecodesign manual called *Promise* was published in 1994. Three years later an updated version was launched under the auspices of the United Nations Environment Program (UNEP). This ecodesign approach has been an inspiration for several other international and local ecodesign manuals.

BASIC PRINCIPLES

Ecodesign is a sophisticated form of *ecoefficiency* in the field of product development. Ecoefficiency primarily means doing more with less: creating more goods and services with fewer resources and less waste and pollution. The term was coined by the World Business Council for Sustainable Development (WBCSD) in its 1992 publication *Changing Course*. According to the WBCSD, ecoefficiency is achieved through the delivery of "competitively priced goods and services that satisfy human needs and bring quality of life while progressively reducing environmental impacts of goods and resource intensity throughout the entire life-cycle to a level at least in line with the Earth's estimated carrying capacity" (Business Council for Sustainable Development 1993). The 1992 Earth Summit endorsed ecoefficiency as a means for companies to put Agenda 21 into practice in the private sector.

The environmental performance of ecodesign will be optimized through the use of a *life-cycle assessment* or analysis that measures the environmental impact of a product or service throughout its life span. It requires the assessment of raw material production, manufacture, distribution, use, and disposal, including all intervening transportation steps. Environmental aspects should be analyzed for every stage of the life cycle, from the consumption of resources (energy, materials, water, or ground) and the emissions to air, water, or the ground through to the waste and waste products and issues such as noise and vibration.

A new and innovative way of thinking about life cycles was launched by William McDonough and Michael Braungart in their 2002 book *Cradle to Cradle: Remaking the Way We Make Things*. This book challenges the "cradle-to-grave" manufacturing model that the authors see at work in the area of ecoefficiency. To them, ecoefficiency works within the same system that caused environmental problems in the first place. "Relying on eco-efficiency to save the environment will in fact achieve the opposite; it will let industry finish off everything, quietly, persistently, and completely" (McDonough and Braungart 2002, p. 62). In their cradle-to-cradle approach, "waste equals food." Products should be designed from the outset so that they will provide nourishment for something new after their useful lives.

PHILOSOPHICAL ISSUES

In the cradle-to-cradle approach nature is taken as model for making things. This idea of learning from nature is present, implicitly or explicitly, in concepts such as the natural step and in new research areas such as industrial ecology. Learning from nature was put forward by Janine Benyus in her 1997 book *Biomimicry: Innovation Inspired by Nature*. Biomimicry (from *bios*, meaning "life," and *mimesis*, meaning "to imitate") is "a new discipline that studies nature's best ideas and then imitates or takes inspiration from these designs and processes to solve human problems" (Benyus 1997, p. iv).

This notion of learning from nature evokes many philosophical questions, particularly at the interface of the philosophy of science and the theory of evolution. In his 2003 article "Nature's Swell, but Is It Worth Copying?," Steven Vogel stated that the theory of evolution provides no justification for assuming perfection in natural design and rejects the belief that natural design is better than human-made technology as overly romantic. "Natural selection suffers from lack of foresight, near impossibility of cross-lineage transfer of innovations, great difficulty making anything but incremental alterations, severe lock-in of established if fundamentally inferior designs, unavoidably multifunctional devices, and limitation to locally available resources, just to mention a few of the constraints under which it labours" (Vogel 2003, p. 404). Moreover, technology does many things with few or no natural analogues, "even things we think might be useful to other organisms" (Vogel 2003, p. 404).

Learning from nature can be no more than an analogy or an inspiring example. Only in a few cases can a real scientific relation be found between human design and evolutionary development. Moreover, there is always a danger that the heuristic use of the learning from nature argument will be accompanied or replaced by rhetorical appeals that are meant to claim cognitive authority or superiority for certain, otherwise unwarranted statements or insights.

ENVIRONMENTAL EDUCATION

During the first decade of the twentieth century, education scholars concerned about the urban migration of rural youth created a curricular movement called ''nature studies,'' intended for the nation's rural schools. The hope was that if rural students developed an intellectual appreciation for the natural world around them, migration to the city would slow. Curricular guides and teaching strategies were disseminated across the country with the blessing of such notables as Liberty Hyde Bailey and John Dewey. Although the nature-study movement was short-lived, it is fair to call it one of the first concerted attempts to insert environmental education into the public-school experience.

Over time, of course, there have been many extracurricular experiences focused on learning about nature and the physical environment. *Outdoor education* was a popular phrase for decades and a concept conscientiously advanced by such groups as the Boy Scouts and Girl Scouts of America, as well as many other youth and adult groups. As American public education came to be increasingly connected to preparation for an occupation, to jobs and the economy, far less thought was given to experiential learning opportunities of the sort that placed students out in nature to study it. As a result, environmental education was marginalized outside of the core public-school program of instruction.

This situation began to change during the 1960s, when such works as Rachel Carson's *Silent Spring* and Paul Ehrlich's *The Population Bomb* were published. Greater levels of public concern for the environment meant that some curricular attention was paid to the health and well-being of nature, particularly in science and social-studies classes. But concern for the environment was merely one cause among many at a time when civil-rights struggles, antiwar efforts, and the emerging women's movement dominated public attention.

Only after 1985, especially in the wake of David Orr's 1992 classic *Ecological Literacy*, did environmental education emerge as a respected subfield in American curriculum studies. Creative teachers encouraged a kind of curricular activism and in the process contributed to such environmental victories as forcing McDonald's to forego the use of Styrofoam packaging. Hard on the heels of student participation in these efforts, Congress passed the National Environmental Education Act of 1990, essentially creating an education wing of the Environmental Protection Agency. A large part of this effort involved the identification of outstanding environmental-education practices through grants and the dissemination of grant results.

By all accounts, both entities established by the National Environmental Education Act—the National Environmental Education Advisory Council and the Federal Task Force on Environmental Education—advanced systematic curricular and instructional work throughout the 1990s. But this was also a decade that witnessed a significant change in educational policy and practice: a shift to a focus on *outcomes* via the identification of learning standards, and a similar shift to a focus on *assessment* via the creation and implementation of standardized tests used to measure the achievement levels related to those standards. In the wake of this movement, environmental education began to slip out of American public-school curriculum.

That slippage was dramatically accelerated by the No Child Left Behind Act of 2002. Some observers have suggested that this piece of legislation was nothing more than an attempt to move public conversation on education away from inputs, such as per-pupil spending, concerns about equality, and so on, to outputs that focus solely on teachers and students, standards met or not met, test scores achieved or not achieved. Others have suggested that the law was designed to paint public education as a failed endeavor, one that should be supplanted by a system of private, for-profit educational ventures. Regardless of the motives behind this law, it completely ignores environmental education.

By contrast, environmental education has moved much closer to mainstream education elsewhere in the world. The Foundation for Environmental Education, based in Denmark, has focused curricular and instructional attention on the health and wellbeing of the earth's physical environment. It sponsors several programs intended to create this focus in schools around the globe. The organization got its start in 1981, with France, Germany, Spain, and Denmark as founding members. In 2007 the organization consisted of forty-eight member nations from all parts of the globe, though the United States has not sought membership.

Pesticide Protest Walk, 2002. *Students at Chapham College in Pittsburgh, Pennsylvania take part in a walk to protest pesticides. The walk was part of a program at the school to commemorate Rachel Carson's* Silent Spring, *the famed environmental piece. Many schools have been making an effort to bring environmental education back into the classroom.* **AP IMAGES.**

In the United States, environmental education has been relegated to a marginal position comparable to that of the time when it was primarily extracurricular. The heavy pressure to generate acceptable test scores in reading and mathematics severely inhibits the ability of teachers to engage students in environmental-education lessons. In keeping with conservative opinion, the environmental-education advisory groups of the Environmental Protection Agency have promoted the message that environmental education is the concern only of the science classroom and that, as the 2005 report to Congress stressed, environmental educators must possess "the ability to present multiple perspectives on environmental issues without advocating a particular viewpoint" (National Environmental Education Advisory Council, 2005, p. 36). In other words, calls for action on the environment must be balanced with opinions advocating a laissez-faire approach.

The federal position on environmental education does not mean that efforts at environmental education have disappeared; far from it. Advances in learning theory, in understanding how humans come to understand, have sparked increased interest in close study of the world that surrounds students. Put simply, constructivist learning theory contends that understanding develops via the cognitive interplay of new and old information *in a context conducive to making sense of it all*. Sophisticated teachers put students in a context within which lessons can most easily come to be understood. A sterile classroom and a textbook filled with good information lacks context, a necessary ingredient for producing understanding. Students can, of course, acquire information in a classroom from an information-filled text, and that information may be held long enough to be reproduced on a test that measures low-level comprehension, but students may not understand the significance of the information acquired in this way, and such information may not remain useful for long.

The ascendancy of constructivist theory in the scholarly field of learning has helped keep many promising curricular and instructional practices from disappearing in the wake of 2002–2008 federal education policy. Project-based learning, place-based pedagogy, community-based studies, and environmental education all overlap, and all garner legitimation from what we now know about how to produce human understanding.

Though federal education policy prescribed by the No Child Left Behind initiative ignores environmental education, the 1990 Environmental Education Act remains in force. It continues to serve as a rationale for teachers who hope to educate the students in their responsibility for the health and wellbeing of their immediate physical environment. Still, with heavy state and federal pressure for students to perform well on standardized exams, teachers and administrators must weigh the pros and cons of hands-on environmental education of the sort that occurs outside the classroom.

Despite attempts to develop standards for environmental education—attempts to define what it is and what it should be—the area is too political to generate any kind of consensus analogous to, say, standards for mathematics. It is not even possible to identify a typical curriculum outline for elementary-, middle-, or high-school classes. Generally, however, science-focused environmental education tends to center around large concepts: land, ocean, atmosphere, climate, and the like. In contrast, social-studies classes tend to center around specific environmental problems, such as air pollution, global climate change, deforestation, food safety.

Resources for teachers abound. Practically every environmental organization one might think of gets involved in the preparation of lessons or ideas that teachers can use at all levels in public schools. Also, textbook companies have entered the environmental-education market, largely because several states have mandated some student exposure to environmental education. Sometimes this exposure is embedded in various classes, but sometimes it takes the form of a stand-alone class—a fact that creates at least a small market for textbooks. To judge by reviews published by the Environmental Literacy Council, most of these textbooks do a poor job of providing any insight into the connection between the environment and economic activity. This is to be expected, since to maximize sales, publishing companies must avoid becoming labeled controversial in any way. Thus, for instance, arguments that might be interpreted as critical of capitalism are usually omitted.

Most teachers preparing lessons in environmental education use the Internet to acquire lesson plans from such organizations as the North American Association for Environmental Education, the Environmental Literacy Council, or the National Environmental Education and Training Foundation, among many others. Teachers need only google a problem on the Internet, and they will be presented with Web sites such as Stop Global Warming (http://www.stopglobalwarming.org) and Save Our Environment (http://www.saveourenvironment.org), many of which provide sophisticated information in the form of research studies and reports, if not in ready-made lesson plans, that might augment their classroom instruction.

Missing in environmental education in 2007 is any concerted attention to environmental ethics, ethical behavior related to our natural environment. The current policy position on environmental education seems to be that any kind of ethical deliberation must be minimized, if not eliminated, in favor of a general acceptance of all perspectives related to the environment—a position that legitimates environmental degradation in the pursuit of profit and raises it above reproach.

This neutral position is acceptable to the American public because the public-school endeavor has been defined largely in terms of its economic utility, whether at the individual or societal level. Children are sent off to school in the hope that it will help prepare them for a good job someday. U.S. society spends enormous sums on public education so that it will remain competitive in the global economy. As long as a kindergarten through twelfth-grade education is focused on employment, the presence or absence of environmental education will remain a matter of little concern.

When public-school systems were created in the 1830s and later throughout the nineteenth century, their goal was nearly the reverse of what we see today. School systems were created to help citizens fulfill the responsibilities of democracy. In discussing the economic benefits of education, public-school advocates would add a vibrant account of the political dimensions of education. At the beginning of the twenty-first century, less is heard about the contribution of a public education to the political duties incumbent on citizens, but we hear a good deal about the ostensible connection between good schools and a good economy. The success of environmental education probably requires that schools give due attention to the development of what has been called the "democratic arts." Schools offering such instruction would be open to ethical deliberation. Such schools would cultivate the student's ability to create an argument, be persuasive, build and use evidence, listen intently, and work toward compromise. There is likely no better forum for the cultivation of these skills than environmental education. One can only hope that significant progress can be made in this direction before environmental circumstances create untenable and unstable societal conditions.

ENVIRONMENTAL HISTORY

Environmental history assumes that human history is shaped to a major extent by the relationship of human culture to nonhuman nature. As a subfield of history, it seeks to understand human beings as they have lived, worked, and thought in relationship with the rest of nature. In *The Ends of the Earth*, Donald Worster, a preeminent American environmental historian, described environmental history as "part of a revisionist effort to make the discipline far more inclusive in its narratives than it has traditionally been" (1988, p. 290). Indeed, established historians have usually treated the natural environment as a given, a static backdrop for their accounts of political and military events and the actions of national, economic, and religious groups. Environmental historians, in contrast, portray nature as an actor that joins in directing the course of human history. They tend also to believe that the contemporary environmental crisis can best be understood by way of a study and elucidation of past human interactions with the natural world.

MAJOR THEMES

Environmental history centers on three major themes. First, it investigates the history of impacts of natural changes—whether geological, climatic, or biological—on human societies. Of course, the natural environment has a history, but the study of its changes, such as volcanic eruptions and ice ages, is usually left by historians to the natural sciences. What interests environmental historians is the effect of such changes on human history. Did they set off migrations, cause competition over resources, or stimulate inventions? Environmental history does not concern itself primarily with the history of the environment but with the interaction of humans and environment. That being said, it is also true that knowledge of what science can reveal about the history of the environment is an indispensable element of environmental history. After all, humans are part of nature, dependent on ecosystems, and not entirely in control of their own destiny. Properly understood, environmental history should be a corrective to the prevailing tendency to see humans as separate from nature, above nature, and masters of nature. Of the themes to be discussed here, however, this first theme—the history of impacts of natural changes on human societies—has been developed by fewer environmental historians than the other two.

The second theme is the investigation of human impacts on the natural environment in various places and in selected periods, as well as the ways in which changes caused by those impacts rebound and cause reciprocal changes in human societies. For example, settlers plowed the North American High Plains, removing the resilient vegetative cover that had protected the soil and thus subjecting vast tracts of land to wind and water erosion. That intervention resulted in the Dust Bowl and the eventual abandonment of the land by thousands of farmers. Studies of resource development, forestry, mining, grazing, agriculture, water diversions, industrialization, energy development, urbanization, air and water pollution, nuclear power and weapons, and the environmental effects of warfare have provided subjects for uncounted studies in environmental history. All these human activities affect the natural environment in many ways, both positively and negatively, from a human point of view. A large coterie of environmental historians has devoted attention to the ways in which governments and organizations have attempted to accentuate positive change and limit damage through pollution control and the conservation of natural resources, including the preservation of sections of land as national parks, wildlife reserves, and other protected areas, and the safeguarding of threatened and endangered species. Others trace the tangled tale of political decision making about the environment, including the battles that have pitted the environmental movement against its opponents and business against government.

A third theme, the one most closely related to environmental philosophy, is the study of human thought about and attitudes toward nature, including the scientific study of nature, especially ecology, and the ways in which popular culture and systems of thought such as religions, philosophies, and political ideologies have influenced human relationships to the natural environment. These aspects of intellectual history can yield insights into the past, present, and future of the earth and its diverse living systems. What individuals and societies believe about nature influences their treatment of it: Temporary economic advantage and sheer basic needs have often trumped high principle.

Closely connected with this third theme is the study of the lives of influential figures in environmental thought, supplemented by commentaries on their works.

Environmental historians and environmental philosophers, when dealing with the same authors or figures, do not always take approaches defined mainly by their disciplines. For example, in *Companion to a Sand County Almanac* (Callicott 1987), a collection of essays on Aldo Leopold—an important mid-twentieth century wildlife biologist and ecological theorist—contributions by environmental philosophers such as J. Baird Callicott and Holmes Rolston III give careful attention to the historical setting of the author and his works, whereas historians such as Susan Flader, Curt Meine, and Roderick Nash emphasize the importance of his ideas to a philosophy of ecology. Historians can use the work of philosophers, and vice versa.

HISTORY OF THE FIELD

In the United States, environmental history first became a distinct scholarly discipline during the 1960s and 1970s; later it spread to the other English-speaking countries, continental Europe, India, and beyond. Many themes of environmental history had already emerged in the works of earlier historians. Also, attention had been given by historians to the American conservation movement, including advocates of nature preservation such as John Muir (1838–1914) and the so-called Progressive Conservation Movement, for the prudent and scientifically based use of natural resources urged by the geologist John Wesley Powell (1834–1902), the forester Gifford Pinchot (1865–1946), President Theodore Roosevelt (1858–1919), and President Franklin D. Roosevelt (1882–1945). Samuel P. Hays provided a critical analysis of this period in *Conservation and the Gospel of Efficiency* (1959), depicting conservation during the so-called Progressive Era, presided over by Theodore Roosevelt, as an emphasis on scientific management and organizational efficiency. Roderick Nash, in *Wilderness and the American Mind* (1967), put conservation in the context of intellectual history, emphasizing preservationist rather than utilitarian thought, and established the wilderness as a leading interest within the nascent field of American environmental history. In subsequent work Hays defined the transformation in American attitudes toward the environment after 1945, when the environmental movement superseded the conservation movement. In his book *Beauty, Health, and Permanence* (1987), Hays noted the emergence of new environmental values, including the desire for environmental amenities, recreation, aesthetics, and health, all of which were associated with rising standards of living. Americans also had become concerned with environmental issues such as increasing smog and the dangers of radioactive contamination by fallout from nuclear bomb tests. Rachel Carson, in her 1962 book, *Silent Spring*, warned of damage from the persistent use of pesticides. Emerging environmental movements reached nationwide awareness on the first Earth Day, April 22, 1970, and ecology, formerly an obscure science, became a household word. That the historians who created the field of environmental history in the 1960s and 1970s were mostly environmentalists no doubt helps to account for their choice of subject. Nevertheless, they strove to do professional historical research, not environmental journalism or environmentalist propaganda.

A group of scholars—mostly historians, a significant number of philosophers involved in what was newly termed ''environmental ethics,'' and scholars studying literature with environmental themes—formed the American Society for Environmental History (ASEH) in 1976, with the U.S. historian John Opie as its first president. The group included Canadian scholars from the start and has held meetings in Canada. The journal of the society began publication in the same year and was successively titled *Environmental Review* (1976–1989), *Environmental History Review* (1990–1995), and *Environmental History* (1996–). The change in titles reflects the gradual transformation of the society's scholarly efforts from a broadly interdisciplinary venture into a subfield of history. Nonetheless, environmental history has remained from its inception a necessarily interdisciplinary endeavor, practiced in all vigorous academic communities. The journal *Environment and History* began publication in 1995 in the United Kingdom, with Richard Grove as editor. Although a European journal, it presents research on every part of the world. The European Society for Environmental History (ESEH) was founded in 1999 and has held biennial conferences since 2001. Both ASEH (2008) and ESEH (2008) have useful Web sites. Other regions with active cooperative work in environmental history include Latin America/Caribbean, which has a society and periodic conferences; South and Southeast Asia; Australia and New Zealand; China; and South Africa.

Although the environmental history began to emerge as an academic activity only in the 1960s, themes of environmental history had surfaced in the work of historians, philosophers, and geographers well before the mid-twentieth century. The idea that climate influences human culture, for example, is ascribed to the early Greek philosopher Parmenides, and is found in the writings of the historian Herodotus and the medical writer, Hippocrates. One can find a more specific explanation of the influence of the environment on human history in the work of the great ancient Greek historian Thucydides (c. 460–404 BCE), who theorized that because Attica, the district around Athens, had soil that was thin and dry, its unattractiveness to potential invaders saved it from war and preserved it from depopulation (1972). Its relative safety

made it a shelter for refugees fleeing from wars elsewhere, further increasing the numbers of residents until they exceeded the capacity of the land to feed them. So Athens, he believed, relieved the pressure by sending out settlers to colonies.

The idea that human efforts cause changes within the environment occurs in the writings of the Greek philosopher Plato (c. 428–347 BCE). He observed historical deforestation of the mountains of Attica, offering archaeological evidence: Large roof beams in buildings that still stood in his own day had been cut from mountains where only "food for bees" (flowering herbs and bushes) remained (trans. R. G. Bury, 1966). Massive erosion had removed rich soil, leaving only the rocky framework of the land, which Plato compares to the bony body of a man wasted by disease.

A comparison may be made between Plato and the Chinese philosopher Mencius (c. 372–289 BCE), who described deforestation in his homeland. A section of his book that has caught attention from modern environmental historians is the description of Ox Mountain which had been denuded of its forests over the years by logging and where grazing made deforestation permanent by preventing the growth of trees (trans. D. C. Lau, 1970).

In the Middle Ages, Ibn Khaldûn (1332–1406), an Islamic philosopher, speculated about the influence of the environment on human history. In his influential work *Muqaddimah* (1958), he described the climatic zones of the earth and ascribed the characteristics of human groups to environmental influence. His most original environmental theory concerns the influence of the desert on the Bedouins in North Africa, whose strenuous life kept them from getting obese, toughened them against famine, and made them more self-reliant than townsfolk. Inhabitants of cities, though derived from desert forebears, gradually shed their traditional attitudes and descended into extravagance and debauchery, while desert tribes that become dependent on cities for necessities of life were subjugated by urban rulers.

Historical thought in Europe during the Middle Ages was shaped by the biblical view that God guides history and that nature is God's creation, given to man to use and to care for. Monastic writers such as Bernard of Clairvaux (1090–1153) observed human efforts to change the landscape, with fields and orchards replacing disordered wild growth; he noted river-control projects that sought to divert the waters for irrigation and tap their energy for milling. These changes he saw as useful and beautiful.

Richard Grove, in *Green Imperialism* (1995), showed that scientists sent out by European powers in the early modern period noted environmental changes on oceanic islands, changes so rapid that they could be chronicled within the span of one human life. Recording evidence of human-induced deforestation and desiccation, they asserted that humans have caused environmental alterations around the world and that many of these represented not progress but degradation.

Scientists argued that it was in the interest of colonial governments to prevent degradation of the environment in the territories they controlled. "The state," as the economist Richard Cantillon (1680–1734) proposed, is "a tree with its roots in the land" (1995, p. 221). But, Grove observes, "States will act to prevent environmental degradation only when their economic interests are shown to be directly threatened. Philosophical ideas, science, indigenous knowledge and threats to people and species are, unfortunately, not enough to precipitate such decisions" (1995, p. 42). Ironically, had those in power listened to the keen observers of nature among their contemporaries, they might have profited in the long run.

A modern writer who presaged environmental history was George Perkins Marsh (1801–1882), a long-time U.S. ambassador to Italy. He observed "the character and extent of the changes produced by human action in the physical condition of the globe we inhabit," and warned, in *Man and Nature*, that "the result of man's ignorant disregard of the laws of nature was deterioration of the land" (1965 [1864], pp. 10–11). Dissenting from the prevailing economic optimism of the times, he saw "man" as the disturber of nature's harmonies, observing that activities such as deforestation deplete the natural resources on which civilization depends. Marsh may be regarded as the first to systematically investigate the question of human-caused environmental deterioration and potential exhaustion of natural resources. Marsh was not a defender of immaculate nature; his salient point is that many of the changes humans make in the natural environment, whether through good intentions or neglect, injure the environment's usefulness to humans. His desideratum is a balance between man and nature in which man's needs are met and nature's harmonies preserved. He believes that man can be a coworker with nature, a restorer of disturbed harmonies.

In the early and middle twentieth century a group of historians based in France, called the *Annales* School (after the title of the journal founded in 1929 in which many of their papers were published), emphasized the importance of viewing history within the context of the environment at a large scale, both temporally and spatially. A founder of the school was Lucien Febvre (1878–1956). Among others prominent in the group were Marc Bloch (1886–1944), Fernand Braudel (1902–1985), and Emmanuel Le Roy Ladurie (1929–). Febvre's book *A Geographical Introduction to History* (1925) is a classic. He is aware that human activities are damaging the earth: "The civilized man directs his exploitation of the earth with a mastery which has

ceased to astonish him, but which, when we reflect on it for a moment, is singularly disturbing." (p. 355). Braudel's study, *The Mediterranean and the Mediterranean World in the Age of Philip II* (1966), offers a magisterial argument for the importance of landscape to history. Philip II, one of the most powerful kings of Spain, ruled from 1527 to 1598. Braudel's work, however, is by no means limited to that period, but ranges widely over Mediterranean history. Changes in the climate, Braudel believed, are often the result of changes caused by humans. A more extensive study of climatic change was undertaken by Le Roy Ladurie in *Times of Feast, Times of Famine* (1967).

Another impetus to environmental considerations in history came from American frontier historians such as Frederick Jackson Turner (1861–1932) and Walter Prescott Webb (1888–1963). Their theory held that the western frontier had kept egalitarian enterprise alive, representing an environmental safety valve that the closing of the frontier around 1890 had closed. Webb described his method as an approach to history through geography and the physical environment. James Malin's *The Grassland of North America* (1967 [1947]) provided awareness of the ecological changes that accompanied the settling of the Great Plains. It is hard to imagine any American historian of the mid-twentieth century who would not have been familiar with the strand of research exemplified by Turner, Webb, and Malin. This is undoubtedly a reason why the United States was the theater for the initial development of environmental history as a self-conscious inquiry in the later twentieth century.

The library of works in environmental history in the United States and around the globe is so extensive that it is possible to give only a brief overview of the field in an essay of this length. Among those that are worldwide in scope are John R. McNeill's "Observations on the Nature and Culture of Environmental History" (2003) and J. Donald Hughes's *What Is Environmental History?* (2006), which contains a bibliography on the historiography and philosophy of environmental history. On a much larger scale is the *Encyclopedia of World Environmental History*, edited by Shepard Krech III, John R. McNeill, and Carolyn Merchant (2004). Peter Coates penned a guide to environmental history in the Americas unconventionally titled "Emerging from the Wilderness (or, from Redwoods to Bananas)" (2004). "Environmental History in Australasia" (2004), by Libby Robin and Tom Griffiths, covers Australia and New Zealand. For the United States there is *The Columbia Guide to American Environmental History* by Carolyn Merchant (2002) and two journal articles by Richard White: "American Environmental History" (1985) and its sequel, "Afterword, Environmental History" (2001). For Europe there is a collected series of essays by Verena Winiwarter and others, "Environmental History in Europe from 1994 to 2004: Enthusiasm and Consolidation" (2004).

ISSUES AND CONTROVERSIES

Some scholars have accused environmental historians of environmental determinism, the theory that history is inevitably guided by forces that are beyond human origin or human choice. Such critics have especially targeted studies that emphasize the roles of climate and disease epidemics. The basic conception of environmental history is that human societies interact with the physical world, without prejudging which factor is dominant; among environmental historians opinions on this causal nexus range from one extreme to the other. Near the environmental determinist end of the spectrum, for example, is the geographer Jared Diamond. In *Guns, Germs, and Steel* (1997) he argues that human societies are thoroughly embedded in the natural matrix and have developed by dealing creatively with it. At the other end of the spectrum—cultural determinism—is William Cronon, who, with other authors in the volume *Uncommon Ground: Toward Reinventing Nature* (1995), argues that untrammeled nature no longer exists because humans have reshaped the planet. Wilderness, he proclaims, is entirely a cultural invention. Cronon argues further that the very idea of nature is a human creation and there is no way of relating to nature without culture. Notwithstanding their disparate perspectives, both Diamond and Cronon insist that they are analyzing an interaction between nature and culture. Diamond argues for the reality of human choice, especially in his later book, *Collapse: How Societies Choose to Fail or Succeed* (2005), and Cronon acknowledges that nature really exists and that there is a meaningful human cultural interaction with it. In *Uncommon Ground*, for example, he says, "the autonomy of nonhuman nature seems to me an indispensable corrective to human arrogance" (Cronon 1995, p. 87). Most environmental historians find themselves in a broad middle ground, although it is always more difficult for a scholar to define a balance than to stake out a radical position.

Other critics of environmental history have raised the charge of anachronism. These critics argue that the perception of environmental problems as such is an ephemeral, contemporary phenomenon, noting that the word *environmentalism* did not come into general use until the 1960s. Is environmental history, therefore, an attempt to read today's concerns back into past historical periods in which they were not operative or in which human participants were not conscious of them? The problem with this criticism is that it is fundamentally an argument against history itself as an intellectual endeavor. Modern problems exist in their present forms

Bare Landscape Outside Petra, Jordan, 1976. *This eroded and desiccated landscape near Petra, Jordan, shows the present results of environmental history in an area that human societies have used and misused over millennia. Terraces visible in the distance formerly bore flourishing agriculture, and the heights once had forests. While the causes are debated, the picture of degradation of the land seems undeniable.* **COURTESY OF J. DONALD HUGHES.**

because they are the results of historical processes. The relationship with nature was the earliest challenge facing humankind. It would take a particularly egregious form of denial not to see a precedent for the market economy in the exchange of a tribal nomad's meat and skins for a village agriculturalist's grain and textiles. The Columbian transfer of Europeans—along with their crops, weeds, animals, and diseases—to the New World in large part explains the history and present state of the Americas, as Alfred Crosby proposed in *The Columbian Exchange* (1972). Neither the European conquistadores and colonists nor the indigenous inhabitants of the Americas were aware of the existence of viruses and bacteria; is it anachronistic, then, for historians such as Crosby to detail the enormous political, social, and cultural effects of microorganisms on both sides of the Atlantic in the sixteenth and seventeenth centuries? The study of past effects of environmental forces on human societies and, conversely, the impact of past human activities on the environment, contributes to an understanding of the dilemmas of the contemporary world.

A third criticism is that narratives written by environmental historians tend to be ''declensionist''—that they invariably see human activity as the precipitant of environmental depredation. For example, the biologically rich forests of Brazil's Atlantic coast were hacked away from the time of conquest by Europeans down to the present, according to an exemplary environmental history by Warren Dean, *With Broadax and Firebrand* (1995). Also, the Mezquital Valley in Mexico, a productive region when farmed by pre-Columbian people, was transformed through overgrazing by Spanish sheep into ''an almost mythologically poor place renowned for its aridity, for the poverty of its indigenous inhabitants, and for exploitation by large landowners,'' according *A Plague of Sheep* (1997, p. 17), a compelling account by Elinor Melville. When expanded to the world scale, such regional examples become a story of global degradation, and it is hard to avoid expecting further catastrophe.

Does declensionist narrative have cautionary value? Today most historians assiduously avoid forecasting the

future, because earlier historians who ventured to describe coming events often turned out to be wrong. Hence the charge of insupportable catastrophism is largely unwarranted. Deterioration of the environment as a result of human activities is, in many cases, a fact revealed by careful research, not an inveterate prophecy of doom.

Historians are sometimes accused of being light on theory by their colleagues in philosophy, economics, and political science. Environmental historians have not escaped this criticism, which is sometimes deserved. There are notable exceptions, such as Carolyn Merchant in "The Theoretical Structure of Ecological Revolutions" (1987), Madhav Gadgil and Ramachandra Guha in "A Theory of Ecological History" (1992), and James O'Connor in "What Is Environmental History? Why Environmental History?" (1998).

Among the many possible dimensions of theory in environmental history, three merit mention here. One such dimension is that its subject includes nature and culture concurrently. In its simplest terms, it requires that a study can qualify as environmental history only if it considers and correlates change both in human societies and in the aspects of the natural world with which they interact. The relationship between the two is in almost every case that of reciprocal influence. A change made by humans in the environment virtually always rebounds and generates change in cultural conditions. A history that does not include both terms is not environmental history. This assertion may seem self-evident, but there are scholars such as A. T. Grove and Oliver Rackham who contend that environmental history is simply the history of the environment and define the environment as including "climate, geology, and geomorphology, not living things" (2001, p. 376). A history that includes living things, they insist, should be called ecological history. Even with the change in terminology, however, they focus attention on changes in the landscape, not social, economic, or other cultural changes. There is no doubt that such observations are useful; an environmental historian needs to know them to help in the reconstruction of the past, but he or she must retain human history and anthropogenic changes as integral parts of the narrative. Some might argue that to frame the inquiry in these terms makes environmental history an anthropocentric enterprise. So it is, but it must never lose sight of human interactions with the environment, including other forms of life.

A second dimension of environmental history has to do with methodology. It involves environmental historians' use of both history and science, their attempt to bridge the gap between what C. P. Snow (1959) called "the two cultures" (science and the humanities) within the modern academic community. Environmental historians, being historians, must be consistent and thorough in their employment of the historical method, searching out all the available written sources, subjecting them to external and internal criticism, and interpreting them carefully. Like all historians, they must pass disciplinary muster with their colleagues. But in order to understand the environment, they must become fluent in the language of natural science, capable of mining the insights of science. As Snow said, the failure to comprehend both sides of the cultural divide "is leading us to interpret the past wrongly, to misjudge the present, and to deny our hopes of the future" (1959, p. 60). The sciences provide much of the needed evidence for that account. Scientific techniques for studying ecosystems, biodiversity, climate, introductions of organisms, diseases, atmospheric chemistry, and many other factors of change are of obvious use to the environmental historian, no matter what period or region constitute the area of study. Environmental history developed in some measure out of the recognition that ecological science has implications for the understanding of the history of the human species, that all human civilizations, even the most technically advanced, are subject to the principles of nature. Ecology places the human species inside the web of life, dependent on it for subsistence and survival. One cannot deny the importance of scientific literacy in principle for environmental history, notwithstanding any practical difficulties this presents for the preparation and continuing education of environmental historians.

A third dimension of environmental history is that of scale in time and space. At its widest and longest, environmental history, as a scholarly effort, assumes a sweeping global perspective, stretching from dim beginnings to the present and even, dangerously, peering into the mist-obscured future. Some environmental histories, all equally scholarly, are narrowly focused on single region, say the Carolina piedmont, over a well-defined period, say during the Great Depression, and thus stand at the other end of the spatiotemporal scale. Environmental history can investigate every period in the human saga, from prehistory to the ancient, medieval, modern, and postmodern eras. The scope of environmental history is limited only by the consideration that human societies have always interacted with the natural environment, not by the idea that there was any particular mode of interaction or any particular form of recognition of that interaction. The common, even if sometimes unarticulated, idea that environmental history should be exclusively concerned with the modern world because of its accelerating rate of environmental change and environmental awareness, is naive. The ancient and medieval periods, in which the majority of human modes of environmental relationships and the institutions that surround them originated and developed toward their modern expressions, also merit careful study.

What holds true of time also holds true of space. Even though specific areas of study are delimited, for the

discipline in general the whole earth is the subject. Perhaps its purview extends even beyond the earth, because energy from the sun, the variability of the earth's orbit around the sun, meteor impacts, and the tides caused by the moon are also important environmental influences. Just as every modern historical moment is connected to a long formative past, so every locality or region exists within the setting of the ecosphere, and historians neglect that fact at their peril. Even to write the environmental history of a single garden requires a sense of its place on the planet. Each study must be limited to a particular place and time, however narrow or wide, because research and writing must have a stop, at least until the next book. But theoretically, serious environmental history by its very nature must recognize the many links to a more inclusive set of systems.

THE FUTURE OF ENVIRONMENTAL HISTORY

A number of issues are worthy of more attention by environmental historians. For example, a forum on the subject "What's Next for Environmental History?" in *Environmental History* (2005) includes brief essays by twenty-nine leading environmental historians, not all from the United States, on directions they detect and/or recommend for future work in this field. John McNeill calls issues like these "paths not (much) taken" (2003), and for him they include military dimensions, history of soils, mining, migrations, and the environmental history of the sea. Others that merit inclusion are growth of populations, the declining power of local communities over their own environments, the history of energy and energy resources, loss of biodiversity, and the effects of climatic change on human societies.

ENVIRONMENTAL IMPACT STATEMENT

Environmental impact statements (EISs) are reports of environmental assessments designed to identify and predict the environmental effects of proposed projects, programs, or policies. These statements usually are required by law for public agencies if their actions may have a substantial impact on the environment. Although primarily written for decision makers, EISs are published for public review and therefore serve as a conduit of information to a wide range of stakeholders.

THE ORIGIN OF EIS

EISs were first required by the 1969 U.S. National Environmental Policy Act (NEPA). Through NEPA, Congress legislated a national environmental policy. Although Congress weakened a proposed recognition that "each person has a fundamental and inalienable right to a healthful environment" (Caldwell 1998, p. 63) to a much weaker formulation—"each person should enjoy a healthful environment"—it nonetheless committed the federal government to "use all practicable means, consistent with other essential considerations of national policy," to act as "trustee of the environment for succeeding generations" and "assure for all Americans safe, healthful, productive, and aesthetically and culturally pleasing surroundings" (National Environmental Policy Act, §101). NEPA further created a three-member Council on Environmental Quality (CEQ). The members were to serve as advisors to the president and the Congress, interpreting environmental trends, appraising the programs and activities of the federal government, formulating national policies to promote and improve the environment, and promoting the use of NEPA's environmental policy by federal and state agencies.

Although NEPA devoted only one of its fourteen sections to the EIS process, EISs have emerged as NEPA's most important legacy. The EIS requirement was unique when enacted because, unlike most environmental laws that required specific substantive outcomes (such as cleaner air), NEPA instead stipulated a process for investigating and reporting environmental impacts. It did not obligate agency decision makers to choose environmentally preferred options, but rather required preparation of a "detailed statement" subject to interagency review, whereby agency officials might become informed of environmental concerns, aware of alternatives and mitigation strategies, and open to hearing the perspectives of the public and environmental agencies. In theory this information would improve agency decision making by enabling agency officials to integrate environmental quality into their decision making. The initial response by agencies to the EIS requirement, however, was tepid. Agencies prepared weak statements that officials largely ignored. Not surprisingly, agency-specific priorities were favored over environmental ones.

PUBLIC-INTEREST GROUP CHALLENGES AND THE COURTS

Whether intended by Congress or not, the EIS requirement significantly strengthened the role of public-interest groups in project assessment. As enacted, EISs were subject to external review and challenge under laws governing federal-agency review processes. A list of EIS elements presented in §102(2)(C)—namely, assessment of environmental impacts of the proposed action, unavoidable adverse effects, alternatives to the proposed action, relationship between short- and long-term effects, and irreversible commitments of resources—served as the basis

for these challenges and allowed EISs to become a vital tool for promoting environmental quality.

Environmental activists were quick to see this potential and, through lawsuits, greatly expanded the impact of the EIS requirement. Cases brought by a wide range of environmental groups, particularly the Natural Resources Defense Council and the Sierra Club, challenged agency interpretations of their obligations under NEPA. The suits focused on procedural questions about the adequacy of EISs, the range of alternatives that must be considered, conditions under which an EIS is required, and the substantive acceptability of decisions that neglected to minimize environmental impacts identified in EISs.

The courts were mostly sympathetic to procedural challenges, requiring strict compliance with specific EIS provisions as interpreted by the courts. Courts were split on questions of whether NEPA intended to substantively change agency decision making until two cases heard by the U.S. Supreme Court in 1978 and 1980. These cases determined that, although NEPA set forth significant substantive goals, its mandate to the agencies was essentially procedural. NEPA did not require agencies to elevate environmental concerns over other goals, nor were the courts empowered to overrule agency priorities.

FEDERAL AGENCY RESPONSE AND THE EIS PROCESS

As a result of early court cases that stopped many projects on procedural grounds, federal agencies increasingly sought to protect their projects from litigation by listing every conceivable environmental concern and impact, with little sense of priorities. EISs were often exceedingly long, with volumes of information presented to decision makers who lacked the capacity to interpret them. Although the CEQ published guidelines for writing EISs in 1970, 1971 and 1973, these guidelines were viewed as discretionary by other federal agencies and did not effectively rationalize the EIS process. Under President Carter's Executive Order 11992, which authorized CEQ to issue enforceable regulations, CEQ published more specific guidelines in 1978. These guidelines dramatically altered the conduct of environmental assessments by codifying EIS processes in ways that focused them on significant environmental issues and improved their usefulness to agencies and the public while reducing paperwork and delay.

Under CEQ guidelines, the initiating agency first conducts a concise, internal Environmental Assessment (EA). The agency may alter the initial proposal to mitigate environmental impacts at this stage. If the agency determines that remaining impacts are not significant, it issues a "finding of no significant impact" (FONSI). Otherwise, it produces an EIS.

The EA and FONSI process has significantly reduced the number of EISs produced each year. A 1993 CEQ survey estimated that while federal agencies prepared 50,000 EAs annually, more than 90 percent of these resulted in a FONSI. From a peak of 2,000 in 1973, the number of EISs declined to 370 in 1989 before rising to approximately 550 per year since the mid 1990s. Although seventy federal agencies are subject to NEPA, half of all EISs are produced by three agencies: the Forest Service, the Army Corps of Engineers, and the Federal Highway Administration.

If significant impacts are expected, the agency conducts a scoping procedure, with input from other agencies, the public, and stakeholders to determine the range of issues and alternatives to be addressed by the EIS. The scoping process allows for early input into the design and implementation of the EIS process. After conducting an Environmental Impact Assessment (EIA), the agency publishes a draft EIS that presents the analysis and the alternatives considered. The draft EIS may include mitigation measures to reduce environmental impacts. The draft EIS undergoes review by environmental agencies and is open to public comment. A final EIS is issued in response to this input.

If other federal agencies disagree with the final EIS, CEQ may arbitrate differences. If public-interest groups disagree, they may seek to block action through the courts. From a peak of 189 cases reported in 1974, approximately 100 cases a year have been filed since the early 1990s. Although early court cases usually strengthened the power of environmental activists vis-à-vis the agencies, later cases have yielded mixed results. Such lawsuits are often strategically used by activists to slow down specific projects, to allow time for political measures to be used to block or alter the project.

As environmental concerns have become more integrated into public decision making internationally and the EIA process has become more rationalized, EIS processes have spread extensively around the globe. EIS processes were established in over twenty-five U.S. states, primarily in the 1970s; in Canada, Australia, and throughout Europe in the 1970s and 1980s; and in nearly all nations outside of Africa and the Middle East since then. In addition, international agencies such as the United Nations Environment Programme (UNEP) have established guidelines, and international funding bodies such as the World Bank often require EISs as part of their approval process.

ONGOING CHALLENGES FACING EIS PRACTICE

Four challenges to EIS practice are particularly significant:

1. First, the emergence of the sustainability paradigm in the late 1980s, with its focus on integrating environmental quality into public decision making, has

called into question the traditional focus of EISs on projects, which precludes more integrated assessments of linked decisions. Systems for strategic environmental assessment (SEA) that apply environmental assessment procedures to more comprehensive policies, programs, and plans are therefore being developed.

2. Second, the environmental-justice movement, with its focus on the unequal impact of environmental decisions across society, has led to more careful consideration of social impacts in environmental assessments.
3. Third, the appropriate relationship between policy goal setting, which is fundamentally linked to values, and EIA inquiry, which seeks to apply principles of science and neutrality, is often hard to sustain in the design and implementation of EIA processes and in political decision making. The role of affected stakeholders in the design, conduct, and use of EIA processes remains of central concern.
4. Finally, although efforts to standardize and bureaucratize the EIS process have allowed agencies to incorporate EIAs into their procedures, they have also largely neutralized the potential of EIAs to promote more integrative environmental policy. Bureaucratic decision making essentially dissects environmental choices into piecemeal decisions, thereby marginalizing efforts to manage the environment more systemically.

To achieve the comprehensive incorporation of environmental quality into national and international decision making envisioned in NEPA, the EIS will need to evolve with and into new governance systems, ones that stretch across bureaucratic lines to encourage participation, information exchange, and collaboration across public, private, and jurisdictional divides. EIS processes will increasingly need to promote more holistic and sustainable policy, integrated into partnerships such as those envisioned for community-based environmental-management systems and natural resource-based planning councils.

ENVIRONMENTAL JUSTICE

Environmental justice, in theory and in practice, addresses a wide range of issues, combining the concerns of social justice and environmentalism. Scholars in this field typically view the environment not as a purely natural phenomenon but as a set of socially and politically conditioned relationships; hence writings on this subject often examine the social, cultural, and political settings in which people live, work, and play.

Environmental justice encompasses a variety of notions of justice: distributive, participatory, political, and cultural. The field has generated interdisciplinary contributions from scholars in philosophy, legal studies, cultural studies, history, literature, the arts, the social sciences, and the "hard" sciences, especially biology. Citizens and activists have also made major contributions to the literature and activities of the environmental justice movement (EJM), an informal designation that is commonly applied to the international body of theory and practice that has grown up around this concept. For instance, the Soshisho movement of Japan is one example of an EJM, launched on behalf of the victims of Minamata disease, a debilitating intergenerational neurological disorder caused by a chemical factory's release of methyl mercury into industrial wastewater from the 1930s through the 1960s; the toxins bioaccumulated in the local fish and shellfish consumed by the local population. In a similar vein the Latheen Catholica Matsya Thozhilali Federation is a grassroots organization fighting for traditional fishing rights and equal representation of artisanal fishers in Kerala, India. Other examples include the decades-old Australian Aboriginal civil rights movement and the Green Belt Movement in Kenya, led by the 2004 Nobel Peace Prize winner Wangari Maathai. The international scope and gathering influence of this fusion of social-justice and environmental concerns prompted Lois Gibbs (the founder and director of the Center for Health, Environment, and Justice)

to comment that "the EJM is the fastest-growing, largest social movement in the world" (Gibbs 2003).

THEORETICAL DIMENSIONS

Environmental justice movements usually advance issues and principles of distributive fairness. It poses questions such as, How are environmental benefits and burdens distributed across populations? In what ways are citizens compensated for inequities in environmental burdens? What are the acceptable moral, social, and physical criteria for the distribution of environmental burdens? Examples of environmental burdens include exposure to industrial pollution and hazardous materials, unsanitary or unsafe working conditions, the exploitation and loss of traditional environmental heritage, and the depletion of essential natural resources. Environmental benefits include access to clean, safe environments at home and at work, and access to nonindustrial milieus like national parks and forests and regional open-space preserves.

In the United States the EJM or environmental justice movement began to pose issues of distributive justice as it became clear that a disproportionate burden of environmental harms was falling on African Americans, Latino/a Americans, Native Americans, Asian Americans, the working class, and the poor. Distributive-justice analyses not only delineated inequities but also focused attention on the hidden processes of political influence and decision making that have underlain this inequitable distribution of environmental burdens.

ENVIRONMENTAL JUSTICE IN THE UNITED STATES

The modern U.S. EJM environmental justice movement began with the merging of civil rights and environmental concerns in the communities of the poor and people of color during the early 1980s. There were several precursors to this movement. Robert Gottlieb, in *Forcing the Spring* (1993), notes environmental justice concerns reaching as far back as the nineteenth century. Urban environmentalism arose during the Progressive Era of the early twentieth century, which saw efforts like Jane Addams's and Alice Hamilton's Chicago's Hull House, a fusion of ideals of community development and scientific investigation that prefigured environmental sciences such as epidemiology. Their activism also anticipated latter-day environmental concerns about protecting workers against hazardous materials and limiting residential exposure to toxic industrial and municipal waste.

The civil rights movement in opposition to segregation in the South, led by Martin Luther King Jr. during the 1950s and 1960s, gave rise to concerns about the inequitable burdens suffered by African Americans in housing, health, and working conditions. In the 1960s and 1970s the United Farmworkers Union, led by César Chávez and his key negotiator, Dolores Huerta, led the struggle of Chicano and Filipino-American migrant farmworkers against unsafe working conditions, labor discrimination, and pesticide contamination. Native Americans have long fought for land rights, cultural and tribal sovereignty, and healthful living conditions. Another watershed event in the U.S. environmental justice movement was the campaign led by Lois Gibbs and the Love Canal Homeowners Association, which sparked the national antitoxics movement by forcing state and federal agencies to relocate more than 900 families from their neighborhood, which had been built on top of 21,000 tons of buried chemical waste. Gibbs's example inspired many other women to take up the cause of environmental justice as well. Indeed, since the 1970s a vast majority of grassroots leadership in the movement have been working-class women, many of whom are women of color. These movements and events combined to spur journalistic and scholarly investigations into environmental injustices beginning in the 1980s. The combined force of these grassroots movements and academic studies had buoyed the U.S. environmental justice movement EJM to a position of enduring influence by the turn of the twenty-first century.

A critical milestone for the environmental justice movement occurred in 1982, when 500 arrests resulted from nonviolent civil-disobedience protests against a new toxic landfill in Warren County, North Carolina. Located in a community with a largely African-American population, within a county with the highest percentage of African Americans and the second-highest poverty level among North Carolina counties, the landfill initially contained toxic soil laced with polychlorinated biphenyl (PCB), a carcinogen. Despite these protests, the landfill remained open for several decades. Eventually, treatment of the contaminated soil beginning in 2002 lasted over a year; the contaminants of 82,000 tons of soil were shipped to an incinerator, while soil was returned to the landfill. On January 12, 2004, the landfill received a "closure celebration," but Robert D. Bullard, leading scholar on environmental racism, contends the community of Afton is owed both formal apology and $18 to $20 million, according to different reparation formulas (Bullard 2004).

In the wake of the Warren County protests, the U.S. Government Accountability Office (GAO) issued *Siting of Hazardous Waste Landfills and Their Correlation with Racial and Economic Status of Surrounding Communities* (1983), a study of the incidence of hazardous- waste facilities in minority and poor communities in the Environmental Protection Agency's (EPA) Region 4 (composed of eight southeastern states encompassing six Native American tribes). With this study's confirmation of a higher incidence of such facilities in these communities, a spate of follow-up studies appeared, the most controversial of which was the

first nationwide study, *Toxic Wastes and Race in the United States* (1987), undertaken by the United Church of Christ's Commission on Racial Justice (UCC). This study reported that "although socioeconomic status appeared to play an important role in the location of commercial hazardous waste facilities, race still proved to be more significant" (UCC 1987, p. xiii). This conclusion gave rise to concepts like *environmental discrimination* and *environmental racism*, the latter term receiving its widest circulation up to that time in Reverend Dr. Benjamin F. Chavis Jr.'s presentation of *Toxic Wastes and Race* to a 1987 meeting of the National Press Club in Washington, D.C. Chavis described environmental racism as "racial discrimination in environmental policy making, and the unequal enforcement of environmental laws and regulations ... the deliberate targeting of people of color communities for toxic waste facilities ... the official sanctioning of the life-threatening presence of poisons and pollutants in people of color communities for toxic waste facilities ... the history of excluding people of color from the leadership of the environmental movement" (Chavis 1993, p.4).

The study by the UCC invokes three fundamental dimensions of justice: distributive, participatory (decision-making power), and recognition (exclusionary history). The distributive dimension is evident in least-resistance strategies, whereby government officials determine the location of toxic facilities, compensation, and remediation procedures according to the racial, ethnic, religious, and socioeconomic character of communities. For instance, the 1984 report *Political Difficulties Facing Waste-to-Energy Conversion Plant Siting* was compiled by the Cerrell Associates, Inc., a private consulting firm hired by the California Waste Management Board. The report advised the state to target neighborhoods based upon characteristics of high unemployment, high-school (or lower) average education levels, and Catholic congregations. Furthermore, the report insisted "middle and higher socioeconomic strata neighborhoods should not fall within the one-mile and five-mile radius of the proposed site" (Bullard 1993a, p.18). A similar instance was a report that evaluated the political feasibility of siting a low-level radioactive waste dump in North Carolina (Gibbs 1998, p. 2). The North Carolina Radioactive Waste Management Siting Authority hired Epley Associates, a public relations firm, to assist in this process. According to the Epley report likely targets for least-resistance siting are "black populations," and their residential structures are termed "shacks" (Gibbs 1998, p. 2).

A 1992 investigation in the *National Law Journal* published the results of an investigation into every U.S. environmental lawsuit over a period of seven years, as well as every residential toxic waste site over a twelve-year period of the EPA's Superfund program. The investigation was intended to decipher if any significant differences between white and minority communities existed in the EPA's designation, compensation, and remediation strategies. This work uncovered dramatic differences between white communities and people of color communities in the time it took to mitigate hazardous sites; there were also marked disparities in compensation measures, the penalties against polluters and violators of pollution-law, and the stringency of cleanup solutions. The findings, authored by Marianne Lavelle and Marcia A. Coyle, indicated that "racial imbalance ... often occurs whether the community is wealthy or poor," with white communities protected by higher fines and faster and more rigorous cleanups at a time when more and more studies revealed minorities were bearing a significantly larger brunt of hazardous wastes nationwide (Lavelle and Coyle 1993, p.136).

The UCC report also revealed the existence of saturation strategies against people of color and poor communities. Once a community receives a toxic waste facility, the chances for more facilities rise considerably: "In communities with two or more facilities or one of the nation's five largest landfills, the average minority percentage of the population was more than three times that of communities without facilities (38% vs. 12%)" (UCC 1987, p.xiii).

Critics of these studies challenge their methodology, their definitions of community, and the ways in which they define the terms *race* and *racism.* One challenge to methodology concerns the basis used to define a community that is at risk. The UCC report used zip codes to define the communities studied. A University of Massachusetts study by Doug Anderton and others (1994), funded by Chemical Waste Management (CWM), argued that census blocks, as opposed to zip codes, are a better demographic device for determining the distribution of hazardous-waste facilities. The report concluded that industrial workers suffered the most burdens of toxic-waste siting and that an analysis according to race and ethnicity did not reveal any notable trends. This study, however, drew criticisms for flaws in its own methodology. Anderton's group used older styles of census readings that avoided populations over 50,000 people and therefore omitted two of CWM's largest hazardous-waste facilities: one in Kettleman City, California, a community with a population that is 95-percent Latino, more than 40 percent of which speaks only Spanish; the other in Emelle, Alabama, known as the "Cadillac of landfills," well documented in environmental justice literature because of its huge size and location in a predominantly African-American community.

Today census blocks are far more closely specified. The 2007 UCC publication, *Toxic Wastes and Race at Twenty: 1987–2007*, is the first national study to use the 2000 census measurements; the authors, all key veterans of this debate, conclude, "Although the current assessment uses newer methods that better match where people

and hazardous waste facilities are located, the conclusions are very much the same as they were in 1987'' (UCC 2007, p. 12). Another asymmetry between the Anderton and UCC studies is in the subjects themselves. The UCC included five minority groups under its rubric of ''race,'' whereas Anderton concentrated only on Latinos and African Americans.

Other key variables relate to time and markets. The law professor Vicki Been (1994) has observed that studies of the locations of environmental burdens do not indicate whether the residents came to the nuisance or the other way around. Pinpointing these patterns is vital for understanding the distributive dimension of environmental racism, and it sometimes contravenes some of the saturation and least-resistance arguments. Property values are known to decline when industrial facilities, especially hazardous-waste facilities, are located nearby. Poorer citizens may very well be drawn to lower property values, and more affluent citizens may enjoy even greater mobility in moving away from burdens before experiencing the loss of property value and self-esteem. On this account maximizing efficiency and cognizance of market forces are attributed not only to the corporations and agencies siting facilities but also to the average consumer, job seeker, and home buyer: If people have less money, they might be inclined to move closer to work and buy cheaper homes; if they have less education, they might seek out industrial jobs. Been's challenge does not necessarily rule out racism in the market, in zoning decisions for commercial and residential areas, or the institutionalized elements of racism that play out in education, lending institutions, or health care. But she does suggest that these characteristics are secondary to the market dynamics of siting decisions.

Another market-logic challenge in the distributive vein focuses on compensatory packages. Communities could either approach or be approached by corporations and agencies for the locally unwanted land use in order to compete in one of the few markets available to areas with high unemployment or abandonment by industries. Facilities bring jobs and revenue, and corporations and agencies often offer millions of dollars in benefits in exchange for community acceptance of a facility. In the case of Emelle, Alabama, CWM supplies hundreds of jobs and millions of dollars in paychecks and community development. Nevertheless, the question of equitable distribution of burdens persists. For instance, various school districts in Emelle have different racial makeups and do not receive the same amounts of community-development funds; there are also infrastructural differences between black and white neighborhoods. Furthermore, the jobs/revenue-compensation argument must confront the moral issue of whether some communities are so desperate that they are likely to accept burdens (under particular compensatory packages) that more prosperous towns would not accept. The Mescalaro Apache Tribe reportedly sought to host a temporary radioactive waste facility for forty years, but, as Kristen Shrader-Frechette (2005) argues, the options available to the tribe and its history of poverty and isolation left it vulnerable to pressures to yield to steep environmental costs. This echoes the problems of least resistance strategies, but supporters argue to block the voluntary and compensated siting is an act of paternalism against the tribe's wishes. Shrader-Frechette argues that this anti-paternalism argument oversimplifies the vulnerabilities of the tribe to accept, including the lack of state and local environmental enforcement on the reservation as well as the participatory limits of tribal members. In addition, traditional political theory does permit a limited paternalism when third parties could be harmed by the decision. In this case, Shrader-Frechette defends the limited paternalism argument on behalf of third parties, which ultimately kept the facility from being constructed (Shrader-Frechette 2005).

The tendency in market forces logic is to rely on least-resistance strategies and therefore to undermine the extent to which communities (and even city governments) can be fully informed and self-interested political agents. In Emelle, for example, some accounts report that residents believed that the facility was going to be a brick factory. In Kettleman City, hearings and environmental-impact reports dramatically underestimated the resistance of the Spanish-speaking residents, who formed *El Pueblo para Aqua y Aire Limpio* (People for Clean Air and Water) to mobilize against CMW on the grounds that they had not been granted full participation in and knowledge of the process.

Peter Wenz (2001) addresses the issue of environmental racism by appealing to a strict principle of distributive justice—the principle of commensurability—which dictates that, all things being equal, citizens enjoying environmental benefits (pertaining to consumption of resources) should bear commensurate environmental burdens. He proposes to distribute environmental burdens to those who consume the most and who enjoy the most environmental benefits, particularly the most affluent communities in the United States. Wenz argues that this policy would lead the most politically influential citizens to dramatically reduce consumption and/or abate the impact of industrial pollution. Wenz's insight is that it is unjust—even if currently legal—to channel noxious wastes and pollutants to economically disenfranchised populations who do not deserve to suffer burdens imposed by the high consumption levels that others enjoy. Wenz projects that redistributing the waste to those enjoying commensurable benefits would eliminate approximately 70 percent of the environmental racism in the United States. But, this claim depends largely on reducing race and ethnicity of minorities to socioeconomic characteristics, and also overlooks

some of the points made by the studies mentioned above regarding instances where socioeconomic characteristics are secondary to the racial and ethnic demographics of a community. Reflecting on Been's market forces argument, Wenz's proposal underestimates the mobility of affluent communities away from environmental burdens, and the mobility that market forces create for poor and minority communities who may be drawn to the environmental burdens as a result of historical and social stressors that lead these populations to live closer to industries where low-skilled, undesirable jobs are available and transportation and property costs tend to be significantly reduced. It also underestimates the importance of grassroots identity in environmental justice and the charge of *discriminatory environmentalism*, which refers to the dramatic underrepresentation of minorities in the mainstream environmental-organization membership. This point brings out the participatory and recognition dimensions of environmental justice. For instance, people of color, the poor, and indigenous communities have little representation in state and federal environmental agencies, the environmental-science sector, and the environmental-law sector. Thus, while distributive justice may assume equality and rights of citizen participation, without the strong history and place-based identity citizens require, this dimension of environmental justice can also effectively abstract the identity of peoples to a universal context, while the grassroots struggles of environmental justice advocates require much more specific, case-by-case attention to and respect for the lives, identities, and values of community members. Indeed, the *Principles of Environmental Justice*, adopted by the First National People of Color Environmental Leadership Summit, Washington, D.C., in 1991, include only two references to distributive justice in the seventeen principles. The remaining principles emphasize participatory justice and recognition justice, including rights against discrimination, decision-making equality for disenfranchised and marginalized identities, and respect for diverse cultural perspectives. Iris Young's "Justice and Hazardous Wastes" (1983) challenges strictly distributive-justice approaches for failing to take into full consideration the principle of self-determination, which would require that citizens experience the decision-making power over the political actions that would affect them the most—in this case, whether or not it is acceptable to receive an environmental burden. Young further develops her thesis with Christian Hunold over a decade later in 1998, arguing for substantive and procedural conditions of communicative democracy in the decision-making process. Under these conditions, citizens would experience self-determination upon the initial phases of toxic waste discourse, including the location of sites, the scientific and political requirements, the compensatory and safety measures, the ability to decline the burden, and ultimately a substantive voice in the determination of whether or not the very industrial practices that produce the waste should be part of the consumption chain of a society.

ENVIRONMENTAL JUSTICE AND THE LAW

The courts have played a major role in determining the course of environmental justice in the United States. A host of early cases challenging the inequitable distribution of environmental burdens on African American communities were confounded by, on the one hand, defining racism according to constitutional law, in which the Fourteenth Amendment's Equal Protection Clause requires evidence of intentional discrimination on the basis of race and ethnicity; or, on the other, according to congressional law, in which specifically Title VI and other elements of the Civil Rights Act of 1964 includes disparate impacts on different racial and ethnic groups. Appealing to the 14th Amendment is known as the "intent standard," while appealing to the Civil Rights Act of 1964 regards the "effects standard." Environmental justice advocates have long argued that in post-segregation America, where legal and structural racism have been stricken from the law books, unintentional and institutional forms of racism are increasingly significant measures; hence they appeal to Title VI. Echoing Chavis's early definition of environmental racism, Bullard has also offered a preferred definition of "any policy, practice, or directive that differentially affects or disadvantages, whether *intended* or *unintended*, groups or communities based on race"; this definition provides an argument in favor of the effects standard (Bullard 1993b, p. 47). But the courts have not always applied this standard in their rulings.

Despite the U.S. Supreme Court decision in *Griggs v. Duke Power Company* (1971), which called for the evaluation of racism according to the effects rather than the intent, subsequent landmark cases on environmental racism in the Supreme Court and lower courts have consistently ruled according to the intent standard. Most notably, in *Village of Arlington Heights v. Metropolitan Housing Development Corporation* (1977), *East Bibb Twiggs v. Macon-Bibb County Planning and Zoning Commission* (1989), and *R.I.S.E., Inc. v. Kay* (1991) communities pleaded environmental racism on the basis of the Title VI standard of effects, but in these decisions the courts ruled by evaluating racism under the conditions of historically overt racist intent under the provisions of the Fourteenth Amendment. Ironically, using California environmental law rather than federal civil rights law, the court in the Kettleman City case sided with *El Pueblo* against CMW on the grounds that the democratic participation required was obstructed by English-only documentation and an environmental impact

report that failed to account for the accumulation of burdens (its preexisting site, the poor air basin, and the chemical exposure residents experience as agricultural workers). For environmental racism activists the Kettleman City case indicates that language is also a marker for environmental justice and discriminatory practices (Figueroa 2001, Cole and Foster 2001).

Environmental justice advocates continue to press the Title VI interpretation of racism, which explicitly requires the involvement of a federal agency in redressing the pattern of disparate inequities. The primary logic of this strategy is that because the EPA must assess the installation of any legal facility and aforementioned empirical studies such as the *National Law Journal* assessment of EPA practices were building a case at the federal level, Title VI interpretations had legal standing. Involving the EPA, which has representation at the level of the president's cabinet, brought the environmental racism controversy to a level of federal involvement that the EJM had not seen since 1981, when President Jimmy Carter signed the evacuation and buyout order for the Love Canal residents. People of color communities forged networks of environmental justice, and the First National People of Color Environmental Summit (1991) indicated the existence of a much larger collective force than could be mustered by the ad hoc, single-issue community groups that had, until then, been pushing the agenda of environmental justice.

Federal involvement reached into the U.S. House of Representatives Judiciary Committee in March of 1993 at a series of hearings titled "Environmental Justice: Hearings before the Subcommittee on Civil and Constitutional Rights." The hearings heard testimony from key scholarly and activist champions of the EJM; it also heard from advocates of market forces arguments. The hearings led to a consensus view that minority communities and the poor of the nation were indeed bearing the inequitable distribution of environmental burdens, even if there was contention over whether race and ethnicity or socioeconomic status was the key consideration. In response, on February 11, 1994, President Bill Clinton issued Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations." It required every federal commission to take cognizance of environmental justice considerations in matters such as interagency cooperation, policy overhaul, research development, enforcement of right-to-know laws, and judicial review.

A heightened sensitivity to issues of environmental justice from the 1980s onward did not always translate into tangible results. For example, Benjamin Goldman and Laura Fitton's *Toxic Wastes and Race Revisited* (1993) documented worsening conditions and burden disparities for minorities. A more effective federal approach found hope when the EPA initiated the 1998 Interim Policy on Title VI, which explicitly assesses disparate impacts and emphasizes effects rather than intent. The same year the EPA Interim Policy was put into place, residents in Convent, Louisiana, were able to use it against the Shintech Corporation, and force a halt to construction of a highly polluting plant in the town. Nevertheless, the current aggregate risk-assessment standards employed by the EPA still often disregard disparate impacts, as documented in the updated 2007 UCC study. Many analysts have pointed to the federal government's slow and woefully inadequate response to the disastrous consequences of Hurricane Katrina—which afflicted mostly poor African Americans—as a confirmation of this interpretation.

GLOBAL ENVIRONMENTAL JUSTICE

Environmental racism is only one of the concerns of the environmental justice movement. For indigenous and marginalized peoples—not just in the United States but around the world—environmental justice also extends to issues of colonialism, the global environmental commons, and the effects of the corporate globalization. The concerns of global environmental justice began to emerge in the 1970s, when international agencies began to tout the merits of sustainable development. The "Declaration of the United Nations Conference on the Human Environment," issued in Stockholm in 1972 (UNEP 1972); *Our Common Future* (the Brundtland Report) (1987); and Agenda 21, authored at the UN Conference on Environment and Development (Earth Summit) in 1992 (UNDESA 1992) express the sovereign right of nations to manage development practices. These conferences addressed the dilemma faced by the globalSouth nations whose ambitions for industrial development are increasingly constrained by growing concerns about climate change, biodiversity, and dwindling natural resources.

Ironically, the nations of the global North—whose industrial development and overconsumption of resources has contributed so heavily to these problems—are now among the most vehement in advocating pro-environmental measures, which many less-developed nations resent as a curb on their economic development. Appeals to technological solutions complicate the picture by proposing remedies that are affordable only by the wealthier nations. Sustainable development discourse has proved problematic for global environmental justice movements. In order to address issues such as the ecological debt the North's development is owed to the South's restraint upon development, as well as the impending crisis of overpopulation in many areas of the globe in the face of climate change, sustainability discourse has shifted from development emphasis to an increase of "environmental sustainability" (Agyeman, Bullard, and Evens 2003) as "environmentally benign development"

became a catch phrase of these movements. The burdens of climate change are likely to increase environmentally displaced populations (environmental refugees) by a factor of five, affecting as many as 250 million people by 2050. Moreover, the displaced populations will not only be dramatically overburdened, but they will themselves become the environmental burdens to populations who receive the migrations.

Distributive, participatory, and recognition justice are fundamental to environmental justice movements throughout the globe, however much their demands and goals might differ in details. As Daniel Faber and Deborah McCarthy have observed, these movements are "united in the larger struggle for ecological democracy. . . . For the organizations within these various wings all share a passion for linking grass-roots activism and participatory democracy to problem-solving the issues of environmental abuse, unsustainable economic development, racial oppression, social inequality, and community disempowerment" (Faber and McCarthy 2003, p. 46).

ENVIRONMENTAL LAW

Environmental law deals with two different categories of issues. The first category relates to the protection of human health and welfare and involves primarily issues such as pollution of air and water and contamination of soils. The federal Clean Air Act and Clean Water Act are the best-known examples. In its largest scope this category also includes climate change and the massive impacts it may create, such as rising sea levels and the displacement of large populations, as well as water shortages and/or floods. The Kyoto Protocol, the 2005 international framework treaty for controlling global climate change, is the best-known example. The second type of problem, best known in the form of the federal Endangered Species Act and the Wilderness Act of 1964, involves the protection of nature and is directed toward loss of biodiversity or protection of natural amenities as an aesthetic value. At a much more far-reaching level, environmental claims for protection extend to assertions that the earth is a self-regulating system that has its own imperatives, though such claims have little support in existing laws. Whether environmental law should be viewed as including issues of animal rights and the suffering of individual sentient creatures remains a matter of debate, though laws prohibiting cruelty to or mistreatment of animals have been in effect for generations.

The first category of environmental law, though it takes new forms in modern society and raises a number of complex issues of public policy, falls within the conventional theoretical framework of the law: It may be thought of as nuisance and trespass law writ large. The second category, however, engages a broad range of ethical and philosophical issues that pose novel challenges to jurisprudential thought.

UTILITARIAN CONCERNS

Utilitarian thinking dominates in the first category. There is little if any dispute about the responsibility of the law to protect human health and security. The primary questions involve how the society collectively should deal with risk, a matter in which individual preferences vary. Are nuclear plants safe enough if it is known that there is a one in a thousand, million, or ten million chance of a serious accident? How much should industry be required to spend to save each human life? How much data is needed to prohibit a potentially harmful behavior (the problem of the so-called precautionary principle)? What should people do in the face of inevitable ignorance (for example, scientists lack certainty because they cannot experiment on human subjects)? Another aspect of the problem arises from uncertainty about the future and whether policy should be based on technological optimism or technological pessimism. The classic example, known as Malthusian pessimism, was the claim that an increasing population would outrun the food supply. That concern came to be considered obsolete in view of modern improvements in agricultural productivity. The renewed debate about the ability to sustain growing populations with limited reserves of petroleum or water versus the claim that human ingenuity is the most reliable and inexhaustible resource illustrates the central policy conflict in contemporary society.

The role of science also is subject to considerable debate and often misunderstanding. The ability to respond intelligently to environmental issues is almost always science-dependent but not science-determinative. It is impossible to think clearly about what must be done unless people have some idea of what is at stake. Science usually can provide good data on risk, but it cannot determine how risk-averse people should be. Moreover, the distinctions science makes for its own purposes of research and understanding do not necessarily conform to distinctions that the law should make. For example, it may be interesting for research purposes to maintain every possible variation in the salmon spawning habitat, but there may be legitimate cost concerns or competing human needs that make such protection seem unwarranted as a matter of public policy.

Sometimes legitimate values are in conflict. One controversial example is the tension between advocates for free trade and advocates for increased environmental protection. Import restrictions on tuna that were designed to promote dolphin-safe tuna fishing constitute a well-known example. Such efforts usually are opposed by free-trade advocates because of their potential to serve as economic protectionism, insulating domestic industries from foreign competition.

Two Views of the Denver Skyline, 2004. *The same skyline is seen only two days apart, first on a clear day and next on a morning filled with smog. Scientists at the Environmental Protection Agency, among others, continue to look at options for healthier air by tightening smog standards. Over half of the United States breathes in illegal levels of smog, mainly in large cities on the East Coast and West Coast. The greatest challenge for contemporary environmental law is creating precedent in an issue, protection of the natural world, that was rarely before seen as a societal priority.* **AP IMAGES.**

Such debates sometimes are viewed as inappropriate not simply as examples of different perspectives on policy but as ethically tainted. The question then turns to whether environmental protection, at least in some contexts, should be treated as trumping other societal demands in the way constitutional values such as free speech and religious freedom prevail over other claims. From a purely legal perspective that position has no historical support, at least as far as the U.S. Constitution is concerned, and environmental values are not encompassed within any traditional concepts of natural law. Whether law should seek to embody certain environmental values as having such higher-order standing has been debated and remains unresolved.

ADDING AN ETHICAL DIMENSION: LOSS OF BIODIVERSITY

The second category of issues mentioned above, of which loss of biodiversity provides the most familiar example, presents a rich mix of philosophical and ethical concerns that have drawn the legal system into unfamiliar territory. Of course, even the most far-reaching claims for the need to protect biodiversity can be and often are based on utilitarian considerations. The utilitarian approach notes that the biological heritage is a storehouse of potential knowledge that can generate cures for diseases and scientific advances. The basic claim here is that failure to act is imprudence rising to the level of collective gross negligence.

At a more philosophical level those considerations conjoin with concerns about intergenerational equity and are put forward as ethical obligations. The notion is that the biological heritage is the product of the entire evolutionary history of the earth and is effectively essential biological capital. Any decision that imperils that capital, made by a particular group at a particular moment in time, is said to act as a kind of mortal wound to all humanity through all time and is seen as an act of supreme and unjustified arrogance. That idea has been expressed by the scientist Edward O. Wilson in *The Diversity of Life*:

> Humanity coevolved with the rest of life on this particular planet; other worlds are not in our genes. . . . [I]t is reckless to suppose that biodiversity can be diminished indefinitely without threatening humanity itself. Field studies show that as biodiversity is reduced, so is the quality of the services provided by ecosystems. . . . The loss of a keystone species is like a drill accidentally striking a powerline. It causes lights to go out all over. (Wilson 1992, pp. 347–348)

INTERGENERATIONAL EQUITY

Declining biodiversity also triggers debates over sustainability and thus over what is called intergenerational equity: the asserted responsibility of the present generation to the future. In general the law recognizes no such responsibility, though there are rare exceptions, such as the notion that a monarch is merely a trustee of the crown jewels and must pass them on to his or her successor. The usual rule is to the contrary: A rich person can spend his entire fortune and leave nothing to his children; a landowner can cut down her ancient forest and leave the soil bare. There are prudential economic notions that effectively benefit future generations, such as spending only one's income and preserving capital. There also are statutes that call for practices such as sustained-yield forestry, but no extant legal principle that mandates limits on contemporary behavior in order to safeguard resources for future generations.

This issue has generated much discussion, including questions such as whether standard economic discounting techniques should be applied to environmental issues. For example, everyone agrees that the right to get a dollar today is vastly more valuable than the right to get a dollar a century from now. The obvious reason is that because money earns interest that is compounded year after year, it would take only a tiny sum today to produce a dollar a hundred years from now. To apply this reasoning to an environmental issue, one may take the example of a very slowly recharging aquifer containing groundwater that sustains an agricultural area. If people continue to pump at current rates, there will be no water left for their descendants a century from now. Should people pump only at a rate that will make water equally available a century from now, or should they calculate that a gallon used today is so much more valuable than a gallon that will not be used for a hundred years that prudence dictates using it now? The question is whether these two situations are really comparable. It would be foolish to trade today's dollar for a future dollar, but would a person be foolish to trade the current added benefit from pumping against his or her great-grandchild's livelihood?

Perhaps such questions should be seen as variations on the optimism/pessimism divide that was mentioned above. Although one sometimes hears the issue characterized with the dismissive expression "what has posterity ever done for me?" or the claim that no one is here to speak for the future, people do care about the future, though usually with a focus on their own descendants. It may be that the operative divide is between optimists who believe that new discoveries and new technologies have always provided inventive ways to deal with the world as future generations found it and pessimists who see precaution as the only decent course of action. Or perhaps the problem is essentially a psychological one: People tend to focus on satisfactions that come from immediate gratification and to underestimate potential risks that seem distant. Whatever the explanation, it seems unlikely that the problem is simply the absence

of anyone extant who can speak for the future. Surely it goes far deeper than lack of legal standing in court for people who have not been born.

ENVIRONMENTAL JUSTICE

Another issue in which benefits to some may entail harm to others is called environmental equity or environmental justice. The most environmentally unfriendly facilities, such as heavy industry and waste disposal sites, often are sited in areas where poor people live. This is distressing but not surprising. Real estate prices reflect amenity value. One would not expect the richest people to live next to the local landfill while the poorest lived in areas overlooking Central Park. An analogous problem arises on the international level. As richer countries raise their environmental standards, harmful activities tend to migrate to nations that have lesser restrictions but need and want economic development. When that happens, from an environmental perspective the problem is not addressed; it simply is moved to a less resistant location.

The legal question is what sort of remedy is called for. Is the problem lack of equal protection against environmental harm? Or should it be sufficient to demand a minimally acceptable environmental standard for all while accepting some differences growing out of differential wealth or differing luck in where one happened to be born? Nothing at the heart of this issue seems to be unique to environmental law. These are effectively human rights issues that parallel the controversies raised by differential standards for worker safety, educational opportunity, and basic health care independently of wealth or nationality.

BIOCENTRISM AND HUMAN VALUES

The environmental issue that is least familiar to the legal tradition arises from the demand to preserve nature for its own sake regardless of human needs or desires. This issue goes under various names, such as biocentrism and ecocentrism, and the sources for such claims are various, among them the biblically founded assertions of the stewardship responsibility of humankind to safeguard God's creations as well as secular claims built on the view that the natural world has value independent of any benefits it may generate for people. A related view known as the Gaia hypothesis asserts that the earth is a living entity, a self-regulating functioning system that operates by principles that are independent of the goals of human societies. The power of these theories, insofar as they are accepted, lies in their capacity to trump the usual arguments made in favor of balancing interests against one another, for example, reduced harvesting of ancient forests versus the provision of more affordable housing.

NOVEL CHALLENGES TO THE LAW FROM BIOCENTRISM

Once human valuing is removed from the equation, it seems fair to say that the traditional legal system is at a loss about how to proceed. Essentially, the law is structured to implement societal preferences and enforce human rights, whether civil rights such as freedom of speech, property rights in a house or a contract, or entitlements to a pension or an education. People have preferences and goals, and people have rights. Some thinkers believe that at least some animals also should have rights, for example, the right to humane treatment that prevents suffering or avoidable suffering, though at bottom this also may be a human value about how animals should be treated.

But can trees have rights? The issue first was raised by Christopher Stone in 1972 in an article titled "Should Trees Have Standing? Toward Legal Rights for Natural Objects." Although cases have named plants or animals and even rivers as plaintiffs, the courts have never deviated from the traditional view that some human interest (though it may be recreational or aesthetic rather than economic) must be affected adversely for there to be legitimate standing to bring a legal action.

Moreover, however plausible the notion that inanimate objects have existence rights may be as a philosophical position, it presents extraordinary challenges to the legal system. If nature has rights, as opposed to people deciding about the societal desirability or necessity of preserving specified natural values, what would the rights of nature be? Would trees have a right not to be chopped down? Would some trees have more rights than others (rare ancient redwoods versus imported, fast-spreading eucalyptus)? Once one is in a legal milieu, these are the sorts of questions that must be answered. A judge or a legislature would have to decide if anyone, or everyone, cutting down trees, for whatever purpose, must be enjoined. Perhaps the closest the law has come to this notion is the federal Endangered Species Act, which requires protection for species whose continued existence, as determined by scientific studies, is found to be in jeopardy. However, that law does not protect individual animals, and it provides greater protection to endangered animal species than to endangered species of plants. It also does not prohibit hunting so long as a species is not in danger of extinction.

Although the notion that the functioning of natural systems is important and the idea that diminishing biodiversity is a serious problem are undoubtedly matters of great moment for any legal system, it would require a vast leap beyond such concerns to seek to implement, as part of an operative legal system, conceptions such nature's rights, nature for its own sake, and nature as a living system with its own rules.

Laws require specification of knowable rules or standards or some principle of rights that has a generally understood and accepted content. Thus, one might have rules that prohibit timber harvesting within a certain distance of rivers or on certain slopes or rules that prohibit harvesting altogether in certain places or of certain species. A society can provide protection against disturbance of natural systems as broadly as it wishes, but it must provide workable guidance about what is permitted and what is forbidden. Because essentially all human activity, even in subsistence societies, disturbs nonhuman natural systems to some extent, it cannot be sufficient simply to speak of the rights of natural objects or the rights of natural systems without providing some guidance about how the interaction of human living with those systems is to be managed.

Although there are very general and controversial legal principles such as due process and religious freedom, even concepts as broad as those have lengthy histories that have shaped commonly understood meanings for them or at least concretely infused them with social content.

However controversial it may be to speak of the scope of religious liberty that should be afforded to some religious sect (for example, believers in polygamy), or what process is due someone charged with a crime, from the perspective of a legal system there is a vast difference between the difficulty of interpreting the very broad language of some constitutional norms and a claim about the rights of trees or nature's own rules.

THE PERCEIVED INADEQUACY OF THE CONVENTIONAL LAW

The central challenges for environmental law may arise not from the difficulty of treating nature or natural objects as having rights independent of human society but from centuries of legal and economic development in which protecting natural systems was not a societal priority. The following observations may help put environmental legal concerns into perspective.

First, the earth has been organized under a system of property rights designed to facilitate and reward productive human activity such as agriculture, manufacturing, and the production of housing. All those activities necessarily involve disturbance of natural systems. The property system conceives of land as being in a passive state, waiting to be put to human use. Insofar as land is doing something else, such as providing a habitat for wildlife, property law considers such functions expendable. Land has been subdivided and fenced, excluding wildlife so that it could support domesticated grazing animals. Forests and grasslands have been cut and plowed to support agriculture and build cities, and rivers have been dewatered to provide irrigation and drinking water.

Getting rid of the natural, or at least domesticating it, has been a primary task of human settlements and was therefore a primary function of the laws governing natural resources. The system worked very efficiently to bring about those transformations. Nothing in it provided incentives to encourage the preservation of natural systems, nor did any rights exist in anyone to invoke the law to do so. The law thus has been the intentionally efficient cause of ecological destruction.

The second central fact about the traditional legal system is that the elements of the world that have not been cut up into parcels and subjected to the imperatives of the property system, such as the oceans and the ambient air, have been governed as unmanaged commons. They were subject to unrestricted exploitation and to unrestricted use for waste disposal. That arrangement assured similarly deleterious impacts on their capacity to sustain natural-system functioning.

The third fact is that the lines of division by which societies determine separate ownership or separate governmental authority bear no relation to ecologically rational divisions such as watersheds or habitat requirements for animal populations, the boundaries that reflect what is required for natural systems to flourish. States and nations often have their frontiers down the middle of a river, and rivers flow from one country into another so that the pollution caused in one jurisdiction has impacts in another. Animals may be well protected in a public refuge in the summer, only to descend to their winter range and find themselves in a privately owned and newly developed residential subdivision.

The Devil's Hole Pupfish. *The Devil's hole pupfish (*Cyprinodon diabolis*) is an endangered species of fish found east of the Death Valley region of Nevada, in a geothermal aquifer called, unsurprisingly, Devil's Hole. The species, possibly over 20,000 years in existence, was listed as endangered in 1967. The Supreme Court upheld this decision to preserve the species with their ruling in* Cappaert v. United States *(426 U.S. 128), when they denied the Cappaert's request to pump additional groundwater from Devil's Hole.* **U.S. FISH & WILDLIFE SERVICE.**

In short, the legal system has been structured in ways that assure the steady degradation of nature. In an earlier time it seems to have been thought that a sort of separate-zone policy would work, setting aside parks and refuges that had high natural values so that the rest of the land could be put to work to meet human needs. Great faith was put in technology, so that as fish habitat was seen to decline in the age of hydropower, fish hatcheries were established as a substitute. Those approaches, along with an unrealistically optimistic view of the vastness and resilience of nature, seem to have convinced previous generations that the human productivity–based legal system described above could continue to function unmodified while the benefits of fecund natural systems would continue largely unabated. It is known now that none of those beliefs was justified.

POTENTIAL AND EMERGING STRUCTURAL CHANGES IN ENVIRONMENTAL LAW

The central question for environmental law today seems to be whether it is possible to reengineer the legal system so that it can continue to meet human needs while maintaining and restoring functioning natural systems to some desired level of vigor and sustenance. What that level should be is not self-evident, at least so far as jurisprudential thinking is concerned. Moreover, whatever it is or ought to be, it will have to be compatible with a system that is also acceptably functional to meet human needs. Although it may not be possible to describe a system that is perfectly accommodating, some elements of a humanity-sustaining legal order that also highly values the maintenance of healthy natural systems can be identified.

Duties of Property Owners Those holding private property rights will have to bear some affirmative responsibility to minimize adverse impacts on natural systems as they exploit their property for private benefit. In the past such affirmative responsibility was limited by physical boundary notions such as trespass. Under an ecologically sensitive regime it would be recognized that even within one's own borders natural processes of importance to the larger community may be ongoing and justify some public restriction of private uses.

The World as a Common If natural processes, habitat, and biodiversity are recognized as important public values, land and waters will have to be reconceived as in some respects a common in which the society at large has legitimate interests. Such a commons would overlay and coexist with individual, private rights. To some extent that conception already exists in regard to large lakes and rivers, which are understood to be public resources held in public trust open to public uses such as navigation and fishing and subject to legal protection for such purposes, coexisting with private rights of use. The old idea of public rights to navigation can, and to some extent already has, evolved into a public right in the protection of sustaining populations of indigenous fish and a healthy riparian habitat.

Access to the Legal System If these changes are to occur, the means for enforcing public rights will have to be as potent as the established means for enforcing private rights. Government protects many public entitlements through public health measures, fire safety laws, drug testing, and the like. However, individuals can protect their private rights as property owners, tenants, or purchasers. As public rights in the protection of functioning natural systems are recognized, invocation of the law by members of the public to safeguard those rights would have to be on an equal footing with the access rights associated with private entitlements. The presence of global public rights does not suggest that the legitimate interests of local populations in nearby resources would be ignored. Such interests, such as maintaining a viable local economy, would be an important element in the application of a workable environmental legal standard.

An International Legal Regime Many of the most important environmental issues are of international scope, transcending national boundaries just as they transcend individual land ownership boundaries. Although an international regime of governance is appropriate for such issues, the claims made on behalf of national sovereignty undoubtedly will continue to be felt for the foreseeable future. Nonetheless, various international legal strategies can be effective. However strongly nations value their sovereign status, there are often benefits in adopting mutual obligations. The most familiar example is the rules of war, in which each nation agrees to constrain its treatment of enemy soldiers in the expectation of safeguarding its own troops. Some environmental examples are obvious: Two nations may share several rivers, with one country being upstream on one river and downstream on another. Alternatively, a nation may be willing to make environmental concessions to exact concessions in an area where it needs the assistance of other countries. Such practical motives and incentives underlie many bilateral international agreements.

More embracing standards can be articulated in multilateral conventions or treaties by nations that are willing to adopt them. Such agreements can be useful even if they are not adhered to universally, and the presence of those agreements can create an international standard to which laggard nations eventually feel obliged to conform.

International tribunals, where they exist, add a level of legal legitimation to international environmental claims even when they may not be available in domestic law. International legal standards also may provide a basis for

making claims in domestic courts and for bringing domestic enforcement up to international standards. Although international law remains partial and imperfect, it can constitute an essential institutional component of a global ecological commons.

CONCLUSION

Some environmental problems present familiar demands to protect human health and welfare. Others, such as loss of biodiversity, present more novel challenges that have a powerful ethical dimension and raise difficult policy questions about how to harmonize contemporary needs with adequate provision for the future as well as the need to conceive the earth outside its conventional form as discrete tracts of property within arbitrarily drawn political boundaries. Some structural changes in conventional law, focused essentially on exploitation of natural resources, are both necessary and practical. International agreements, though still imperfect, are an important step toward recognition of the earth as a global commons.

ENVIRONMENTAL PHILOSOPHY

This entry contains the following:

I. ANCIENT PHILOSOPHY

Ancient philosophy comprises mostly Greek and some Roman writers who derived their philosophy from Greek precedents, over approximately the eighth century BCE to the second century CE. The intellectual experience of the ancient Greeks offers a background and resource for the contemporary discussion of philosophy relating to the environment. The seminal role of Greek thought as a formative and oft-renewed influence on Western philosophy is widely recognized, so it is not surprising that a number of scholars interested in environmental ethics from the 1970s onward have turned to the ancient world. To use an environmental metaphor, the roots of Western philosophy lie in Greece, and so in some respects do the roots of environmental crises, and therefore the search for the relationship between them merits a reexamination of ancient Greek thinking.

NATURE AS THE THEATER OF THE GODS

Greek philosophy developed in, and reacted against, an intellectual climate where explanations of phenomena depended on the existence of supernatural beings. Traditionally, the Greeks regarded nature as a realm in which the gods, who exhibited many human qualities, were dominant. Since nature manifested activities of the gods, a human action that affected the environment might provoke the reaction of some god or goddess, and presented an occasion for caution. Thus it might be expected that they would treat the environment with awe and care, and this was true to some extent. Practices demanded or prohibited by the gods included some that imply a prephilosophical ethics.

The Greeks perceived order in nature, feeling that the gods, or a principle of justice that even the gods must obey, operated to keep everything in its appropriate place. To overstep the bounds by attempting to change the natural arrangement of land and sea was to demonstrate hubris, a presumptuous pride that challenged the gods and could provoke nemesis, their inescapable retribution. It was believed that Zeus, when he divided the world with his brothers Poseidon and Hades, had established an ordered cosmos and set the limits of its constituent parts, including the land and sea. Herodotus says that when the people of Cnidus began digging a canal through the isthmus that connected them to Asia, flying rock splinters injured many workmen. Seeking the cause, they consulted the Delphic Oracle, who, uncharacteristically, replied clearly: "Do not fence off the isthmus; do not dig./ Zeus would have made an island, had he willed it" (7.141). They stopped immediately.

Earth herself, Gaia, Mother of All, oldest of gods, had her own law, deeper than human enactments and beyond repeal. As Xenophon remarked in *Economy* (5.12): "Earth is a goddess and teaches justice to those who can learn, for the better she is served, the more good things she gives in return." Those who treat her well receive blessings; those who treat her ill suffer famine, disease, and death. Artemis, Lady of Wild Things, was paradoxically both huntress and protector of animals. Her worship included conservation practices by hunters, such as sparing young creatures, and initiation rituals that identified children with bears and other animals.

Greek religion had a strong sense of locality. Great gods and lesser spirits haunted wild locations such as springs, caves, and groves. Some patches of landscape, especially groves of trees, were designated as sacred and protected from mundane activities such as cutting timber, hunting, fishing, cultivation, and building. For instance, custom forbade catching tortoises on Mount Parthenius because they belonged to Pan. Taboos against pollution are common in traditional texts; Hesiod (fl. 700 BCE) cautioned against urinating or defecating in springs or rivers. Rules like this may embody an astute response of the ancestral Greeks to experiences with disease and poisoning.

NATURE AS THE THEATER OF REASON: THE PRESOCRATICS

Greek philosophers formulated the idea of nature (*physis*) as properly an object of rational investigation. This was first done by the natural philosophers among the pre-Socratics, who wondered what the basic elements of the universe were, and how they interacted. At the outset, philosophy rejected the gods as explanations of natural phenomena or as a basis for ethics. Indeed Xenophanes (c. 570–470 BCE) cited the lack of ethical standards in traditional myths as one reason for not believing in the gods portrayed in them. The only remaining role for the gods was metaphorical. When Thales (c. 585 BCE) said, "All things are full of gods" (fragment 22), he was talking about magnetism and energy, not indwelling deities. As an illustration of the assertion, he pointed to the lodestone and its mysterious attraction for iron.

For Thales, the primal matter was water. Others advanced air, fire, and earth as basic elements, alone or in combination. These philosophers shared an assumption about the natural world: that it can be understood by the human mind because it contains rational order. Some thinkers made rationality a creative force; Heraclitus (fl. 500 BCE) called it *logos* (word) and Anaxagoras (500–428 BCE) called it *nous* (mind). But the result of

this initial excursion of the Greeks into natural philosophy was to develop mutually exclusive systems of explanation, all of which were rational, but none of which could defeat the others.

The oneness of nature can be found in Orphic thought, and philosophers such as Pherecydes (c. 544 BCE), Pythagoras (fl. 530 BCE), Philolaus (470–390 BCE), and Empedocles (492–432 BCE) refined this idea. Orphic cosmology envisioned an organic unity of the world and the cyclical interplay and balance of elements and creatures within it. Art and literature show the mythic Orpheus as expressing the harmony of nature; when he played the lyre and sang, animals and even trees in which his song awakened sympathetic attraction surrounded him. Pherecydes, reputedly Pythagoras' teacher, identifies the first principles as Time (Chronos), Life (Zas), and Earth (Chthoniê); the latter two through their union created the world as a winged Tree of Life, a single organism of which all creatures were parts.

The Pythagoreans were pantheists who held that the universe is spherical, animate, ensouled, and intelligent. The British atmospheric scientist James E. Lovelock advanced a hypothesis in the 1970s that recalls this idea. He suggested that the totality of life on Earth, in tending to maintain temperatures, an atmospheric composition, and other conditions that benefit itself, acts as if it were an organism with that intention. Recognizing the Greek roots of the idea, Lovelock named the organism Gaia after the Greek goddess who personifies Earth. Empedocles held that all things share the same elements, so that there is a constant interchange in which every entity comes out of elements that preexisted and are never destroyed. There is a constant process of recycling in a natural cycle that is balanced, not chaotic. Philolaus defined harmony as "a unity of mixed elements that are various, and an agreement of elements that disagree" (fragment 10). The Pythagoreans believed that harmonies could be expressed as mathematical proportions. Since all living things, including humans, have a common origin and natural ties, and are formed of the same components, including the soul, all are related and should be treated with respect. Pythagoreans forbade killing animals or plants, as well as eating food that required killing an organism. Thus they banned eating beans and many other plant foods in addition to meat. Foods that could be consumed without killing, so far as they knew, such as milk, cheese, honey, wine, oil, the flesh of fruits and leafy vegetables, they regarded as permissible. The reason they adduced for not killing was that all living things have the same kind of souls, and after death these souls pass into other bodies. Empedocles said, "In the past I have been a boy and a girl, a bush, a bird, and a silent water-dwelling fish" (fragment 117).

PLATO

Plato (429–347 BCE) was a friend and admirer of the philosopher Socrates (469–399 BCE), and cast him as the leading character in many of his dialogues, which as a consequence form the major literary source for Socrates's philosophical ideas.

In his dialogue *Republic* (10.614b–621d), following the Pythagoreans, Plato used metempsychosis as the basis of the so-called Myth of Er: Souls are reborn in the forms they deserve on the basis of their actions and their achieved levels of consciousness. He asserted in the *Timaeus* (30d) that the cosmos is "a living creature, one and visible, containing within itself all living creatures which are by nature akin to itself." This great entity is "endowed with soul and reason." Harmony and order can be discerned in the visible world, which is an image or reflection of eternal truth and therefore offers clues for human understanding. But for the most part he made human society rather than the natural environment the object of inquiry.

It might be supposed that since Plato placed ultimate reality in the world of Forms and held physical objects to be imperfect manifestations, he would be unconcerned with the environment, but such is only part of the picture. Plato often voiced admiration of nature, notably in the *Phaedrus* (230b), where Socrates remarks: "Upon my word, a delightful resting place, with this tall spreading plane tree, and a lovely shade from the high branches of the willow. Now that it's in full flower, it makes the place ever so fragrant. And what a lovely stream under the plane tree, and how cool to the feet!" However, a few lines after this lyrical description, Plato made Socrates add that trees and open country wouldn't teach him anything, since he was interested only in what he could learn from men in the city. His ethics was concerned with establishing an absolute standard of justice between human beings—a human or culture-centered worldview. Even so, his writings are full of insights about the relationship between human beings and nature, the environmental problems that arise in that relationship, and possible solutions.

In the section of the *Critias* concerning Atlantis (111b–d), Plato described the deforestation of Attica and resultant soil erosion and drying of springs, so "what now remains compared with what then existed is like the skeleton of a sick man, all the fat and soft soil having wasted away, and only the bare framework of the land being left." He clearly blames humans for the destruction of forests, noting that the cut timber still existed as beams in large buildings, leaving only "food for bees" (flowering herbs and shrubs) on the hillsides. In the *Laws*, he urged regulations to prevent deforestation: Goats, which devour small trees, should be watched by keepers (639a); gathering of firewood should be regulated by district foresters (849d); and fires must not be allowed to spread (843e). He advises

the planting of trees to conserve water supply (761b–c). The American diplomat and writer George Perkins Marsh, who postulated environmental reasons for the decline and fall of the Roman Empire, was educated in the Greek and Latin classics and constantly refers to them, including Plato, in his work. Marsh's analysis of deforestation and soil erosion as destructive results of human actions on the natural environment were contained in his book *Man and Nature*, published in 1864, which gave impetus to the conservation movement and the study of environmental history. Although Marsh does not quote the passage in the *Critias* mentioned above, his description of deforestation and erosion in the Mediterranean area contains the same ideas, and he must have been familiar with it.

ARISTOTLE AND THE PERIPATETICS

Aristotle (384–322 BCE) insisted that nature, and all its parts, living and nonliving, are directed by the principle of *telos* (purpose). As he maintained (*Politics* 1256b20), "Nature does nothing in vain." He investigated questions about the natural world in a way that was more systematic and inductive than that of the natural philosophers. He gathered that the living and nonliving merged with one another in gradual stages, but his scheme was hierarchical. Although he thought making sharp distinctions between classes of beings was difficult, so that for example, "in most of the other animals can be discerned traces of the psychical modes which attain their clearest differentiation in man" (*Historia Animalium* 588a13–b17), still, as Anthony Preus (p. 217) explained, "there is one ultimate ruler, and each level is subordinate to the next higher level, as in an army." Aristotle asserted that plants exist for the sake of animals, animals for the sake of humans, and that inferior men are natural slaves of the superior. This doctrine supports use of nature in any way conducive to human good, and has been influential in the history of Western environmental philosophy. Aristotle himself would not have justified misuse of animals, but others derived from his teaching that animals and plants are of lower orders subservient to human needs the corollary that they have no purpose of their own and no intrinsic value.

Aristotle, whose philosophy clearly emphasizes the natural world, was interested in the relationships among living things and between them and the physical environment. He observed in the *Metaphysics* (107a17–20), "All things are ordered together somehow, but not all alike—fishes and fowls and plants; and the world is not such that one thing has nothing to do with another, but they are connected." It is this principle that makes the study of ecology possible, and Aristotle's observations on biological relationships were so perceptive that he receives credit for introducing ecologic considerations into literature. He noted the competition between animals that depend on the same food; he described a spectacular population increase among mice and subsequent crash due to weather. Other ecological relationships described by Aristotle include territoriality among mammals and birds and behavior such as competition within species and migration.

Although Aristotle did not enunciate an environmental ethic, he believed that economy depends on nature, and therefore that conservation was a function of a well-run city, which led him to counsel, for example, that its resources be kept safe by "Inspectors of Forests" and "Wardens of the Country," provided with guardhouses and mess halls (*Politics* 1331a–b).

Aristotle's student Theophrastus (371–287 BCE) did not accept the idea that other creatures exist only to serve mankind. He did not deny that there is purpose in nature; he found the purpose of an annual plant, for example, in production of seed to provide for a new generation. Since the purpose of things in nature is not always evident, he asked in his *Metaphysics* (9.34) for an "effort to determine the conditions on which real things depend and the relations in which they stand to one another" through careful observation rather than the assigning of higher causes. His philosophy seems to have the potential to evolve an ethics of consideration for other forms of life, but he did not elaborate it that far. Paul W. Taylor, an American philosopher, in *Respect for Nature* (1986) develops a theory of ethics regarding living beings that is teleological, and perhaps closer to the idea of Theophrastus than to Aristotle. For Taylor, however, purpose exists in individual organisms, not in species or ecosystems, and each organism has an equal claim to moral consideration.

Theophrastus, whose most important surviving scientific treatises deal with plants, was the most consistently ecological ancient writer. He observed that a plant flourishes best in an appropriate place, which now might be termed its habitat. He discussed the effects of moisture, soil types, slope, exposure to wind and sun, and elevation on the occurrence and growth of plants. He did not consider plants only as individuals, but investigated the effects that they exercise on one another when growing in groups and their interactions with animals—conceptual steps toward the science of ecology. He examined human effects on plants, including cultivation and extinctions, and effects of removal of vegetation on climate. More than half of Theophrastus's botanical writings deal with ecological observations.

THE MATERIALISTS

A contrasting concept came from Leucippus (fl. 440 BCE) and Democritus (c. 460–370 BCE), who maintained that

the world is purely physical, composed of indivisible particles (atoms) whose movements are mechanical and governed by necessity. The aggregations of atoms—the bodies they form—come to be by accident, the outcome of chance. According to Epicurus (341–270 BCE), whose cosmology followed Democritus, there is no creator and nature works through blind physical cause. His ethics, based on anthropocentric hedonism, held little promise as a caution against environmental damage. Still, some Epicureans supposed that animals and plants could not have been created for human use, because so many people are fools, and there is not enough human intelligence in the world to make creation worthwhile. Lucretius (94–51 BCE) thought that Earth was deteriorating and that part of the reason was human destructiveness, including deforestation and killing wildlife.

The Stoic school was founded by Zeno of Citium (335–263 BCE) and taught in Roman times by the slave Epictetus (c. 55–135 CE), his student Arrian (86–160 CE), and the philosopher-emperor Marcus Aurelius (121–180 CE). Like the Epicureans, the Stoics were materialists. The Stoics held that the cosmos is sentient, rational, and pervaded by harmony in which all living things partake. It is self-sufficient because it nourishes and is nourished from itself. The cosmos has unity, order, and cyclical development, and is animated by a fiery soul of which all individual souls are fragments. Within this world, humans have an obligation to act with justice, which is a compact between humans. The Stoics accepted Hesiod's dictum (*Works and Days*, 277–279) that "human beings have no compact of justice with irrational animals," and Aristotle's hierarchy of plants, animals, and man. All decisions regarding the environment, therefore, should be made with respect to the possible effect on other humans. The Stoics argued with the Neoplatonists, who were even more Pythagorean than Plato had been, over the question as to whether beasts are rational or not; the Neoplatonists claimed they were.

An idea of environmental influence derived from ancient thinking is the notion that people who live closer to nature are morally superior to those in urban centers. This is the theme of the *Euboean Discourse* of Dio Chrysostom (40–117 CE), a Stoic-Cynic orator who described the visit of a shipwrecked traveler to a hunter's family in the wilds of a large island. The hunters were self-sufficient, living on what they obtained directly from nature. After describing their idyllic home, where they lived in natural honesty, hospitality, and unspoiled nobility, the author brought them into confrontation with the corruption of "civilized" urban citizens, an idea reflected in the eighteenth century by Jean Jacques Rousseau.

Stoic philosophy recognized human ability to change the environment. The design of the world, Seneca (1–65 CE) noted, required human activities: Metals, for example, are hidden in the Earth, but people possess the ability to discover them. Humans were the natural caretakers of the Earth, and its creatures were placed in their custody. Well-planned efforts make the Earth more serviceable for human purposes; in this view, beauty and utility are synonymous. Mankind improves plants and animals through domestication. In the same way, the extension of civilization was seen as making up a defect of the wilderness, which was a haunt of beasts, a barren waste. Stoic ethics taught that individuals should do the jobs fate had assigned them, performing them well with responsibility to all.

CONCLUSION

To what degree did the ideas held by the Greeks about nature affect their ethical treatment of the Earth and its living inhabitants? There is no simple answer. Philosophers encouraged the rational use of the mineral, vegetable, and animal realms. They not only pointed out problems, but sometimes suggested solutions. Certain ethical systems provided motives for conservation, while others left humans free to exploit the environment.

There remains the undeniable fact that the natural environment suffered considerable damage at the hands of ancient people, though not as serious or widespread as that which has occurred in modern times, and some areas of the Mediterranean survived with relatively little impairment. It is almost impossible to identify a general pattern of environmental effects deriving from the competitive philosophies of the ancient world. Some forms of philosophy, upon elaboration, could have provided constructive environmental attitudes. But these would not have been effective in environmental conservation without knowledge of the workings of nature and the effects of human actions. And as the American philosopher J. Baird Callicott tellingly indicates in *Earth's Insights*, the dominant Greek legacy in environmental philosophy is dualism (Plato), mechanism (Democritus), and hierarchy (Aristotle), none of which is a firm foundation for environmental ethics. Callicott does note, however, that Plato's idea of community good as a basis for ethics has application in the environmental realm.

Science, and ecology in particular, had only small beginnings among the Greeks. It would have been difficult, then, to decide which practices were likely to bring the best results when an environmental problem appeared for the first time, or was exacerbated from a tolerable level to an intolerable one.

II. MEDIEVAL PHILOSOPHY

The term *medieval* comes from the New Latin *medium aevum,* meaning "the middle age," a phrase that situates this long epoch between antiquity and modernity. Such a view is retrospective, having arisen in the fifteenth century, at a time when it was felt that a new, "modern" epoch was arriving. Just as the "medieval" concept privileges modernity, it also assumes the viewpoint of the Western Roman Empire, the decline of which in the fifth century is usually seen as the beginning of this epoch, despite the fact the Eastern Empire persisted and flourished until its fall to the Ottoman Turks in 1453, during which time its citizens did not think of themselves as "Byzantine" but simply as Romans, embodying an experience of fundamental continuity with antiquity. Terminal dates for the Middle Ages range from 1453 (the fall of Constantinople), 1455 (the Gutenberg Bible), 1492 (Columbus's first voyage to the New World), or 1517 (the posting of Luther's Ninety-five Theses).

The Middle Ages was the period that blended and synthesized the powerful intellectual currents of antiquity, above all Greek philosophy, with the great religious traditions of the Middle East—Christianity (the predominant religion of Europe for 1,000 years), Judaism, and Islam: It was the marriage of "Athens" and "Jerusalem." This synthesis had a profound effect on our view of nature. It was institutionalized with the establishing of Constantinople as the New Rome, the Christian capital of the Empire, in 330, and with the earlier First Council of Nicaea (held across the Bosporus from Constantinople in 325), which drew together the resources of Greek thought with the spirituality of Christianity and its background in Judaism, first establishing Christian doctrine in what came to be called the Nicene Creed. Accordingly, 325 was the approximate beginning of an epoch in which nature was newly understood. The dissolution of the medieval view of nature in later Scholasticism (the philosophical and theological teachings that developed in the cathedral "schools" of Western Europe) during the fourteenth and early fifteen centuries, which is discussed below, signaled the gradual end of this epoch.

MODERN CRITIQUES OF MEDIEVAL VIEW OF NATURE

Any discussion of medieval concepts of nature and their impact on modern attitudes and practices must address three influential critiques that have been readily and sometimes uncritically embraced in various environmental circles. All of them imply that abuse of the natural environment has distinctively Christian, especially medieval, foundations: (1) the claim of Friedrich Nietzsche (1844–1900) that Christianity, particularly in its medieval form, advanced a purportedly Platonic devaluation of the visible and earthly and thus is guilty of not being "true to the earth"; (2) the view of Martin Heidegger (1889–1976) that medieval Christianity pursued a

project of "onto-theology," seeing God as the highest being (*summan ens*) and natural entities as essentially artifactual, as divinely produced or created things (*ens creatum*), thereby obscuring their true naturalness; (3) the claim of Lynn White Jr. (1907–1987), a historian of medieval technology, that medieval Christianity in the Latin West (although not in the Greek East) took literally the charge to humanity in Genesis 1:28 to "subdue" and "have dominion over" the created order, fashioning aggressive technologies with little sense of nature's rootedness in a divine order. Many scholars regard these interpretations as selective and tendentious. Some suggest that it was not medieval civilization but rather the Enlightenment, with its gradual dissolution of medieval religious sensibilities and the attendant, unprecedented rise in secular and mechanistic worldviews, that provided the foundation for environmental degradation.

COMMON ELEMENTS OF MEDIEVAL PHILOSOPHY

It was indeed during that long period from the fourth to the fifteenth century that European thought accrued many of its characteristic features and themes, especially its synthesis of philosophy and religion, of Athens and Jerusalem. Accordingly, physical nature was itself experienced and understood with reference to two sometimes competing outlooks: via Athens, nature was understood as indifferent self-emergence (*physis*), always threatening to overwhelm; and via Jerusalem (and later Alexandria, Rome, and Constantinople), nature was understood as ordered creation (*ktisis*), correlative and proportionate to humanity; its tendency to overwhelm is thus, taken as a manifestation of the glory of the creator. Both views, in fact, were necessary for the rise of modern science, for without the "Athens" perspective there is no compelling requirement to interrogate nature, and without the "Jerusalem" perspective there are no grounds to expect intelligible answers. Common to both traditions, however, is an emphasis on grasping the close interrelation between the visible and the invisible, the temporal and the eternal, the earthly and the heavenly. This common element was further developed in the Middle Ages.

A mainstream or classical view of nature prevailed throughout this period, expressed in both the paradoxical language of mysticism and the precise language of Scholasticism. This view, even if not shared by all philosophers and theologians, was always at least their point of departure. Two central tenets of this shared worldview challenge the claims of Nietzsche and White. (1) Given the litany in Genesis 1 proclaiming that, at each stage of creation, "God saw that it was good," creation must be seen as possessing an inherent, divinely instituted goodness, thereby refuting as heretical any Gnostic or Manichean devaluation of nature as inherently "dark"; (2) nature is seen as revelatory of the creator, its goodness and beauty marking it as an original and continuing revelation of the divine, preceding scripture and prophets, and thus as a foundation of religious piety. Nature is thereby understood and honored as divine epiphany.

NATURE IN EARLY MEDIEVAL PHILOSOPHY

The first major philosopher to draw together the two predecessor schools of thought was the first-century Jewish philosopher Philo of Alexandria, also known as Philo Judaeus (15–10 B.C.E.–45–50 C.E.). Philo saw in the orderliness of nature the workings of divine providence, and he was the one of the first to maintain that the Platonic forms, principles of this manifest order inherent in creation, were the eternal ideas of God. Beyond this, he posits an eternal *Logos*, philosophically a "form of forms," that, like manna, is a heavenly gift, connecting God and world, in which human rationality takes part and by means of which the cosmos itself coheres. This idea of divine principles that inhere in nature and through which the divine order can be apprehended or understood—of a manna-like connection between heaven and earth—runs through medieval philosophy like a golden thread, intact until the fourteenth century. For example, in his *Hexaemeron,* St. Basil the Great (330–379) reflects on how the "beauty and grandeur" of creation—"earth, air, sky, water, day, night, all visible things"—is a "training ground" for the soul to "learn to know God, since by the sight of visible and sensible things our intellect (*nous)* is led, as by a hand, to the contemplation of invisible things." (Hex. 71, 55).

Basil's student Evagrius of Pontos (345–399) was one of the earliest of the Christian "Desert Mystics" and wrote extensively of *theoria physike*, the noetic or contemplative knowledge of nature that becomes possible once the soul undergoes purification *(katharsis)* from passions such as anger and avarice. Monasticism in the Christian east became closely associated with natural wilderness and took inspiration from it regularly—in the deserts of Egypt, Sinai, Syria, and Palestine; in the high plateaus of Cappadocia in Anatolia; and, eventually, deep in the Russian *taiga*. Probably writing as a Syrian monk, St. Dionysius the Areopagite (early sixth century) presented a mystical vision of nature that, as Umberto Eco puts it, "presents the universe as a cascade of beauties springing forth from the First Principle, a dazzling radiance of sensuous splendors which diversify in all creation," advancing within medieval philosophy an influential vision of nature that he calls "*pankalia*, the beauty of all things." Eco goes on to speak of a prevailing "medieval pancalistic sensibility" running throughout medieval civilization (1988, pp. 23–26). In the west,

St. Augustine (354–430) vigorously affirmed the inherent goodness of the world against the Manichean attempt to denigrate it, frequently invoking the beauty of nature as evidence for its creator. Searching in natural things for knowledge of God, he reflects in the *Confessions*: "My question was my gazing upon them, and their answer was their beauty." Later, Boethius (c. 480–525) advanced an essentially aesthetic view of the cosmos, seeing it in a Pythagorean manner as musical and mathematical.

NATURE IN LATER MEDIEVAL PHILOSOPHY

What is this connection, prominently aesthetic, between the earthly and heavenly? What is the link between heaven and earth? Is the relation between them one of ontological participation, the being of the latter sharing in the being of the former, such that the connection might be apprehended or intuited in "noetic" or contemplative seeing? Is it a semiotic or symbolic relation, to be grasped through the imagination? Or is it a relation of cause and effect, to be comprehended through inferential or discursive rationality? All these variants affirm a strong connection between God and world but differ significantly over the degree of externality between God and nature, and thus in their sense of the approachability of God through creation. In what sense does nature exist as theophany, or manifestation of the divine? In the east, the distinction between the radically transcendent and unknowable essence (*ousia*) of God and the all-present, apprehensible divine energies (*energeiai*) allowed for a mystical orientation to nature that can contemplate the divine energies in all things without compromising the transcendent and mysterious nature of the divine essence.

This distinction of essence and energies, however, never took root in the Latin west, where a gradual transition occurred from understanding the relation as predominantly symbolic to seeing it as largely causal. John Scotus Eriugena (c. 810–c. 877) translated many eastern texts, including those of Dionysius, introducing Byzantine elements into Latin thought while leaning toward Augustine's view of nature as symbolic. Throughout the Latin Middle Ages there arose an elaborate complex of symbolic correspondences between heaven and earth that endured even into the Renaissance, with everything in nature referring to something sacred and eternal.

In the Greek east a more immediately mystical and sacramental orientation toward nature persisted. Philosophically, this cosmic mysticism was articulated by the Byzantine philosopher and theologian St. Maximus the Confessor (c. 580–662), who saw the eternal *Logos* mirrored by an infinity of individual *logoi* possessed by every leaf, twig and pebble, thus providing an intuitive or noetic principle of intelligibility and eternal significance for every individual being. St. Symeon the New Theologian (949–1042) developed perhaps the most comprehensive medieval view of the cosmos as theophany, advancing the view that humanity is intended to exercise a cosmic priesthood, consecrating nature through contemplation of the divine energies operating within it.

The Latin tradition reached its culmination in St. Thomas Aquinas (1224–1274), in whose thought the connection between God and nature receives a multifaceted consideration. His cosmological proofs seek to demonstrate the causal connection between creator and creation, providing an inferential link between heaven and earth. In contrast to the thinkers of the Greek east, Aquinas maintains that there can ordinarily be no direct or non-discursive experience of God within this lifetime. Nevetheless, he argues, the order of creation, especially its aesthetic elements, so compellingly points to the divine that Gilson (1955) can suggest as a title for Aquinas's cosmology *De imitatione Dei*. The overall medieval sensibility of proximity between heaven and earth persists in the work of Aquinas. His theory of analogy—according to which we can understand the visible and temporal (such as the finite beauty of a flower or the relative goodness of fresh spring water) through an analogy of proportion with the invisible and the eternal (the infinite beauty or the absolute goodness of God)—serves as a metaphysical and epistemological bridge between these two orders. Thus, it is as not a "singular" exception, as White believes, but as a summit of Latin spirituality that St. Bonaventure says of St Francis of Assisi's befriending of grasshoppers, "he had learned, even in the most insignificant creatures, to admire the wonderful works of the Creator" (1955, p. 82). In the Christian east, stories of saints conversing with animals had been common from the earliest days of desert monasticism in the fourth century.

THE OVERTURNING OF THE TRADITIONAL VIEW OF NATURE

It was, then, not until the work of William of Ockham (1285–1347) emerged that this continuity between visible and invisible worlds was severed. Ockham believed that the traditional view, according to which we can know and even contemplate divine principles or eternal forms in nature, compromised the unfathomable sovereignty of God, which he understood as primarily volitional. The world is how it is not because God has woven universals into it but because God willed it to be just as it is. Ockham's nominalism—his belief that there are no forms or universals or archetypes—is often cited as engendering the empiricism of modern natural science, because it claims that we must learn about nature by

observing it case by case, making generalizations only afterward. At the same time, however, it uproots the cosmos from its deeper moorings, allowing nature to be seen as sheer artifact, as *ens creatum* in Heidegger's sense, an aggregate of natural substances (*natura naturata*) without any deeper, inner coherence or dynamism (*natura naturans*). The willful, almighty deity of Ockham, who cannot be approached through the goodness or beauty of creation but through revelation alone, and for whom (contrary to Socrates in the *Euthyphro*) good things are "good" only because God chooses to will them, became an important influence on Reformation figures such as Luther and Calvin. Ockham's work also inaugurated the nominalistic tradition of British empiricism.

NATURE AND MEDIEVAL PHILOSOPHY

Did medieval philosophy lay the foundation for later environmental ruin? A careful examination of its history suggests that it was not medieval philosophy, but rather its dissolution in the philosophy of William of Ockham and the nominalist school that opened this door by promoting a concept of creation that is radically removed from the divine being: nature as *ens creatum* in Heidegger's sense, no longer intelligible as theophany. Though differing views followed, such as those of Nicholas of Cusa (1401–1464), it was Ockham's vision that prevailed, leading to the deeply desanctified sense of nature in the mechanistic worldview of the Enlightenment, which lay the foundation for environmental domination in modern technology.

Far from engendering the environmental crisis, the medieval sense of nature as theophany has inspired, directly or indirectly, much of modern environmentalism, from European romanticism to American transcendentalism to the work of nature writers such as John Muir and Annie Dillard, all of which have retrieved elements of the medieval experience of a nature that manifests divine energies through the beauty of creation.

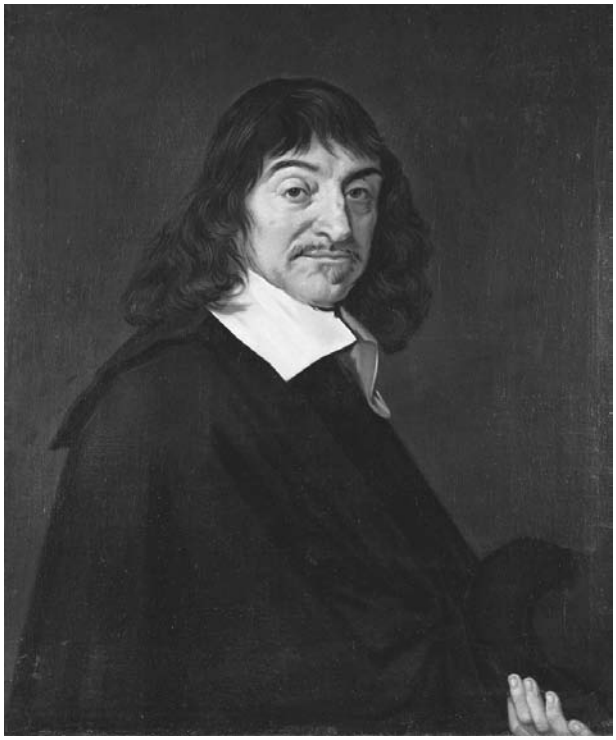
III. EARLY MODERN PHILOSOPHY

Early modern philosophy is the philosophy that accompanied the rise of modern science in the West. Francis Bacon (1561–1626) was the herald; Immanuel Kant (1724–1804) marks the transition to something new, though, as indicated below, that something new took many different directions.

EMPIRICISM

In the medieval period, the project of the learned was to transmit knowledge from authoritative sources to their own times. Learning was important, because sound teaching of correct doctrine contributed to the salvation of humans and their ultimate happiness in the world to come. The beginning of modern thought was marked by the innovative argument that learning might be useful in another way: to make life in this world more comfortable.

Bacon developed this argument in his *Advancement of Learning*, published in 1605. His key point was that knowledge might be practically useful, but he went on to claim that if this was what was wanted, people had to abandon the assumption that had ruled hitherto, namely that all important knowledge was essentially already there in either the Bible or the books of antiquity. And the methodology of learning, which, before modern science,



René Descartes. *Descartes (1596–1650) is an influential early modern philosopher known for his original concept of the mind and his ideas about physicality. Some contemporary theorists believe that the ideas developed by early modern philosophers, such as Descartes, contributed to a later careless attitude toward the environment.* **IMAGNO/AUSTRIAN ARCHIVES/GETTY IMAGES.**

had relied on re-presenting ancient and sacred texts through translations and preparing aids to their correct construal through commentaries, had to be supplemented by a very different approach. One had to use the human senses to observe phenomena and devise experiments to fuel those observations.

Bacon insisted on the importance of the senses because he thought that the new search for knowledge had to focus on "secondary causes"—what we simply call *causes* today—in contrast to the medieval preoccupation with purposes and functions (What was God's purpose in creating the world? What was the function of, for example, "the firmness of the skins and hides of living creatures" [one of Bacon's examples]?). He thought that the way to study secondary causes was through observation and experiment.

PHYSICALITY

Bacon's plea for new knowledge took hold, and as it did so, a new conception of the universe emerged. The backdrop was set by René Descartes (1596–1650), often noticed as the originator of a new concept of mind, but more importantly a sponsor of a new way of thinking

ISAAC NEWTON

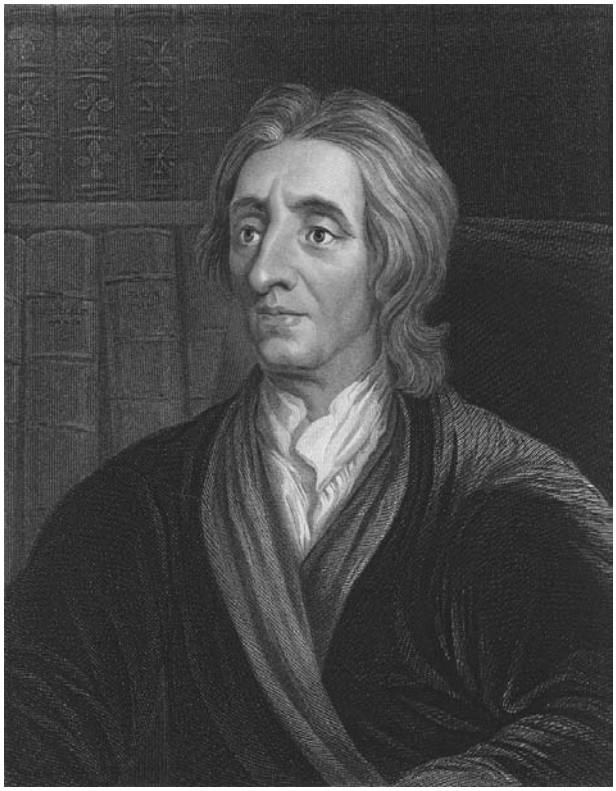
Born in Lincolnshire and educated at Cambridge University, Isaac Newton (1642–1727) was elected Lucasian Professor of Mathematics in 1669 and President of the Royal Society in 1703. His work as a mathematician and physicist was fundamental to the scientific conception of the physical universe that took shape at the end of the seventeenth century and remained broadly intact for two centuries. It was Newtonian physics that underpinned the deterministic vision at the heart of the Enlightenment.

Newton's physics displaced the physics of Descartes, whose plenum theory posited that the idea of empty space is incoherent. On Newton's view, in contrast, material bodies are indeed located in space, and space is otherwise empty. To explain their behavior, he spoke of bodies as being subject to gravity.

The most straightforward construal of his proposal is to have him positing a force acting across the empty space that he thought often separated bodies. Alternatively, he can be understood as describing a patterning among events without saying anything about what underlies that patterning. His formulas, of which the law of gravitation is just one, would then be understood as summarizing certain aspects of the movement of bodies and allowing reliable predictions.

Part of Newton's achievement was to show that one and the same set of formulas covered the movements of bodies of all kinds, wherever they are located in the universe. This did much to consolidate the assumption that everything that happened, whatever it was, happened in a regular, law-governed way.

It is argued that the scientific worldview that Newton did so much to establish (not to be confused with his own worldview) brought with it a distinctive policy toward human dealings with the natural world. There is held to be a link between seeing the world as made up of particles subject to forces and regarding it as open to unrestrained exploitation. Against this view, it is denied that attitudes were less exploitative when the assumption was that the world had been created for the support of human beings and was in any case fully or partially "corrupt." It remains true that when science began to be applied in manufacturing processes in the nineteenth century, it transformed those processes into instruments of globally destructive potential.



John Locke. *John Locke (1632–1704) is known for contributing the notion of mentality to the early modern philosophic tradition. One of his important contributions to modern environmental ethics is the idea that an individual has the capacity to own and acquire land.* **PHOTO BY STOCK MONTAGE/GETTY IMAGES.**

about physicality. The medieval assumption was that everything had a nonphysical aspect called its form. Descartes argued on the contrary that the universe consisted of a material or stuff without any form; adding that in the case of a limited number of small bits of this universal matter there was, associated with each bit, a non-material mental substance. These mental substances, though attached to bits of matter (bodies), were for Descartes the essential core of the human being, the mind.

Descartes posited a number of eddies or whirlpool-like swirlings within the plenum—the single expanse of continuous stuff that was, according to him, the physical universe—and the simplest of these eddies, theorized Descartes, could be regarded as a first approximation of material particles. The material objects of ordinary experience, in their turn, could be regarded as made up of these.

Other theorists arrived at a particle or corpuscularian conception of physical reality along different routes, and the outcome was a consensus among seekers after new knowledge, by the end of the seventeenth century, based on corpuscularianism. Opinions differed over what properties the corpuscles possessed, and over what forces there were that might affect them (see sidebar), but they were generally considered to be lifeless and mindless, inert entities moving under the influence of a limited number of forces. The movements of these corpuscles, and the configurations they got into, were held to be responsible for all the features of the experienced universe.

It has been argued that modern science and early modern philosophy oversaw the elimination of the spiritual from these nonhuman bits of the created universe, the descralization of nature. The restriction of mentality to human beings is also argued to have supported the conclusion that animals have no feeling and are therefore free of any kind of suffering.

MENTALITY

John Locke (1632–1704) developed the notion that mentality, like physicality, consisted essentially of corpuscles—but mental "corpuscles," not physical ones. Just as physics proposed to explain physical phenomena in terms of corpuscles and the forces acting upon them, so the mind was to be scientifically studied with the parallel assumption that everything mental was to be understood in terms of ideas and the mental forces to which they were subject. The theory of mental causation that developed out of Locke's approach was dubbed *associationism*, because of the laws of association that were assumed to govern the linking up of ideas.

Locke considered himself to be in a good position to prosecute the sense-based study of the mind and its workings because he thought a person could look inside him or her self and observe what was going on in their own minds. Introspection was a kind of sense. Expressing the so-called empiricist manifesto that knowledge had to be based on sense experience, Locke insisted that all ideas must come from sense experience—either from the outer senses of sight, hearing, and so on, or from the inner sense of reflection.

RATIONALISM

Bacon advocated experiment and observation as the key to establishing new knowledge, but others placed the emphasis elsewhere. Taking as their model the role of mathematics in advancing knowledge of the movements of heavenly bodies, they thought that the way forward lay with the more general application of reasoning. Descartes was one of these, founding his philosophy on the notion that whenever an idea is "clear and distinct," it is bound to be true. His examples included "I think, therefore I exist" and "God exists."

Benedict de Spinoza (1632–1677) took to its limits the idea that human reason is an instrument of discovery, maintaining that the universe is governed by laws that can be worked out by thinking alone, just as geometrical

theses can be proved by thinking, without resort to observation of any kind. (In a wonderful irony, he earned his living by grinding spectacle lenses.) More important for the Romantics was his suggestion that nature is divine, either because it is infused with God or because it is actually identical with him.

THE HUMAN BEING

For Descartes, the human being is an association of something physical with something mental. By *physical* he meant whatever occupied space. By *mental* he meant that which manifests the capacity for thought. For him, the mental is the key to what a human being is: a thinking thing. A person is to be identified with his mind, and the Cartesian mind became identified with the human soul.

Once the framework of the mental and the physical as two different types of existent had been introduced, different possibilities within that framework were explored. Thomas Hobbes (1588–1679) defended the idea that there was only the physical. George Berkeley (1685–1753) claimed that there was nothing physical, that all was mental. With his wonderful but baffling notion of monads, each representing the whole universe and each a closed windowless world, so may have Gottfried Wilhelm Leibniz (1646–1716).

Giving the key role to observation implied that at birth—before he or she had had a chance to use their senses—the human being was an empty vessel—or in the image Locke used, a tabula rasa, a writing tablet with nothing on it. According to Charles Taylor (1989), on this view the self is dimensionless until made into something by the causal influences that come to bear on it as it matures. Two opposing doctrines exploited this conceptual innovation: Jean-Jacques Rousseau (1712–1778), adopting a reverential attitude toward the world untouched by humanity, argued that the environment of European high civilization served to enchain. In contrast, Voltaire (François-Marie Arouet, 1694–1778), horrified by Rousseau's vision, maintained that a civilized education liberated and enriched.

THEORIES OF ETHICS

Both ancient and medieval philosophers thought that human beings seek happiness, though there were differences about how this was to be achieved and over what exactly happiness is. For Plato, happiness is "contemplation of the Good." While not exactly disagreeing, modern philosophers interpreted happiness as of a state of mind, something that Aristotle, for example, had specifically argued against. Human behavior, according to early modern philosophers, was driven in large part by humans striving to rid themselves of uncomfortable feelings and enrich themselves with enjoyable ones. Locke reached for the term *uneasiness* to make the point. Pain is a species of uneasiness, and so are hunger, lust, and cold. Whenever human beings initiate behavior, they do so to lessen their uneasiness. Jeremy Bentham (1748–1832) spoke simply of "mankind's twin masters, pain and pleasure." David Hume (1711–1776) agreed in seeing these two as "the chief spring and moving principle" of all action.

This perspective on the drivers of human behavior—while not strictly incompatible with an approach that continued to think of morality in terms of commandments issued by God (as defended by Locke and a tradition that continued into the Enlightenment and beyond)—left the door open to deterministic alternatives. The most compelling application of Baconian empiricism to thinking about morality is by Hume. Hume saw morality as a product of the principle that humans try to maximize pleasure and avoid pain, yet even Hume was not fully deterministic in his thinking, since the principle he invokes is teleological. One source of pain, Hume believed, is the suffering of others. Seeing them suffer causes pain in us—a phenomenon he called *sympathy*. It is sympathy, he theorized, that leads to behavior that would otherwise appear to be altruistic.

This idea has been taken up by environmental philosophers since the 1990s. If Hume's theory of morality is correct, the planet will be saved only if human sympathy can be extended beyond family and neighbors and the wider human family to embrace animals and plants and, as may then be necessary, the world itself.

When it came to working out what social policies should be adopted in an individualistic world, it was clear to Bentham what the touchstone should be: Do that which produces the greatest pleasure. In the nineteenth century John Stuart Mill (1806–1873) adopted this perspective as a principle for guiding the actions of individuals, a principle that became known as utilitarianism. The principle continues to recommend itself, as it does to some environmental thinkers, once the happiness (pleasure) to be taken into account has been widened to include that of animals and all other sentient entities.

SOCIETY

The Cartesian emphasis on the conscious experience of the individual, experience that was essentially private according to Descartes, was but one aspect of a developing theme of early Modernity: the rise of the individual.

An early landmark of individualistic thought was *The Prince*, by Niccolò Machiavelli (1469–1527), purporting to be a manual for the guidance of would-be rulers in the new world, guidance based on the assumption that both would-be ruler and prospective subject could be counted on to pursue with total focus their own individual interest. Others began to look at social life not as a given, but as

the outcome of individuals coming together. Hobbes asked, What reason would individuals have for giving up their independence and agreeing to put themselves under the restrictions of communal living? His answer: security. The individual person is prey to every other individual person unless they together agree to set up some kind of authority charged with keeping the peace. One should think of society as bound together by a kind of conditional agreement: individuals agreeing with each other to give up their freedom for effective security. For such security Hobbes thought there needed to be a central authority, which, with some prudence, he declared could be one person, such as a king, or a collective body, such as a parliament. This entity, in pursuit of its mission, was to be thought of as devising both morality and law.

Locke adopted a different starting point. Morality is God-given and hence was in place before society was established. This natural law endowed individuals with rights, such as the right to own property. And in an innovation that had direct implications for conceptions of the environment, Locke endowed the new individual with the capacity to own land—not only to own it, but to acquire it through the simple expedient of using it in some way.

Locke's thinking on this point was the thinking of a European before the beginning of the eighteenth century looking outward to a New World of apparently unlimited natural resources. These unlimited natural resources included land, which, in the European perception, was owned by nobody and there for the taking. Such an attitude—misconceived in more than one way and not completely extinct even today—can be seen with hindsight to have fueled the heedless exploitation that has created the contemporary world and now threatens its end. This element of Locke's political philosophy has been argued to structure environmental attitudes today.

Even though Locke considered all people to be essentially equal, a central authority was necessary, he thought, because rights needed enforcing. His theory was that people transfer what little enforcement power each individual possesses to a single entity, which ends up with sufficient power to do what is asked of it. Unlike Hobbes's sovereign power, Locke's was not the author of all law but the subject of natural laws legislated, prior to society, by God. If these constraints were flouted, citizens were justified in rebelling. The founders, much influenced by Locke, thought that the rebellion of the United States against the British monarch was a case in point.

Rousseau's social contract was another variant on the theme of individuals having reasons to come together. To preserve their essential freedom while setting up a central authority, Rousseau proposed that individuals should think of themselves as contributing their individual wills to a composite General Will, a new entity thereby legitimized as the supreme authority. Napoleon for one thought that the General Will massively shaped the revolution of 1789 and its aftermath.

SECULARISM

The backdrop to the changes in conceptions of the universe and its denizens is the growing secularism within culture. In insisting that what happens in the world is the result of the operation of secondary causes, the early Moderns became committed to the tenet that events are determined by universal laws (see sidebar). Among those who sought to retain their religious commitment, this led to a theology called *deism*: There was a Creator, but what he created was essentially a set of universal laws and a machine that has been running in accordance with them ever since.

This was the creed of Voltaire, one of the group of thinkers known as the *philosophes*. This group drove the great encyclopedia project that did much to define the Enlightenment: *Encyclopédie, ou dictionnaire raisonné des sciences, des arts et des métiers* (Encyclopedia, or a Systematic Dictionary of the Sciences, Arts, and Crafts), under the editorship of Denis Diderot (1713–1784) and Jean le Rond d'Alembert (1717–1783). A register to be made of all the knowledge that could be seen as sponsored by the new science, by then a mighty undertaking, it conveyed the message that the Baconian enterprise had already yielded substantial improvements to the human condition and that, as the enterprise marched on, progress would continue. The encyclopedia was eventually curtailed for its anticlericalism, but not before its anticlericalism had been clearly conveyed. Socializing in the salons of mid-eighteenth-century Paris were a mix of theists and deists, atheists and skeptics and agnostics. Their common ground was not religious commitment, but commitment to the modern project of developing new knowledge in the service of human well-being. In his famous essay "What Is Enlightenment?" (1784), Kant gave powerful encouragement to the growing secular sentiment by answering, the courage to use one's own judgment.

It was the philosopher David Hume who gave the profoundest exposition of the "anticlericalist" case. There are no valid proofs of the existence of God. Our senses, which are the only sources of substantial knowledge, can tell us little indeed, presenting us with only a passing sequence of chaotic, unconnected impressions, and the self to which they make their presentations are only another set of passing impressions. Hume's challenge, of explaining how from these unpromising raw materials we derive our belief that we are persistent beings in a persistent world, is with us today—being addressed most promisingly by cognitive science.

In underwriting the Baconian project, the *philosophes* and their supporters sponsored the profound and far-reaching eighteenth-century program of improvement. Through revolutionary developments across the Western economies, but especially in food production and sea trade, the physical environments in which people lived were transformed, and the exploitation of natural resources worldwide were taken to new levels.

ESCAPE FROM CAUSALITY

At the end of the early modern period, the Baconian plea to concentrate on secondary causation was challenged not from within the now established and flourishing science but by a new turn in philosophy. Kant, fearful of the deterministic implications of Baconianism when applied to human beings, argued that humans live partly in a world not subject to causality. In this domain, the noumenal world, rational beings are free in one sense to pursue goals, although in another sense they are constrained by their rationality, which demands that they avoid inconsistency. This rationality, Kant thought, is the source of morality.

Kant maintained that his grounding of morality in rationality could be expressed in a number of ways, for example, in the formula "You should always treat people as ends and not solely as means." Such a gloss highlights the sharp distinction that he draws between human beings (as creatures with rationality and thus ends) and all other entities of which we humans have experience, including nonhuman animals and natural systems like rivers and oceans and indeed the earth itself. In carving out a place for morality, he thus insisted on a moral boundary between human beings and nonhuman animals, which Bentham and Hume had begun to erode, and buttressed philosophically the disturbing cruelty of farm and laboratory that marked his period and those that followed. In the realm of aesthetics, Kant appears to have thought that the appreciation of works of art and of landscapes relies on regarding them as free, like morality, of the causal nexus—an idea built on in contemporary aesthetics of nature.

SAVING THE FUTURE

It is somewhat received opinion that the early modern outlook, as partially reflected in its philosophizing, nourished the roots of a profligate, careless, and disastrous attitude toward the environment. It is not clear that this charge is justified. Despite some vivid writing, Bacon, at the outset, urged that we should do what we can to improve the world that our children and their children have to live in. This ambition contrasts with the focus of almost all the medieval thinkers, fixed on the world to come, and with that of modern neo-romantics, who seek guidance not from evidence-based science, but from faith-based authorities and intuition. It was, after all, the heirs of Bacon who hoisted the warning flags against the impending disasters that presently threaten us—disasters for a long while ignored by the nonscientific world. And it is they, it may be argued, who have the most promising policy for addressing it.

IV. NINETEENTH-CENTURY PHILOSOPHY

Many nineteenth-century philosophers—including Georg Wilhelm Friedrich Hegel, Arthur Schopenhauer, John Stuart Mill, and Friedrich Nietzsche—held views about nature and animals that are relevant to and sometimes

Georg Wilhelm Friedrich Hegel, 1884. *Hegel (1770–1831) was a nineteenth century German philosopher. Hegel's views about nature fell somewhat between those of his contemporaries: he believed that nature was rational rather than creative, but believed that this rationality was still inferior to that of human beings.* **THE LIBRARY OF CONGRESS.**

anticipate environmental ethics. Their views on these subjects also reflect broader developments in nineteenth-century philosophy.

Until the 1840s idealism in the forms developed by the Germans Johann Gottlieb Fichte, Friedrich Wilhelm Joseph Schelling, and Hegel was the dominant outlook in philosophy. Central to German idealism was the belief that human beings are free, with freedom (or autonomy) defined as the ability to act and think independently of causal determination. From the 1840s onward a range of more naturalist philosophical approaches became dominant. According to those approaches, human beings are natural, part of the natural universe understood as a causal order. The later nineteenth century saw a resurgence of idealism, with many philosophers combining elements from idealism and materialism. Both German idealism and naturalism have mixed implications for environmental ethics.

GERMAN IDEALISM AND NATURE: FICHTE AND SCHELLING

German idealism developed out of Immanuel Kant's philosophy. The German idealists endorsed Kant's view that human beings are autonomous, capable of breaking from causal determination to set their own values and thoughts. However, Kant thought that human beings not only are autonomous but also appear empirically—in everyday experience—to be part of nature, which he understood as the fully determined causal order of Newtonian science.

On the basis of these Kantian views, Fichte held that the self's freedom conflicts with its empirical status as a natural, embodied person whose sensations are causally determined. This conflict prompts the self to strive to overcome its determination by nature and become completely free. The self therefore endlessly strives to dominate and impose its will on nature (Fichte 1987 [1800]). The more the self succeeds in "determining" or shaping the character of nature through its activities, the more the self, in being determined by nature, actually remains self-determined.

Schelling reacted against Fichte's insistence on the conflict between self and nature. Schelling argued that human freedom is possible only if it emerges out of and depends on a preexisting form of freedom within nature. In his *First Outline of a System of the Philosophy of Nature* (2004 [1799]) he maintains that nature is free in the sense that it originally consists in a pure "productivity" or creativity that fixes itself in a succession of particular natural objects.

Schelling devised his account of nature partly through a priori reasoning about what nature must be like for human freedom to be possible and partly by drawing together the results of the empirical sciences of his time, such as contemporary chemistry, which seemed to reveal creative, self-transforming energies in nature. *Naturphilosophie*—"philosophy of nature"—was what Schelling called his partly speculative, partly empirical form of inquiry into nature, which became popular among early nineteenth-century scientists and led to some real discoveries, such as electromagnetism. Although midcentury scientific materialists repudiated *Naturphilosophie*, insisting that scientific inquiry must be purely empirical, *Naturphilosophie* influenced forerunners of ecology such as Ernst Haeckel.

Outside Germany, contemporary environmental philosophers seldom discuss Schelling. However, he anticipated environmental ethics with his rejection of Fichte's advocacy of human domination over nature, contrasting emphasis that human freedom depends on the freedom of nature, and replacement of mechanistic views of nature with the idea of nature as a creative whole.

GERMAN IDEALISM AND NATURE: HEGEL

Hegel's position on nature lies midway between those of Fichte and Schelling. In his *Philosophy of Nature* (1970 [1830]), Hegel sees nature as rational rather than creative. For Hegel the natural world is rational not only in being intelligible to people but also in that natural things in themselves form a rational order in which some things resolve internal conflicts within others. Like Schelling, Hegel reached his conclusions about nature on a partly a priori and partly empirical basis. Also like Schelling, Hegel insisted that human rationality depends on the rationality of nature, and he saw nature not as a mechanism but as a rational whole.

However, Hegel thought that the rationality of nature is inferior to that of humanity because nature is mind that is "outside itself," that is, not self-conscious. As a result, Hegel argued in his political philosophy that human beings should appropriate and impose their will on natural things so that those things will come to reflect the higher, more fully developed rationality that human beings possess. To this extent Hegel, like Fichte, provides a philosophical justification for human mastery over nature.

Thus, German idealism can support the domination of unfree nature by free humanity (Fichte) or can treat human freedom as depending on and requiring the freedom of nature (Schelling). The two philosophical strands can be combined by reinterpreting the freedom of nature as rationality and seeing it as an inferior version of human rationality (Hegel).

During the middle of the nineteenth century, German idealist thought became unpopular with philosophers, but some of its ideas were revived later in the century by the British idealists, including F. H. Bradley and T. H. Green. Green revived aspects of Hegel's political philosophy, while Bradley's metaphysics was influenced by Hegel, among others. However, nature was not a major preoccupation for the British idealists as it had been for the German idealists.

SCHOPENHAUER ON COMPASSION AND THE WILL IN NATURE

Schopenhauer's ethics of compassion, which he developed in the 1810s, has influenced contemporary environmental ethics. His ethics rests on his metaphysics, which shares features with the German idealist systems but also presages the rise of naturalism in the later nineteenth century.

Following Kant, Schopenhauer claimed in *The World as Will and Representation* (1969 [1844], first edition 1819) that the world appears to consist of distinct items causally related in space and time because of the nature of human perception. To explain what the world is like really rather than what it apparently is, Schopenhauer first claims that I perceive my own body as one spatiotemporally located, causally related item among others. However, when I perform actions with my body, I am directly aware that those actions express my "acts of will." I therefore know that those acts of will are the reality underlying and manifesting itself in my body as it appears to me. Moreover, my conscious and deliberate acts of will emerge from my deeper unchosen and unconscious will to live: to stay alive and reproduce (sexually). Yet because there appear to be individual items only because of my mode of perception, my will cannot really be *my* will as distinct from the wills of others. In reality, there can be only one will that all things manifest. The will-to-life, then, occurs in all living creatures, not only all human beings.

Indeed, ultimately, because the will is undivided, it must pervade nonorganic nature too. Schopenhauer drew on strands of contemporary empirical science that supported this view that all natural processes (including gravitation, magnetism, and crystal formation) are pervaded by will. The result is a partly a priori, partly empirical theory of nature that is not unlike those of Schelling and Hegel; this is ironic because Schopenhauer reviled German idealism as pretentious nonsense. Unlike the German idealists, Schopenhauer denied that human individuals are free. His more naturalistic view was that human actions, like those of all living beings, ultimately are determined by the will-to-life. (The will itself, though, is free, because causality applies only to appearances.)

In ethics, Schopenhauer held that all human beings are more or less egoistic because they cannot help pursuing whatever they think will further their survival. The superior ethical attitude, though, is one of compassion for other human individuals and for animals. This attitude rests on the insight that all beings are driven by the same will-to-life as oneself and that these beings—if they are sentient, as humans and animals are—undergo suffering as a result because their endless willing leaves them forever unsatisfied. The ideally compassionate person will be as concerned about reducing the sufferings of other human beings, and to a lesser extent those of nonhuman animals, as about relieving his or her own suffering. The sufferings of nonhuman animals are of less concern because animals suffer less intensely than humans with their "enhanced clearness of consciousness" (Schopenhauer 1969 [1844], p. 372). Consequently, Schopenhauer thought, humans may kill or extract work from animals but may not treat them cruelly or vivisect them. Schopenhauer's metaphysically based ethics of compassion influenced Albert Schweitzer's reverence-for-life environmental ethic, which recommends "practising the same reverence toward all will-to-live [especially that of humans, animals, and plants], as toward [one's] own" (Schweitzer 1989 [1923], p. 33).

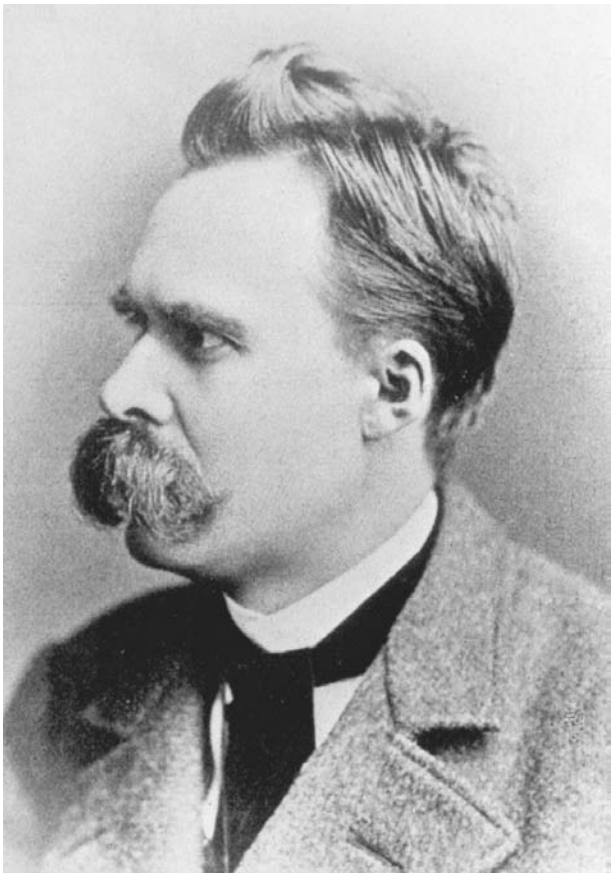
JOHN STUART MILL ON ANIMALS AND NATURE

The middle part of the nineteenth century saw the rise of a variety of naturalist philosophical approaches, including scientific materialism, which treated the natural universe as a vast godless mechanism and Comteian positivism, which considered science rather than metaphysics to be the paradigm for knowledge. The most important naturalist philosopher was John Stuart Mill. For Mill humans are part of nature, sentient creatures who desire pleasure and shun pain, and ethics must be based on these facts.

Mill developed Jeremy Bentham's utilitarianism. According to Bentham's well-known axiom, an action is right if it increases the overall amount of happiness or pleasure. Because nonhuman animals can suffer even if they cannot talk or reason, Bentham held that the pleasures and pains of animals should be factored in when one is calculating the utility of actions and laws. Mill defended Bentham's position on animals against William Whewell's objection that it meant—absurdly in Whewell's opinion—that human happiness sometimes has to be sacrificed for the greater pleasure of animals. Regarding Whewell's objection as little more than a selfish prejudice, Mill replied that an action or institution is wrong if it "causes more pain to animals than it gives pleasure to man" (Mill 1969 [1852], p. 187).

As Mill's opposition to cruelty to animals illustrates, he advocated reconstructing society and laws on a rational, utilitarian basis. He therefore argued in his essay "Nature" (1874) against conservative appeals for people to act "according to nature." For Mill those appeals merely sanctify the status quo, which appears "natural" because of its longevity. To refute those conservative views Mill distinguishes two main senses of the term *nature*. First, in contrast to the "supernatural," nature means "all the powers existing in either the outer or the inner world and everything which takes place by means of those powers" (Mill 1958 [1874], p. 6) or, in short, "all facts actual and possible" (Mill 1958 [1874], p. 5). Second, in contrast to the "artificial," nature means whatever exists or happens "without the voluntary and intentional agency of man" (Mill 1958 [1874], p. 6). In neither sense is nature a moral standard: Under the first sense people cannot not act according to nature, whereas under the second sense people cannot avoid acting unnaturally.

More dubiously, Mill also argued in "Nature" that people positively ought to act against nature (in the second sense)—that is, transform and improve it—because nature is wantonly destructive. He speaks as if nature deliberately acted wrongfully in inflicting hurricanes, diseases, and other ills on humanity. This contradicts both Mill's denial that nature exercises intentional agency and his advice that people should not personify nature. Nonetheless, Mill had valid utilitarian grounds for recommending that people should transform and improve nature. For Mill, this should be done to increase the happiness of humans and other sentient creatures, whereas natural things (nonhuman animals excepted) do not merit moral consideration because they are not sentient.



German Philosopher Friedrich Nietzsche. *Nietzsche (1844–1900) is known for employing a naturalistic philosophical outlook toward the environment. He advocated a "loyalty to the earth" attitude, and is always cited by animal ethicists for his claim that man is not inherently superior to any other animal.* **TIME LIFE PICTURES/MANSELL/TIME LIFE PICTURES/GETTY IMAGES.**

NIETZSCHE AND NATURALISM

The nineteenth-century philosopher most often discussed by contemporary environmental thinkers is Friedrich Nietzsche. His philosophical outlook is largely naturalistic. Nietzsche rejected the traditional Christian devaluation of the natural world in favor of the "beyond" and devaluation of human bodies and instincts in favor of the soul. Summing up this rejection, Nietzsche advocated "loyalty to the earth" in *Thus Spoke Zarathustra* (1883–1885). His this-worldly orientation has commended him to some environmental ethicists.

Nietzsche's this-worldly orientation includes an insistence that human beings are an animal species. Sometimes he suggests that humans are simply a highly evolved species of ape, but elsewhere he suggests that humans' highly developed mental and moral powers indicate that they have evolved beyond being apes. Generally, though, Nietzsche stresses that humans are neither different in kind from nor inherently superior to other animals. These claims—and Nietzsche's copious use of animal imagery—have made his work of interest to animal ethicists.

Despite claiming that humans evolved from apes, Nietzsche was critical of Charles Darwin's account of evolution by natural selection (Nietzsche's understanding of that account was not wholly correct). Nietzsche understood Darwinism to be the "reactive" view that organisms are formed by their interactions with their environment and by their struggle for survival. In contrast, Nietzsche favored the "active" view that the development of organisms is driven by vital, creative forces within them (their "will-to-power"), forces that seek to expand in power, not merely to survive.

Nietzsche and Animality It fell to Nietzsche to give a naturalist explanation for the features that appear to make human beings different in kind from (other) animals, especially humanity's level of moral conscience, culture and self-awareness. In *On the Genealogy of Morality* (1994 [1887]) Nietzsche explained those features by constructing a history of how conflicts between human groups, urbanization, and religion have inhibited human beings from discharging their aggressive, destructive instincts—which they share with beasts of prey—outward in violence toward others. Instead, humans have learned to turn their aggression inward onto themselves, partly by judging, reflecting upon, and cultivating themselves. Thus, for Nietzsche, civilization results from human beings having turned some of their aggressive energies against the rest of those energies. This process has left conformist instincts, which humans share with herd animals, free to become dominant within them.

Nietzsche did not want people to regain the uninhibited cruelty of beasts of prey. Instead, he thought that human beings should turn their acquired capacity for cruelty to themselves against their ingrained moralism and conscientiousness. This would transform (a select, sufficiently "strong" few) people from "camels," burdened with acquired self-cruelty and domesticity, into "lions," at war with their own moral habits, and finally into "children," liberated from morality to create new values playfully (Nietzsche 1961 [1883–1885], pp. 54–56).

As Nietzsche's parable of the camel-lion-child metamorphosis shows, he valued beasts of prey—eagles, serpents, lions—over domesticated and herd animals—lambs, cows, camels. Here Nietzsche seems to rely on traditional stereotypes that associate each animal species with a particular human quality: eagles with pride, serpents with wisdom, lions with courage. Perhaps, then, Nietzsche's real interest was not in nonhuman animals as such but in promoting pride, wisdom, and courage in humans and in rooting out humanity's ingrained meekness, conformity, and resignation.

Arguably, though, Nietzsche thought that animal species have evolved and adapted to acquire particular characteristics, so that when people display, for example, wisdom, they really are adopting a serpentine way of being. Even so, this means that Nietzsche's concern is to promote certain animal traits, such as serpentine wisdom, within human beings rather than to promote the flourishing of nonhuman animals. Indeed, he tended to condemn compassion for animals on the grounds that this attitude bespeaks a person too domesticated and enervated to endure any cruelty. He associated compassion for animals with Schopenhauer, who greatly influenced him but against whom he later reacted. Unlike Schopenhauer, Nietzsche thought that people must affirm and embrace rather than try to alleviate the suffering that life entails and thus must not flinch from their own cruelty

Nietzsche and Nature Nietzsche was largely but not entirely a naturalist. The account of the natural world as a system of interacting forces that he sketched in his posthumously published notebooks *The Will to Power* (1967 [1901]) has idealist aspects, reflecting the late-nineteenth-century trend toward combining naturalism and idealism. According to this account, which is influenced by Schopenhauer's idea of the will-to-life, all things are essentially "will-to-power"; that is, they consist of plural forces, each striving to dominate and harness the others. For instance, human beings are composed of various drives or instincts, including aggressive and conformist ones. Nietzsche maintained that each force interprets the world in relation to its goal and continually adapts and reinterprets its goal to harness other forces to it. He thus regarded forces as self-determining and as having some kind of intentionality.

It has been claimed that Nietzsche's idea of the world as will-to-power anticipates ecological ideas of nature as a living process or self-regulating system. Yet Nietzsche does not suggest that people should respect natural things as self-determining. Because for him everything is will-to-power, humans can do nothing other than pursue enhanced power for some of their instincts, and this often will require harnessing and dominating other natural things.

CONFLICTING IDEAS ABOUT NATURE

Some idealists, such as Schelling, argue that nature is autonomous and therefore should not be dominated. But because for idealists it is autonomy that confers value on natural things, idealists readily reassert the superior worth of human beings, whose autonomy is more apparent or highly developed. In contrast, more naturalistic philosophers such as Mill and Nietzsche place humanity back within nature, as an animal species, and thus tend to reject or at least qualify assertions of human superiority over other animals. However, these naturalistic philosophers also tend to think that human beings should not hesitate to transform nature in their own interests whether because nature lacks the sentience that is the criterion of moral standing (Mill) or because people should embrace the tyrannical pursuit of power that is essential to all things (Nietzsche).

V. CONTEMPORARY PHILOSOPHY

Environmental philosophy in its modern form developed in the late 1960s, the product of concerns arising from diverse quarters: naturalists, scientists and other academics, journalists, and politicians. A sense of crisis and doom pervaded the time, reflecting fears about the Cold War and the threat of nuclear annihilation; this malaise helped to spawn the protest music and countercultural protests of the 1960s. In 1962 Rachel Carson published the best-selling book *Silent Spring*, which documented the accumulation of dangerous pesticides and chemical toxins throughout planetary food webs. In 1968 the journal *Science* published "The Tragedy of the Commons" by Garrett Hardin, who argued that human self-interest and a growing population would inevitably combine to deplete resources and degrade the environment. In the same year another best-seller, Paul Ehrlich's *Population Bomb*, anticipated hundreds of millions of deaths in the coming decades because of the failure of food supply to keep pace with an ever-expanding global population. Ehrlich also claimed to foresee an imminent and dramatic decline in U.S. population and life expectancy, and some of these gloomy predictions were echoed in *The Limits to Growth: A Report for the Club of Rome's Project on the Predicament of Mankind* (Meadows et al. 1974).

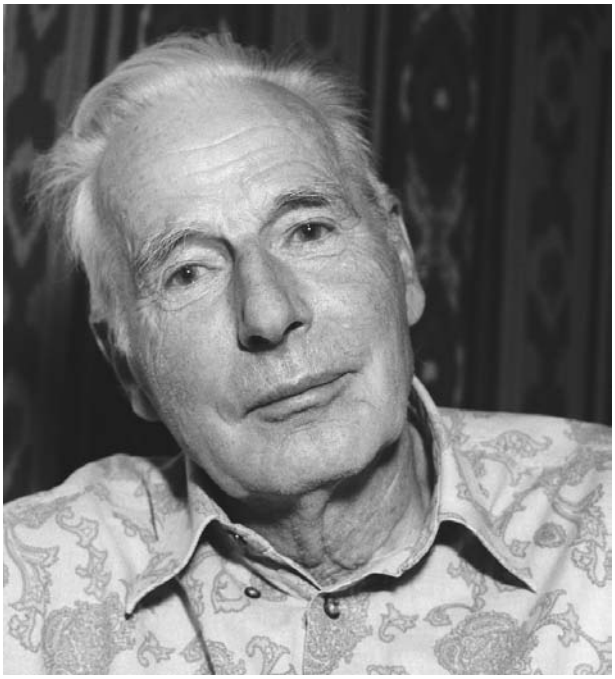
Fears about nuclear war, threats of pollution, and emerging awareness of social injustice coalesced first in popular and folk music and then found less poetic expression in academic work. In a seminal essay that appealed to increasingly disenchanted Marxist and left-leaning thinkers, Murray Bookchin remarked that ecology was a critical science with "explosive implications" because "in the final analysis, it is impossible to achieve a harmonization of man and nature without creating a human community that lives in a lasting balance with its natural environment" (Bookchin 1970 [1965]). When the historian Lynn White Jr. published an essay in 1967 claiming that Judeo-Christian thought was itself a major driver of environmental destruction, the scene was set for full-scale philosophical and ethical soul-searching. Inspired by the work of the American ecologist, forester, and environmentalist Aldo Leopold (1887–1948), thinkers in Australia and the United States produced new defenses of the key ideal of his land ethic: that "land is to be loved and respected is an extension of ethics" (Leopold 1949, Foreword, pp. viii-ix). Richard Routley (who later took the name Richard Sylvan) argued that a narrow focus on humans as the only morally valuable things on earth was a kind of unjustifiable discrimination—"human chauvinism" (Routley 1973, pp. 207ff). Routley proposed the following thought experiment: Consider a case where the last people on earth can choose to eliminate all other living

things after their own demise. If humans are the only morally valuable things on the planet, then the last people seemingly do no moral wrong by eliminating all these other forms of life. Yet, Routley pointed out, there is a strong intuition, shared by many people, that such a destructive final act would be morally abhorrent. One basis for such an intuition would be the presence of some kind of intrinsic or inherent value in nonhuman organisms (Routley 1973, Routley and Routley (1980).

A key ingredient in Leopold's land ethic was the notion that the community of life itself matters, not just its individual members; he wrote that "a thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise" (Leopold, 1949, pp. 224–225). Holmes Rolston III explored the implications of this view by looking for ways in which to make sense of the idea that humans have duties not only to individual humans and animals but also to larger wholes—species and ecosystems, for example. Like Routley's last-person argument, Rolston's ideas were illustrated by imagined cases: for example, the butterfly collector who considers eliminating the last members of a rare *Papilio* species to enhance the value of his own specimens (Rolston 1975). This example is meant to prompt the following question: In addition to any duties humans might have to individual butterflies, do they also have duties to preserve the species and processes that sustain life on earth? On Rolston's natural theological view biological processes merit respect because they are intrinsically valuable, embodying the sacred nature of God (Rolston 1989, 1999).

DEEP ECOLOGY AND ANIMAL LIBERATION

The development of Deep Ecology by the Norwegian Arne Naess followed a rather different route (see Witoszek and Brennan 1999 for a historical survey). During a climbing expedition to Nepal, Naess found that Sherpa people would not venture onto sacred mountains. In the wake of this discovery, Naess and two of his Norwegian friends discussed formulating a new philosophy that would extend such reverence for mountains to all of nature, emphasizing the interconnectedness of each thing in larger webs of value. In place of the isolated or atomic individual, Naess postulates people and other things as constituted by their relationships with others—as knots in a larger web of life (Naess 1973). While such a relational conception of the self might be thought to resonate with animist, Confucian, or Buddhist traditions (Naess had no problem with such conflations), Naess himself claimed to draw his philosophical inspiration largely from the seventeenth-century Dutch philosopher Baruch Spinoza (1632–1677). Taking relationships seriously,



Arne Naess. *In 1973, Naess coined the term "deep ecology," intending to highlight the importance of norms and social change in environmental decisionmaking.* **PHOTO COURTESY OF SIJMEN HENDRIKS.**

Naess argues, means that humans should care for the extended, or ecological, self because each person is more than just his or her body. Extended self-concern obliges humans not only to connect with and care about the other people who have made them what they are but also to care for the multifarious systems and beings on which continued human existence depends.

In his early work Naess seemed to regard all living things as having equal value, at least in principle, but by the 1980s he was prepared to support only the weaker claim that the flourishing of all life, both human nonhuman, has value in its own right. In collaboration with George Sessions, Naess also formulated a Deep Ecology platform in 1984, listing the eight points on which deeply committed conservation philosophies could agree while leaving up to individuals how best to interpret such principles in specific cases (Witoszek and Brennan 1999). Whereas Routley and Rolston argued against the human-centered bias of conventional moral theory, Naess's early work in Deep Ecology cast doubt on the individualistic and decontextualized nature of much European and North American philosophical and moral theory.

Through the 1970s and 1980s these themes of atomism, human-centeredness, and the scope of what is intrinsically valuable set much of the agenda for further theorizing. With the introduction of the idea of "'animal liberation" in 1973 (Singer 2003), there was a swell of support for the idea that

the capacity to feel pleasures or pains might be a significant criterion of moral value, or at least of moral considerability. On this view, although things that are morally valuable ought to be protected, things that are "morally considerable" ought to figure directly in human thinking and planning but need not necessarily be protected. In the North American and European ethical tradition, moral considerability has been connected with notions of rationality, self-awareness, consciousness, and other typically human features. Environmental philosophy has explored new criteria of such considerability, including being alive (Goodpaster 1978); being a community or a holistic entity of a certain kind (Callicott 1980, 1987; Rolston 1994); being an entity or organism that has an end (or telos) in itself (Taylor 1981, 1986, Rolston 1994); being a subject of a life (Regan 1983); lacking intrinsic function (Brennan 1984); being a product of natural processes (Rolston 1989, Elliott 1982); or being naturally autonomous (Katz 1997). While no agreement on such a criterion emerged, it was clear that the notions of respect for nature, nature's value, nature's intrinsic worth, and the moral considerability of natural things were not only intelligible but also capable of being hotly debated in considerable depth.

Val Plumwood. *One of the most important feminists to emerge in environmental philosophy, much of Plumwood's work focused on analyzing, critiquing, and providing alternatives to dualisms that she believed lie at the heart of the domination of women, nature, and others.* © NEWSPIX.

A DEVELOPING FIELD

Alongside the growth in publications and research on environmental ethics, metaphysics, and the status of nature, new courses and units sprang up in universities across the world. Baird Callicott taught the first environmental philosophy course in the United States in 1971, at the University of Wisconsin, Stevens Point. A year later William Blackstone organized the first conference on environmental ethics which was held at the University of Georgia, and its proceedings contained many seminal papers (Blackstone 1974); the following year Bookchin's Institute for Social Ecology was established at Goddard College in Vermont. The 1970s saw a remarkable mushrooming of meetings, seminars, classes, and conferences in the English-speaking world. Alongside the new environmental ethics the field of environmental theology also started to develop, stimulated by discussion of whether Christian humanism was incompatible with radical environmentalism and whether the work of thinkers such as Teilhard de Chardin was environmentally relevant (Teilhard de Chardin 1959; Cobb 1972, 1990). The journal *Environmental Ethics* was launched in 1979 under the editorship of Eugene Hargrove. Although Hargrove also contributed to the literature of environmental philosophy, a major part of his influence in directing and consolidating the field has been his editorship of this journal since its inception.

By 1974 an early backlash had occurred in the form of the contention of the Austrialian philosopher John Passmore that the Judeo-Christian ethical tradition already contained resources enough to ensure protection and stewardship of nature (Passmore 1974). The issue of whether there really was need for a new ethic for the environment dominated much of the philosophical discussion for the next decade (Rodman 1977, 1983; Attfield 1983; Callicott 1986; Rolston 1986). Continuing into the 1980s, the debate expanded beyond questions of value and ethics and extended to metaethical issues (the meaning of moral terms and the objectivity of value), metaphysical issues (the nature of the cosmos and the place of humans within it), and wider questions about human consciousness, identification, and awareness. The appearance of a number of systematic single-author books and collections of essays (Bookchin 1980, Elliot and Gare 1983, van de Veer 1986, Attfield 1983, Rolston 1988, Brennan 1988, Callicott 1989, Hargrove 1989, Norton 1991) helped to solidify and clarify the main currents of thought in environmental philosophy.

It soon became possible to classify environmental philosophies in terms of various positions or movements: for example, wise use, Social Ecology, ecofeminist, the land ethic, reverence for life, Deep Ecology, bioregionalism, ethics of place, radical activism, wilderness ethics, and animist or panpsychist metaphysics.

Those who regarded themselves as "deep green" were not only the followers of Naess and Deep Ecology but also those who were "fundamentalist" rather than "realist" in their environmental politics. The terminology of "Fundis" and "Realos" was coined in the context of a long-running dispute in the German Green Party during the 1980s and 1990s, with the Fundis committed to veganism, animal rights, and decentralization, while the more pragmatic Realos cooperated with mainline political actors, such as governments, corporations, and existing community organizations (Dobson 1995). Bioregionalists, often inspired by anarchist and socialist models, maintained that small communities located in or around geographically defined zones (the shores of lakes or the areas served by watersheds) would be best able to build sustainable and efficient settlements; feminists sometimes suggested that human-centeredness was a variant of male-centered thinking. Few writers exemplified just one of these positions, and many key writers span several of them. For example, some feminists supported deep ecology and bioregional understandings (Plumwood 1993).

Although some writers argued for a holistic metaphysics and ethics (Fox 1995, 2007), others—Rolston, for example—proposed a hierarchical ethic attributing value not only to individual things but also to entire species and ecosystems. Callicott's defense of a Leopold-inspired land ethic became increasingly complex and nuanced as he tried to give weight to different scales and degrees of obligation to the various communities in which human beings live (Lo 2001).

By the early 1990s the field of environmental philosophy was well established, as evidenced in the appearance of new societies and journals. An initiative by Holmes Rolston III established the International Society for Environmental Ethics (ISEE), the first newsletter of which appeared in 1990; the International Association for Environmental Philosophy (IAEP) held its inaugural conference in 1998. An important and pioneering interdisciplinary journal, *Organization and Environment,* was launched in the United States in the late 1980s, deepening academic interest in the field; it was soon followed by *Environmental Politics* (1990) and another interdisciplinary journal, *Environmental Values*, which debuted in the United Kingdom in 1992. By then dozens of postgraduate and undergraduate courses in environmental philosophy had been established at several centers in the United Kingdom, the United States, Israel, and Australia, along with several interdisciplinary-studies programs with a philosophy or ethics component. Degree programs had begun to emerge, such as the Lancaster University (U.K.) M.A. in values and the environment, announced in 1990. The launch of the journal *Ethics and the Environment* in 1996 bore further testimony to the growth and liveliness of what had by then become a new subdiscipline of philosophy and a focus of interdisciplinary research. In the following year another new journal—*Worldviews: Environment, Culture, Religion*—broadened the range of publishing opportunities in the field. With a focus on continental and comparative philosophy, the IAEP launched its journal—*Environmental Philosophy*—in 2004.

Holmes Rolston III. *One of the key figures in contemporary environmental ethics, Rolston's 1975 article, "Is There an Ecological Ethic?" sparked interest in the subject within academic philosophy. A long-time professor at Colorado State University, Rolston used imagined cases to prompt individuals to consider their duties toward nature.* **PHOTO BY BILL COTTON. As feminists and political and literary theorists increasingly turned their attention to environmental issues, more debates and schisms arose from the 1980s onward. Indeed, the ways in which the environment and nature have been construed in philosophical, political, and literary texts has furnished the materials for a new area of literary theory: "ecocriticism" or "ecocritique" (Meeker 1972, Buell 1995, Glotfelty and Fromm 1996, Luke 1997, Morton 2007). Although the preservation of the wilderness was the focus of

many of the writings in the 1970s and 1980s, the following decades saw an increasing concern with issues such as restoration, urban environments, pollution, and resource depletion and their connections with poverty, dispossession, housing, environmental policy, social justice, economics, and sustainability (Wenz 1988, Sagoff 1990, Guha and Martinez-Allier 1997, Light 2001, Norton 2003, Shrader-Frechette 2005). In this way the burgeoning of environmental concerns helped philosophy to reconnect with and develop the concerns and speculations of scientists and other thinkers.

PHILOSOPHICAL CONTROVERSIES

Since the time of the eighteenth-century German philosopher Immanuel Kant (1724–1804), nature has been a preoccupation of aesthetic theory. With the intensification of environmental concern has come a renewed interest in the question of nature's aesthetic value. This issue has spawned debates among several schools of thought: those who think that natural science can reveal aesthetic qualities (Callicott 1994, Rolston 1995), those who believe that immersion or engagement rather than understanding is the key to aesthetic experience (Berleant 2005), and those who follow John Muir in finding positive value in that which is untouched by humans (Hargrove 1989, Carlson 1984).

By the turn of the twenty-first century, contemporary environmental philosophy had ramified into nearly all areas of philosophical, social, cultural and political theory. Meanwhile, the sciences continued to influence and be influenced by it, as shown, for example, in the fourth volume of the journal *Environmental Values,* which devoted an entire issue in 1995 to the emerging field of ecosystem health.

Discussions in environmental philosophy have imparted fresh impetus to the consideration of problems that are central to mainstream philosophy. One example is the debate over moral pluralism, pursued vigorously since the late 1980s in environmental ethics and now reemerging as a key issue in moral philosophy. One of the twentieth century's best-known moral theorists, W. D. Ross, outlined a pluralistic ethic in which various moral duties—such as keeping promises, self-improvement, and acting justly—are not reducible to any single duty or principle (Ross 1930). Ross's original argument for pluralism makes use of an intuition about "what we really think." Even if some systematic moral theory based on a single principle or duty (or a set of such duties) were to yield satisfying answers to moral problems, Ross argues that such a system would not match "what we really think" when we engage in moral reflection. According to him, "what we really think" is that we have many different—and irreducible—sources of moral obligation.
