## Acknowledgments

On behalf of my late husband, David Liu, I would like to convey his sincere gratitude and respect for all the coauthors who helped, directly or indirectly, currently or in the past, in this product's development. With your help, he accomplished his goal: a comprehensive, authoritative, and current reference. The valuable expertise, strong support, and dedication of all the coauthors will make the *Environmental Engineers' Handbook* an unqualified success.

Special appreciation is extended to Béla Lipták and Paul Bouis, who did the final technical review of manuscript, art and page proofs, sharing their valuable time and advice to complete David's work.

Irene Liu

## CONTRIBUTORS

### PREFACE

The Condition of the Environment  
The Condition of the Waters  
The Condition of the Air  
The Condition of the Land  
Energy  
Population

### FOREWORD

## **1 Environmental Laws and Regulations**

---

- 1.1 Administrative Laws
- 1.2 Information Laws
- 1.3 Natural Resource Laws
- 1.4 Pollution Control Laws

## **2 Environmental Impact Assessment**

---

- 2.1 Background Conceptual and Administration Information
- 2.2 EIA Methods: The Broad Perspective
- 2.3 Interaction Matrix and Simple Checklist Methods
- 2.4 Techniques for Impact Prediction
- 2.5 Decision-Focused Checklists
- 2.6 Preparation of Written Documentation
- 2.7 Environmental Monitoring
- 2.8 Emerging Issues in the EIA Process
- 2.9 International Activities in Environmental Impact Assessment

## **3 Pollution Prevention in Chemical Manufacturing**

---

- 3.1 Regulations and Definitions
- 3.2 Pollution Prevention Methodology
- 3.3 Pollution Prevention Techniques
- 3.4 Life Cycle Assessment
- 3.5 Sustainable Manufacturing
- 3.6 R & D for Cleaner Processes

- 3.7 Reaction Engineering
- 3.8 Separation and Recycling Systems
- 3.9 Engineering Review
- 3.10 Process Modifications
- 3.11 Process Integration
- 3.12 Process Analysis
- 3.13 Process Control
- 3.14 Public Sector Activities

## **4 Standards**

---

### ***Air Quality Standards***

- 4.1 Setting Standards
- 4.2 Technology Standards
- 4.3 Other Air Standards

### ***Noise Standards***

- 4.4 Noise Standards

### ***Water Standards***

- 4.5 Water Quality Standards
- 4.6 Drinking Water Standards
- 4.7 Groundwater Standards

### ***International Standards***

- 4.8 ISO 14000 Environmental Standards

## **5 Air Pollution**

---

### ***Pollutants: Sources, Effects, and Dispersion Modeling***

- 5.1 Sources, Effects, and Fate of Pollutants
- 5.2 VOCs and HAPs Emission from Chemical Plants
- 5.3 HAPs from Synthetic Organic Chemical Manufacturing Industries
- 5.4 Atmospheric Chemistry
- 5.5 Macro Air Pollution Effects
- 5.6 Meteorology
- 5.7 Meteorologic Applications in Air Pollution Control
- 5.8 Atmospheric Dispersion Modeling

### ***Air Quality***

- 5.9 Emission Measurements
- 5.10 Air Quality Monitoring
- 5.11 Stack Sampling
- 5.12 Continuous Emission Monitoring
- 5.13 Remote Sensing Techniques

### ***Pollutants: Minimization and Control***

- 5.14 Pollution Reduction
- 5.15 Particulate Controls
- 5.16 Dry Collectors
- 5.17 Electrostatic Precipitators
- 5.18 Wet Collectors
- 5.19 Gaseous Emission Control
- 5.20 Physical and Chemical Separation

5.21 Thermal Destruction

5.22 Biofiltration

### ***Fugitive Emissions: Sources and Controls***

5.23 Fugitive Industrial Particulate Emissions

5.24 Fugitive Industrial Chemical Emissions

5.25 Fugitive Dust

### ***Odor Control***

5.26 Perception, Effect, and Characterization

5.27 Odor Control Strategy

### ***Indoor Air Pollution***

5.28 Radon and Other Pollutants

5.29 Air Quality in the Workplace

## **6 Noise Pollution**

---

6.1 The Physics of Sound and Hearing

6.2 Noise Sources

6.3 The Effects of Noise

6.4 Noise Measurements

6.5 Noise Assessment and Evaluation

6.6 Noise Control at the Source

6.7 Noise Control in the Transmission Path

6.8 Protecting the Receiver

## **7 Wastewater Treatment**

---

### ***Sources and Characteristics***

7.1 Nature of Wastewater

7.2 Sources and Effects of Contaminants

7.3 Characterization of Industrial Wastewater

7.4 Wastewater Minimization

7.5 Developing a Treatment Strategy

### ***Monitoring and Analysis***

7.6 Flow and Level Monitoring

7.7 pH, Oxidation-Reduction Probes and Ion-Selective Sensors

7.8 Oxygen Analyzers

7.9 Sludge, Colloidal Suspension, and Oil Monitors

### ***Sewers and Pumping Stations***

7.10 Industrial Sewer Design

7.11 Manholes, Catch Basins, and Drain Hubs

7.12 Pumps and Pumping Stations

### ***Equalization and Primary Treatment***

7.13 Equalization Basins

7.14 Screens and Comminutors

7.15 Grit Removal

7.16 Grease Removal and Skimming

7.17 Sedimentation

7.18 Flotation and Foaming

7.19 Sludge Pumping and Transportation

### ***Conventional Biological Treatment***

- 7.20 Septic and Imhoff Tanks
- 7.21 Conventional Sewage Treatment Plants

### ***Secondary Treatment***

- 7.22 Wastewater Microbiology
- 7.23 Trickling Filters
- 7.24 Rotating Biological Contactors
- 7.25 Activated-Sludge Processes
- 7.26 Extended Aeration
- 7.27 Ponds and Lagoons
- 7.28 Anaerobic Treatment
- 7.29 Secondary Clarification
- 7.30 Disinfection

### ***Advanced or Tertiary Treatment***

- 7.31 Treatment Plant Advances
- 7.32 Chemical Precipitation
- 7.33 Filtration
- 7.34 Coagulation and Emulsion Breaking

### ***Organics, Salts, Metals, and Nutrient Removal***

- 7.35 Soluble Organics Removal
- 7.36 Inorganic Salt Removal by Ion Exchange
- 7.37 Demineralization
- 7.38 Nutrient (Nitrogen and Phosphorous) Removal

### ***Chemical Treatment***

- 7.39 Neutralization Agents and Processes
- 7.40 pH Control Systems
- 7.41 Oxidation-Reduction Agents and Processes
- 7.42 ORP Control (Chrome and Cyanide Treatment)
- 7.43 Oil Separation and Removal

### ***Sludge Stabilization and Dewatering***

- 7.44 Stabilization: Aerobic Digestion
- 7.45 Stabilization: Anaerobic Digestion
- 7.46 Sludge Thickening
- 7.47 Dewatering Filters
- 7.48 Dewatering: Centrifugation
- 7.49 Heat Treatment and Thermal Dryers

### ***Sludge Disposal***

- 7.50 Sludge Incineration
- 7.51 Lagoons and Landfills
- 7.52 Spray Irrigation
- 7.53 Ocean Dumping
- 7.54 Air Drying
- 7.55 Composting

## **8**

### **Removing Specific Water Contaminants**

---

- 8.1 Removing Suspended Solid Contaminants
- 8.2 Removing Organic Contaminants
- 8.3 Removing Inorganic Contaminants
- 8.4 Inorganic Neutralization and Recovery

- 8.5 Oil Pollution
- 8.6 Purification of Salt Water
- 8.7 Radioactive Liquid Waste Treatment

## **9** Groundwater and Surface Water Pollution

---

### ***Principles of Groundwater Flow***

- 9.1 Groundwater and Aquifers
- 9.2 Fundamental Equations of Groundwater Flow
- 9.3 Confined Aquifers
- 9.4 Unconfined Aquifers
- 9.5 Combined Confined and Unconfined Flow

### ***Hydraulics of Wells***

- 9.6 Two-Dimensional Problems
- 9.7 Nonsteady (Transient) Flow
- 9.8 Determining Aquifer Characteristics
- 9.9 Design Considerations
- 9.10 Interface Flow

### ***Principles of Groundwater Contamination***

- 9.11 Causes and Sources of Contamination
- 9.12 Fate of Contaminants in Groundwater
- 9.13 Transport of Contaminants in Groundwater

### ***Groundwater Investigation and Monitoring***

- 9.14 Initial Site Assessment
- 9.15 Subsurface Site Investigation

### ***Groundwater Cleanup and Remediation***

- 9.16 Soil Treatment Technologies
- 9.17 Pump-and-Treat Technologies
- 9.18 In Situ Treatment Technologies

### ***Storm Water Pollutant Management***

- 9.19 Integrated Storm Water Program
- 9.20 Nonpoint Source Pollution
- 9.21 Best Management Practices
- 9.22 Field Monitoring Programs
- 9.23 Discharge Treatment

## **10** Solid Waste

---

### ***Source and Effect***

- 10.1 Definition
- 10.2 Sources, Quantities, and Effects

### ***Characterization***

- 10.3 Physical and Chemical Characteristics
- 10.4 Characterization Methods
- 10.5 Implications for Solid Waste Management

### ***Resource Conservation and Recovery***

- 10.6 Reduction, Separation, and Recycling

- 10.7 Material Recovery
- 10.8 Refuse-Derived Fuel
- Treatment and Disposal***
- 10.9 Waste-to-Energy Incinerators
- 10.10 Sewage Sludge Incineration
- 10.11 Onsite Incinerators
- 10.12 Pyrolysis of Solid Waste
- 10.13 Sanitary Landfills
- 10.14 Composting of MSW

## **11 Hazardous Waste**

---

### ***Sources and Effects***

- 11.1 Hazardous Waste Defined
- 11.2 Hazardous Waste Sources
- 11.3 Effects of Hazardous Waste

### ***Characterization, Sampling, and Analysis***

- 11.4 Hazardous Waste Characterization
- 11.5 Sampling and Analysis
- 11.6 Compatibility

### ***Risk Assessment and Waste Management***

- 11.7 The Hazard Ranking System and the National Priority List
- 11.8 Risk Assessment
- 11.9 Waste Minimization and Reduction
- 11.10 Hazardous Waste Transportation

### ***Treatment and Disposal***

- 11.11 Treatment, Storage, and Disposal Requirements
- 11.12 Storage
- 11.13 Treatment and Disposal Alternatives
- 11.14 Waste Destruction Technology
- 11.15 Waste Concentration Technology
- 11.16 Solidification and Stabilization Technologies
- 11.17 Biological Treatment
- 11.18 Biotreatment by Sequencing Batch Reactors

### ***Storage and Leak Detection***

- 11.19 Underground Storage Tanks
- 11.20 Leak Detection and Remediation

### ***Radioactive Waste***

- 11.21 Principles of Radioactivity
- 11.22 Sources of Radioactivity in the Environment
- 11.23 Safety Standards
- 11.24 Detection and Analysis
- 11.25 Mining and Recovery of Radioactive Materials
- 11.26 Low-Level Radioactive Waste
- 11.27 High-Level Radioactive Waste
- 11.28 Transport of Radioactive Materials

# Preface

---

---

---

---

---

*Dr. David H.F. Liu passed away during the preparation of this revised edition.  
He will be long remembered by his co-workers,  
and the readers of this handbook will carry his memory into the 21st Century*

Engineers respond to the needs of society with technical innovations. Their tools are the basic sciences. Some engineers might end up working *on* these tools instead of working *with* them. Environmental engineers are in a privileged and challenging position, because their tools are the totality of man's scientific knowledge, and their target is nothing less than human survival through making man's peace with nature.

When, in 1974, I wrote the preface to the three-volume first edition of this handbook, we were in the middle of an energy crisis and the future looked bleak, I was worried and gloomy. Today, I look forward to the 21st Century with hope and confidence. I am optimistic because we have made progress in the last 22 years and I am also proud, because I know that this handbook made a small contribution to that progress. I am optimistic because we are beginning to understand that nature should not be conquered, but protected, that science and technology should not be allowed to evolve as "value-free" forces, but should be subordinated to serve human values and goals.

This second edition of the *Environmental Engineers' Handbook* contains most of the technical know-how needed to clean up the environment. Because the environment is a complex web, the straining of some of the strands affects the entire web. The single-volume presentation of this handbook recognizes this integrated nature of our environment, where the various forms of pollution are interrelated symptoms and therefore cannot be treated separately. Consequently, each handbook section is built upon and is supported by the others through extensive cross-referencing and subject indexes.

The contributors to this handbook came from all continents and their backgrounds cover not only engineering, but also legal, medical, agricultural, meteorological, biological and other fields of training. In addition to discussing

the causes, effects, and remedies of pollution, this handbook also emphasizes reuse, recycling, and recovery. Nature does not cause pollution; by total recycling, *nature makes resources out of all wastes*. Our goal should be to learn from nature in this respect.

## **The Condition of the Environment**

To the best of our knowledge today, life in the universe exists only in a ten-mile-thick layer on the 200-million-square-mile surface of this planet. During the 5 million years of human existence, we lived in this thin crust of earth, air, and water. Initially man relied only on inexhaustible resources. The planet appeared to be without limits and the laws of nature directed our evolution. Later we started to supplement our muscle power with exhaustible energy sources (coal, oil, uranium) and to substitute the routine functions of our brains by machines. As a result, in some respects we have "conquered nature" and today we are directing our own evolution. Today, our children grow up in man-made environments; virtual reality or cyberspace is more familiar to them than the open spaces of meadows.

While our role and power have changed, our consciousness did not. Subconsciously we still consider the planet inexhaustible and we are still incapable of thinking in time-frames which exceed a few lifetimes. These human limitations hold risks, not only for the planet, nor even for life on this planet, but for our species. Therefore, it is necessary to pay attention not only to our physical environment but also to our cultural and spiritual environment.

It is absolutely necessary to bring up a new generation which no longer shares our deeply rooted subconscious belief in continuous growth: A new generation which no longer desires the forever increasing consumption of space, raw materials, and energy.

It is also necessary to realize that, while as individuals we might not be able to think in longer terms than centuries, as a society we must. This can and must be achieved by developing rules and regulations which are appropriate to the time-frame of the processes that we control or influence. The half-life of plutonium is 24,000 years, the replacement of the water in the deep oceans takes 1000 years. For us it is difficult to be concerned about the consequences of our actions, if those consequences will take centuries or millennia to evolve. Therefore, it is essential that we develop both an educational system and a body of law which would protect our descendants from our own shortsightedness.

Protecting life on this planet will give the coming generations a unifying common purpose. The healing of environmental ills will necessitate changes in our subconscious and in our value system. Once these changes have occurred, they will not only guarantee human survival, but will also help in overcoming human divisions and thereby change human history.

## The Condition of the Waters

In the natural life cycle of the water bodies (Figure 1), the sun provides the energy source for plant life (algae), which produces oxygen while converting the inorganic molecules into larger organic ones. The animal life obtains its muscle energy (heat) by consuming these molecules and by also consuming the dissolved oxygen content of the water.

When a town or industry discharges additional organic material into the waters (which nature intended to be disposed of as fertilizer on land), the natural balance is upset. The organic effluent acts as a fertilizer, therefore the algae overpopulates and eventually blocks the transparency of the water. When the water becomes opaque, the ultraviolet rays of the sun can no longer penetrate it. This cuts off the algae from its energy source and it dies. The bacteria try to protect the life cycle in the water by attempting to break down the excess organic material (including the dead body cells of the algae), but the bacteria require oxygen for the digestion process. As the algae is no longer producing fresh oxygen, the dissolved oxygen content of the water drops, and when it reaches zero, all animals suffocate. At that point the living water body has been converted into an open sewer.

In the United States, the setting of water quality standards and the regulation of discharges have been based on the "assimilative capacity" of the receiving waters (a kind of pollution dilution approach), which allows discharges into as yet unpolluted waterways. The Water Pollution Act of 1972 would have temporarily required industry to apply the "best practicable" and "best available" treatments of waste emissions and aimed for zero discharge by 1985. While this last goal has not been reached, the condition of American waterways generally improved during the last

decades, while on the global scale water quality has deteriorated.

Water availability has worsened since the first edition of this handbook. In the United States the daily withdrawal rate is about 2,000 gallons per person, which represents roughly one-third of the total daily runoff. The bulk of this water is used by agriculture and industry. The average daily water consumption per household is about 1000 gallons and, on the East Coast, the daily cost of that water is \$2-\$3. As some 60% of the discharged pollutants (sewage, industrial waste, fertilizers, pesticides, leachings from landfills and mines) reenter the water supplies, there is a direct relationship between the quality and cost of supply water and the degree of waste treatment in the upstream regions.

There seems to be some evidence that the residual chlorine from an upstream wastewater treatment plant can combine in the receiving waters with industrial wastes to form carcinogenic chlorinated hydrocarbons, which can enter the drinking water supplies downstream. Toxic chemicals from the water can be further concentrated through the food chain. Some believe that the gradual poisoning of the environment is responsible for cancer, AIDS, and other forms of immune deficiency and self-destructive diseases.

FIG. 1 The natural life cycle.

While the overall quality of the waterways has improved in the United States, worldwide the opposite occurred. This is caused not only by overpopulation, but also by ocean dumping of sludge, toxins, and nuclear waste, as well as by oil leaks from off-shore oil platforms. We do not yet fully understand the likely consequences, but we can be certain that the ability of the oceans to withstand and absorb pollutants is not unlimited and, therefore, international regulation of these discharges is essential. In terms of international regulations, we are just beginning to develop the required new body of law. The very first

case before the International Court of Justice (IJC) wherein it was argued that rivers are not the property of nation states, and that the interests of nations must be balanced against the interests of mankind, was heard by IJC in 1997 in connection with the Danube.

### The Condition of the Air

There is little question about the harmful effects of ozone depletion, acid rain, or the greenhouse effect. One might debate if the prime cause of desertification is acid rain, ex-

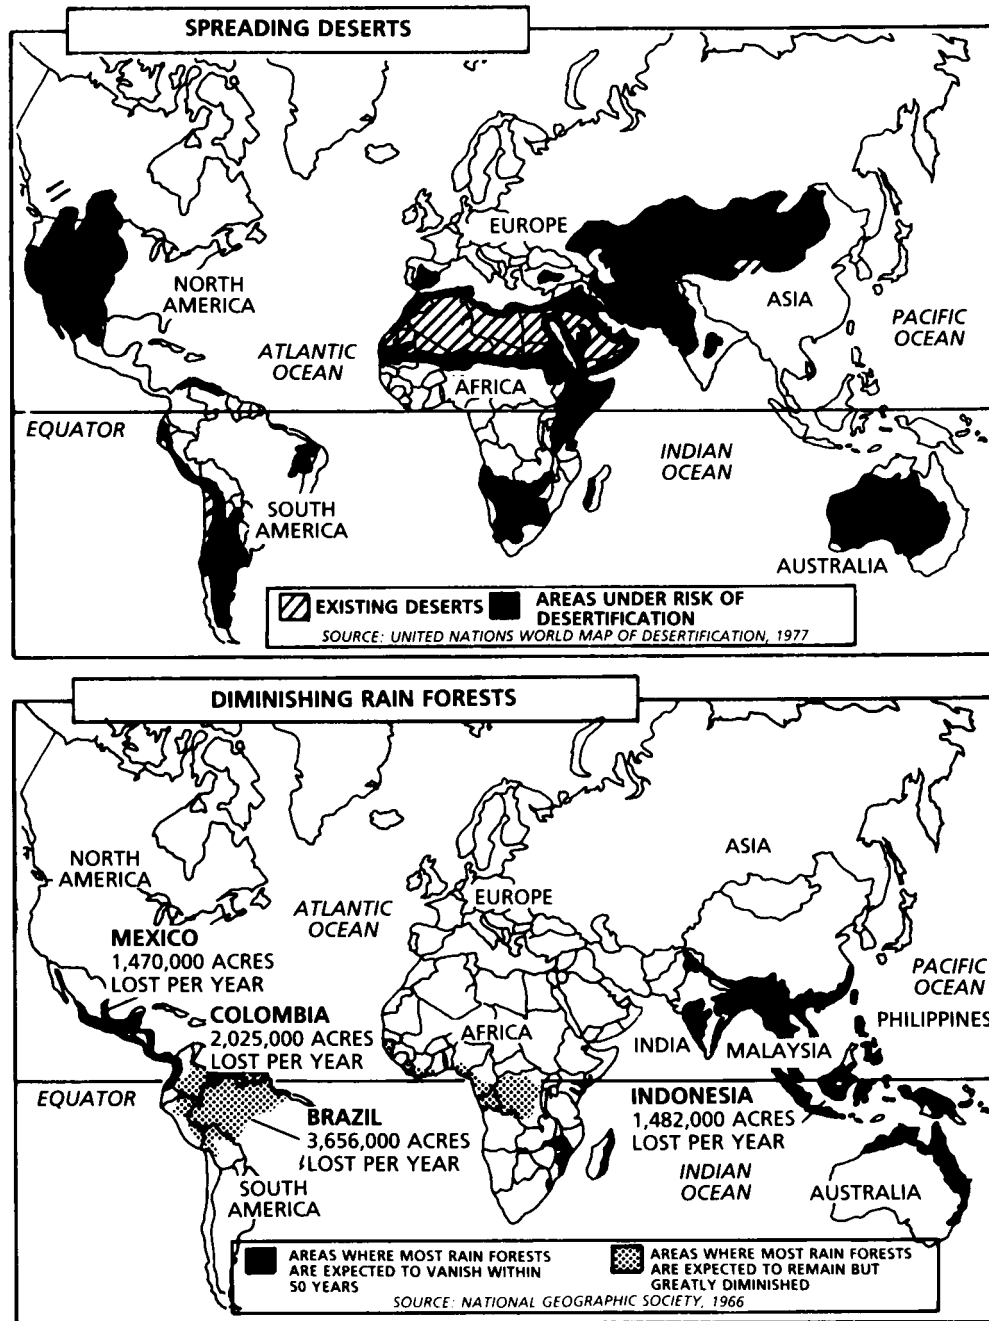

FIG. 2 Areas of diminishing rain forests and spreading deserts.

cessive lumbering, soil erosion, or changes in the weather, but it is a fact that the rain forests are diminishing and the deserts are spreading (Figure 2). We do not know what quantity of acid fumes, fluorinated hydrocarbons, or carbon dioxide gases can be released before climatic changes become irreversible. But we do know that the carbon dioxide content of the atmosphere has substantially increased, that each automobile releases 5 tons of carbon dioxide every year, and that the number of gas-burning oil platforms in the oceans is approaching 10,000.

Conditions on the land and in the waters are determined by complex biosystems. The nonbiological nature of air makes the setting of emission standards and their enforcement somewhat easier. As discussed in Chapter 5 of this handbook, the United States has air quality and emission standards for particulates, carbon monoxide, sul-

fur and nitrogen oxides, hydrocarbons, photochemical oxidants, asbestos, beryllium, and mercury.

For other materials, such as the “possible human carcinogens,” the furans and dioxins (PCDD and PCDF), there are no firm emission or air quality standards yet. These materials are the byproducts of paper bleaching, wood preservative and pesticide manufacturing, and the incineration of plastics. Because typical municipal solid waste (MSW) in the U.S. contains some 8% plastics, incineration is probably the prime source of dioxin emissions. Dioxins are formed on incinerator fly ash and end up either in landfills or are released into the atmosphere. Dioxin is suspected to be not only a carcinogen but also a cause of birth defects. It is concentrated through the food chain, is deposited in human fat tissues, and in some cases dioxin concentrations of 1.0 ppb have already been found in mother’s milk.

An essentially “linear” or open materials economy. The objective is to increase annual production (GNP) by maximizing the flow of materials. The natural pressure, therefore, is to decrease the life or quality of the items produced.

A circular or closed materials economy. Limits on the total amount of materials or wealth will depend upon the availability of resources and energy and the earth’s ecological, biological and physical system. Within these limits, the lower the rate of material flow, the greater the wealth of the population. The objective would be to maximize the life expectancy and, hence, quality of items produced.

**FIG. 3** The “open” and “closed” material-flow economies.

Although in the last decades the air quality in the U.S. improved and the newer standards (such as the Clean Air Act of 1990) became stricter, lately we have seen misguided attempts to reverse this progress. Regulations protecting wetlands, forbidding clear-cutting of forests, and mandating use of electric cars have all been relaxed or reversed. In the rest of the world, the overall trend is continued deterioration of air quality. In the U.S., part of the improvement in air quality is due not to pollution abatement but to the exporting of manufacturing industries; part of the improvement is made possible by relatively low population density, not the result of conservation efforts.

On a per capita basis the American contribution to worldwide pollutant emissions is high. For example, the yearly per capita generation of carbon dioxide in the U.S. is about 20 tons. This is twentyfold the per capita CO<sub>2</sub> generation of India. Therefore, even if the emission levels in the West are stabilized or reduced, the global generation of pollutants is likely to continue to rise as worldwide living standards slowly equalize.

## The Condition of the Land

Nature never produces anything that it can not decompose and return into the pool of fresh resources. Man does. Nature returns organic wastes to the soil as fertilizer. Man often dumps such wastes in the oceans, buries them in landfills, or burns them in incinerators. Man's deeply rooted belief in continuous growth treats nature as a commodity, the land, oceans, and atmosphere as free dumps. There is a subconscious assumption that the planet is inexhaustible. In fact the dimensions of the biosphere are fixed and the planet's resources are exhaustible.

The gross national product (GNP) is an indicator based on the expectation of continuous growth. We consider the economy healthy when the GNP and, therefore, the quantity of goods produced increases. The present economic model is like an open pipeline which takes in resources at one end and spills out wastes at the other. The GNP in this model is simply a measure of the rate at which resources are being converted to wastes. The higher the GNP, the faster the resources are exhausted (Figure 3). According to this model, cutting down a forest to build a parking lot increases the GNP and is therefore good for the economy. Similarly, this open-loop model might suggest that it is cheaper to make paper from trees than from waste paper, because the environmental costs of paper manufacturing and disposal are not included in the cost of the paper, but are borne separately by the whole community.

In contrast, the economic model of the future will have to be a closed-loop pipeline (Closed-GNP). This will be achieved when it becomes more profitable to reuse raw materials than to purchase fresh supplies. This is a function of economic policy. For example, in those cities where only newspapers printed on recycled paper are allowed to be sold, there is a healthy market for used paper and the

volume of municipal waste is reduced. Similarly, in countries where environmental and disposal costs are incorporated into the total cost of the products (in the form of taxes), it is more profitable to increase quality and durability than to increase the production quantity (Figure 3).

In addition to resource depletion and the disposal of toxic, radioactive, and municipal wastes, the natural environment is also under attack from strip mining, clear cutting, noise, and a variety of other human activities. In short, there is a danger of transforming the diverse and stable ecosystem into an unstable one which consists only of man and his chemically sustained food factory.

## Energy

When man started to supplement his muscle energy with outside sources, these sources were all renewable and inexhaustible. The muscle power of animals, the burning of wood, the use of hydraulic energy were man's external energy sources for millions of years. Only during the last couple of centuries have we started to use exhaustible energy sources, such as coal, oil, gas, and nuclear. This change in energy sources not only resulted in pollution but has also caused uncertainty about our future because we can not be certain if the transition from an exhausted energy source to the next one can be achieved without major disruptions.

The total energy content of all fossil deposits and uranium 235 (the energy source of "conventional" nuclear plants) on the planet is estimated to be  $100 \times 10^{18}$  BTUs. Our present yearly energy consumption is about  $0.25 \times 10^{18}$  BTUs. This would give us 400 years to convert to an inexhaustible energy source, if our population and energy demand were stable and if some energy sources (oil and gas) were not depleted much sooner than others.

Breeder reactors have not been considered in this evaluation because the plutonium they produce is too dangerous to even contemplate a plutonium-based future. This is not to say that conventional nuclear power is safe. Man has not lived long enough with radiation to know if millions of cubic feet of nuclear wastes can be stored safely.

We receive about 100 Watts of solar energy on each square meter of the Earth's surface, or a yearly total of about  $25 \times 10^{18}$  BTUs. Therefore, 1% of the solar energy received on the surface of the planet could supply our total energy needs. If collected on artificial islands or in desert areas around the Equator, where the solar radiation intensity is much higher than average, a fraction of 1% of the globe's surface could permanently supply our total energy needs. If the collected solar power were used to obtain hydrogen from water and if the compressed hydrogen were used as our electric, heat, and transportation energy source, burning this fuel would result in the emission of only clean, nonpolluting steam. Also, if the combustion took place in fuel cells, we could nearly double the present efficiency of electric power generation (about 33%) or the efficiency of the internal combustion engine

FIG. 4 Growth of human population.

(about 25%) and thereby substantially reduce thermal pollution.

Today, as conventional energy use increases, pollution tends to rise exponentially. As the population of the U.S. has increased 50% and our per capita energy consumption has risen 25%, the emission of pollutants has soared by 2000%. While the population of the world doubles in about 50 years, energy consumption doubles in about 20 and electric energy use even faster. In addition to chemical pollution, thermal pollution also rises with fossil energy consumption, because for each unit of electricity generated, two units of heat energy are discharged into the environment.

It is time to redirect our resources from the military—whose job it is to protect dwindling oil resources—and from deep sea drilling—which might cause irreversible harm to the ocean's environment—and use these resources to develop the new, permanent, and inexhaustible energy supplies of the future.

## Population

Probably the most serious cause of environmental degradation is overpopulation. More people live on Earth today than all the people who died since Creation (or, if you prefer, the "accidental" beginning of "evolution"). Three hundred years ago the world's population doubled every 250 years. Today it doubles in less than a life span. When I was editing the first edition of this handbook, the population of the planet was under 4 billion; today it is nearing 6 billion (Figure 4). During that same time period, the population of the Third World increased by more than the total population of the developed countries.

The choice is clear: we either take the steps needed to control our numbers or nature will do it for us through famine, plague, and loss of fertility. We must realize that the teaching which was valid for a small tribe in the desert ("Conquer nature and multiply") is no longer valid for the

overpopulated planet of today. We must realize that, even if we immediately take all the steps required to stabilize the population of the planet, the total number will still reach some 15 billion before it can be stabilized.

To date, food production has kept pace with population growth, but only at a drastic price: increases in pesticide (300%) and fertilizer (150%) use, which in turn further pollutes the environment.

The total amount of land suitable for agriculture is about 8 billion acres. Of that, 3.8 billion acres are under cultivation and, with the growth of the road systems and cities, the availability of land for agricultural uses is shrinking. The amount of water available for irrigation is also dropping. Without excessive fertilization, one acre of land is needed to feed one person: therefore, the human population has already exceeded the number supportable without chemical fertilizers. As chemical fertilizer manufacturing is based on the use of crude oil, models simulating world trends predict serious shortages in the next century (Figure 5).

While all these trends are ominous, the situation is not hopeless. The populations of the more developed countries seem to have stabilized, the new communication technologies and improved mass transit are helping to stop or even reverse the further concentration of urban masses. Environmental education and recycling have been successful in several nations. New technologies are emerging to serve conservation and to provide nonpolluting and inexhaustible energy sources.

When Copernicus discarded the concept of an earth-centered and stationary Universe, the Earth continued to travel undisturbed in its orbit around the Sun, yet the consequences of this discovery were revolutionary. Copernicus' discovery changed nothing in the Universe, but it changed our subconscious view of ourselves as the "centerpiece of creation." Today, our concept of our immediate universe, the Earth, is once again changing and this change is even more fundamental. We are realizing that the planet is exhaustible and that our future depends

FIG. 5 Computer simulation of world trends.

on our own behavior. It took several centuries for Copernicus' discovery to penetrate our subconscious. Therefore, we should not get impatient if this new understanding does not immediately change our mentality and life style. On the other hand, we must not be complacent. Human ingenuity and the combined talent of people, such as the contributors and readers of this handbook, can solve the problems we face, but this concentrated effort must not take centuries. We do not have that much time.

Protecting the global environment, protecting life on this planet, must become a single-minded, unifying goal for all of us. The struggle will overshadow our differences, will give meaning and purpose to our lives and, if we succeed, it will mean survival for our children and the generations to come.

# Foreword

---

---

---

---

---

The revised, expanded, and updated edition of the *Environmental Engineers' Handbook* covers in depth the interrelated factors and principles which affect our environment and how we have dealt with them in the past, how we are dealing with them today, and how we might deal with them in the future. Although the product is clearly aimed at the environmental professional, it is written and structured in a way that will allow others outside the field to educate themselves about our environment, and what can and must be done to continue to improve the quality of life on spaceship earth. *Environmental Engineers' Handbook CRCnetBASE 1999* covers in detail the ongoing global transition among the cleanup of the remains of abandoned technology, the prevention of pollution from existing technology, and the design of future zero emission technology. The relationship of cost to benefit is examined and emphasized throughout the product.

The Preface will remind the reader of Charles Dickens' famous *A Christmas Carol*, and we should reflect on its implications carefully as we try to decide the cost-to-benefit ratio of environmental control technology. Following the Preface, *Environmental Engineers' Handbook CRCnetBASE 1999* begins with a thorough review of environmental law and regulations that are then further detailed in individual chapters. The chapter on environmental impact assessment is the bridge between the release of pollutants and the technology necessary to reduce the impact of these emissions on the global ecosystem. Chapters on the source control and/or prevention of formation of specific pollutants in air, water, land, and our personal environment follow these introductory chapters. A chapter on solid waste is followed by the final chapter on hazardous waste, which tries to strike a balance between the danger of hazardous wastes and the low probability that a dangerous environmental event will occur because of these wastes.

The type of information contained in every chapter is designed to be uniform, although there is no unified format that each chapter follows, because subject matter varies so widely. The user can always count on finding both introductory material and very specific technical answers to complex questions. In those chapters where it is relevant, in-depth technical information on the technology and specific equipment used in environmental control and cleanup will be found. Since analytical results are an intricate part of any environmental study, the user will find ample sections covering the wide variety of analytical methods and equipment used in environmental analysis. Several chapters have extensive sections where the derivation of the mathematical equations used are included. Textual explanations usually also accompany these mathematical-based sections.

A great deal of effort has gone into providing as much information as possible in easy-to-use tables and figures. We have chosen to use schematic diagrams rather than actual pictures of equipment, devices, or landscapes to explain or illustrate technology and techniques used in various areas. The bulk of material is testimony to the level of detail that has been included in order to make this a single-source handbook. The user will also find ample references if additional information is required. The author of a section is given at the end of each section and we encourage users to contact the author directly with any questions or comments. Although extensive review and proof-reading of the manuscript was done, we ask users who find errors or omissions to bring them to our attention.

Finally, we wish to acknowledge the numerous individuals and organizations who either directly or indirectly have contributed to this work, yet have not been mentioned by name.

## Introduction

Environmental law consists of all legal guidelines that are intended to protect our environment. Much of the environmental legislation in the United States is initiated at the federal level. Various regulatory agencies may then prepare regulations, which define how activity must be conducted to comply with the law. In practice, the terms *law*, *statute*, and *regulation* are often used interchangeably. Regulations are generally more volatile than laws (statutes), of more applicability in determining compliance.

However, to obtain copies of laws or regulations, one must differentiate between statutes (laws) and regulations. Laws can be accessed through their public law number from the U.S. Printing Office and are compiled under the *United States Code (USC)*. Regulations are printed in the *Federal Register (FR)* and are compiled annually in the *Code of Federal Regulations (CFR)*.

Regulatory compliance is a significant aspect of conducting business today. The scheme of obligations posed by environmental legislation represents two costs: the effort and expenditure required to achieve compliance and the fines, penalties, and liabilities that may be incurred as a result of noncompliance. Whether preparing for environmental audits, developing an emergency response plan, or participating in an environmental impact study, environmental engineers must be conversant in environmental law and environmental policy. Ignorance of regulatory requirements is viewed by federal, state, and local governments as no excuse for noncompliance.

An overview of federal environmental laws is provided in this chapter. The chapter is divided into four sections and an appendix.

**Government Agencies and Administrative Law.** This section outlines some of the procedures under which laws are developed and applied. It is a “broadbrush” characteriza-

tion of administrative law which focuses on the practice of government agencies.

**Information Laws.** This section includes statutes used to gather and disseminate information as a central part of their regulatory schemes. This section includes the National Environmental Policy Act and the Emergency Planning and Community Right-to-Know Act.

**Natural Resource Laws.** This section includes statutes such as the Endangered Species Act and the Coastal Zone Management Act which protect habitat and regulate land use.

**Pollution Control Laws.** Statutes discussed in this section, such as the Clean Air Act, Clean Water Act, Resource Conservation and Recovery Act, and Toxic Substances Control Act, generally focus on regulating the pollutants which create risk to human health and the environment.

**Federal Environmental Protection Agencies.** The organization of the Environmental Protection Agency and the addresses and telephone numbers of the headquarters and regional offices and state and territorial agencies are presented in the appendix.

This chapter provides an overview and a general understanding of the key features of the major environmental statutes. The discussions of statutes should pave a way for further, in-depth study into the environmental laws.

It should be noted that environmental laws are dynamic and subject to change, interpretation, and negotiation. Although the following discussions of these federal laws provide important information, the reader is advised to determine if any updates or revisions of these laws are in effect. The information provided on these statutes is no substitute for up-to-date advice from licensed practitioners.

# 1.1

## ADMINISTRATIVE LAW

---

---

This section provides an overview of government agencies and their characteristics, limitations on agencies, and the judicial review of agency actions.

### Government Agencies

The government can be divided into the executive, legislative, and judicial branches. Agencies within the executive branch perform a large part of the day-to-day business on environmental protection. This branch is comprised of many agencies including the Environmental Protection Agency (EPA) and other cabinet-level agencies, such as the Department of Interior and the Department of Commerce.

Administrative agencies have the essential attributes of the three branches of our government. They generally have legislative, executive, and judicial powers.<sup>1</sup> As organizations, agencies possess many of the same powers and limits as the three government branches do.

### LEGISLATIVE

Agencies regulate according to the statutes developed by Congress. In addition, agencies are responsible for developing and promulgating regulations. Regulations generally are more specific statements of the rules found in statutes. For example, in response to Congressional mandates in the Clean Water Act, the EPA has promulgated specific regulations for storm water permits.

Agencies often develop regulations through an informal rulemaking that involves input from the EPA's technical and policy specialists and from interest groups which expect to be affected by those regulations.<sup>2</sup> Agencies initially develop proposed regulations. The EPA then publishes the proposed regulations and allows a period for public comment. (See Section 4.6). This process allows interested parties, such as industries and nongovernmental organizations, to review the proposed regulations and provide the

1. The discussion here focuses on executive branch agencies. However, the term *executive* is used as an adjective to describe, in general, the executive functions of agencies.

2. Usually, when an agency legislates or develops regulations, it follows procedures commonly known as notice and comment or informal rulemaking. Informal rulemaking requires the agency to notify the public that it is considering developing a rule, commonly referred to as a proposed rule. The agency must publish a draft of the proposed rule and invite comments from the public in response. Other kinds of rulemakings include formal, hybrid, and negotiated rulemaking. However, the scope of this discussion does not go beyond the informal rulemaking model.

EPA with their comments.

If enough interest exists, hearings may be scheduled to discuss and clarify the proposed regulations. The input of various parties during the comment and hearing period, like the input of legislators, all goes into what finally becomes the regulation or rule. Once all the comments are reviewed, the agency publishes a final rule or regulation.

### EXECUTIVE

After an agency promulgates regulations, the rules are implemented or applied. Usually, the agency which develops the regulations also applies them. Under the Clean Water Act, for example, the EPA has the authority not only to promulgate regulations, but also to implement them.<sup>3</sup>

### JUDICIAL

Agencies are also adjudicatory. In other words, they work like courts and hand down judgments regarding issues which arise in the context of their programs. When an agency adjudicates, it performs trial-type procedures which are similar to civil trials performed by the judicial branch of government.<sup>4</sup> Parties participate in hearings, present evidence and testimony, conduct cross-examinations, and develop a written record. Hearings take place before a neutral administrative law judge. Finally, agency adjudications may be appealed within an agency as well as to state or federal courts.

### Limitations on Agencies

The three branches of government exercise numerous controls over agencies. For example, Congress is responsible for creating and empowering agencies as well as defining an agency's role.<sup>5</sup> Congress has also developed the Administrative Procedures Act (APA) (5 *USC* §§501–506) which sets forth various standards for all agency actions.

The executive branch controls the nomination of agency

3. The EPA can also delegate the authority to implement regulations to a state environmental agency. Many states, for instance, have their own water discharge permit programs which they implement themselves. Others do not. This delegation, however, does not change the executive function which agencies—state or federal—possess.

4. Some significant differences between agency adjudications and standard civil bench trials include relaxed rules of evidence. Pretrial discovery (information-gathering) rules may also be different.

5. Enabling legislation is typically the law that creates an agency, gives it authority, and defines its role.

directors and administrators. However, these upper-level appointments are subject to confirmation by the Senate. Congress and the executive branch also control an agency's budget. These provisions translate into a large amount of control over an agency. Finally, courts define and limit agency action. They review agency decisions within the judicial framework of statutory and common law.

*Due process* is one of the most fundamental legal principles which courts apply to agencies when reviewing their relationship to and treatment of citizens. The term is found in the fifth and fourteenth amendments to the U.S. Constitution. The fifth amendment states that "No person [shall] be deprived of life, liberty or property without due process of law."<sup>6</sup>

Due process generally implies sufficient notice and a right to a hearing. It involves the application of certain procedures which seek to assure fairness, participation, accuracy, and checks on the concentration of power in government's hands.

## Judicial Review of Agency Actions

Several observations can be made about the court system's review of agency decisions. First, parties must initially use or *exhaust* all the avenues of agency review before they take their complaints to the court system. Second, several U.S. Supreme Court decisions define a court's role in reviewing agency actions. Generally, the Supreme Court has held that courts should acknowledge and accommodate agency expertise, rely upon the controlling statutory authority in making their judgments, and avoid imposing further rulemaking procedures on an agency without showing extraordinary circumstances.<sup>7</sup>

### EXHAUSTION

Parties that disagree with the results of an agency adjudication are typically required to *exhaust administrative remedies* within that agency before going to the court system. This requirement means that if an agency has established appeal procedures, the party must follow those procedures before entering an appeal in court. Unless a party fully exhausts agency review, it cannot take the next step and get review in the court system.

### STANDARDS OF REVIEW

The APA (5 *USC* §§501–706) provides a statutory basis for the review of agency actions, with two exceptions.<sup>8</sup>

6. The Fourteenth Amendment to the U.S. Constitution contains similar language: "[N]or shall any State deprive any person of life, liberty, or property, without due process of law. . . ."

7. See *Baltimore Gas and Electric Co. v. Natural Resources Defense Council (NRDC)*, 462 U.S. 87 (1983); *Chevron U.S.A., Inc. v. NRDC*, 467 U.S. 837 (1984); *Vermont Yankee Nuclear Power Corp. v. NRDC*, 435 U.S. 519 (1978).

The APA (5 *USC* §701[a]) does not apply "to the extent that (1) statutes preclude judicial review; or (2) agency action is committed to agency discretion by law."<sup>9</sup> The first exception applies, for example, where a statute explicitly precludes review. The second exception has been clarified by judicial interpretation.

The *Citizens to Preserve Overton Park, Inc., v. Volpe* (401 U.S. 402, 411 [1971]) case involved the second exception. In this case, the Court reviewed the secretary of transportation's authorization of funds to build a highway through a public park. The statute at issue allowed the secretary to use funds for highways except in situations where a feasible and prudent alternative was available. Environmentalists successfully argued that the secretary of transportation did not have the discretion to authorize the funds, as he maintained, and that he had not considered alternatives to the highway construction.

The *Overton Park* case emphasizes the arbitrary and capricious standard for nonadjudicative agency actions. This test establishes a minimum standard which agencies must meet to justify their decisions. In reviewing the record upon which an agency bases its decision, a court must find some basis for the agency's decision. If no basis exists for the agency's decision within the record, a court can hold that the agency was arbitrary and capricious, i.e., that it failed to meet the minimum standard for justifying its decision. In the *Overton Park* case, the Supreme Court found a sufficient basis for overturning the lower court's decision that upheld the original agency action.

### DEFERENCE TO THE AGENCY

Although many cases deal with administrative law and the role of agencies, the *Chevron U.S.A. Inc., v. Natural Resources Defense Council, Inc.* (467 U.S. 837 [1984]) case readily demonstrates how courts should review an appeal from an agency action.

Because courts frequently lack the expertise to make technical decisions associated with environmental issues, they often show deference to agencies. If an agency presents a justifiable basis for its decisions, a court frequently relies on the agency's expertise. In the *Chevron* case, the Supreme Court reviewed the EPA's interpretation and administration of the Clean Air Act. The Court was faced with the issue of what rules of interpretation to apply in considering whether the EPA was justified in defining a Clean Air Act term: *stationary source*.

The *Chevron* case establishes the procedures for a court to follow in reviewing an agency's interpretation of the statutes it administers. First, a court must ask: "has

8. The standard of review of factual issues in adjudications is the substantial evidence test. This standard requires a reviewing court to uphold the decision of a lower court unless the reviewing court can find no substantial evidence in the record to support the holding.

9. See also Levin. 1990. *Understanding unreviewability in administrative law*. *Minn. L.R.* 74:689.

Congress spoken to the issue explicitly (*Chevron U.S.A. Inc., v. Natural Resources Defense Council, Inc.*, 842). In other words, does the language in the statute discuss the issue? If it does not, but rather “the statute is silent or ambiguous with respect to the specific issue, the question for the court is whether the agency’s [interpretation] is based on a permissible construction of the statute” (*Id.*). The court noted that the agency’s interpretation did not have to be the only interpretation, or even one which the court would have adopted. Rather, an agency only has to provide a “permissible construction of the statute.” (*Id.* at 843).

## Finding Regulations

The *Code of Federal Regulations (CFR)* is the primary source for information on government regulations. The *CFR* is a government publication which contains nearly all federal regulations and is compiled annually in July. It is organized by title and updated quarterly. New regulations which are not yet in the *CFR* can often be found in the *Federal Register (FR)*.

Each volume of the *CFR* provides guidelines on how to use it. The volume cover lists the number, parts included, and revision date. An *Explanation* section at the beginning of each volume lists information such as issue dates, legal status, and how to use the *CFR*. More detailed information on using the *CFR* is included at the end of the volume. The *Finding Aids* section is composed of the following subsections:

1. Materials approved for incorporation by reference
2. Table of *CFR* titles and chapters
3. Appendix to List of *CFR* sections affected
4. List of *CFR* sections affected.

*CFR* Title 29 contains regulations mandated by the Occupation Safety, Health, and Safety Administration (OSHA); Title 40 contains EPA regulations; the

Department of Transportation (DOT) regulations are found in Title 49. Regulatory actions are codified in numbered parts and sections. These parts designate general subject areas, and sections within each part are numbered consecutively. Thus, 40 *CFR* 141.11 is interpreted as an EPA regulation in which 141 identifies the regulation as the National Primary Drinking Water Regulations, and 11 specifies maximum contamination levels for inorganic chemicals in drinking water supplies.

The *FR* is a weekly and daily, official newspaper of the regulatory side of the federal government, published by the Government Printing Office. Much of the material in the *FR* eventually is incorporated into the *CFR*. The *FR* typically contains notice of repealed regulations and proposed regulations. The contents are organized alphabetically by issuing agency, such as, the National Labor Relations Board and National Mediation Board.

While the *FR* is the most up-to-date source of federal regulations, going through each *FR* published subsequent to the newest *CFR* available is time-consuming. Rather than going through each *FR* to establish any changes in regulation, a researcher can consult a monthly companion to the *CFR* entitled the *List of CFR Sections Affected (LSA)*.

The *LSA* can be used once a researcher has established the date at which the *CFR* coverage ends. The most recent *LSA* should then be consulted. A researcher can refer to the regulation by title and number. The *LSA* indicates whether the regulation has been revised or amended. If changes have been made, the *FR* which contains the altered regulations is referenced.

## INFORMATION LAWS

---

---

This section provides an overview of the information laws including:

- The National Environmental Policy Act
- The Freedom of Information Act
- The Occupational Safety and Health Act
- The Emergency Planning and Community Right-to-Know Act

### National Environmental Policy Act

The National Environmental Policy Act (42 *USC* §§4321–4370; 40 *CFR* Parts 1500–1508).

#### STATUTORY ROADMAP

§4321	Congressional declaration of purpose
SUBCHAPTER 1.	POLICIES AND GOALS
§4331	Congressional declaration of national environmental policy
§4332	Cooperation of agencies, reports, availability of information, recommendations, international and national coordination of efforts
§4333	Conformity of administrative procedures to national environmental policy
§4334	Other statutory obligations of agencies
SUBCHAPTER 2.	COUNCIL ON ENVIRONMENTAL QUALITY
§4341	Reports to Congress; recommendations for legislation
§4342	Establishment, membership, chairman, appointments
§4343	Employment of personnel, experts, and consultants
§4344	Duties and functions
SUBCHAPTER 3.	MISCELLANEOUS PROVISIONS

#### PURPOSE

The National Environmental Policy Act of 1969, 1992 (42 *USC* §4321 *et seq.*), commonly referred to as NEPA, is a procedural statute created to insure that certain federal projects are analyzed for their environmental impacts before they are implemented. The NEPA was the first major environmental law enacted in the 1970s. It was signed into law by President Nixon on January 1, 1970.

NEPA's purposes are far-reaching. They serve as a foundation for environmental goals in the United States and

for many policies set forth in other environmental statutes. First, the NEPA (§2, 42 *USC* §4321) sets forth a national policy to “encourage productive and enjoyable harmony between man and his environment [and] to promote efforts which will prevent or eliminate damage to the environment and biosphere and stimulate the health and welfare of man.” In addition, the NEPA (§101[a], 42 *USC* §4331[a]) establishes a continuing federal government policy “to use all practicable means and measures . . . to create and maintain conditions in which man and nature can exist in productive harmony, and fulfill the social, economic, and other requirements of present and future generations of Americans.”

#### SPECIFIC PROVISIONS

The heart of NEPA 42 *USC* §4332 is based in section 102. In accordance with this section, federal agencies must comply with NEPA's procedural mandates if these agencies are conducting a federal action that significantly affects the quality of the human environment. The procedural requirements are meant to further the policies of the NEPA.

#### Council of Environmental Quality

The NEPA (§202, 42 *USC* §4342) created the Council of Environmental Quality (CEQ), composed of three members appointed by the president. The CEQ's functions include:

- Assisting the president in preparing an annual environmental quality report to Congress
- Gathering, analyzing, and interpreting information about current and prospective trends in environmental quality
- Reviewing federal programs in light of NEPA's environmental policy and making subsequent recommendations to the president
- Recommending other national policies to the president which improve environmental quality
- Conducting studies to make recommendations to the president on matters of policy and legislation (*NEPA* §204, 42 *USC* §4344).<sup>1</sup>

The CEQ issued the initial guidelines to meet the NEPA's procedural requirements. After seven years, the CEQ replaced the guidelines with official regulations pur-

1. See also, Whitney. 1991. The role of the president's Council on Environmental Quality in the 1990's and Beyond. *J. Envtl. L.* 6:81.

suant to Executive Order 11991. The new regulations apply to all federal agencies and seek to improve implementing the NEPA's procedural mandates (40 *CFR* §1500–1508).

## Environmental Impact Statements

The NEPA achieves its policies and objectives by requiring federal agencies to consider the environmental effects of their activities. In accordance with NEPA section 102 (42 *USC* §4332(c)), every federal agency's recommendation or report on proposals for legislation and other *federal actions significantly affecting the quality of the human environment* must include a detailed statement by the responsible official on

1. The environmental impact of the proposed action
2. Any adverse environmental effects which cannot be avoided if the proposal is implemented
3. Alternatives to the proposed action
4. The relationship between local short-term uses of man's environment and the maintenance and enhancement of long-term productivity
5. Any irreversible and irretrievable commitments of resources involved in the proposed action if it is implemented.<sup>2</sup>

This detailed statement, known as an environmental impact statement or EIS, is not intended to be a simple disclosure document. Rather, federal agencies are required to make thorough inquiries into federal projects before the projects are undertaken. The purpose of the EIS is to insure that NEPA's policies and goals are incorporated into the actions of the federal government. The EIS must include an assessment of the environmental impacts of a project and propose reasonable alternatives to minimize the adverse impacts of the project. Environmental impact statements should be clear, concise, and supported by evidence showing that the agency made the necessary analysis (40 *CFR* §1502.1).

Section 102 contains key statutory language which has resulted in significant judicial and administrative interpretation. These interpretations have typically served to broaden the NEPA's jurisdiction. For example, a "major federal action" is not limited to projects funded or carried out by the federal government. Instead, courts have interpreted "major federal actions" to include projects which merely require federal approval or are potentially subject to federal control.<sup>3</sup> Courts have also addressed questions involving the scope of an EIS as well as what triggers the EIS mandate.<sup>4</sup>

2. *National Environmental Policy Act*. Section 102(c). *U.S. Code*. Vol. 42, sec. 4332(c). Emphasis added.

3. See, e.g., *Minnesota Public Interest Group v. Butz*, 498 F.2d 1314 (8th Cir. 1974).

4. See Battle, J.B. 1986. *Environmental decisionmaking and NEPA*. Cincinnati: Anderson Publishing Co.)

The CEQ regulations also serve to interpret the jurisdiction of the NEPA. For example, they propose that federal actions typically fall within one of four categories: the adoption of official policy, formal plans or programs, the approval of specific construction projects, or management activities in a defined geographic area (40 *CFR* §1508). Thus, the courts define the NEPA's procedural mandates, i.e., jurisdiction, and EIS scope and content, through statutory and regulatory interpretation.

## Environmental Assessments

The NEPA requires an agency to prepare an environmental assessment (EA) when the need for an EIS is unclear. EAs create a reviewable record to assess if an EIS is required. Both federal agencies and courts need a reviewable environmental record to determine whether a major federal action is significantly affecting the environment.

The EA should contain evidence and analysis sufficient to determine if the agency should prepare an EIS or make a finding of no significant impact (FONSI) (40 *CFR* §1508.9). The EA is basically a mini-EIS. It is a brief document which includes a discussion of the need for the proposed action, alternatives to the proposed action, environmental impacts, and a list of agencies and persons consulted.

## Categorical Exclusion

Federal agencies must make an initial inquiry to determine if an EIS is needed for a proposal or if the proposal falls under categorical exclusion. The NEPA provides for "a category of actions which do not individually or cumulatively have a significant effect on the human environment . . . and [for] which, therefore, neither an environmental assessment nor an environmental impact statement is required" (40 *CFR* §1508.4). Thus, under limited circumstances, neither an EIS nor an EA is required.

## SUMMARY

The NEPA establishes a broad, protective national environmental policy as a goal to be furthered by the procedural mandates of it and other environmental statutes (*NEPA* §101).

The NEPA requires all federal agencies to prepare an environmental impact statement for major federal actions significantly affecting the quality of the environment (*NEPA* §102).

The NEPA requires the president to submit an annual environmental quality report to Congress (*NEPA* §201).

The NEPA creates the CEQ to assist the president in preparing the environmental quality report, to develop national environmental policies, and to create rules for implementing the procedural requirements of the NEPA (*NEPA* §§202–204).

# Freedom of Information Act

The Freedom of Information Act (5 *USC* §552).

## STATUTORY ROADMAP

§552 Public information; agency rules, opinions, orders, records, and proceedings

## PURPOSE

The Freedom of Information Act (FOIA) (1988, 5 *USC* §552) was enacted in 1966 to assure public access to certain federal agency records. The United States Supreme Court has stated that FOIA's purpose is "to ensure an informed citizenry, vital to the functioning of a democratic society, needed to check against corruption and to hold the governors accountable to the governed." (*National Labor Relations Board v. Robbins Tire & Rubber Co.*, 437 U.S. 214, 242 [1978]).

## SPECIFIC PROVISIONS

The FOIA includes provisions for disseminating available information, defining key terms, procedural requirements, statutory exemptions and exclusions, and using a reverse FOIA.

### Available Information

The FOIA requires federal agencies to publish information related to agency business in the *FR*. This information includes descriptions of agency organization, functions, procedures, and substantive rules and statements of general policy (*FOIA*, 5 *USC* §552[a][1]).

Agencies are also required to provide public access to "reading-room" materials. These materials include adjudicatory opinions, policy statements, and administrative staff manuals. Agencies must index the materials to facilitate public inspection (*FOIA*, 5 *USC* §552[a][1]). They must also provide an opportunity to review and copy the materials (*FOIA*, 5 *USC* §552[a][2]).

An FOIA request can be made for any reason regardless of relevancy. However, the act has nine exceptions to this disclosure requirement in which a record may fall (*FOIA*, 5 *USC* §552[b]), along with three law enforcement exclusions (*FOIA*, 5 *USC* §552[c]). The exclusions and exemptions balance the needs of an informed public against the security and confidentiality required of certain government information.

### Definitions

The FOIA applies only to records maintained by federal agencies as defined by the act (*FOIA*, 5 *USC* §552[f]).

Agencies include any executive or military department or establishment, government or government-controlled corporation, or any independent regulatory agency. The FOIA does not require disclosure of records from state agencies, municipalities, courts, Congress, or private citizens. Nor does it require disclosure from the executive office or any presidential staff whose sole purpose is to counsel the president. However, states may have a functional equivalent of this federal act.

The FOIA does not explicitly define the term *record*. Nevertheless, the Supreme Court (*Department of Justice v. Tax Analysts*, 492 U.S. 136, 144–145 [1989]) has established a two-part test for determining an agency record. An agency record must be (1) created or obtained by an agency and (2) under the agency's control at the time of the request.

Any *person* can make an FOIA request. Under the act (*FOIA*, 5 *USC* §551[2]), a person includes United States citizens, foreign citizens, partnerships, corporations, associations, and foreign and domestic governments. However, no person can make an FOIA request in violation of the law.

## Procedural Requirements

An information request under section (a)(3) must follow procedural requirements including a fee payment to cover governmental costs. Every federal agency must publish its own specific procedural regulations in the *FR* (*FOIA*, 5 *USC* §§552[a][3], [a][4][A]). The regulations include the types of records maintained by the agency, a description of how to access such records, fees and fee waivers, and the agency's administrative appeal procedures. Generally, any person can access agency records provided that the agency's procedures are followed (*FOIA*, 5 *USC* §552[a][3][B]) and the request reasonably describes the records sought (*FOIA*, 5 *USC* §552[a][3][A]).

Once an agency receives an FOIA request, the agency must inform the applicant of its decision to grant or deny the request within ten working days (*FOIA*, 5 *USC* §552[a][6][C]). If access is granted, an agency typically releases the records after the ten day period (*FOIA*, §552[a][6][C]). Agencies can obtain time extensions if the request involves an extensive or voluminous search, or if the request requires consultation with other agencies (*FOIA*, 5 *USC* §552[a][6][B]).

Agencies which deny requests must provide the applicant with the reasons for denial, the right of appeal, and the names of the persons responsible for the denial (*FOIA*, 5 *USC* §552[a][6][A][1]). If the administrative appeal upholds the denial, the administrative opinion must also provide the appellee with the reasons for denial, the right for judicial review in the federal courts, and the name of the persons responsible for the denial (*FOIA*, 5 *USC* §552[a][6][A][ii]).

## Statutory Exemptions and Exclusions

Agencies are required to provide FOIA applicants with the records they request unless the request falls within one of the statutory exemptions or exclusions. When one of the nine statutory exemptions applies, agencies can use discretion to disclose or withhold the information. The exemptions apply to the following nine types of documents (*FOIA*, 5 *USC* §552[b]):

1. Classified documents
2. Internal personnel rules and practices
3. Information exempt under other laws
4. Trade secrets and other privileged or confidential information
5. Internal agency letters and memoranda
6. Information relating to personal privacy
7. Certain records or information relating to law enforcement
8. Information relating to financial institutions
9. Geological information

In addition to exemptions, the FOIA lists three types of documents which are excluded from public access. The three FOIA exclusions were added to the act as part of the Freedom of Information Reform Act of 1986 and were designed to protect sensitive law enforcement matters.<sup>5</sup>

## Reverse FOIA

A reverse FOIA prevents the disclosure of information. It is designed to protect businesses and corporations that submit information to an agency. This protection is allowed when a third party makes an FOIA request to obtain the agency records containing that business' information (*CNA Financial Corp. v. Donovan*, 830 F.2d 1132 [D.C. Cir. 1988]). Nevertheless, an agency can release the records if an exemption does not apply, or if one does apply, but, in the agency's discretion, the release is justified (*CNA Financial Corp. v. Donovan*).

## SUMMARY

The FOIA ensures public access to certain information obtained, generated, and held by the government.

The FOIA contains nine exemptions which balance the public's interest in information against the government's interest in efficient operation and security.

## Occupational Safety and Health Act

The Occupational Safety and Health Act (29 *USC* 651 *et seq.*; 29 *CFR* Parts 1910, 1915, 1918, 1926).

5. See *Freedom of Information Act. U.S. Code*. Vol. 5 sec. 552(c)(1)–(3).

## STATUTORY ROADMAP

§651	Congressional statement of findings and declaration of purpose and policy
§654	Duties of employers and employees
§655	Standards
§656	Administration
§657	Inspections, investigations, and record-keeping
§659	Enforcement procedures
§660	Judicial review
§666	Civil and criminal penalties

## PURPOSE

The Occupational Safety and Health Act of 1970 (OSH Act) (29 *USC* §651 *et seq.*) differs from the other federal laws examined in this overview because it is directed toward protecting the workplace and its environment rather than the more traditional ambient environment. The OSH Act's purpose (§2[b], 29 *USC* §651[b]) makes this direction evident in "assur[ing] so far as possible every working man and woman in the Nation safe and healthful working conditions and preserv[ing] our human resources. . . ." This discussion of the OSH Act concentrates on the act's focus towards controlling hazardous substances in the occupational environment.

## SPECIFIC PROVISIONS

The act creates two general duties for employers to keep the workplace free from hazards. First, employers must provide employees with a place of employment "free from recognized hazards that are causing or likely to cause death or serious physical harm . . ." (*OSH Act* §5[a][1], 29 *USC* §654[a][1]). Secondly, and more directly related to controlling hazardous substances in the environment, employers must comply with the occupational safety and health standards promulgated under the act (*OSH Act* §5[a][2], 29 *USC* §654[a][2]). In addition, employees must comply with the act's standards as well as all other rules and regulations related to the act (*OSH Act* §5[b], 29 *USC* §654[b]).

## Occupational Health and Safety Administration Standards

The Department of Labor's Occupational Health and Safety Administration (OSHA) is required to promulgate health and safety standards to protect workers at their places of employment (*OSH Act* §6, 29 *USC* §655). The original standards, sometimes referred to as source standards, have been in effect since April 28, 1971. These standards originated from private groups such as the National Fire Protection Association as well as from previously established federal safety standards. While some of the orig-

inal source standards were revoked because they were unrelated to health or safety,<sup>6</sup> most of the standards are in effect today. All other OSHA standards are adopted in accordance with the procedures in section 6(b) of the act (*OSH Act* §6[b], *29 USC* §655[b]).<sup>7</sup>

Source standards generally apply to air contaminants in the workplace for which the act creates threshold limits which cannot be exceeded. Approximately 380 substances are currently subject to these limits.<sup>8</sup> The OSHA has adopted approximately twenty additional standards pursuant to section 6(b). These standards are largely based upon acute health effects, chronic health effects, and carcinogenicity.

The scope of OSHA's standards is divided into two principal areas, General Industry Standards (*29 CFR* pt. 1910) and Construction Industry Standards (*29 CFR* pt. 1926). Nevertheless, certain industries may be exempt from a standard when another federal agency "exercise[s] statutory authority to prescribe or enforce standards or regulations affecting occupational safety or health (*OSH Act* §4[b][1], *29 USC* §653[b][1]).

The act also provides a temporary variance and a permanent variance which facilities can obtain to avoid the OSHA standards. A temporary variance can be granted for up to two years from the effective date of a standard provided that either the means for meeting the standard are not currently available or the controls cannot be installed by the standard's effective date (*OSH Act* §6[b][6], *29 USC* §655[b][6]).<sup>9</sup> A permanent variance can be granted when the employer can demonstrate the workplace is "as safe and healthful as those which would prevail if he complied with the standard (*OSH Act* §6[d], *29 USC* §655[d]).<sup>10</sup>

## Hazard Communication Standard

In November of 1983, the OSHA published a hazard communication standard (HCS) which requires employers to inform employees of the hazards associated with the chemicals they are exposed to in the workplace (*29 CFR* §1910.1200). The HCS also requires employers to inform employees of how to protect themselves from health risks associated from such exposure (*29 CFR* §1910.1200). Finally, the HCS creates labeling standards for containers of hazardous substances in the workplace (*29 CFR* §1910.1200[f][1]). In effect, the HCS created an information dissemination system in which employers obtain information from manufacturers, importers, and distributors of chemicals and, in turn, employers inform and train employees regarding potential hazards.

The HCS requires chemical manufacturers and im-

porters to prepare a material safety data sheet (MSDS) for every hazardous chemical produced or imported (*29 CFR* §1910.1200[g]). Limited exceptions exist for trade secrets.<sup>11</sup> The initial MSDS and all subsequent revisions must be provided to all current and future distributors and manufacturing purchasers. Some of the minimum MSDS requirements include identifying the name and hazardous characteristics of the chemical, the health hazards of the chemical, the permissible exposure limit, precautions for safe handling and use, and emergency and first aid measures.<sup>12</sup> Employers must maintain copies of all MSDSs and assure that employees have access to them during working hours.

## PREEMPTION

OSHA's hazardous communication standard preempts, or takes precedence over, all state right-to-know legislation.<sup>13</sup> Notably, occupational safety is the only federal right-to-know legislation which explicitly preempts similar state legislation.

## ENFORCEMENT

The OSHA inspects workplaces to insure compliance with its standards. If an employer refuses to allow an OSHA compliance officer onto the premises to conduct an inspection, the compliance officer must obtain a warrant based upon probable cause. The OSHA can then issue a citation if it believes that the act is being violated (*OSH Act* §9[a], *29 USC* §658[a]). The citation references the alleged violation, fixes a reasonable time for abatement, and proposes a penalty (*OSH Act* §9[a], *29 USC* §658[a]). Employers must contest the citation within fifteen days of receipt or the citation becomes final and enforceable (*OSH Act* §§10[a,b], 17[1], *29 USC* §§659[a,b], 666[1]).

## SUMMARY

The OSH Act assures safe and healthful working conditions in the nation's workplace and preserves the nation's human resources (§651).

The OSH Act requires employers to provide employees with a workplace free from recognized hazards that are likely to cause death or serious bodily harm (§654).

The OSH Act requires employers to comply with specific occupational safety and health standards promulgated pursuant to the act (§654).

The OSH Act creates the OSHA, which inspects and investigates conditions in the workplace, provides for citations and notices of proposed penalties for violations, and provides for both civil and criminal penalties (§§657-660).

# Emergency Planning and Community Right-To-Know Act

The Emergency Planning and Community Right-To-Know Act of 1986 (42 *USC* §§11001–11050).

## STATUTORY ROADMAP

- SUBCHAPTER I. EMERGENCY PLANNING AND NOTIFICATION
- SUBCHAPTER II. REPORTING REQUIREMENTS
- SUBCHAPTER III. GENERAL PROVISIONS

## PURPOSE

The Emergency Planning and Community Right-to-Know Act (EPCRA) was enacted in 1986 as Title III of the Superfund Amendments and Reauthorization Act (EPCRA 001, 42 *USC* §§11001–11050). Despite its origin, the EPCRA is not a part of the Comprehensive Environmental Compensation and Liability Act but rather is an individual federal statute. The EPCRA provides for the gathering and dissemination of information on local industries' use of hazardous substances. It also provides for local community planning to deal with potential chemical-related emergencies, such as the accidental release of methyl isocyanate in Bhopal, India in 1984.

## SPECIFIC PROVISIONS

The EPCRA provides for emergency planning and notification and specifies reporting requirements and its relationship to other laws.

### Emergency Planning and Notification

The EPCRA (§301, 42 *USC* §11001) requires states to establish a state-level emergency response commission and local emergency planning districts to prepare and implement emergency plans. Each planning district designates a local emergency planning committee comprised of impact groups in the community (EPCRA §301[c], 42 *USC* §11001[c]).<sup>14</sup> Each local committee establishes its own procedures and rules for handling public requests for information.

The planning and notification requirements of the EPCRA are triggered by certain extremely hazardous substances. The EPA lists over 350 chemicals which it considers extremely hazardous. The list is published in Appendix A of the *Chemical Emergency Preparedness*

14. For example, representatives from the state, local officials, fire departments, community groups, and owners and operators of facilities subject to the EPCRA.

*Program Interim Guidance*.<sup>15</sup> Any facility which has a threshold amount of a listed substance must notify the state emergency response commission. Threshold amounts vary depending upon the toxicity of the substance.

Any release of a regulated substance triggers the statute's emergency notification procedures.<sup>16</sup> Generally, any facility must report the release of a reportable quantity of any listed substance to the local emergency planning committee and the state emergency response commission (40 *CFR* §355.40). The EPCRA divides releases into four categories (EPCRA §304[a], 42 *USC* §11004[a]); all trigger the notification requirement by the facility owner or operator (EPCRA §304[b], 42 *USC* §11004[b]). The reporting requirements have several statutory exceptions. These exceptions include releases resulting in exposure solely within the facility's boundaries and any federally permitted release pursuant to CERCLA §101(10) (EPCRA §304[b], 42 *USC* §11004[b]).

### Reporting Requirements

The EPCRA requires facility owners or operators to complete forms providing information about chemicals found within or released from a facility. With the exception of the limited provisions for securing trade secrets (EPCRA §322, 42 *USC* §11042), the information is generally made available to the public (EPCRA §324[a], 42 *USC* §11044[a]).

Facility owners and operators who prepare an OSH Act (29 *USC* §§651–658) MSDS for hazardous chemicals must submit an MSDS for each applicable chemical to the state emergency response commission, the local emergency planning committee, and the local fire department (EPCRA §311[a], 42 *USC* §11021[a]). An MSDS contains the name and hazardous characteristics of each applicable chemical, the related health hazards, permissible exposure limit, precautions for safe handling and use, and emergency and first aid measures.

Alternatively, the facility can submit a list of all chemicals for which an OSH Act MSDS is required (EPCRA §311[a][2][A], 42 *USC* §11021[a][2][A]). The facility must identify the hazardous components of such chemicals, and the EPA may require additional information (EPCRA §§311[a][2][A–B], 42 *USC* §§11021[a][2][A–B]).

Facilities must also submit emergency and hazardous chemical inventory forms to provide information on the types, location, and quantities of hazardous chemicals at the facilities (EPCRA §312, 42 *USC* §11022). The inventory forms are divided into tier I information, which is

15. See *Federal Register* 51, (17 November 1986):41570.

16. Release is defined as "any spilling, leaking, pumping, pouring, emitting, discharging, injecting, escaping, leaching, dumping, or disposing into the environment (including the abandonment or discarding of barrels, containers and other closed receptacles) . . ." (*Emergency Planning and Community Right-to-Know Act*, sec. 329[5]. *U.S. Code*, Vol. 42, sec. 11049[5].)

provided in all instances, and tier II information, which is provided upon special request (*EPCRA* §§312[a][2], [e], 42 *USC* §§11022[a][2], [e]). The EPA can also request information on individual hazardous chemicals (*EPCRA* §312[d][1][C], 42 *USC* §11022[d][1][C]). As with the MSDS, this inventory form must be filed with the state emergency response commission, the local emergency planning committee, and the local fire department (*EPCRA* §312[a][1], 42 *USC* §11022[a][1]).

Finally, facility owners and operators must submit an annual toxic chemical release form to provide information about toxic chemicals released from a facility during its normal business operations (*EPCRA* §313[a], 42 *USC* §11023[a]). This requirement applies to facilities which employ ten or more full-time employees; which are categorized in Standard Industrial Classification (SIC) Codes 20 through 39; and which manufacture, use, or process a toxic chemical above the stated threshold quantity (*EPCRA* §313[a], 42 *USC* §11023[a]).<sup>17</sup>

The EPA also has authority to require individual facilities to complete the form although such facilities are not under the appropriate SIC code (*EPCRA* §313[b][2], 42 *USC* §11023[b][2]). The release form should provide information to the federal, state, and local governments, as well as to the general public (*EPCRA* §313[h], 42 *USC* §11023[h]).

### Relationship to Other Laws

The *EPCRA* (§321[a], 42 *USC* §11041[a]) does not explicitly preempt any state or local law or interfere with any obligations or liabilities under any other federal law. This relationship differs from the *OSH Act* requirements related to hazardous information disclosure in the workplace which explicitly preempts any related state laws. Nevertheless, any state or local law which requires facilities to file a MSDS must at least comply with the format and content requirements under the *EPCRA* (§321[b], 42 *USC* §11041[b]).

### SUMMARY

Facilities must complete an MSDS containing the name and hazardous characteristics of each applicable chemical, the related health hazards, permissible exposure limit, precautions for safe handling and use, and emergency and first aid measures (*EPCRA* §311).

Facilities must complete annual emergency and hazardous chemical inventory forms which are sent to the EPA and an appointed state official (*EPCRA* §312).

Facilities must complete toxic chemical release forms to report on regular operational releases of hazardous substances from them. The forms are filed annually with the EPA and an appointed state official (*EPCRA* §313).

The *EPCRA* provides for administrative, civil, and criminal penalties for noncomplying owners and operators of facilities (*EPCRA* §325).

The *EPCRA* provides for citizen suits against facility owners and operators, the EPA, a state governor, or a state emergency response commission for inaction under the act (*EPCRA* §326[a]).

§1544	Annual cost analysis

#### PURPOSE

Enacted in 1973, the Endangered Species Act (ESA) (16 *USC* §§1531–1543) is a relatively simple statute which is sweeping in its scope. The ESA seeks to protect species of fish, wildlife, and plants, and the habitat associated with those species. Congress has declared the purposes of the ESA (§2[b], 16 *USC* §1531[b]) are “to provide a means whereby the ecosystems upon which endangered and threatened species depend may be conserved, to provide a program for the conservation of such endangered species and threatened species . . . ,” and to meet the United States’ duties under other fish and wildlife protection treaties and conventions. The ESA regulates mainly by prohibiting persons from taking listed species and by protecting habitat.

#### SPECIFIC PROVISIONS

This overview of the ESA examines its regulatory structure in conjunction with key terms defined under the act.

#### Species

The terms *species* and *fish and wildlife* are broadly defined under the act. Species includes not only true species, but also subspecies and *distinct populations* of fish, wildlife, or plants (ESA §3[16], 16 *USC* §1532[6]). Fish and wildlife is defined as any member of the animal kingdom, “including without limitation any mammal, fish, bird (including any migratory, nonmigratory, or endangered bird for which protection is also afforded by treaty or other international agreement), amphibian, reptile, mollusk, crustacean, arthropod, or other invertebrate, and includes any part, product, egg, or offspring thereof, or the dead body parts thereof” (ESA §3[8], 16 *USC* §1531[8]).

#### Taking

The concept of *taking* an endangered species is much more than simply, for example, shooting a bald eagle. Taking is defined broadly to include actions like “harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt to engage in any such conduct” (ESA §3[19], 16 *USC* §1532[19]).

The term *harm* is even more broadly defined in Fish and Wildlife Service regulations promulgated pursuant to ESA section 3(19), and later in the court case which first construed those regulations.<sup>1</sup> Harm is defined as an act which kills or injures. “Such an act may include significant habitat modification or degradation where it actually kills or injures wildlife by significantly impairing essential behavioral patterns, including breeding, feeding, or sheltering” (50 *CFR* §17.3 [1990]).

The concepts of harm and taking were applied in the *Palila v. Hawaii Department of Land and Natural Resources* (649 F.Supp. 1070 [1986], *aff’d*, 852 F.2d 1106 [9th Cir. 1988]) case which involved a state-maintained flock of sheep which was destroying the habitat of the palila, an endangered species of bird. The palila relied on the vegetation on which the sheep were browsing. The court found that the actions of the sheep constituted harm, and therefore taking under the Fish and Wildlife Service’s regulations which had been promulgated pursuant to the ESA.

1. The Fish and Wildlife Service eventually settled on the current definition of *harm* which is found in *Federal Register* 46, (4 November 1981): 54748, 54750.

## Listing Endangered Species

To receive protection under the act, species must first be listed. The listing process is an assessment of the relative vulnerability of certain species.<sup>2</sup> While it has been changed several times, the listing process can be initiated by private individuals, who petition the Secretary of Interior.<sup>3</sup> To determine if a species should be listed, the Secretary of the Interior considers the best scientific and commercial data available and also takes into account the efforts being made by any state or foreign nation, or political subdivision of a state or foreign nation to protect such species (*ESA* §4[b][1][A], 16 *USC* §1533[b][1][A]).

## Classifying Endangered Species

Once listed, species are classified as either endangered or threatened. Those species “in danger of extinction throughout all or a significant portion of their range” are classified as endangered (*ESA* §3[6], 16 *USC* §1532[6]). For a species to be classified as threatened, the petitioner must show that the species “are likely to become an endangered species within the foreseeable future throughout all or a significant portion of their range” (*ESA* §3[6], 16 *USC* §1532[6]).

## Critical Habitat

Once the secretary determines that a species should be listed as either endangered or threatened, he must also establish a critical habitat for that species (*ESA* §3[5][A][i], 16 *USC* §1532[5][A][i]). Critical habitats are specific areas within the geographical areas occupied by the species at the time the species are listed. Critical habitats also have physical and biological features considered essential to conserving the species and which may require special management considerations or protection (*ESA* §3[5][A][i], 16 *USC* §1532[5][A][i]).<sup>4</sup>

## Persons

Finally, a *person* for purposes of the *ESA*, is also defined broadly. A person is “an individual, corporation, partner-

ship, trust, association, or any private entity, or an officer, employee agent, department, or instrumentality of the Federal Government, of any state, municipality, or political subdivision of the state; or any other entity subject to the jurisdiction of the United States” (*ESA* §3[13], 16 *USC* §1532[13]).

## SUMMARY

The *ESA* provides broad definitions of taking, species, and person (*ESA* §3).

The *ESA* specifies listing procedures and classification on the basis of species’ vulnerability (*ESA* §4).

The *ESA* provides for listed species’ critical habitat (*ESA* §3[5]).

## Coastal Zone Management Act

The Coastal Zone Management Act (16 *USC* §1451 *et seq.*; 15 *CFR* Parts 931.1 *et seq.*, 930.1 *et seq.*, 923.1 *et seq.*, 926.1 *et seq.*).

## STATUTORY ROADMAP

§1453	Definitions
§1454(b)	Program requirements
§1455	Administrative grants
§1455b	Protection of coastal waters

## PURPOSE

The Coastal Zone Management Act (CZMA) (16 *USC* §§1451–1464), originally enacted in 1972 and reauthorized in 1990 (*Coastal Zone Act Reauthorization Amendments* §6201–17), controls land use along the nation’s coastal zone. This area is particularly susceptible to pressure from population and development. Consequently, Congress developed the CZMA to protect and enhance the nation’s coastal zone (CZMA §302[a], 16 *USC* §1451[a]). The act seeks to achieve this goal by implementing four national policies and calling for states to implement programs which meet minimum federal standards. The four national policies under the CZMA are:

1. To preserve, protect and develop, and where possible to restore and enhance the coastal zone (CZMA §303[1], 16 *USC* §1452[1])
2. To assist states in developing their own coastal management programs (CZMA §303[2], 16 *USC* 1452[2])
3. To encourage the preparation of management plans for special areas to protect natural resources and allow for reasonable coastal-dependent economic growth (CZMA §303[3], 16 *USC* §1452[3])

2. The term is used by Michael Bean. See Bean, M. *The evolution of national wildlife law*. 1983. New York. For provisions regarding the listing and identification of endangered and threatened wildlife and plant life, see *Code of Federal Regulations*, Title 50, secs. 7.1, 217.1 *et seq.*, 424.01 *et seq.*, and Title 60, sec. 227.1 *et seq.*

3. The Secretary of Commerce may, in certain cases, be the authority to petition. The Department of the Interior, through its Secretary, can also initiate the listing process. Apart from the petition process, the Secretary of Agriculture is authorized to enforce the *ESA* with respect to plants. See *Endangered Species Act*, sec. 3(15), *U.S. Code* Vol. 16, sec. 1532(15). These sections also apply to the changing of a species’ status and the removal of species from the list, i.e., delisting.

4. Specific areas outside the geographical areas occupied by the species are considered as critical habitat under certain circumstances.

4. To encourage the participation of federal, state, regional, and local government bodies in achieving the purposes of the act (CZMA §303[4], 16 USC §1452[4])

## SPECIFIC PROVISIONS

The CZMA provides for coastal zone management programs and specifies its applicability.

### State Coastal Zone Management Programs

To promote its policies, the CZMA requires states to develop coastal management programs to meet the performance standards prescribed in it. An acceptable state coastal program must, at a minimum, provide for:

1. The protection of wetlands, floodplains, estuaries, beaches, dunes, barrier islands, coral reefs, and fish and wildlife and their habitat within the coastal zone
2. The management of coastal development in hazardous areas to minimize loss to life and property
3. Priority consideration given to coastal-dependant uses and an orderly process for situating major facilities related to defense, energy, fisheries development, recreation, ports and transportation, and the location, to the maximum extent practicable, of new commercial and industrial developments in or adjacent to areas where such development exists
4. Public access to the coast for recreational purposes
5. Assistance in redevelopment of waterfronts and other aesthetic, cultural, and historic coastal features
6. Coordination of government decision-making regarding the coastal zone, and coordination with federal agencies
7. Public participation in coastal management decision-making
8. Comprehensive planning, conservation, and management for living resources (CZMA §303[2][A-K], 16 USC §1452[2][A-K])

Many states with coastal management programs have implemented coastal area permit programs which regulate development in the coastal zone. Typically, states establish criteria which an applicant must meet. For example, in California and North Carolina, permits are required for activities that affect designated areas such as wetlands, estuaries, and shorelines. Permit requirements vary from state to state. However, the permitting process generally

serves as a review of projects which may create detrimental effects to a state's coastal zone. Permits are enforced through the surveillance and monitoring of permitted projects.

## Applicability

The act applies only to areas designated as the coastal zone. This area varies from state to state and, consequently, from program to program. The CZMA adopts the territorial sea as its seaward or outermost limit. This limit extends three nautical miles from the shore and, according to federal law, all of the submerged lands and resources within that area are owned by the states. The inland boundary, however, is the portion of the coastal zone which varies. The act calls for the coastal zone to extend "only to the extent necessary to control shorelands, the uses of which have a direct and significant impact on the coastal waters" (CZMA §304[1], 16 USC §1453[1]). Thus, the coastal zone can include an entire state, such as Florida or Hawaii, or it can be a much smaller portion of land.

## SUMMARY

The CZMA seeks to protect coastal resources, manage those resources, and prevent conflicts in their use. The CZMA mandates the development of state programs, meeting federal minimum requirements, which permit and regulate activity in their own coastal zones. While state programs vary, the federal government has authority to require state programs to promote the four coastal management goals and to meet the federal minimum performance standards. Coastal programs are typically implemented around a permitting application and review scheme.

## POLLUTION CONTROL LAWS

---

---

This section discusses the pollution control laws including:

- The Clean Air Act
- The Resource Conservation and Recovery Act
- The Comprehensive Environmental Response, Compensation, and Liability Act
- The Noise Control Act
- The Safe Drinking Water Act
- The Federal Water Pollution Control Act
- The Toxic Substance Control Act
- The Federal Insecticide, Fungicide, and Rodenticide Act
- The Pollution Prevention Act

### Clean Air Act

The Clean Air Act (42 USC §§7401–7671q; 40 CFR Part 50).

### STATUTORY ROADMAP

SUBCHAPTER I.	PROGRAMS AND ACTIVITIES
<i>Part A.</i>	<i>Air quality and emission limitations</i>
§7401	Findings and purpose
§7409	National primary and secondary ambient air quality standards
§7410	State implementation plans
§7411	Standards of performance for new stationary sources
§7412	Hazardous air pollutants
§7413	Federal enforcement procedures
<i>Part C.</i>	<i>Prevention of significant deterioration</i>
§7470	Purpose
§7472	Initial classifications
§7473	Increments and ceilings
§7474	Area redesignation
§7475	Preconstruction requirements
§7479	Definitions
<i>Part D.</i>	<i>Plan requirements for nonattainment areas in general</i>
Subpart 1.	Nonattainment areas in general
Subpart 2.	Additional provisions for ozone nonattainment areas
Subpart 3.	Additional provisions for carbon monoxide nonattainment areas
Subpart 4.	Additional provisions for particulate matter nonattainment areas

Subpart 5.	Additional provisions for areas designated nonattainment for sulfur oxides, nitrogen dioxide, and lead
SUBCHAPTER II.	EMISSION STANDARDS FOR MOVING SOURCES
<i>Part A.</i>	<i>Motor vehicle emission and fuel standards</i>
<i>Part C.</i>	<i>Clean fuel vehicles</i>
SUBCHAPTER III.	GENERAL PROVISIONS
§7603	Emergency powers
§7604	Citizen suits
§7607	Administrative proceedings and judicial review
§7619	Air quality monitoring
SUBCHAPTER IV.	ACID DEPOSITION CONTROL
SUBCHAPTER V.	PERMITS
SUBCHAPTER VI.	STRATOSPHERIC OZONE PROTECTION

### PURPOSE

The goal of the Clean Air Act (CAA) (§§101–618, 42 USC §§7401–7671q) is to prevent and control the discharge of pollutants into the air which can harm human health and natural resources. It regulates pollution by establishing ambient air quality standards at which pollutants can be safely tolerated. The act also regulates emission sources through a system of limitations on specified pollutants and a permit program for major sources.

The current act is comprised of several amendments that address air pollution problems over the last twenty years. Most of the major provisions were developed in the 1970, 1977, and 1990 amendments (CAA [1990], CAA §§101–618, 42 USC §§7401–7671q). The central part of the act is its provisions for National Ambient Air Quality Standards for criteria pollutants. Other features of the act include standards for areas which meet the ambient air quality standards, attainment areas, and more stringent standards for nonattainment areas. In addition, the act provides for prevention of significant deterioration, air toxics, state implementation plans, permits, and the control of mobile sources.

### SPECIFIC PROVISIONS

The CAA has specific provisions for the National Ambient Air Quality Standards, attainment and nonattainment, ozone, prevention of significant deterioration, air toxics,

state implementation plans, permits, and mobile sources. These provisions are summarized next.

## National Ambient Air Quality Standards

National Ambient Air Quality Standards (NAAQS) are health-based standards used to measure and protect the air around us.<sup>1</sup> Section 108 directs the EPA to identify criteria pollutants which may reasonably endanger public health and welfare. The list of criteria pollutants includes:

- Sulfur dioxide (SO<sub>2</sub>)
- Carbon monoxide
- Ozone (smog)
- Nitrogen oxides (NO)
- Lead
- Particulate matter

The act directs the EPA to establish two levels of NAAQS for the criteria pollutants. First, the EPA developed primary air quality standards to protect human health and provide a margin of safety to protect sensitive members of the population, e.g., pregnant woman, children, and the elderly. The EPA can also establish stricter secondary standards to avoid adverse impacts on the environment and protect public welfare by preventing harm to agricultural crops and livestock.

## Attainment and Nonattainment

The attainment of ambient standards is a central purpose of the CAA. Areas are in attainment if they meet the NAAQS. Pollution sources in attainment areas are subject to the prevention of significant deterioration (PSD) requirements discussed next.

An area is designated in nonattainment if it exceeds the NAAQS for a given pollutant more than once a year. This determination is made for each criteria pollutant. Consequently, an area can be in nonattainment for one pollutant, while at the same time be in attainment and subject to PSD provisions for another.

Though similar to the classification scheme in the 1977 amendments, the 1990 amendments divide nonattainment areas into categories depending on the severity of each area's problem. It also allows boundaries to be adjusted to accommodate areas that have come into attainment. Amended section 107(d) requires states to designate regions as:

“Nonattainment”—any area that does not meet (or contributes to ambient air quality in a nearby area that does not meet) national primary or secondary ambient air quality standards for the pollutant;

“Attainment”—any area that does meet the standard for the pollutant, or

“Unclassifiable”—any area that cannot be classified attainment or nonattainment on the basis of available information.

Any state not meeting implementation deadlines is subject to a moratorium on the construction of new major stationary sources of pollution or on any major modifications of existing major sources in nonattainment areas. A major source is one with emissions or potential to emit 100 tons or more per year of a pollutant subject to regulation under the act.<sup>2</sup> A major modification is any physical change in the operation of a major stationary source that would result in a significant net increase in a pollutant subject to regulation under the act.<sup>3</sup>

Section 173 requires states to adopt permit programs for the construction or modification of major stationary sources in nonattainment areas. It also imposes a more demanding technology requirement, the lowest achievable emission rate (LAER) on those sources. Finally, permits for modified sources in nonattainment areas can be issued only if emissions from existing sources in the area decrease enough to offset the increase in emissions from the new or modified source and continue reasonable further progress.

## Ozone

Ozone, commonly known as smog, is the most serious and common nonattainment problem. The 1990 amendments contain requirements for ozone nonattainment areas (CAA §181, 42 USC 7511). Section 181 divides ozone nonattainment areas into five categories depending on their degree of nonattainment:

- Marginal
- Moderate
- Serious
- Severe
- Extreme

Each category is assigned a design value, which is a measure of its ambient air quality expressed in parts per million. Attainment deadlines vary among areas and are measured from November 15, 1990, the enactment date of the 1990 amendments. The attainment deadline for each category follows:

- Marginal areas—three years
- Moderate areas—six years
- Serious areas—nine years
- Severe areas—fifteen years
- Extreme areas—twenty years

On the basis of its category and design value, each area is responsible for its own category requirements as well as

1. See *U.S. Code*, Vol. 42, secs. 7408–9; *Federal Register* 36, 1971, 8186; *Code of Federal Regulations*. 1991, Title 40, part 50.

2. See *Code of Federal Regulations*, 1984, Title 40, sec. 52.24(f)(4)(i)(a).

3. See *Clean Air Act*, sec. 110(a)(2)(I); *U.S. Code*, Vol. 42, sec. 7410(a)(2)(I); *Code of Federal Regulations*, Title 40, sec. 52.24(f)(5)(i).

the requirements for categories of lesser nonattainment. Thus, moderate areas are responsible for their own requirements as well as those applicable to marginal areas. For example, a state with a marginal ozone area must submit:

1. An inventory of all actual emissions to the EPA by November 1992
2. Revisions to its state implementation plans (SIP) designed to meet the three-year deadline for attainment, including the implementation of reasonably available control technology (RACT)
3. Permit programs for new and modified sources
4. An increase in the offset requirement for new sources and modifications, from 1 to 1 to 1.1 to 1
5. The retention of the vehicle inspection and maintenance program previously required for the area

A moderate area must submit requirements (1) through (5) listed for marginal areas, as well as all requirements assigned to moderate areas which include:

1. A revision of its SIP to provide for reasonable further progress through a 15% reduction in emissions within six years for volatile organic compounds (VOCs)
2. Any other annual reductions of VOCs and NO necessary to reach attainment by the deadline
3. The implementation of RACT for each category of VOC source covered by existing control techniques guidance.

### Prevention of Significant Deterioration

Areas in attainment for NAAQS are subject to provisions for PSD (CAA §§160–169[B], 42 USC §§7470–7479[B]). PSD provisions seek to protect areas that already enjoy cleaner air than that required by the ambient standards, and to keep that air from deteriorating in quality.<sup>4</sup> PSD provisions also require new major facilities to apply for a preconstruction permit and to use the best available control technology (BACT) for each pollutant regulated under this section.<sup>5</sup>

The BACT is determined on a case-by-case basis and reflects the most effective controls currently in use. The Act defines the BACT as the maximum degree of reduction which considers energy, environmental, economic, and other impacts.

PSD regulations divide the country into three classes on the basis of air quality:

- Class I (large national parks and wilderness areas)
- Class II (very clean areas allowing some industrial growth)
- Class III (Class II areas established for industrial development)

4. See *Code of Federal Regulations*, Title, 40 sec. 52.51 for PSD requirements and PSD provisions in SIPs.

5. See *Federal Register* 53 at 40656.

For each class, the act establishes maximum allowable increases over baseline concentrations (increments) of pollutants (SO<sub>2</sub>, NO, and PM-10). Baseline concentrations are established based on the ambient concentrations measured at permit application. Allowable increases cannot create concentrations greater than those sanctioned by the NAAQS.

Section 165 of the act controls PSD permits (CAA §165, 42 USC §7475). This section requires new and modified sources to undergo a preconstruction review. The review includes a hearing with public comment to assess a project's potential impact and to consider alternatives to the proposed project. After completing air quality monitoring, the owner or operator must also demonstrate that the expected emissions from the operation or construction of the project will not exceed the limit on the increment of clean air in that area.

### Air Toxics

The issue of air toxics is treated separately from attainment and nonattainment of ambient air quality and the prevention of significant deterioration (CAA §112, 42 USC §7412).<sup>6</sup> The 1970 act authorized the EPA to set health-based national emission standards for hazardous air pollutants (NESHAPS). However, the EPA acted on only a limited number. The 1990 amendments, under section 112, mandates the establishment of technology-based standards for 189 hazardous substances. Section 112 also calls for the use of maximum achievable control technology (MACT) to regulate the emission of these substances.

The 1990 amendments create a two-step approach to controlling air toxics. First, new sources must use MACT to achieve a reduction level equal to levels reached by the least-polluting existing sources within given categories. All categories of sources are supposed to be promulgated by November 2000: 25% of all standards are to be promulgated by November 1994, and 50% of all standards are to be completed by November 1997. The second step establishes residual risk standards which are more stringent than MACT. Residual risk standards should be used to protect the public health with an ample margin of safety.

The EPA has already issued some MACT standards. One example is the hazardous organic NESHAP (HON) rule, which sets standards for reducing the emissions of 149 toxic chemicals from synthetic-organic chemical manufacturing (SOCMI) processes.<sup>7</sup> The rule applies to processes that develop chemicals considered primary products, which are distinct from other by-products created in these processes. The HON applies to any plant that is con-

6. See also *Code of Federal Regulations*, Title 40, part 61.

7. National Emission Standards for Hazardous Air Pollutants for Source Categories; Organic Hazardous Air Pollutants from the Synthetic Organic Chemical Manufacturing Industry and Seven Other Processes, *Federal Register* 57, (31 December 1992):62608.

sidered a major source and is a model for future MACT standards developed at the federal level.

The EPA has also developed a final rule on the toxics early reductions program for hazardous air pollutants (57 *FR* 61970 *et seq.*).<sup>8</sup> This program encourages industrial facilities to pursue early reductions before the final MACT standards are established. Facilities that qualify for the program can defer their compliance with MACT standards for six years if they agree to and can demonstrate reductions of their emissions by 90 and 95% before the MACT standards take effect (*CAA* §112[d], 42 *USC* §7412[d], 40 *CFR* §63.70 *et seq.*). Because industries under this program can choose how to reduce their toxics emissions, in theory they have the flexibility to make the most economically viable choices for themselves.

The EPA has published an initial list of categories of major sources and area sources of air toxics (57 *FR* [16 July 1992] 31576). An area source is defined as a stationary source that is not a major source (*CAA* §112[a][2], 42 *USC* §7412[a][2]). The regulation of area sources is meant to include small diverse sources, such as dry cleaners and service stations, which substantially contribute to the emission of hazardous pollutants. Instead of being subject to MACT, area sources are subject to less stringent standards called generally available control technology (GACT).

## State Implementation Plans

The act requires each state to submit a plan for implementation and enforcement of the national standards within its jurisdiction (*CAA* §110, 42 *USC* §7410, 40 *CFR* §§51.01 *et seq.*, 52.01 *et seq.*, 52.2370 *et seq.*). SIPs are based on emission inventories and computer models that predict whether violations of the NAAQS will occur. States can decide to meet the NAAQS as long as the regulatory requirements they choose enable them to attain the national standards. Once an SIP is approved, it becomes an element of state and federal law and is enforceable under either. In attainment areas, SIP planning must also account for PSD issues.

In nonattainment areas, SIPs provide for attainment of NAAQS and include:

1. Provisions for RACT
2. Reasonable progress in attaining the required reductions
3. A current emissions inventory
4. Permits for new and modified major stationary sources
5. Emission offset requirements

8. This program is implemented through the Title V operating permits program. The EPA has developed a guidance document outlining procedures for facilities to follow in applying for this program, Enabling Document for Regulations Governing Compliance Extensions for Early Reductions of Hazardous Air Pollutants (EPA-450/3-91-013 [December 1992]).

6. A contingency plan if unable to meet NAAQS by the specified date

SIPs must also contain procedures for the review and permitting of new or modified stationary sources and their impact on the attainment and maintenance of NAAQS. SIPs regulate these sources on the basis of their general provisions. SIPs also contain provisions that apply to individual sources. To obtain a variance or be exempted from SIP provisions, however, involves a lengthy process which includes revising the SIP and review by the state authorities and the EPA.

Some SIPs contain provisions for alternative compliance, which streamline review and allow for in-state revisions of the requirements for individual facilities. In some contexts, the use of “bubbles” provides another means for facilities to make changes within their plant without triggering an SIP revision.<sup>9</sup> Put simply, bubbling is the consolidation of multiple emission sources. Bubbling creates one source (for regulatory purposes), which allows certain limited changes in emissions from the sources within the bubble.

If a state fails to gain approval of its SIP, the EPA can promulgate a plan for that state. This plan is called a federal implementation plan (FIP). An implementation plan includes the following requirements:<sup>10</sup>

1. Enforceable emission limits
2. Necessary monitoring
3. Program for enforcement including a permit program
4. Interstate and international requirements
5. Adequate personal funding and authority
6. Self-monitoring requirements
7. Emergency authority
8. Revision authority
9. Nonattainment plan
10. PSD plans
11. Air quality modelling
12. Federal requirements
13. Consultation and participation

## Permits

Generally, the federal government delegates the responsibility for issuing permits to the states through the SIPs. Prior to implementing the new operating permit program under the 1990 amendments, new source review was the means for issuing permits to new or modified industrial facilities. Permit requirements vary, depending on whether the project is in a PSD or nonattainment area.<sup>11</sup> Apart from PSD

9. The EPA first developed a bubble policy in 1979 but revised it to include not only existing sources but also emissions trading and new sources. *Federal Register* 51, (1986):43814.

10. For SIP minimum criteria, see *Federal Register* 56, (26 August 1991):42216.

11. See discussions of Prevention of Significant Deterioration and Nonattainment *supra*.

and nonattainment concerns, permitting is a two-step process which requires initial authorization to construct a project and then authorization to operate a source.

The permit program under the 1990 amendments brings together the requirements for individual facilities and places them in one document. It also provides a financial basis for the program through permit fees. New permits contain emissions standards, monitoring, record-keeping, and reporting requirements. Major sources, sources subject to air toxics regulation, and all sources subject to new source performance standards are required to obtain a permit.

### Mobile Sources

The 1970 act regulated emissions from automobiles. It called for a 90% reduction of emissions below the then-current levels. Subsequently, the 1977 amendments adjusted the NO emissions to allow for a 75% reduction. These standards are applied on a national basis because automobiles move from state to state.

The 1990 amendments go further in reducing emissions from mobile sources (*CAA* §§202–250, *42 USC* §§7521–7590). They establish more stringent tailpipe standards and establish clean fuel requirements.

To implement the new emission standards, the 1990 amendments establish a tier system which phases in standards for NO between 1994 and 1995, and for non-methane hydrocarbons and carbon monoxide between 1994 and 1998. A second tier, if the EPA finds it necessary, will provide for even stricter standards. These standards will be developed between 2003 and 2006. The EPA must also develop controls for emissions resulting from fuel evaporation.

The clean fuel program promotes the use of some fuels like methanol, ethanol, reformulated gasoline, and other fuels such as electricity and natural gas. Reformulated gas, for areas with high ozone levels, has lower levels of oxygen, aromatic hydrocarbons, and benzene. For carbon monoxide nonattainment areas, the oxygenated fuel program will require a minimum oxygen content in fuels.

The 1990 amendments also target fleets of cars and trucks. Fleets of ten or more which can be centrally fueled are subject to the clean fuel requirements. Lesser standards apply to heavy-duty trucks. These standards apply to all cars and trucks in serious, severe, and extreme ozone nonattainment areas.

### OTHER FEATURES OF THE CAA AMENDMENTS OF 1990

The 1990 amendments to the CAA establish a new nonattainment program and contain new deadlines and divide nonattainment areas into several categories.

Deadlines range from 1993 for marginal areas to 2010 for Los Angeles.

Section 112 on air toxics lists 189 regulated hazardous air pollutants and directs the EPA to establish technology-based standards based on MACT. The amendments also provide for a program to prevent accidental releases.

Modeled on the Clean Water Act's National Pollution Discharge Elimination System, sections 501 to 507 of title V establish a federal permit program for existing stationary sources. The EPA can veto permits not in compliance with the act, and citizens have certain rights to challenge them.

The new acid rain program seeks to reduce sulphur dioxide emissions nationwide to 8.9 million tons per year. It also mandates a reduction of annual NO emissions by approximately two million tons. These reduction provisions are part of a market-based emission allowance program.

### SUMMARY

The CAA sets primary and secondary standards for major pollutants (§7409).

The CAA requires states to establish air quality control regions and develop SIPs to achieve the nation's ambient air standards within reasonably statutorily defined time periods (§§7404, 7406).

The CAA requires the EPA to establish NSPSs to limit emissions from new or expanding sources to the fullest extent possible (§7411).

The CAA requires the EPA to establish emission standards for hazardous air pollutants (§7412).

The CAA mandates the EPA to follow specific strategies for limiting emissions from stationary sources in both attainment and nonattainment areas (§§7470 *et seq.*, 7501 *et seq.*).

The CAA mandates the EPA to follow a specific strategy for controlling mobile air emission sources (§7521 *et seq.*).

The EPA can commence a civil or criminal action for a violation of any requirement of an applicable implementation plan. Additionally, the CAA provides for citizen suits to insure that the EPA is performing all of its nondiscretionary duties (§§7413, 7604).

The CAA amendments of 1990 add substantial content to the act including provisions focusing on urban air pollution, mobile sources, toxic pollutants, permits, and the problems associated with acid rain.

### Resource Conservation and Recovery Act

The Resource Conservation and Recovery Act (*42 USC* §6901 *et seq.*, *40 CFR* Parts 240–271).

## STATUTORY ROADMAP

- SUBCHAPTER I. GENERAL PROVISIONS
- SUBCHAPTER II. OFFICE OF SOLID WASTE: AUTHORITIES OF THE ADMINISTRATOR
- SUBCHAPTER III. HAZARDOUS WASTE MANAGEMENT
- SUBCHAPTER IV. STATE AND REGIONAL SOLID WASTE PLANS
- SUBCHAPTER V. DUTIES OF THE SECRETARY OF COMMERCE IN RESOURCE RECOVERY
- SUBCHAPTER VI. FEDERAL RESPONSIBILITY
- SUBCHAPTER VII. MISCELLANEOUS PROVISIONS
- SUBCHAPTER VIII. RESEARCH, DEVELOPMENT, DEMONSTRATION, AND INFORMATION
- SUBCHAPTER IX. REGULATION OF UNDERGROUND STORAGE TANKS
- SUBCHAPTER X. DEMONSTRATION MEDICAL WASTE TRACKING PROGRAM

## PURPOSE

Enacted in 1976, the Resource Conservation and Recovery Act (RCRA) (1992, 42 *USC* §§6901–6991i) regulates the transportation, handling, storage, and disposal of solid and hazardous waste. The RCRA was amended in 1984 by the Hazardous and Solid Waste Amendments. Originally conceived as a law to control the disposal of solid waste and encourage recycling, the RCRA's emphasis is the regulation of hazardous waste.

The central mechanism in the RCRA is the manifest system which creates documentation on hazardous waste and monitors the movement of hazardous waste. The RCRA also establishes standards for treatment, storage and disposal facilities, and state hazardous waste programs.

The general objective of the RCRA (§1003[a], 42 *USC* §6902[a]) is “to promote the protection of health and the environment and [the conservation of] valuable material and energy resources...” This objective should be achieved through the development of solid waste management plans and hazardous waste management practices. The RCRA also sets forth a national waste management policy: “wherever feasible, the generation of hazardous waste is to be reduced or eliminated as expeditiously as possible. Waste that is nevertheless generated should be treated, stored, or disposed of so as to minimize the present and future threat to human health and the environment” (RCRA §1001[b], 42 *USC* §6902[b]).

## SPECIFIC PROVISIONS

The RCRA provides for a manifest system, regulated wastes, regulating hazardous wastes, releases and ground water monitoring, closure, and underground storage tanks.

## The Manifest System

The RCRA requires waste to be monitored from its generation to its ultimate disposal. Thus, the RCRA is commonly referred to as a cradle-to-grave statute. A manifest is a written description of a container's contents, source, and destination. The manifest must accompany the waste at all times.<sup>12</sup> This information must also be made available to the regulatory authorities, enabling them to monitor waste generation, shipment, and disposal.

## Regulated Wastes

A person's status under the RCRA depends upon the type of waste he is handling. The RCRA regulates solid waste and hazardous waste, both of which are defined by the statute and its regulations.

### SOLID WASTE

The RCRA defines solid waste as “any garbage, refuse, sludge from a waste treatment plant, water supply treatment plant, or air pollution control facility and other discarded material, including solid, liquid, semisolid, or contained gaseous material resulting from industrial, commercial, mining and agricultural operations, and from community activities...” (RCRA §1004, 42 *USC* §6903[27]). The remainder of the definition excludes certain materials from solid waste, thus omitting them from solid waste regulation under the RCRA.

States are encouraged to develop solid waste management plans which enable waste to be controlled on a local level. While the RCRA does not directly regulate state solid waste programs, it directs the EPA to develop guidelines for states to follow. These guidelines are developed under subtitle D of the act. In addition, the RCRA establishes minimum requirements upon which states can model solid waste plans. The requirements prohibit open dumping of solid waste and mandate the closing or the upgrading of operational open dumps.

### HAZARDOUS WASTE

Under the RCRA (§1004[5], 42 *USC* §6903[5]), hazardous waste is defined as any solid waste which, because of its quantity, concentration, or physical, chemical, or infectious characteristics may—

(A) cause, or significantly contribute to an increase in mortality or an increase in serious irreversible, or incapacitating reversible, illness; or

(B) pose a substantial present or potential hazard to human health or the environment when improperly treated, stored, transported, or disposed of, or otherwise managed (RCRA §1004[5], 42 *USC* §6903[5]).

12. *Code of Federal Regulations*. Title 40, parts 264, 265. Manifest requirements and the reporting requirements are in Subparts E of these parts.

Solid waste is considered hazardous if it is listed as hazardous or if it has hazardous characteristics.<sup>13</sup> If the EPA designates a waste hazardous through rulemaking, then it is a listed hazardous waste. Alternatively, the EPA can find a waste to be hazardous based upon the waste's characteristics.

The EPA has developed four criteria for measuring the characteristics of substances: ignitability, corrosivity, reactivity, and toxicity (*RCRA* §1022[a], 42 *USC* §6921[a]). Depending on their classification, wastes are assigned a hazardous waste classification number: ignitable (D001), corrosive (D002), and reactive (D003).

A liquid solid waste is determined ignitable if it has a flash point lower than 60 degrees centigrade.<sup>14</sup> A solid material is ignitable if it is "capable at a temperature of 25 degrees centigrade and a pressure of one atmosphere, of causing fire through friction, absorption of moisture or spontaneous chemical changes, and when ignited, burns so vigorously and persistently that it creates a hazard" (40 *CFR* §261.21).

A corrosive waste is a solid waste with a pH of less than 2 or greater than 12.5 (40 *CFR* §261.22). Reactive wastes are solid wastes which are normally unstable, react violently or generate toxic fumes when they come in contact with water, contain cyanide or sulfide, (when exposed to pH conditions between 2 and 12.5) generate toxic fumes, or are explosive.

The final criterion for determining a hazardous waste is the toxicity characteristic. This characteristic is determined by the toxicity characteristic leachate procedure (TCLP) test.<sup>15</sup> Waste which contains concentrations greater than those listed in the TCLP tables are considered toxicity characteristic hazardous wastes.<sup>16</sup>

Specific rules apply to mixtures of a hazardous waste with nonhazardous waste, as well as to their treatment. The mixture of toxicity characteristic hazardous waste with nonhazardous waste is considered hazardous if it retains a hazardous characteristic (40 *CFR* §261.3[a][2][iii]). The mixture of listed hazardous waste with nonhazardous waste is considered hazardous unless other criteria are met.<sup>17</sup> Finally, any residue from the treatment of listed or toxicity characteristic hazardous wastes is also considered hazardous waste.<sup>18</sup>

13. Certain solid wastes including household wastes are excluded from hazardous waste designation depending on conditions. *Code of Federal Regulations*. Title 40, sec. 261.4.

14. 140 degrees Fahrenheit. *Code of Federal Regulations*. Title 40, sec. 261.21.

15. In the past, the EPA used the extraction procedure (EP) test which was designed to test for inorganic compounds only. The current TCLP test can test for both inorganic and organic compounds.

16. See *Code of Federal Regulations*. Title 40, sec. 261.24, Table No. 1.

17. See *ibid.*, sec. 261.3(a)(2)(iv).

18. This rule is known as the derived-from rule. *Ibid.*, sec. 261.3(c)(2).

## Regulating Hazardous Wastes

Hazardous wastes are regulated under the RCRA's subtitle C which incorporates the manifest system to track waste from its point of generation to its point of disposal. The regulations vary according to where the hazardous waste is located and how long the waste will remain at the site. Generally, the RCRA regulates generators; transporters; and treatment, storage, and disposal facilities (TSDFs).

### GENERATORS

Individuals who generate hazardous waste are subject to licensing and other regulatory requirements under the RCRA. A generator is any person whose act or process produces hazardous waste or whose actions cause hazardous waste to become subject to regulation (40 *CFR* §262.10). Generators are subject to a number of requirements, including:

1. Testing materials they generate to determine if they are hazardous
2. Keeping accurate records which identify quantities and constituents of the hazardous waste they generate
3. Labeling storage, transport, and disposal containers
4. Providing information on the wastes they are transporting, storing, or disposing
5. Complying with manifest system and notification rules (40 *CFR* §261.10)

Any person who generates hazardous waste must obtain a generator identification number (40 *CFR* §262.12). That person must also notify the EPA at least thirty days prior to generating the waste (40 *CFR* §262.12). A generator that transports or provides for the transport of hazardous waste for treatment, storage, or disposal offsite must fully prepare a manifest before the waste leaves the site (40 *CFR* §§262.20–262.23). The manifest must include the generator's name, address, telephone number, EPA identification number, and a description of the waste's constituents and quantity. It must also contain the name and EPA identification number of each transporter, the designated receiving facility, and an alternative receiving facility (40 *CFR* §262.20–262.23).

Typically, the generator must sign the manifest, obtain the signature of the first transporter, and enter the date on which the waste is accepted. The generator must also submit a copy of the manifest to the state agency in charge of administering that state's hazardous waste program. If the destination of the waste is out of state, the generator typically must use the receiving state's manifest form and send a copy of it to that state's agency in charge. A generator must also retain a copy of the manifest for a minimum of three years.

The TSDF receiving the waste must return a copy of the manifest, signed by the TSDF operator, to the generator. If the generator does not receive notice from the TSDF within a specified time, the generator must contact the

TSDF. If the manifest does not come, the generator must notify the state agency in charge of the hazardous waste program. The notice provided to the state agency is referred to as an exception report. It includes a copy of the original manifest and a letter stating the efforts made by the generator to locate the material which it shipped off-site (40 *CFR* §262.42).

The RCRA provides an exemption for small quantity generators, those which create less than 100 kg of hazardous waste per month (40 *CFR* §261.5). However, acute hazardous waste in excess of 100 kg per month, or with a total of 100 kg or greater of residue, contaminated soil, or debris from a cleanup of a spill of acute hazardous waste, subjects the generator to full regulation. A conditionally exempt small quantity generator can treat hazardous waste onsite or send the waste to an authorized TSDF.

#### **TRANSPORTERS**

Transporters of hazardous waste are subject to many of the same regulatory requirements as generators. For instance, a transporter must adhere to strict recordkeeping and labeling requirements and must comply with the manifest system (RCRA §3003, 42 *USC* §6923). Additional requirements are found at 40 *CFR* part 263.

#### **TSDFs**

The types of TSDFs vary as much as the technologies for handling hazardous waste. For instance, a TSDF can be an incinerator; chemical, physical, or biological treatment plant; or a container or tank system. They also include generators that store hazardous waste onsite for more than ninety days as well as those generators that treat or dispose of wastes themselves.

The RCRA (§3004, 42 *USC* §6924; 40 *CFR* pts. 264, 265, 267) places controls on TSDFs. All TSDF owners and operators must obtain an RCRA permit or be designated as interim status to be legally operating (RCRA §3005, 42 *USC* §6925; 40 *CFR* pt. 270). The permit must last the life of the unit, including the closure period. Interim status applies to facilities which:

1. Are in existence on or prior to November 19, 1980, or the effective date of statutory or regulatory changes which make the facility subject to the RCRA's permit requirements
2. Have complied with the general notification requirements of section 6930
3. Have applied for an RCRA permit

Part A of the RCRA permit requires applicants to provide their name, address, and facility location. Also required are the operator's name and address; a general description of the business; a scale drawing of the facility; a description of the processes used to treat, store, and dispose of hazardous waste; as well as a list and an estimate

of the quantity of hazardous waste onsite. In addition, Part A requires a list of the permits which the facility holds under other environmental programs.

Part B of the permit calls for detailed technical information explaining the type of TSDF involved (e.g., an incinerator) and a thorough chemical and physical analysis of the facility's hazardous waste. It also requires a description of security procedures; the facility inspection schedule; as well as procedures for preventing spills, runoff, contamination, and exposure. Applicants must also provide an outline of training programs, a copy of the facility closure plan, and proof of insurance coverage. Finally, the permit must be signed by a responsible corporate officer.

TSDFs have numerous other requirements under the RCRA. A TSDF, for instance, must obtain an identification number from the EPA. They must also comply with notice requirements, analyze all wastes that their facility produces, and develop a waste analysis plan.

### **Releases and Groundwater Monitoring**

The RCRA regulations (40 *CFR* pts. 264–265, subpts. F) establish procedures to follow in the event of a release from a TSDF. To assure detection, compliance, and corrective action, TSDFs must practice groundwater monitoring by installing monitoring wells.

Facilities must initially perform detection monitoring for hazardous constituents listed in their RCRA permit. When groundwater protection standards are exceeded for the facility's hazardous constituents, more stringent compliance monitoring is also required.

Certain facilities are excluded from groundwater monitoring requirements. Facilities are excluded if they:

1. Receive and contain no liquid
2. Are designed and operate without liquid
3. Contain inner and outer layers of containment enclosing
4. Have a leak detection system
5. Have continual operation and maintenance of a leak system
6. Do not allow migration of hazardous constituents beyond the outer containment layer.

### **Closure**

TSDFs must assure their financial ability to cover any liability involved in closure before they are granted a permit to open (40 *CFR* pts. 264–265, subpts. G). TSDF permits contain closure plans which assure a regulated closing. When a TSDF plans to close, it must meet requirements which assure a clean closure (i.e., no contaminated equipment or contamination in the soil or groundwater on the facility site remains).

## Underground Storage Tanks

The RCRA sought to regulate underground storage tanks after its 1984 amendments (*RCRA* §§9001–9010, *42 USC* §6991–6991i), but final regulations for the underground storage tank program were not promulgated until 1988 (53 *FR* [23 September 1988] 37082). The regulations require release detection and prevention, as well as corrective action.

Underground storage tanks are defined as “any one or combination of tanks (including underground pipes connected thereto) which is used to contain an accumulation of regulated substances, and the volume of which (including the underground pipes connected thereto) is 10 per centum or more beneath the surface of the ground (*RCRA* §9001[1], *42 USC* §6991[1]).

Owners or operators of underground storage tanks must notify the EPA of their existence. Tanks installed after December 22, 1988, must comply with a national code of practice. This code establishes requirements for new tanks, such as corrosion protection and leak detection devices. All underground storage tank owners must comply with the regulations for releases of regulated substances. The regulations also impose requirements for closure of tanks as well as various aspects of financial responsibilities.

## SUMMARY

The RCRA provides statutory goals and objectives and declares the national solid waste and hazardous waste disposal policy (*RCRA* §§1002–1003).

The EPA establishes standards for generators of hazardous waste. These standards include requirements for recordkeeping, labeling of storage, transport, and disposal containers, and the use of a manifest system to track hazardous wastes (*RCRA* §3002).

The EPA establishes standards for transporters of hazardous wastes, including requirements for recordkeeping, labeling, and the use of a manifest system (*RCRA* §3003).

The EPA establishes standards for TSDFs. These requirements ensure the safe handling of hazardous wastes by TSDF owners and operators (*RCRA* §3004).

TSDFs must obtain a permit from the EPA or an authorized state (*RCRA* §3005).

The EPA develops guidelines for state and regional solid waste plans. Plans must meet minimum federal requirements including provisions for prohibiting new open dumps and the closing or upgrading of all existing open dumps (*RCRA* §§4002–4003).

The RCRA provides for federal enforcement, citizens suits, penalties for imminent and substantial endangerment, and judicial review (*RCRA* §§3008, 7002, 7003, 7006). Owners of underground storage tanks must provide notice to a designated state agency of their existence and

specifications. States must maintain inventories of all underground storage tanks containing regulated substances (*RCRA* §9002).

The EPA establishes regulations for underground storage tanks to control releases. The minimum requirements include maintaining a leak detection system, controlling inventory, reporting and recordkeeping, and maintaining evidence of financial responsibility (*RCRA* §9003).

The EPA establishes regulations for a medical waste tracking program (demonstration program). The medical wastes subject to the program are listed and published by the EPA (*RCRA* §§11001–11003).

## Comprehensive Environmental Response, Compensation, and Liability Act

The Comprehensive Environmental Response, Compensation, and Liability Act (*42 USC* §§9601–9675; *40 CFR* Part 300).

## STATUTORY ROADMAP

SUBCHAPTER I.	RELEASES, LIABILITY, COMPENSATION
§9603	Notification requirements respecting released quantities, regulations
§9604	Response authorities
§9605	National contingency plan
§9606	Abatement actions
§9607	Liability
§9608	Financial responsibility
§9609	Civil penalties and awards
§9611	Use of fund
§9616	Schedules
§9621	Cleanup standards
§9622	Settlements
SUBCHAPTER III.	MISCELLANEOUS PROVISIONS
§9659	Citizens suits
SUBCHAPTER IV.	POLLUTION INSURANCE

## PURPOSE

The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) (1992, *42 USC* §§9601–9675), commonly referred to as the superfund, was enacted in 1980 in response to problems associated with hazardous waste disposal.<sup>19</sup> Together with the Superfund Amendments and Reauthorization Act (SARA) of 1986, the statute provides a multibillion dollar fund for

19. See Grad. 1982. A legislative history of the Comprehensive Environmental Response Compensation and Liability (Superfund) Act of 1980. *J. Envtl. L.* 8 Colum.: 1.

the remediation or cleaning up of hazardous waste sites. The superfund's resources, however, are limited and are not intended to be the primary financial source for covering the costs of cleanup. Rather, CERCLA's far-reaching liability scheme serves to impose the costs of cleanup on those responsible for the waste problem. It also serves as an incentive to prevent hazardous waste sites from becoming unmanageable.

By the late 1970s, the hazardous waste disposal problem was a great concern in the United States. Thousands of abandoned waste sites posed serious risks to public health and the environment. Several well-known environmental disasters—Love Canal and Valley of Drums—swayed public opinion and had a major influence on CERCLA's enactment.<sup>20</sup>

## SPECIFIC PROVISIONS

An understanding of the basic structure of the law and definitions of its key terms is a prerequisite to understanding the specific provisions of the CERCLA.

### Basic Structure of the Law

The EPA is responsible for carrying out CERCLA's mandates. Generally, the EPA can invest the superfund's monies toward cleanup whenever a hazardous substance is released or threatened to be released into the environment. The act authorizes response actions or hazardous waste cleanups which include both remedial and removal activities. However, CERCLA's structure goes beyond this general authority. To understand the details of the statute, the CERCLA can be broken down into four areas to simplify its framework:

- Reporting provisions for releases of hazardous substances
- Investigation, prioritization, and response provisions
- Liability, enforcement, and settlement provisions
- Superfund financing provisions

### Definition of Key Terms

The following definitions are necessary for a basic understanding of the CERCLA.

1. A *hazardous substance* under the CERCLA (§101[14], 42 USC §9601[14]) is defined largely on the basis of

20. Two of the most notorious sites were New York's Love Canal and Kentucky's Valley of the Drums. At the New York site, an estimated 141 pounds of dioxin were buried underground at what became a housing development. The Kentucky site involved nearly 20,000 drums of hazardous waste containing approximately 200 organic chemicals and thirty metals. Roughly one-third of the drums were rusted through and leaking their contents into the ground.

its meaning under other environmental statutes.<sup>21</sup> The definition includes:

- Any hazardous waste under the RCRA
- Any hazardous air pollutant under section 112 of the CAA
- Any hazardous substance or toxic pollutant under sections 307 or 311 of the CWA
- Any hazardous chemical substances or mixtures regulated pursuant to section 7 of the Toxic Substances Control Act
- Any other materials designated as hazardous under CERCLA section 102
- Petroleum products, natural gas, and synthetic gas used as fuel are excluded from regulation as hazardous substances.

2. A *release* is broadly defined as "any spilling, leaking, pumping, pouring, emitting, emptying, discharging, injecting, escaping, leaching, dumping, or disposing into the environment (including the abandonment or discarding of barrels, containers, and other closed receptacles containing any hazardous substance or pollutant or contaminant). . . ." This list is followed by a number of exclusions (*CERCLA* §101[22], 42 USC §9601[22]) including releases in the workplace, which only cause exposure to that confined area, and releases of source, byproduct, or special nuclear materials relating to nuclear incidents, which are covered under the Atomic Energy Act of 1954 (42 USC §2011 *et seq.*).
3. The *environment* is broadly defined to include anything except the inside of a building or any other manmade enclosed areas. The environment includes all land surface and subsurface strata, ambient air, and all waters within the United States or its jurisdiction (*CERCLA* §101[8], 42 USC §9601[8]).
4. A *response* is a federally funded activity which includes both removal and remedial actions and any enforcement activities related to those actions (*CERCLA* §101[25], 42 USC §9601[25]).
5. A *removal action* is a cleanup action aimed at containing or minimizing a release and mitigating damage to the public health without detailed preliminary studies. Removal actions are also referred to as site stabilization actions and generally consist of short-term cleanup measures, such as the installation of fencing around a site, provisions for alternative water supplies, and temporary housing for displaced individuals (*CERCLA* §101[23], 42 USC §9601[23]).
6. A *remedial action* is a long-term or permanent cleanup measure to prevent or minimize the release of a hazardous substance into the environment. A remedial action should also prevent the migration of hazardous substances which may endanger public health or wel-

21. CERCLA hazardous substances are listed in *Code of Federal Regulations*, Title 40, part 302.

fare or the environment. The statute provides a nonexhaustive list of remedial actions, which includes storage, confinement, and perimeter protection of hazardous substances as well as onsite treatment and monitoring to assure that the actions are reaching their goals (*CERCLA* §101[24], *42 USC* §9601[24]).

## Reporting Provisions

*CERCLA*'s notification provisions help the EPA and state agencies identify where response actions are needed. The *CERCLA* mandates two general reporting requirements: spill reporting and facility notification requirements.

Owners of facilities or vessels which spill hazardous substances into the environment must report those releases to the National Response Center (NRC) at the U.S. Coast Guard in Washington, DC (*CERCLA* §103[a], *42 USC* §9603[a]). Owners must also notify the appropriate state agency because states typically have similar reporting requirements. To fall under this reporting requirement, the spill must be greater than or equal to a reportable quantity for the hazardous substance as established under *CERCLA* section 102(a), and it must not be a federally permitted release. Persons who fail to properly notify the NRC may be subject to sanctions and imprisonment (*CERCLA* §103[b], *42 USC* §9603[b]).

In addition, the *CERCLA* (§103[c], *42 USC* §9603[c]) requires facilities to notify the EPA when they treat, store, or dispose of hazardous wastes unless they are within the RCRA notification requirement. This notification requirement was due by June 9, 1981. However, the EPA recommends reports of subsequent findings if the facility does not have an RCRA permit or is without RCRA interim status. The notification should specify the type and amount of hazardous substance found at the facility, any suspected releases, and any other information which the EPA requires. Failure to comply may result in sanctions.

## Investigating, Prioritizing, and Cleaning Up Hazardous Waste Sites

Investigating, prioritizing, and cleaning up hazardous waste sites is accomplished through *CERCLA*'s provisions for the National Contingency Plan (NCP), national priorities list (NPL), investigating sites, and selecting a remedy for site cleanups.

### NCP

The EPA's NCP details guidelines for cleaning up hazardous waste sites.<sup>22</sup> The minimum requirements of the NCP call for:

Developing methods and procedures for discovering, investigating, evaluating, and remedying any releases or

threats of releases of hazardous substances from facilities

Explaining the roles and responsibilities of governmental and nongovernmental entities in carrying out the plan  
Establishing an NPL and a hazardous ranking system (HRS)

Setting forth requirements for removal and remedial response actions (*CERCLA* §105, *42 USC* §9605)

The NCP also provides for national and regional teams to oversee hazardous waste emergencies and other details for responding to hazardous waste releases.

### NPL

The EPA prepares the NPL to determine which superfund sites should get primary cleanup attention. Remedial actions can be conducted only on listed sites. The EPA ranks the sites using the site risk factors of the HRS, which is located in Appendix A of the NCP (40 *CFR* pt. 300 app. A).

States initially develop lists which prioritize sites for remedial action. States revise the lists annually based on some of the risk factors in the HRS (*CERCLA* §105[8][A], *42 USC* §9605[8][A]). The lists are submitted to the EPA and contribute towards the NPL's annual revision. The NPL is published in Appendix B of the NCP (40 *CFR* pt. 300 app. B).

### INVESTIGATING SITES

The *CERCLA* (§116, *42 USC* §9616) imposes deadlines for inspections of listed sites. The EPA or private parties conducting cleanup first perform a remedial investigation and feasibility study (RI/FS) to evaluate the release and cleanup alternatives before proceeding with further action. The EPA has broad authority to enter and investigate sites and gather information, provided it has a reasonable basis to believe that a release of a hazardous substance may occur.

### SELECTING A REMEDY FOR SITE CLEANUPS

As previously defined, a removal action is a short-term control measure implemented to contain the release of a hazardous substance before a remedial action is implemented. A removal action begins with a preliminary assessment and, if necessary, a site inspection, all based on readily available information. According to the NCP, removal actions may also require compliance with any legally applicable or relevant and appropriate standard, requirement, criteria, or limitation (ARARs), depending on the urgency and the scope of the situation.

Remedial actions also begin with a preliminary assessment and a site inspection. The NCP then requires the EPA to develop a plan assessing the remedial alternatives for site cleanup. The *CERCLA* (§121, *42 USC* §9621) establishes cleanup standards containing criteria applicable to remedial actions. The standards typically require that re-

22. The NCP is published in the *Code of Federal Regulations*, Title 40, part 300.

medial actions comply with ARARs, are cost effective, and use permanent solutions and treatment technologies to the maximum extent practicable.

Following the remedy selection process, the EPA publishes its selected remedy in a record of decision. The selection must be supported by site-specific facts, analysis, and policy determinations. Finally, the EPA develops a remedial design used to implement the remedial action.

## Liability, Enforcement, and Settlement

Most superfund cases are resolved through settlements between the potentially responsible parties (PRPs) and the government. Settlements are common because CERCLA's liability scheme imposes substantial penalties on such a broad group of persons. The group of PRPs who can be liable includes:

Both current and past owners of a site  
Generators of waste who arranged for treatment or disposal of waste at a site  
Persons who transported waste to a site (*CERCLA* §107[a], 42 *USC* 9607[a])

In addition, courts have interpreted the CERCLA to impose strict liability on any and all PRPs. This interpretation means that persons are liable for releases of hazardous substances irrespective of fault. CERCLA liability is also both joint and several. This concept means that any or all PRPs can be accountable for the entire cost of cleanup. Generally, a PRP's liability is unlimited for response costs (*CERCLA* §107[c], 42 *USC* 9607[c]).

The CERCLA provides several narrow defenses to its liability scheme. A PRP can avoid liability upon a showing that the release and resulting damages were solely caused by:

An act of God  
An act of war  
An act or omission of a third party who had no contractual relation to the PRP, and the PRP exercised due care and took adequate precautions against any foreseeable acts or omissions (*CERCLA* §107[b], 42 *USC* 9607[b]).

The limited defenses provided for PRPs combined with the CERCLA's stringent liability scheme make it difficult for PRPs to avoid liability. Therefore, a PRP, once identified, usually enters negotiations for settlement with the EPA.

Settlements are authorized under CERCLA section 122. The most common types of CERCLA settlements involve response actions and result in either the PRP performing the removal or remedial action (*CERCLA* §104[a], 42 *USC* 9604[a]) or covering a portion of the cleanup costs. When a PRP negotiates to perform the response action, its duties are explicitly stated in a consent order or decree (*CERCLA* §122[d], 42 *USC* 9622[d]). The EPA can also

authorize a PRP to perform investigations or studies related to a response action (*CERCLA* §104[b], 42 *USC* 9604[b]). These duties are also described in a consent order or decree.

A PRP is bound by any settlement agreement into which it enters. If a PRP fails to comply with a settlement agreement, administrative order, or consent decree, it is subject to civil penalties of up to \$25,000 per day for each violation for as long as the violation continues (*CERCLA* §122[1], 42 *USC* 9622[1]).

## Superfund Use and Financing

The SARA amendments provided for \$8.5 billion to be used over a five year period. The Omnibus Budget Reconciliation Act of 1990 appropriated an additional \$5.1 billion for the period commencing October 1, 1991, and ending September 30, 1994. These resources can finance site investigation and cleanup costs for hazardous substance releases but are generally not used without attempting to cover the costs through the liabilities of private parties. If insufficient funds are derived from private parties, the EPA uses the superfund monies.

The CERCLA designates several uses for the fund which include:

Covering the cost of government response costs  
Covering the cost of injury, destruction, or loss of natural resources including damage assessment  
Providing grants for technical assistance (*CERCLA* §111, 42 *USC* §9611)

Use of the fund for natural resource damage,<sup>23</sup> however, is contingent upon exhausting all administrative and judicial claims to recover the damage cost from persons who may be liable (*CERCLA* §111[2], 42 *USC* §9611[2]).

The superfund generates its monies largely from a network of environmental taxes. These taxes include an excise tax on crude oil and petroleum products, an excise tax on feedstock chemicals, and an environmental tax on corporate profits. Superfund revenues are also generated through appropriations from general revenues, interest, cost recovery actions, and penalties obtained from lawsuits.

## SUMMARY

- The CERCLA includes reporting provisions.
- The CERCLA has provisions for investigation, prioritization, and response.
- The CERCLA provides for liability, enforcement, and settlement.
- Superfund financing provisions are outlined in the act.

23. The term refers to "land, fish, wildlife, biota, air, water, groundwater, drinking water supplies, and other such resources..." *Comprehensive Environmental Response, Compensation, and Liability Act*. Sec. 101(16). *U.S. Code*, Vol. 42, sec. 9601(16).

# Noise Control Act

The Noise Control Act (42 USC §4901 *et seq.*; 40 CFR Parts 204, 211).

## STATUTORY ROADMAP

§4901	Congressional findings and statement of policy
§4902	Definitions
§4903	Federal programs
§4904	Identification of major noise sources
§4905	Noise emission standards for products distributed in commerce
§4907	Labeling
§4908	Imports
§4909	Prohibited acts
§4910	Enforcement
§4911	Citizens suits
§4912	Records, reports, and information
§4913	Quiet communities, research, and public information
§4914	Development of low noise emission products
§4915	Judicial review
§4916	Railroad noise emission standards
§4917	Motor carrier noise emission standards
§4918	Authorization of appropriations

## PURPOSE

In 1972 Congress enacted the Noise Control Act (1992, 42 USC §§4901–4918) in response to the growing concern of the effects of noise on public health and welfare. Congress recognized that noise had to be adequately controlled, particularly in urban areas; that this would best be accomplished at state and local levels; and that national uniformity of treatment would best serve this purpose. Consistent with these congressional findings, the purpose of the act is “to establish a means for effective coordination of federal research and activities in noise control, to authorize the establishment of federal noise emission standards for products distributed in commerce, and to provide information to the public respecting the noise emission and noise reduction characteristics of such products” (42 USC §4901[b]).

## SPECIFIC PROVISIONS

The Noise Control Act provides noise emission standards and other requirements to control noise.

### Noise Emission Standards

The Noise Control Act requires the EPA to establish noise emission standards for various products for which such

determinations are feasible (42 USC §4905). The EPA must first, however, develop and publish criteria relating to noise (42 USC §4904). These criteria reflect the scientific knowledge available to show the effects of differing quantities of noise. The EPA must also publish at least one report containing products which are major sources of noise and an assessment of techniques available for controlling the noise emitted from those products. The noise control techniques should include technical data, costs, and alternative methods of noise control. The criteria and reports should be reviewed and revised from time to time.

Products identified in the report and which fall within a specified category must have regulations established for them. The specified categories of products are:

1. Construction equipment
2. Transportation equipment
3. Any motor or engine
4. Electrical or electronic equipment (42 USC §4905)

In addition, the EPA can promulgate regulations for other products where such regulations are feasible and necessary to protect the public from harmful noise effects. Regulations should include a noise emission standard which considers “the magnitude and conditions of use of such product (alone or in combination with other noise sources), the degree of noise reduction available through the use of the best available technology, and the cost of compliance” (42 USC §4905[c]).

## Other Requirements

Products which emit excessive noise under the act must be labeled to warn its prospective user (42 USC §4907). The distribution of products which violate standards and labelling requirements is prohibited (42 USC §4909). Moreover, the act provides for enforcement through criminal penalties and allows any person to commence a civil action under its citizens suits provision (42 USC §§4910, 4911).

The 1978 amendments to the Noise Control Act added provisions relating to the Quiet Communities Program (42 USC §4913). The purpose of the amendments was to increase state and local noise control programs. The amendments provide for federal grants and contracts to research noise pollution and inform the public about noise pollution issues and concerns. They also develop a national noise environmental assessment program to identify human trends in noise exposure, identify ambient noise levels and compliance data, and determine the effectiveness of noise abatement actions. Finally, the amendments establish regional technical assistance centers and provide for technical assistance to state and local governments to promote local noise control.

In 1981 Congress implemented the administration’s proposal to cease funding the EPA Office of Noise Abatement and Control (ONAC). The act, however, was

not repealed. The standards promulgated under both the Noise Control Act and Quiet Communities Act remain in effect. Because the noise emission and labeling standards remain in effect, they preempt state and local governments from adopting other standards.<sup>24</sup>

## SUMMARY

The EPA establishes noise emission standards for products for which such standards can feasibly be developed (§4905).

Manufacturers of products which emit excessive noise must sufficiently label and warn consumers of the products' loud tendencies (§4907).

States are encouraged to develop noise control programs to deal with local noise-related issues (§4913).

## Safe Drinking Water Act

The Safe Drinking Water Act (16 *USC* §§300f–300j–11, 40 *CFR* Parts 140–149).

## STATUTORY ROADMAP

<i>Part A.</i>	<i>Definitions</i>
<i>Part B.</i>	<i>Public water systems</i>
<i>Part C.</i>	<i>Protection of underground sources of drinking water</i>
<i>Part D.</i>	<i>Emergency powers</i>
<i>Part E.</i>	<i>General provisions</i>
<i>Part F.</i>	<i>Additional requirements to regulate the safety of drinking water</i>

## PURPOSE

Congress first enacted the Safe Drinking Water Act (SDWA) in 1974 (§§1401–1451, 42 *USC* §§300f–300j–11) to protect the nation's drinking water supplies from contaminants.<sup>25</sup> To achieve this goal, the act establishes federal standards for drinking water quality and regulates public water systems and the underground injection of waste. The act's current regulatory scheme, based upon its 1986 amendments (SDWA U.S. Public Law 99–339), still follows this general regulatory approach.

24. The Federal Aviation Administration has authority to abate airport noise under the Noise Control Act and the Aviation Noise and Capacity Act (1990), U.S. Public Law 101–508, secs. 9301–09. The DOT is responsible for the enforcement of the EPA's railroad and motor carrier emission standards. While DOT is funded for this purpose, they do not have the authority to promulgate regulations under the act.

25. *Contaminant* is defined as any physical, chemical, biological, or radiological substance or matter in water. *Safe Drinking Water Act*. Sec. 1401(6). *U.S. Code*. Vol. 42, sec. 300f(6).

## SPECIFIC PROVISIONS

The SDWA has specific provisions for public water systems and underground injections.

### Public Water Systems

The SDWA requires states to enforce various drinking water standards established by the EPA. Specifically, the standards apply to public drinking water systems which provide piped water to the public for various uses including consumption. The act, however, limits the definition of public water systems to those systems which have a minimum of fifteen service connections or provide water supply to at least twenty-five individuals (*SDWA* §1401[4], 42 *USC* §300f[4]).

The EPA promulgates national primary drinking water regulations for public water systems (*SDWA* §1412, 42 *USC* §300g–1). Under these regulations, the EPA must establish both primary and secondary drinking water standards. Notably, the primary standards are enforceable by the states, while the secondary standards are guidelines or goals to be achieved.

### PRIMARY STANDARDS

The EPA establishes primary standards for constituents which may effect human health.<sup>26</sup> Initially, the EPA has set maximum contaminant level goals for contaminants found to have adverse effects on human health and which are known or anticipated to occur in public water systems (*SDWA* §§1412[a][3], [b][3][A], 42 *USC* §§300g–1[a][3], [b][3][A]). These health-based goals are set “at a level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety” (*SDWA* §1412[b][4], 42 *USC* §300g–1[b][4]).

The EPA also establishes maximum contaminant levels which specify the levels to which water contamination must be reduced.<sup>27</sup> These primary standards are set as close to the maximum contaminant level goals as is feasible (*SDWA* §1412g–1[b][4], 42 *USC* §300g–1[b][4]).<sup>28</sup> If the maximum contaminant levels are not economically or technologically feasible, the EPA must specify any known treatment techniques which will sufficiently reduce the levels of the contaminants.

26. See *Code of Federal Regulations*. Title 40, parts 141–142.

27. The act defines *maximum contaminant level* to mean “the maximum permissible level of a contaminant in water which is delivered to any user of a public water system.” *Safe Drinking Water Act*. Sec. 1401(3). *U.S. Code*. Vol. 42, sec. 300f(3).

28. *Feasible* is defined under the act to mean “feasible with the use of the best technology, treatment techniques and other means which [the EPA] finds, after examination for efficacy under field conditions and not solely under laboratory conditions, are available (taking cost into consideration).” *Safe Drinking Water Act*. Sec. 1412g–1(b)(5). *U.S. Code*. Vol. 42, sec. 300g–1(b)(5).

## SECONDARY STANDARDS

The EPA also establishes secondary standards on drinking water issues related to public welfare.<sup>29</sup> For example, secondary standards specify maximum contaminant levels for constituents affecting the odor, color, cloudiness, acidity, and taste of water in public water systems. States are not required to enforce secondary standards.

## Underground Injections

The SDWA regulates underground injections<sup>30</sup> through a permitting scheme which is implemented and administered by individual states. The EPA promulgates regulations for state programs, but the states must adopt their own underground injection control programs (*SDWA* §§1421–1422, 42 *USC* §§300h–h–1). These programs control and authorize underground injections through the issuance of state permits. To be granted a permit, an applicant must demonstrate that the injection will not endanger drinking water sources. Under the act, an underground injection endangers drinking water sources:

if such injection may result in the presence in underground water which supplies or can reasonably be expected to supply any public water system of any contaminant, and if the presence of such contaminant may result in such system's not complying with any national primary drinking water regulation or may otherwise adversely affect the health of persons (*SDWA* §1421[d][2], 42 *USC* §300h[d][2]).

## SUMMARY

The EPA promulgates national primary drinking water regulations for public water systems. These regulations include maximum contamination level goals and maximum contamination levels for each contaminant which may have an adverse effect on human health and may exist in a public water system (*SDWA* §1412).

The EPA delegates the states with primary enforcement responsibility for public water systems provided the state can satisfactorily meet the minimum federal requirements (*SDWA* §1413).

The EPA has ultimate authority to enforce the national primary drinking water regulations where it determines that a state has not commenced appropriate enforcement actions. Moreover, owners and operators of public water systems must notify consumers of violations of the act including the failure to meet applicable maximum contaminant levels, treatment technique requirements, or testing procedures under national primary drinking water regulations (*SDWA* §1414).

29. See *Code of Federal Regulations*. Title 40, part 143.

30. *Underground injection* is defined in the act as “the subsurface emplacement of fluids by well injection [and does not include] the underground injection of natural gas for purposes of storage.” *Safe Drinking Water Act*. Sec. 1421(d)(1). *U.S. Code*. Vol. 42, sec. 300h(d)(1).

A state with primary enforcement responsibility can grant variances and exemptions from national primary drinking water regulations to public water systems within its jurisdiction. For instance, a maximum contaminant level requirement or treatment technique requirement in the regulations can be exempted provided the applicable conditions are satisfied (*SDWA* §§1415–1416).

The act prohibits the use of lead pipes, solder, or flux in the installation or repair of any public water system or in the plumbing of a facility connected to a public water system which provides water for human consumption (*SDWA* §1417).

The state underground injection programs contain minimum requirements to assure that underground injections do not endanger drinking water sources. An approved state program gives the state primary enforcement responsibility for underground water sources. State programs regulate underground injections through permit system (*SDWA* §§1421–1422).

The EPA can exercise its emergency powers and take any action necessary to protect human health when it receives information that a contaminant is present or is likely to enter a public water system or an underground source of drinking water (*SDWA* §1431).

The EPA promulgates regulations requiring public water systems to implement monitoring programs for unregulated contaminants. The regulations include a list of unregulated contaminants which require monitoring. The results of the monitoring go to the primary enforcement authority (*SDWA* §1445).

The act specifically provides for judicial review and includes a citizens suit provision (*SDWA* §§1448–1449).

The act contains other provisions to regulate the safety of drinking water, including a recall of all drinking water coolers with lead-lined tanks, and federal assistance programs for states to remedy lead contamination in school drinking water (*SDWA* §1461–1466).

## Federal Water Pollution Control Act

The Federal Water Pollution Control Act (33 *USC* §§1251–1387; 40 *CFR* Parts 100–140, 40 *CFR* Parts 400–470).

TITLE V.	GENERAL PROVISIONS
§1364	Emergency powers
§1365	Citizen suits
TITLE VI.	STATE WATER POLLUTION CONTROL INVOLVING FUNDS

## PURPOSE

In 1972, Congress enacted the Federal Water Pollution Control Act, commonly known as the Clean Water Act (CWA) (1990, 33 *USC* §§1251–1387). The primary purpose of the act is “to restore and maintain the chemical, physical, and biological integrity of the nation’s waters (CWA §101[a], 33 *USC* §1251[a]). Additionally, the act set forth numerous goals and policies related to protecting the nation’s waters including (CWA §101[a][1], 33 *USC* §1251[a][1]):

- To eliminate discharge into navigable waters
- To protect fish, shellfish, and wildlife
- To provide for recreation in and on the U.S. waters
- To prohibit the discharge of toxic pollutants in toxic amounts
- To develop and implement programs to control nonpoint sources of pollution

Specifically, the 1972 act targeted the elimination of pollutant discharges into navigable waters by 1985. This original deadline was not achieved. The act’s subsequent amendments, however, extended the deadlines and attempted to adopt more realistic goals and solutions to the water pollution problem.

## SPECIFIC PROVISIONS

The CWA has specific provisions for the National Pollutant Discharge Elimination System, categorizing pollutants, technology-based controls and effluent limitations, water quality standards, variances, nonpoint source controls, and dredge and fill permits. These provisions are discussed next.

### National Pollutant Discharge Elimination System

The CWA controls water pollution primarily through its National Pollutant Discharge Elimination System (NPDES). Section 301 of the act states that “the discharge of any pollutant by any person shall be unlawful” except as provided by other sections within the act (33 *USC* §1311). Section 402 of the act establishes the main ex-

ception (33 *USC* §1342), which provides for issuing NPDES permits to control direct discharges of pollutants into U.S. waters. Direct dischargers include both industrial sources and publicly owned treatment works (POTWs). NPDES permits are issued through either the EPA or a delegated state (CWA §402[b], 33 *USC* §1342[b]). The EPA can delegate NPDES authority to a state if the state adopts a permit program which meets minimum federal criteria.

Permits must be obtained by any point source which discharges pollutants into waters of the United States. This regulation generally includes the two types of direct dischargers mentioned previously. A *point source* is defined in the CWA (40 *CFR* §122.2 [1990]) regulations as “any discernible, confined, and discrete conveyance, including but not limited to, any pipe, ditch, channel, tunnel, conduit, well, discrete fissure, container, rolling stock, concentrated animal feeding operation, landfill leachate collection system, vessel or other floating craft from which pollutants are or may be discharged.” *Pollutants* and *waters of the United States* are also specifically defined in the regulations.

An applicant must obtain a permit from either the EPA or an authorized state agency. Point sources are regulated based on numerous factors including the type of pollutants discharged and the character of the receiving water. The permitting authority establishes effluent limits which are written into the permit. Before a permit is issued, both public notice and an opportunity to be heard are required. Permits typically have a five-year duration period and can be renewed.

The CWA generally uses technology-based effluent standards and water quality standards (also known as ambient water standards) to control water pollution. Technology-based effluent standards apply to all direct dischargers and require treatment of pollutants prior to discharge. The goal of technology-based effluent standards is to minimize actual pollutants going into the nation’s waters by installing pollution control technology.

Water quality standards, on the other hand, are based on the receiving water’s ability to absorb a given pollutant. They are not to be confused with ambient water quality-related effluent limits<sup>31</sup> but are site-specific standards which vary according to the characteristics and designated uses of the regulated water segment.

### Categorizing Pollutants

The CWA divides pollutants into three categories and uses this framework to create effluent limits for dischargers. The three categories of pollutants are conventional, toxic, and nonconventional. Conventional pollutants include fecal coliform, biochemical oxygen demand, suspended solids, and pH. Toxic pollutants are listed in the CFR (40 *CFR* §401.15). They include chemicals which in small

31. See *Clean Water Act*, Sec. 302; *U.S. Code*. Vol. 33, sec. 1312.

amounts cause adverse effects on fish, wildlife, and humans. Finally, nonconventional pollutants include all non-toxic pollutants which are not categorized as conventional pollutants.

### Technology-based Controls and Effluent Limitations

The regulating agency establishes technology-based effluent limits which can be incorporated into a facility's permit. These effluent limits are based on the SIC classification of the facility, the type of pollutant the facility discharges, and whether the facility is considered a new or an existing source.

The EPA publishes national effluent guidelines for categories and subcategories of industry types in the CFR. These guidelines establish technology-based effluent limits for standard pollutants discharged from the particular category or subcategory of an industry. The EPA has not yet created effluent guidelines for all categories and subcategories of industries.

At a minimum, existing sources must satisfy the best practicable control technology currently available (BPT) standard. BPT establishes a national floor for effluent treatment (*CWA §304[b][1][A-B]*, *33 USC §1314[b][1][A-B]*). Also existing sources must meet treatment standards according to the three categories of pollutants as follows:

Conventional pollutants are subject to the standard BCT standard (*CWA §304[b][4][B]*, *33 USC §1314[b][4][B]*).

Toxic pollutants are subject to the more stringent best available technology economically feasible (BAT) standard, together with additional health-based standards (*CWA §307*, *33 USC §1317*).

Nonconventional pollutants are also subject to the BAT standard (*CWA §301[b][2][F]*, *33 USC §1311[b][2][F]*).

New sources are regulated pursuant to a different set of technology-based controls. The *CWA* (*§306[a][2]*, *33 USC §1316[a][2]*) defines a new source as one whose construction began after new source performance standards (NSPS) were proposed for it, provided those standards were adopted. The act declares that NSPS be established "through the best available demonstrated control technology, processes, operating methods, or other alternatives, including, where practicable, a standard permitting no discharge of pollutants" (*CWA §306[a][1]*, *33 USC §1316[a][1]*). The EPA is required to compile a list of categories of new sources for which it must propose and publish NSPSs (*CWA §306[b][1][A]*, *33 USC §1316[b][1][A]*). The EPA must also publish toxic effluent standards (*CWA §307[a][2]*, *33 USC §1317[a][2]*) and water quality-related effluent limits (*CWA §302*, *33 USC §1312*).

The EPA has not established a national effluent guideline for every industry which requires a permit. In these cases, the EPA or authorized state permit writers establish

a technology-based limit according to their best professional judgment (BPJ). This limit is known as a BPJ permit limit.

### Water Quality Standards

Water quality standards are an additional control to protect waterbodies. Generally, water quality standards focus on the receiving water's ability to integrate, dilute, or absorb pollutants. A facility may have to install controls beyond those required to achieve technology-based standards to meet water quality standards.

States must adopt water quality standards and submit them to the EPA for all bodies of water within the state (*CWA §303[a]*, *33 USC §1313[a]*). The standards are based upon state designated uses for specific bodies of water together with water quality criteria for the designated use. The EPA reviews the state standards and replaces them if they fail to meet minimum federal requirements (*CWA §§303[c][3-4]*, *33 USC §§1313[c][3-4]*). States are further required to specify and prioritize the waters within their boundaries where technology-based standards are insufficient to meet the established water quality standards (*CWA §303[d][1][A]*, *33 USC §1313[d][1][A]*).

States must set a total maximum daily load (TMDL) for specific waterbodies. The TMDL is the maximum amount of a pollutant that a defined water segment can accept while still achieving the applicable water quality standard. In accordance with section 303(d) of the *CWA* (*§303[d][1][C]*, *33 USC §1313[d][1][C]*), a TMDL "shall be established at a level necessary to implement the applicable water quality standards with seasonal variations and a margin of safety which takes into account any lack of knowledge concerning the relationship between effluent limitations and water quality." States must submit a list of the prioritized waters and their applicable TMDLs to the EPA for approval (*CWA §303[d][2]*, *33 USC §1313[d][2]*). Nevertheless, states do have discretion in allocating the TMDLs among dischargers and establishing corresponding effluent limits on the facilities.

### Variations

In some cases, point sources can obtain variations which provide alternatives to the national effluent controls in section 304. Among the variations in the act are the fundamentally different factors (FDF) variance (*CWA §301[n]*, *33 USC §1311[n]*; *40 CFR* pt. 125 subpt. D), the §301(c) economic variance (*CWA §301[c]*, *33 USC §1311[c]*), the §301(g) water quality variance (*CWA §301[g]*, *33 USC §1311[g]*), and the net/gross limitation (*40 CFR §122.45[g]*). The most notable of these variations is the FDF which may apply when a discharger's characteristics are fundamentally different from the sources which the EPA considered to determine the applicable technology-based standard.

## Nonpoint Source Controls

Nonpoint sources are a significant contributor to water pollution. Nonpoint sources are diffuse sources of pollution created generally by land use. Nonpoint source pollution is caused, for example, by the rainfall and runoff from urban areas, mining, and agricultural sites.

Under the 1972 amendments to the act, the section 208 planning process delegates control of nonpoint source pollution to the states. This section called on state governors to designate areas with substantial water quality control problems and to select a regional planning agency to help develop section 208 plans to address nonpoint issues. This approach is not considered successful in controlling this type of pollution.

The 1987 amendments to the act, however, developed section 319 to address the nonpoint source pollution problem which was ineffectual in section 208 (*CWA* §319, 33 *USC* §1329). States are required to designate water bodies that are unable to meet water quality standards without a nonpoint source program. States must then establish nonpoint source plans for these waterbodies. The plans require best management practices regulations for different categories of sources along the waters, such as construction sites or manure storage sites. Plans must include implementation schedules and other regulatory measures and are subject to EPA approval.

## Dredge and Fill Permits

Section 404 of the act requires permits for discharging dredge and fill materials into waters of the United States. The Army Corps of Engineers, generally, administers the program. However, the EPA has the authority to review section 404 permits and can veto certain permit conditions or an entire permit (*CWA* §334, 33 *USC* §1344[c]). This section is broadly applied based upon the liberal interpretation of key terms such as *waters of the United States* and *dredge and fill materials*.

Tributaries of navigable waters and wetlands are protected under section 404. Regulated activities extend well beyond dredge and fill operations. For instance, section 404 controls activities such as bridge and dam building, flood control construction activities, and dike and drainage systems.

The Army Corps of Engineers can consider several factors when making its decision to issue a section 404 permit. The corps can consider individually or cumulatively the following twelve issues:

... conservation, economics, aesthetics, general environmental concerns, wetlands, historic properties, fish and wildlife values, flood hazards, floodplain values, land use, navigation, shore erosion and accretion, recreation, water supply and conservation, water quality, energy needs, safety, food and fiber production, mineral needs, considerations of property ownership and, in general, the needs and welfare of the people (33 *CFR* §320.4).

Section 404 also includes a review of the requirements developed under other federal environmental acts. A 404 permit application is subject to review under the NEPA, Fish and Wildlife Coordination Act,<sup>32</sup> CZMA, Wild and Scenic Rivers Act,<sup>33</sup> and the ESA.

## SUMMARY

The CWA declares several national goals and policies to restore and maintain the nation's waters (*CWA* §101).

The CWA makes the discharge of any pollutant by any person unlawful unless the discharge is in compliance with specified provisions in the act (*CWA* §301).

States are required to adopt water quality standards for identified waters within their boundaries (*CWA* §303).

The EPA must develop information and guidelines for the implementation and administration of programs under the act. (*CWA* §304).

The EPA is required to establish federal NSPSs for categories of new sources (*CWA* §306).

The CWA establishes procedures for inspection, monitoring, and entry. Owners and operators of point sources are required to maintain records and install and use monitoring equipment or methods. The EPA or its authorized representative can enter and inspect point sources and their records (*CWA* §308).

The CWA's federal enforcement provision authorizes compliance schedules and orders, administrative orders and penalties, as well as criminal and civil penalties (*CWA* §309).

States must adopt nonpoint source management programs to improve water quality within the state (*CWA* §319).

The NPDES establishes a permit program to control the discharge of pollutants from point sources. The program is implemented by the EPA or a delegated state (*CWA* §402).

The Army Corps of Engineers is authorized to issue permits for the discharge of dredged and fill material into waters of the United States. This provision has a significant impact on wetland protection (*CWA* §404).

The EPA can bring suit on behalf of the United States pursuant to its emergency powers. Such powers are used to protect the health and welfare of persons against imminent and substantial endangerment from a pollution source (*CWA* §504).

The CWA has a citizen's suit provision allowing any citizen to commence a civil action against any person who

32. This law, at a minimum, requires consultation with the U.S. Fish and Wildlife Service to assure protection of habitat and species under their protection.

33. This act and the ESA are administered by the Department of Interior (except in the case of rivers in national forests which are subject to the Department of Agriculture).

violates the act. This provision includes suits against the EPA for failure to perform a nondiscretionary duty (CWA §505).

## Toxic Substances Control Act

The Toxic Substances Control Act (15 *USC* §2601 *et seq.*; 40 *CFR* §§700–799).

SUBCHAPTER IV.	LEAD EXPOSURE REDUCTION

### PURPOSE

The Toxic Substances Control Act (TSCA) (1992, 15 *USC* §§2601–2654) was enacted in 1976 as the first major federal law governing toxic substances. The purpose of the TSCA is to understand the health risks of certain chemical substances by developing production and health risk data from the manufacturers of the chemicals and chemical products.

In developing the TSCA, Congress had the following three policy objectives:

1. To require industry to develop data on the effect of chemical substances and mixtures on health and the environment
2. To assure that adequate authority exists to regulate chemical substances
3. To assure that this authority not “impede unduly or create unnecessary economic barriers to technological innovation” in the manufacture of chemicals (*TSCA* §2[b], 15 *USC* §2601[b])

Thus, the TSCA is described as a risk/benefit-balancing statute.

### SPECIFIC PROVISIONS

The TSCA requires manufacturers to notify the EPA at least ninety days prior to manufacturing a new chemical substance or placing it in the market for a new use. The notice must contain health and safety data and an assessment of the impact of that chemical on human health and

the environment. The TSCA applies to chemical manufacturers and processors. A processor is any person who prepares a chemical substance or mixture after its manufacture for distribution into commerce (*TSCA* §§3[10–11], 15 *USC* §§2602[10–11]).

### Testing

The TSCA (§4, 15 *USC* §2603) authorizes the EPA to require testing of chemical substances. The EPA has published testing guidelines pursuant to this authority. Moreover, the EPA can compel manufacturers to test chemical substances for which insufficient data exist to determine their effects on human health and the environment (40 *CFR* pts. 796, 797, 798). To determine if such chemicals present unreasonable risks, this requirement applies to both new chemical substances, as well as those on the market. The EPA can require toxicity tests on a substance “when there is [a] more-than-theoretical basis for suspecting that some amount of exposure occurs and that the substance is sufficiently toxic at that exposure level to present ‘unreasonable risk of injury to health’ ” (*Chemical Manufacturers Assn. v. EPA*, 859 F.2d 977, 984 (D.C. Cir. 1988)).

The act creates the Interagency Testing Committee (ITC) to recommend chemicals for testing (*TSCA* §4[e][2], 15 *USC* §2603[e][2]). The ITC consists of members from eight separate federal agencies who recommend testing. The ITC gives priority to those chemical substances likely to cause or contribute “to cancer, gene mutations, or birth defects.”

Upon listing a chemical substance, the EPA has one year to either initiate a rulemaking proceeding requiring testing or publish in the *FR* the reason why a proceeding was not initiated. The EPA initiates action if testing data or other information provide a basis to conclude that a chemical substance presents a significant risk of human cancer, genetic mutation, or birth defects. Where such significant risk exists, the EPA must act within 180 days of receipt of the information. This period can be extended up to ninety days for good cause.

### Premanufacture Notice Requirements

Chemical manufacturers must provide the EPA with premanufacture notice before any new chemical is manufactured, processed, or put on the market (*TSCA* §5, 15 *USC* §2604). The manufacturer must also provide notice if an existing chemical substance is being used in a new manner. The EPA has regulations to assess the safety of potentially marketable chemicals (40 *CFR* pts. 720–723).

The manufacturer gives the premanufacture notice at least ninety days prior to the intended manufacturing or processing. This notice includes test data showing that the chemical does not present an unreasonable risk. The EPA

can prohibit or limit the manufacturing or processing of the chemical if it receives insufficient information from the manufacturer to make a proper evaluation.

## Reporting

The EPA requires manufacturers, processors, distributors, and importers of chemical substances to report information on chemicals so that the EPA can effectively administer and enforce the TSCA (§8[a], 15 *USC* §2607[a]). The EPA promulgated the Preliminary Assessment Information Rule (40 *CFR* pt. 712, subpt. B) and the Comprehensive Assessment Information Rule (40 *CFR* pt. 704) pursuant to this authority. These rules designate chemical substances which, together with the ITC list, must be reported by manufacturers and processors. Both rules provide forms and instructions for reporting and request information on the qualities of chemicals and worker exposure.

Manufacturers and processors must also maintain records of any allegations of harmful effects caused by chemicals (*TSCA* §8[c], 15 *USC* §2607[c]; 40 *CFR* pt. 717). The EPA can inspect these records upon request. Sources of allegations include lawsuits, workers compensation claims, and employee or customer complaints. A company must retain records of adverse reactions of employees for thirty years from the time an incident is reported. All other records of adverse reactions must be retained for a five-year period.

The EPA can also request and obtain health and safety studies on chemical substances from persons dealing in chemicals (*TSCA* §8[d], 15 *USC* §2607[d]). The EPA defines *health and safety studies* as “any study of any effect of a chemical substance or mixture on health or the environment” (40 *CFR* §716.3). The studies encompass those conducted or initiated by the person, known to the person, or reasonably ascertainable to the person.

Finally, the EPA requires persons dealing in chemicals to report any information which suggests a chemical substance may substantially risk injury to human health or the environment (*TSCA* §8[e], 15 *USC* §2607[e]). The EPA does not have the authority to publish regulations for this requirement, but it has published several guidance documents (43 *FR* [16 March 1978]; *TSCA* §8[e]).

## Authority to Regulate Hazardous Chemical Substances

The EPA has broad authority to regulate the manufacture, processing, distribution, use, or disposal of chemical substances (*TSCA* §6, 15 *USC* §2605). The EPA can limit or prohibit the manufacture or distribution of a chemical substance or may simply require public warnings. This regulatory authority is based on a finding that a reasonable basis exists that such activities “present or will present an unreasonable risk of injury to health or the environment.” The EPA must also consider the benefits of the chemical

substance, any economic effects of the regulatory action, and the health risks created by the chemical’s manufacture. When the EPA regulates a chemical substance, it must apply the least burdensome means of providing adequate protection.

## TSCA’S LIMITED REGULATORY PRACTICE

The EPA has promulgated regulations directed at polychlorinated biphenyls (PCBs), chlorofluorocarbons (CFCs), asbestos, and 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) waste. The controls on the use of PCBs are a good example of this regulation.

PCBs were developed for use in industrial equipment such as electrical transformers and capacitors. PCBs are regulated under section 6 of the TSCA (§6[e], 15 *USC* §2605[e]) and under the rule promulgated pursuant to section 6.<sup>34</sup> Section 6 bans the manufacturing, processing, or distribution of PCBs with a few exceptions. The rule also requires a tracking and manifest system with notification and recordkeeping requirements similar to the RCRA. Moreover, the EPA has a PCB Penalty Policy (August 1990) which subjects violators to penalties of up to \$25,000 per day.

## SUMMARY

The EPA requires testing of chemical substances to insure that they do not present an unreasonable risk of injury to health or the environment (*TSCA* §4).

Manufacturers must provide the EPA with notice if they intend to manufacture a new chemical substance or use an existing chemical substance in a new way (*TSCA* §5).

The EPA has broad regulatory powers over the manufacture, processing, use, or disposal of chemical substances if those substances are found to potentially present an unreasonable risk of injury to health or the environment (*TSCA* §6).

The EPA can commence a civil action to seize a chemical substance or for other relief to protect against an imminently hazardous chemical substance (*TSCA* §7).

The EPA may require recordkeeping and the submission of reports for inspection from manufacturers of chemical substances (*TSCA* §8).

## Federal Insecticide, Fungicide, and Rodenticide Act

The Federal Insecticide, Fungicide, and Rodenticide Act (7 *USC* §§136–136y; 40 *CFR* Parts 162–180).

34. In addition to regulating the disposal of PCB wastes, the TSCA regulates the manufacture and use of products which use PCBs. *Code of Federal Regulations*. Title 40, sec. 761.20.

## STATUTORY ROADMAP

§136	Definitions
§136a	Registration of pesticides
§136c	Experimental use permits
§136d	Administrative review, suspension
§136e	Registration of establishments
§136f	Books and records
§136g	Inspection of establishments, etc.
§136h	Protection of trade secrets and other information
§136i	Use of restricted use pesticides, applicators
§136j	Unlawful acts
§136k	Stop sale, use, removal, and seizure
§136l	Penalties
§136m	Indemnities
§136n	Administrative procedure, judicial review
§136o	Imports and exports
§136p	Exemption of federal and state agencies
§136q	Storage, disposal, transportation, and recall
§136r	Research and monitoring
§136s	Solicitation of comments, notice of public hearings
§136t	Delegation and cooperation
§136u	State cooperation, aid, and training
§136v	Authority of states
§136w	Authority of administrator

## PURPOSE

The Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) is the primary statutory tool regulating pesticides.<sup>35</sup> The FIFRA does not have a specific section designating its purpose. However, it implicitly seeks to prevent adverse effects on human health and the environment by controlling the sale, distribution, and use of pesticides within the United States (7 *USC* §136a[c][5]).

The FIFRA is a risk/benefit statute which calls for an analysis of the risks created by a pesticide compared to the benefits of the product if it enters the market. The 1972 FIFRA amendments (*Federal Environmental Pesticide Control Act [FEPCA]*, 1972) establish the current structure of the act which concentrates on the regulation of pesticides through their registration, classification, and labeling.

## SPECIFIC PROVISIONS

The FIFRA requires all pesticides to be registered with the EPA. Pesticides are then classified according to general or

restricted use (7 *USC* §136a). The EPA registers a pesticide if it determines that the pesticide does not create unreasonable adverse effects on human health and the environment. The registration process requires applicants to provide information on the product's chemistry, residue chemistry, toxicology, field reentry protection, aerial drift evaluation, effect on nontarget organisms, and product performance (40 *CFR* §158.20[c]).

## Defining Pesticides

Since the FIFRA regulates pesticide sale, distribution, and use, the scope of the act largely depends on the definition of the term *pesticide*. The FIFRA (§2[u], 7 *USC* §136[u]) defines a pesticide as “any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest, and any substance or mixture of substances intended for use as a plant regulator, defoliant, or desiccant. . . .”

The FIFRA contains other definitions including explanations of the terms within the definition of pesticide. For instance, an understanding of the term *pest* is needed to apply the definition of pesticide. A pest is defined as “any insect, rodent, nematode, fungus, weed, or any other form of terrestrial aquatic plant or animal life or virus, bacteria, or other micro-organism (except [those] on or in living man or other living animals) which [the EPA] declares to be a pest . . .” (*FIFRA* §2[t], 7 *USC* §136[t]). The EPA has promulgated regulations which clarify what is and is not a pesticide for the purposes of this statute.<sup>36</sup>

## Registering Pesticides

Section 3 of the FIFRA (7 *USC* §136a) requires persons to register pesticides with the EPA before they are sold or distributed within the United States. FIFRA's registration process allows the EPA to evaluate the risks of the pesticide being proposed. This evaluation is accomplished by examining application information.

Applicants must file a statement which includes:

The name and address of the applicant and the name of any other person who appears on the label of the pesticide

The name of the pesticide

A complete copy of the pesticide's label, instructions for its use, and a statement of all claims made of the pesticide

The complete formula of the pesticide

A request that the pesticide be classified for general use, restricted use, or both (*FIFRA* §3[c][1], 7 *USC* §136a[c][1])

35. The *FIFRA* was enacted in 1972 and is codified in the *U.S. Code*, Vol. 7, sec. 136 *et seq.* It was amended in 1975, 1978, 1980, 1983, 1984, 1988 (major amendments, U.S. Public Law 100-532, 102 Stat. 2654) and 1990. The *FIFRA* regulations are found in the *Code of Federal Regulations*, Title 40, secs. 162-180.

36. See *Code of Federal Regulations*, Title 40, part 162.

Additionally, the EPA can request the applicant to include a full description of tests, test results, and other data associated with the pesticide. The EPA has guidelines stating the types of information which an applicant must submit to register a pesticide (*FIFRA* §3[c][2], 7 *USC* §136a[c][2]).<sup>37</sup>

The EPA generally registers a pesticide provided that:

The pesticide is what it is claimed to be in the application  
The applicant complies with labeling and other *FIFRA* application requirements

The pesticide performs its function without unreasonable adverse effects to the environment

The pesticide, when used “in accordance with widespread and commonly recognized practice,” does not cause unreasonable adverse effects to the environment (*FIFRA* §3[c][5], 7 *USC* 136a[c][5]).

The EPA must weigh the economic, social, and environmental costs and benefits to determine whether a pesticide causes unreasonable adverse effects to the environment (*FIFRA* §2[bb], 7 *USC* §136[bb]). The applicant has the burden of providing all information needed by the EPA to determine if the pesticide meets the registration standard.

The *FIFRA* (§3[c][7], 7 *USC* §136a[c][7]) also provides for conditionally registered pesticides under limited conditions. The EPA allows conditional registration if the proposed pesticide is substantially similar to an existing registered pesticide and no unreasonable risks on the environment exist. The conditional registration requires the applicant to submit additional data on the pesticide.

Finally, the act provides for experimental use permits which can be issued by the EPA or an authorized state (*FIFRA* §5, 7 *USC* §136c; 40 *CFR* pt. 172). These permits allow the applicant to sell, distribute, and use the pesticide under restricted conditions until the pesticide is properly registered.

### Classification of Pesticides

As part of the registration procedure, the EPA classifies a pesticide for general use, restricted use, or both (*FIFRA* §3[d], 7 *USC* 136a[d]). A pesticide is classified for general use if it does not cause unreasonable adverse effects on the environment when applied according to its instructions and applicable warnings.

A pesticide is classified for restricted use if its application likely causes unreasonable adverse effects on the environment without additional regulatory restrictions. If the EPA classifies a pesticide for restricted use based on a finding that “the acute dermal or inhalation toxicity of the pesticide presents a hazard to the applicant or to other persons,” the pesticide can be applied only by or under the supervision of a certified applicator. The *FIFRA* (§11, 7 *USC* §136i) has procedures and requirements to become

37. The guidelines are published in the *Code of Federal Regulations*, Title 40, part 158.

a certified applicator which are implemented by the EPA or through a federally approved state certification program.

### Suspension and Cancellation of Registration

The EPA is required to cancel a registered pesticide five years after its registration unless the registrant requests to have the pesticide reregistered (*FIFRA* §6[a], 7 *USC* §136d[a]). Additionally, the EPA can issue an immediate suspension order to a registrant to prevent an imminent hazard (*FIFRA* §6[c], 7 *USC* §136d[c]).

### Reregistration of Pesticides

Many pesticides were registered under the *FIFRA* prior to the 1972 amendments. However, those pesticides were not subject to any risk/benefit analysis prior to registration. Moreover, many registered pesticides also had insufficient warnings and labels. Section 4 of the *FIFRA* (7 *USC* §136a-l) requires that these pesticides and any pesticide issued before November 1, 1984, reregister with the EPA. The implementation of this process has been slow.

In 1978, Congress sought to facilitate the reregistration process by giving the EPA authority to obtain data from holders of existing registered pesticides (*FIFRA* §3[c][2][B], 7 *USC* §136a[c][2][B]). Registrants then have ninety days to provide evidence that they are taking steps to obtain the data. The EPA can issue a notice of intent to suspend the registration if the registrant fails to comply. This notice can lead to a full suspension of the pesticide which could last indefinitely or until the registrant complies with the request for data.

Congress amended the *FIFRA* in 1988 to improve the reregistration process. Congress adopted a new section 4 to the *FIFRA* which created the following five phases for reregistration:

- Phase 1. Listing and prioritizing active ingredients of pesticides for reregistration
- Phase 2. Submission of notices of intent to reregister, and identification of and commitments to replace missing or inadequate data
- Phase 3. Submission of studies on the active ingredients of the pesticides
- Phase 4. Independent initial review by the EPA of submissions under phases 2 and 3, identification of outstanding data requirements, and request for additional data if necessary
- Phase 5. Review of data submitted, and appropriate regulatory action implemented (*FIFRA* §4, 7 *USC* §136a-l)

Additionally, Congress adopted a fee program to cover the expected costs of the new reregistration process (*FIFRA* §4[i], 7 *USC* §136a-l[i]).

## SUMMARY

Pesticides must be registered with the EPA before being manufactured, distributed, or used in the United States (*FIFRA* §3).

Pesticides issued prior to November 1, 1984, must be reregistered (*FIFRA* §4).

The EPA can cancel or suspend a registered pesticide based upon failure to seek reregistration after five years, an imminent hazard, or a showing of unreasonable adverse effects on the environment (*FIFRA* §6).

The FIFRA makes it unlawful to sell or distribute any pesticide which is unregistered or is otherwise improperly accounted for according to the act (*FIFRA* §12).

The FIFRA provides for civil and criminal penalties for violating the act (*FIFRA* §14).

The FIFRA provides for judicial review of nondiscretionary actions by the EPA under the act (*FIFRA* §16).

## Pollution Prevention Act

The Pollution Prevention Act of 1990 (42 *USC* 13101 *et seq.*).

### STATUTORY ROADMAP

§13101	Policy
§13102	Definitions
§13103	EPA's role
§13104	Grants
§13105	Source reduction clearinghouse
§13106	Source reduction and recycling data collection
§13107	EPA report
§13108	Savings provisions
§13109	Authorization of appropriations

### PURPOSE

The Pollution Prevention Act (PPA) of 1990 (§§6601–6610, 42 *USC* §§13101–13113 [Supp. II 1990]) is an holistic approach to environmental protection which seeks to reduce or eliminate pollutants before they are generated. This prevention is done by altering products, procedures, or raw materials in the manufacturing process. The EPA defines pollution prevention as “the use of materials, processes or practices that reduce or eliminate the creation of pollutants or wastes at the source. [It] includes practices that reduce the use of hazardous materials, energy, water or other resources, and practices that protect natural resources through conservation and more efficient use” (U.S. EPA. 1990).

### SPECIFIC PROVISIONS

The PPA (§6602[b], 42 *USC* §1310[b]) establishes a hierarchy of pollution control methods. The fundamental idea

behind the hierarchy is to prevent pollution before it occurs. Pollution which cannot be avoided should be reduced. In turn, that which cannot be reduced should be recycled, then treated. Only after all those methods have been applied should pollution be released into the environment through disposal. This hierarchy is stated as the central policy of the act as follows:

pollution should be prevented or reduced at the source whenever feasible; pollution that cannot be prevented should be recycled in an environmentally safe manner whenever feasible; pollution that cannot be prevented or recycled should be treated in an environmentally safe manner whenever feasible; and disposal or other release into the environment should be employed only as a last resort and should be conducted in an environmentally safe manner (*PPA* §6602[b], 42 *USC* §13101[b]).

The hierarchy reflects a preference to eliminate pollution before it occurs, thereby preventing it from crossing into various media, or even jurisdictions, where its more difficult to trace, recapture, and regulate.

### Reporting

The PPA (§6607, 42 *USC* §13106) requires certain facilities to complete a toxic chemical source reduction and recycling report.<sup>38</sup> Under the PPA, each owner or operator of a facility which must file an annual toxic chemical release form under section 313 of the SARA of 1986 must also include a source reduction and recycling report for the prior calendar year. The report includes the following sections:

1. The quantity of each chemical entering the wastewater, or otherwise released into the environment, prior to recycling, treatment, or disposal, and the percentage change from the previous year
2. The amount of the chemical from the facility which is recycled during the calendar year, the recycling process used, and the percentage change from the previous year.
3. The source reduction practices used with respect to that chemical, reported in accordance with the following categories:
  - a. Equipment, technology, process, or procedure modifications
  - b. Reformulation or redesign of products

38. The EPA has also called for pollution prevention plans in storm water permits under the CWA. See U.S. EPA. *Proposed rule, national pollutant discharge elimination system general permits and reporting requirements for storm water discharges associated with industrial activity. Federal Register* 56, (1991):4094 (proposed 16 August 1991). The EPA has requested comments on the use of incentives under the RCRA to reduce or eliminate the generation of hazardous waste. See U.S. EPA. *Waste minimization incentives: Notice and request for comment on desirable and feasible incentive to reduce or eliminate the generation of hazardous waste. Federal Register* 55, (1990):40881.

- c. Substitution of raw materials
- d. Improvement in management, training, inventory control, materials handling, or other general operational phases of industrial facilities
4. The amount expected to be reported under sections 1 and 2 for the two calendar years immediately following the calendar year for which the report is being filed
5. A ratio of production in the reporting year to that in the previous year
6. Techniques used to identify source reduction opportunities including employee recommendations, external and internal audits, and material balance audits
7. The amount of toxic chemical released into the environment resulting from a catastrophic event, remedial action, or other one-time event and which is not associated with production processes during the reporting year
8. The amount of chemical from the facility which is treated during the calendar year and the percentage change from the previous year

The EPA has several other approaches to encourage pollution prevention, including an information clearinghouse, technical and financial assistance to industry and local government, and waste audits. In addition, the PPA calls for the EPA to “coordinate source reduction activities in each agency office and coordinate with appropriate offices to promote source reduction practices in other federal agencies . . . (PPA §6604[b][3], 42 USC §13103[b][3]).

The practical implications of the PPA appear in the opportunity for facilities to meet emission or discharge limits under other programs, e.g., the CAA and CWA, by reducing at the source rather than removing at the end of the pipe. The informational aspect of the PPA also requires facilities to reassess where they might be wasting raw materials and where they can reuse materials which otherwise would be discharged into various media.

## SUMMARY

- The PPA creates a hierarchy of pollution control methods (§6602).
- The PPA establishes reporting requirements for the use of toxic substances (§6607).

—David Bookchin  
David Farnsworth

## Introduction

The National Environmental Policy Act (NEPA) of 1969 (PL91-190) has been referred to as the Magna Carta for the environment in the United States (Council on Environmental Quality 1993). The thrust of this act, as well as that of subsequent Council on Environmental Quality (CEQ) guidelines and regulations, is to ensure that balanced decision making occurs in the total public interest. Project planning and decision making should consider technical, economic, environmental, social, and other factors. Environmental impact assessment (EIA) can be defined as the systematic identification and evaluation of the potential impacts (effects) of proposed projects, plans, programs, or legislative actions, relative to the physical-chemical, biological, cultural, and socioeconomic components of the environment. The primary purpose of the EIA process, also called the NEPA process, is to encourage the

consideration of the environment in planning and decision making and to ultimately arrive at actions which are more environmentally compatible.

This chapter focuses on NEPA and the EIA process. Following an initial section related to background conceptual and administrative considerations, the chapter's emphasis is on practical methods and approaches used for impact identification, prediction, and assessment (interpretation), and on comparative evaluations of alternatives. Writing considerations and follow-on environmental monitoring are also addressed. The final sections relate to emerging issues and international activities.

## 2.1 BACKGROUND CONCEPTUAL AND ADMINISTRATIVE INFORMATION

---

---

Section 102 of the NEPA has three primary parts related to the EIA process. Part A specifies that all federal government agencies will use a systematic, interdisciplinary approach, which ensures the integrated use of the natural and social sciences and environmental design arts in planning and decision making that may impact the human environment. Part B requires agencies to identify and develop methods and procedures to ensure that presently unquantified environmental amenities and values are considered in decision making along with economic and technical considerations. This part has provided impetus for the development of environmental assessment methods. Part C states the necessity for preparing environmental statements (called environmental impact statements or EISs) and identifies basic items to be included.

To aid the implementation of the EIS requirement, the NEPA also created the Council on Environmental Quality (CEQ) within the Executive Office of the President of the United States. This council has the role of providing overall coordination to the EIA process in the United States. CEQ issued guidelines in 1971 and 1973 for federal agencies to follow in conjunction with EISs. In 1978, the CEQ issued regulations which became effective in mid-1979 for responding to the requirements of the NEPA (Council on Environmental Quality 1978).

## Key Definitions

A key feature of the CEQ regulations is the concept of three levels of analysis; Level 1 relates to a categorical exclusion determination, Level 2 to the preparation of an environmental assessment (EA) and finding of no significant impact, and Level 3 to the preparation of an EIS (U.S. Environmental Protection Agency 1989). [Figure 2.1.1](#) depicts the interrelationships between these three levels. Key definitions from the CEQ regulations related to [Figure 2.1.1](#) include federal action, categorical exclusion, EA, finding of no significant impact, significant impact, and EIS.

Federal actions include the adoption of official policy (rules, regulations, legislation, and treaties) which result in or alter agency programs; adoption of formal plans; adoption of programs; and approval of specific projects, such as construction or management activities located in a defined geographic area, and actions approved by permit or other regulatory decision as well as federal and federally assisted activities. The EIA process is typically applied to proposed projects. Key information needed in applying the EIA process to a proposed project includes items such as:

1. A description of the type of project and how it functions or operates in a technical context

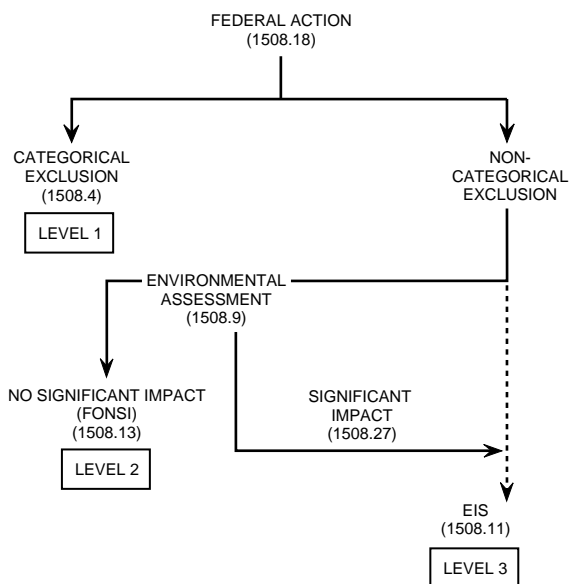

FIG. 2.1.1 Three levels of analysis in the EIA process. Number in parentheses denotes paragraph in CEQ regulations which contains definition (Council on Environmental Quality 1987).

2. The proposed location for the project and why it was chosen
3. The time period required for project construction
4. The potential environmental requirements or outputs (stresses) from the project during its operational phase, including land requirements, air pollution emissions, water use and water pollutant emissions, and waste generation and disposal needs
5. The identified current need for the proposed project in the location where it is proposed (this need could be related to housing, flood control, industrial development, economic development, and many other requirements); project need must be addressed as part of the environmental documentation
6. Any alternatives which have been considered, with generic alternatives for projects including site location, project size, project design features and pollution control measures, and project timing relative to construction and operational issues; project need in relation to the proposed project size should be clearly delineated; the range of alternatives may be limited due to the individual preferences of project sponsors, primary focus on traditional engineering solutions, and time pressures for decision making (Bacow 1980)

A categorical exclusion refers to a category of actions which do not individually or cumulatively have a significant effect on the human environment and have no such effect in procedures adopted by a federal agency in implementation of the CEQ regulations. Neither an EA nor an EIS is required for categorical exclusions.

An EA is a concise public document that serves to provide sufficient evidence and analysis for determining

whether to prepare an EIS or a finding of no significant impact (FONSI), aid an agency's compliance with the NEPA when no EIS is necessary, or facilitate preparation of an EIS when one is necessary. A FONSI is a document written by a federal agency briefly presenting the reasons why an action, not otherwise excluded, will not have a significant effect on the human environment and for which an EIS will not be prepared. A mitigated FONSI refers to a proposed action that has incorporated mitigation measures to reduce any significant negative effects to insignificant ones.

The key definition in the EIA process is *significantly* or *significant impact* since a proposed action which significantly affects the human environment requires an EIS. *Significantly* as used in the NEPA requires considerations of both context and intensity. Context means that significance must be analyzed relative to society as a whole (human, national), the affected region, the affected interests, the locality, and whether the effects are short- or long-term. Intensity refers to the severity of impact. The following should be considered in evaluating intensity:

1. Impacts that may be both beneficial and adverse (A significant effect may exist even if the federal agency believes that on balance the effect will be beneficial)
2. The degree to which the proposed action affects public health or safety
3. Unique characteristics of the geographic area, such as proximity to historic or cultural resources, park lands, prime farmlands, wetlands, wild and scenic rivers, or ecologically critical areas
4. The degree to which the effects on the quality of the human environment are likely to be controversial
5. The degree to which the possible effects on the human environment are uncertain or involve unique or unknown risks
6. The degree to which the action may establish a precedent for future actions with significant effects or represents a decision in principle about a future consideration
7. Whether the action is related to other actions with individually insignificant but cumulatively significant impacts (Significance exists if a cumulatively significant impact on the environment is anticipated. Significance cannot be avoided by terming an action temporary or by breaking it down into component parts)
8. The degree to which the action may adversely affect districts, sites, highways, structures, or objects listed in or eligible for listing in the *National Register of Historic Places* or may cause loss or destruction of significant scientific, cultural, or historical resources
9. The degree to which the action may adversely affect an endangered or threatened species or its habitat that has been determined to be critical under the Endangered Species Act of 1973

10. Whether the action threatens a violation of federal, state, or local law or requirements imposed for the protection of the environment

An EIS is a detailed written statement that serves as an action-forcing device to ensure that the policies and goals defined in the NEPA are infused into the ongoing programs and actions of the federal government. It provides a full and fair discussion of significant environmental impacts and informs decision makers and the public of the reasonable alternatives which would avoid or minimize adverse impacts or enhance the quality of the human environment. An EIS is more than a disclosure document; it is used by federal officials in conjunction with other relevant material to plan actions and make decisions.

The definition of *significantly* from the CEQ regulations considers both context and intensity. Context is primarily related to the “when and where” of the impacts. The preceding ten points for intensity can be divided into two groups as follows: those related to environmental laws, regulations, policies, and executive orders (points 2, 3, 8, 9, and 10 in the list); and those related to other considerations and how they in turn may implicate environmental laws, regulations, policies, and executive orders (points 1, 4, 5, 6, and 7 in the list).

Three types of EISs are pertinent (draft, final, or supplemental to either draft or final). In addition to the earlier generic definition of an EIS, the following information from the CEQ guidelines or regulations is germane (Council on Environmental Quality 1987, 1973):

1. Draft EIS: The draft EIS is the document prepared by the lead agency proposing an action; it is circulated for review and comment to other federal agencies, state and local agencies, and public and private interest groups. Specific requirements with regard to timing of review are identified in the CEQ regulations. In the draft statement the agency will make every effort to disclose and discuss all major points of view on the environmental impacts of the alternatives, including the proposed action.
2. Final EIS: The final EIS is the draft EIS modified to include a discussion of problems and objections raised by reviewers. The final statement must be on file with EPA for at least a thirty-day period prior to initiation of construction on the project. The format for an EIS is delineated in Sections 1502.10 through 1502.18 of the CEQ regulations.
3. Supplemental EIS: Lead agencies will prepare supplements to either draft or final EISs if the agency makes substantial changes in the proposed action that are relevant to environmental concerns; or significant new circumstances or information relevant to environmental concerns and bearing on the proposed action or its impacts exists. Lead agencies may also prepare supplements when the agency determines that the purposes of the Act will be furthered by doing so.

The procedural aspects of filing draft, final, or supplemental EISs with the Office of Federal Activities of Environmental Protection Agency (EPA) are addressed in [Figure 2.1.2](#) (U.S. Environmental Protection Agency 1989).

Public participation can be achieved in the EIA process in three ways:

1. Via an early scoping process to determine the scope of issues to be addressed and to identify the significant issues related to a proposed action
2. Via a public participation program during the EIA study
3. Via the review process for draft EISs

Figure 2.1.2 shows the public participation in environmental impact assessment.

Scoping refers to a process and not to an event or meeting. Some suggestions for planning and implementing the scoping process include:

1. Start scoping after sufficient information is available on the proposed action.
2. Prepare an information packet.
3. Design a unique scoping process for each project, plan, program, and policy.
4. Issue a public notice.
5. Carefully plan and conduct all public meetings.
6. Develop a plan for using received comments.
7. Allocate EIS work assignments and establish a completion schedule (Council on Environmental Quality 1981).

Strategic environmental assessment (SEA) refers to the EIA process applied to policies, plans, or programs (Lee and Walsh 1992). A programmatic EIS is analogous to an SEA. Programmatic EISs (PEISs) can be used in the United States to address the environmental implications of the policies and programs of federal agencies. PEISs can be used to address the impacts of actions that are similar in nature or broad in scope, including cumulative impacts (Sigal and Webb 1989). Site-specific or local-action EAs and EISs can be tiered from the PEIS.

While the NEPA includes the concept of applying the EIA process to policies, plans, and programs, the majority of EISs prepared in the first twenty-five years have been on projects. However, the NEPA should be used in the formulation of policies and the planning of programs (Bear 1993). EAs and EISs can be prepared for policies (including rules, regulations, and new legislation), plans, and programs. Plans and programs can include operational considerations for extant single or multiple projects and repair, evaluation, maintenance, and rehabilitation of extant projects. Decommissioning of existing facilities also requires the application of the EIA process.

## Impact Significance Determination

Impacts resulting from proposed actions can be considered in one or more of the following categories:

- Beneficial or detrimental
- Naturally reversible or irreversible

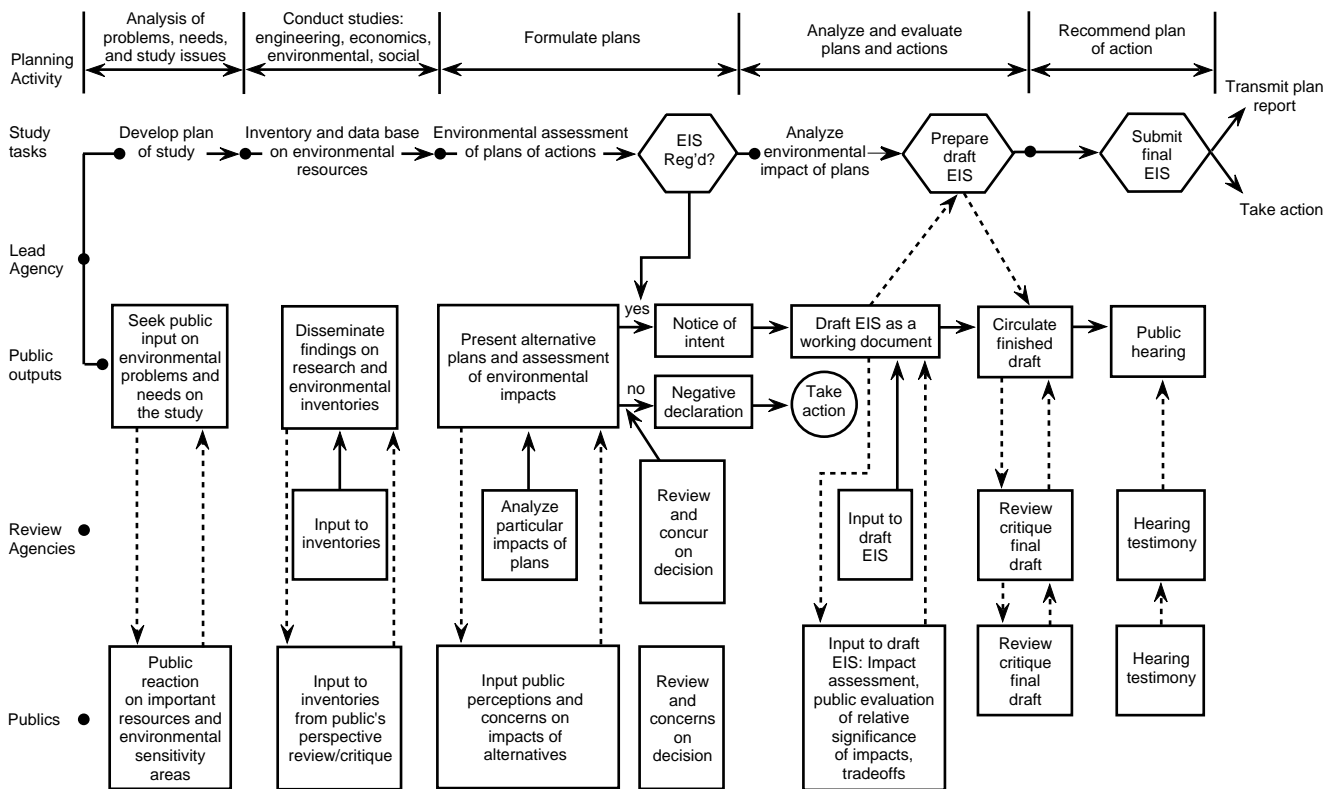

FIG. 2.1.2 Public participation in environmental impact assessment.

- Reparable via management practices or irreparable
- Short term or long term
- Temporary or continuous
- Construction or operational phase
- Local, regional, national, or global
- Accidental or planned (recognized beforehand)
- Direct or primary, or indirect or secondary
- Cumulative or single

Two key terms from the categories are direct or indirect, and cumulative; their definitions are as follows (Council on Environmental Quality 1987):

Effects (or impacts): These terms can be considered as synonymous. Two broad categories of effects are direct and indirect. Direct effects are caused by the action and occur at the same time and place. Indirect effects are caused by the action and occur later or farther removed in distance, but are still reasonably foreseeable. Indirect effects may include growth-inducing effects and other effects related to induced changes in the pattern of land use, population density or growth rate, and related effects on air and water and other natural systems, including ecosystems. Effects include ecological (such as the effects on natural resources and on the components, structures, and functioning of affected ecosystems), aesthetic, historic, cultural, economic, social, or health, whether direct, indirect, or cumulative. Effects also include those resulting from actions which may have both

beneficial and detrimental effects, even if on balance the agency believes that the effect will be beneficial.

Cumulative impact: The impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (federal or nonfederal) or person undertakes such other actions. Cumulative impacts can result from individually minor, but collectively significant, actions taking place over a period of time.

Based on these categories of impacts, several simple to more structured options can be used to determine impact significance. At a minimum, the definition of *significantly* in the CEQ regulations could be applied as described in the previous section.

A sequenced approach for impact significance determination is appropriate. A sequenced approach considers several levels in determining the potential significance of impacts from a proposed federal action. A sequenced approach is achieved by applying the following questions in the order shown (the answers to any question can be used to determine if an EIS should be prepared):

1. Does the proposed project, plan, program, or policy cause impacts that exceed the definition of significant impacts as contained in pertinent laws, regulations, or executive orders?
2. Is a quantitative threshold criterion exceeded in terms of project, plan, or program type, size, or cost?

3. Is the project, plan, or program located in a protected habitat or land-use zone, or within an exclusionary zone relative to land usage? Is the environmental resource to be affected a significant resource?
4. Is the proposed project, plan, program, or policy in compliance with environmental laws, regulations, policies, and executive orders?
5. What is the anticipated percentage change in environmental factors from the proposed project, plan, or program, and will the changes be within the normal variability of the factors? What is the sensitivity of the environment to the anticipated changes; or is the environment susceptible or resilient to changes? Will the carrying capacity of the resource be exceeded?
6. Are there sensitive human, living, or inanimate receptors to the environmental stresses from the proposed project, plan, program, or policy?
7. Can the anticipated negative impacts be mitigated in a cost-effective manner?
8. What is the professional judgment of experts in the substantive areas, such as water quality, ecology, planning, landscape architecture, and archaeology?
9. Are there public concerns due to the impact risks of the proposed project, plan, program, or policy?
10. Are there cumulative impacts which should be considered, or impacts related to future phases of the proposed action and associated cumulative impacts?

Detailed specific questions related to these ten groups of questions can be developed.

One thing that can be done in conjunction with identified significant negative impacts is to consider appropriate mitigation measures to reduce negative impacts within reasonable environmental and economic constraints. Relative to practice in the United States, mitigation includes (Council on Environmental Quality 1987):

1. Avoiding the impact altogether by not taking a certain action or parts of an action
2. Minimizing impacts by limiting the degree or magnitude of the action and its implementation
3. Rectifying the impact by repairing, rehabilitating, or restoring the affected environment
4. Reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action
5. Compensating for the impact by replacing or providing substitute resources or environments

These measures should be used in sequence or ease of application, beginning with avoiding the impact.

Negative impacts fall into three categories: insignificant, significant but mitigable, or significant but not mitigable. When potentially significant negative impacts are identified, and if they can be reduced via mitigation to something of lesser concern, a mitigated FONSI can be prepared following an EA and without doing a comprehensive

study leading to an EIS. However, a mitigated FONSI is possible only if the mitigation requirements are delineated to ensure that the identified measures are implemented.

## Trends in Process Application

During the decade of the 1970s, various federal agencies produced approximately 1,200 final EISs on an annual basis. During the 1980s and early 1990s, the number decreased and currently is in the range of 400 to 500 EISs annually. While it appears that EIA emphasis in the United States has decreased based upon the reduced number of EISs, the number of EAs prepared has significantly increased. Unfortunately, no statistics are available on the number of EAs; however, one EPA official recently estimated that 30,000 to 50,000 EAs are prepared annually (Smith 1989). Approximately 45,000 EAs were prepared in 1992 (Council on Environmental Quality 1993). Concepts such as scoping and mitigation are now included in initial project planning and decision making, thus reducing the need for subsequent preparation of EISs.

The concepts of the EIA process have become fundamental to numerous federal and state-level environmental programs, permits, and reports. The documentation is analogous to a "targeted" EA or EIS. Examples of relevant permits and reports include:

1. Air quality permits and related reporting required by the Clean Air Act Amendments of 1990
2. Point source wastewater discharge permits and related reporting required by the National Pollutant Discharge Elimination System (NPDES) program of the Federal Water Pollution Control Act Amendments (also known as Clean Water Act) and its subsequent amendments
3. Industrial area storm water discharge permits and related reporting required by the NPDES program of the Clean Water Act of 1987
4. Permits for dredging and filling activities in navigable waters as required by Section 404 of the Clean Water Act of 1972
5. Remedial investigations, feasibility studies, and records of decision on uncontrolled hazardous waste sites identified under the auspices of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA or Superfund) of 1981 and the Superfund Amendments and Reauthorization Act (SARA) of 1986 (Sharples and Smith 1989)
6. Replacements, permits, and reports on underground storage tanks regulated by the Resource Conservation and Recovery Act Amendments of 1984
7. Operating permits and closure plans for sanitary landfills or hazardous waste landfills required by the Resource Conservation and Recovery Act Amendments (also called the Hazardous and Solid Waste Act) of 1984 (Sharples and Smith 1989)

8. Reports prepared on site (property transfer) assessments to establish owner, buyer, and lender liability for contamination
9. Reports prepared on regulatory audits
10. Environmental reporting requirements related to new chemical and new product licensing

## 2.2

### EIA METHODS: THE BROAD PERSPECTIVE

---

---

Several activities are required to conduct an environmental impact study, including impact identification, preparation of a description of the affected environment, impact prediction and assessment, and selection of the proposed action from a set of alternatives being evaluated to meet identified needs. The objectives of the various activities differ, as do the methods for accomplishing the activities (Lee 1988). The term *method* refers to structured scientific or policy-based approaches for achieving one or more of the basic activities. Table 2.2.1 contains a delineation of eighteen types of methods arrayed against seven activities that are typically associated with an EIA study. An *x* in the table denotes that the listed method type is or may be directly useful for accomplishing an activity. However, the absence of an *x* for any given type of method does not mean that it has no usefulness for the activity; it merely suggests that it may be indirectly related to the activity.

Based on the information in Table 2.2.1, the following observations can be made:

1. Each type of method has potential usefulness in more than one EIA study activity.
2. Each EIA activity has three or more method types which are potentially useful.
3. In a given EIA study, several types of methods will probably be used even though the study may not completely document all of the methods used. Several reviews of actual method adoption in the EIA process have suggested lack of widespread usage; however, this usage probably reflects a focus on a few of the types of methods (such as matrices or checklists), and not the more inclusive list of methods contained in Table 2.2.1.
4. Each of the types of methods have advantages and limitations; examples of these for checklists, decision-focused checklists, matrices, and networks are described in subsequent sections.
5. While numerous types of methods have been developed, and additional methods are being developed and tested, no universal method can be applied to all project types in all environmental settings. An all-purpose method is unlikely to be developed due to lack of technical information as well as the need for exercising subjective judgment about predicted impacts in the environmental setting where the potential project may occur. Accordingly, the most appropriate perspective is to consider methods as tools which can be used to aid the impact assessment process. In that sense, every method should be project- and location-specific, with the basic concepts derived from existing methods. These methods can be called ad hoc methods.
6. Methods do not provide complete answers to all questions related to the impacts of a potential project or set of alternatives. Methods are not “cookbooks” in which a successful study is achieved by meeting the requirements of them. Methods must be selected based on appropriate evaluation and professional judgment, and

**TABLE 2.2.1 SYNOPSIS OF EIA METHODS AND STUDY ACTIVITIES**

<i>Types of Methods in EIA</i>	<i>Define Issues (Scoping)</i>	<i>Impact Identification</i>	<i>Describe Affected Environment</i>	<i>Impact Prediction</i>	<i>Impact Assessment</i>	<i>Decision Making</i>	<i>Communication of Results</i>
Analogs (look-alikes) (case studies)	X	X		X	X		
Checklists (simple, descriptive, questionnaire)		X	X				X
Decision-focused checklists (MCDM; MAUM; DA; scaling, rating, or ranking; weighting)					X	X	X

Photographs and photomontages			X	X			X
Qualitative modeling (conceptual)			X	X			
Quantitative modeling (media, ecosystem, visual, archaeological, systems analysis)			X	X			
Risk assessment	X	X	X	X	X		
Scenarios				X		X	
Trend extrapolation			X	X			

X: Potential for direct usage of method for listed activity

MCDM = multicriteria decision making; MAUM = multiattribute utility measurement; DA = decision analysis; GIS = geographical information system.

they must be used with the continuous application of judgment relative to data input as well as analysis and interpretation of results.

7. Methods which are simpler in terms of data and personnel resources requirements, and in technical complexity, are probably more useful in the EIA process.

Examples of selected types of methods are presented in subsequent sections, including: matrices and simple checklists for impact identification and describing the affected environment; impact prediction based on a range of meth-

ods, including analogs and qualitative and quantitative modeling; and decision making based on decision-focused checklists.

## 2.3 INTERACTION MATRIX AND SIMPLE CHECKLIST METHODS

Interaction matrices were one of the earliest methods used. The simple matrix refers to a display of project actions or activities along one axis, with appropriate environmental factors listed along the other axis of the matrix. Many variations of the simple interaction matrix have been used in environmental impact studies, including stepped matrices (Economic and Social Commission for Asia and the Pacific 1990, Lohani and Halim 1990, and International Institute for Applied Systems Analysis 1979).

The matrix method developed by Leopold et al. 1971, is an example. The method involves the use of a matrix with one hundred specified actions and eighty-eight environmental items. Figure 2.3.1 illustrates the concept of the Leopold matrix; in its usage, each action and its potential for creating an impact on each environmental item is considered. Where an impact is anticipated, the matrix is marked with a diagonal line in the interaction box. The second step in using the Leopold matrix is to describe the interaction in terms of its magnitude and importance.

The magnitude of an interaction is the extensiveness or scale and is described by assigning a numerical value from one to ten, with ten representing a large magnitude and one a small magnitude. Values near five on the magnitude scale represent impacts of intermediate extensiveness. Assigning a numerical value for the magnitude of an interaction is based on an objective evaluation of facts.

FIG. 2.3.1 Leopold Interaction Matrix (Leopold et al. 1971). M = magnitude; I = importance.

The importance of an interaction is related to the significance, or assessment of the consequences, of the anticipated interaction. The scale of importance also ranges from one to ten, with ten representing an interaction of high importance and one an interaction of low importance. Assignment of an importance numerical value is based on the subjective judgment of the interdisciplinary team working on the environmental assessment study.

A simpler approach than the Leopold matrix can be used in an environmental impact study. Using the matrix entails considering the potential impacts, either beneficial or detrimental, of each project action relative to each environmental factor. Each interaction is delineated in terms of a predefined code denoting the characteristics of the impacts and whether certain undesirable features could be mitigated. Table 2.3.1 displays the concept of this type of an interaction matrix for a proposed wastewater collection, treatment, and disposal project in Barbados (Canter 1991). For this analysis, the following definitions are used for the codes:

- SB = Significant beneficial impact (represents a highly desirable outcome in terms of either improving the existing quality of the environmental factor or enhancing that factor from an environmental perspective)
- SA = Significant adverse impact (represents a highly undesirable outcome in terms of either degrading the existing quality of the environmental factor or disrupting that factor from an environmental perspective)
- B = Beneficial impact (represents a positive outcome in terms of either improving the existing quality of the environmental factor or enhancing that factor from an environmental perspective)
- A = Adverse impact (represents a negative outcome in terms of either degrading the existing quality of the environmental factor or disrupting that factor from an environmental perspective)
- b = Small beneficial impact (represents a minor improvement in the existing quality of the environmental factor or a minor enhancement in that factor from an environmental perspective)
- a = Small adverse impact (represents a minor degradation in the existing quality of the environmental factor or a minor disruption in that factor from an environmental perspective)

**TABLE 2.3.1 INTERACTION MATRIX FOR SOUTH COAST SEWERAGE PROJECT (CANTER 1991)**

<i>Environmental Factor/Resource</i>	<i>Existing Quality</i>	<i>Construction Phase</i>				<i>Operation Phase</i>			
		<i>Collection System</i>	<i>Treatment Plant</i>	<i>Outfall Line</i>	<i>Resultant Quality</i>	<i>Collection System</i>	<i>Treatment Plant</i>	<i>Outfall Line</i>	<i>Resultant Quality</i>
Air quality	In compliance with air quality standards	A/M	A/M	a	Dusts, CO	a (odor at lift station sites)	A/M	O	localized odor
Noise	Typical of urban residential areas	A/M	A/M	a	increase in local noise	a (pumps)	a	a (pumps)	small increase in noise
Ground water	Satisfactory for area	O	O	O	same as existing	b	b	b	better quality due to less sheet water discharge
Graeme Hall	"Natural" biological resource	NA	a/M (no encroachment)	NA	some disturbance, recovery expected	NA	O	NA	same as existing
Beach erosion/coral reef/coastal water quality	Erosion of 0.1 to 0.3 m/yr, deteriorating coral reef and coastal water quality	NA	NA	a (water quality)	turbidity increase	b	SB	NA	improve quality
Coastal fisheries	Some decline due to deteriorating coral reef and coastal water quality	NA	NA	a	local turbidity	b	SB	NA	improve quality
Marine environment at outfall diffuser	Good	NA	NA	a	some local disturbance	NA	NA	a	small decrease in quality
Traffic	Current problem	SA/M	a	a	increase in congestion	a	a	a	continued problem due to tourism increase
Tourism	Important to economy	a	NA	a	traffic congestion might cause decrease	B	B	B	increase in economy

A = adverse impact; M = mitigation measure planned for adverse impact; a = small adverse impact; O = no anticipated impact; NA = environmental factor not applicable; SA = significant adverse impact; b = small beneficial impact; B = beneficial impact; SB = significant beneficial impact

- O = No measurable impact is expected to occur as a result of considering the project action relative to the environmental factor
- M = Some type of mitigation measure can be used to reduce or avoid a small adverse, adverse, or significant adverse impact
- NA = The environmental factor is not applicable or relevant for the proposed project

## Development of a Simple Matrix

Developing a specific matrix for the project, plan, program, or policy being analyzed is better than using a generic matrix. The following steps can be used in preparing a simple interaction matrix:

1. List all anticipated project actions and group via temporal phases
  - a. Construction
  - b. Operation
  - c. Postoperation
2. List pertinent environmental factors from environmental setting and group according to physical-chemical, biological, cultural, and socioeconomic categories; and spatial considerations such as site and region or upstream, site, and downstream
3. Discuss preliminary matrix with study team members and advisors to team or study manager
4. Decide on impact rating scheme (such as numbers, letters, or colors) to be used
5. Talk through the matrix as a team and make ratings and notes to identify impacts and summarize impacts (documentation)

## Summary Observations on Simple Matrices

The following observations are based upon numerous examples of matrices and over twenty years of experience in using such matrices:

1. In using a simple interaction matrix, one must carefully define the spatial boundaries associated with environmental factors, as well as each environmental factor; the temporal phases and specific actions associated with the proposed project; and the impact rating or summarization scales used in the matrix.
2. The most important concept in using an interaction matrix is to consider the matrix as a tool for purposes of analysis, with the key need being to clearly state the rationale used for the impact ratings assigned to a given temporal phase (or project action) and a given spatial boundary (or environmental factor).
3. The development of one or more interaction matrices can be a useful technique in discussing a proposed action and its potential environmental impacts. This development can be helpful in the early stages of a study

to assist each team member in understanding the implications of the project and developing detailed plans for more extensive studies on particular factors.

4. The interpretation of information on resultant impact rating scales should be carefully considered, particularly when large differences in spatial boundaries, as well as temporal phases, for a proposed project may exist.
5. Interaction matrices are useful for delineating the impacts of the first and second or multiple phases of a two-phase or multiphase project; the cumulative impacts of a project when considered relative to other past, present, and reasonably foreseeable future actions in the area; and the potential positive effects of mitigation measures. Creative codes can be used in the matrix to delineate this information.
6. If interaction matrices are used to display comparisons between different alternatives, the same basic matrix must be used in terms of spatial boundaries and temporal phases for each alternative being analyzed. Completion of such matrices for each alternative can provide a basis for tradeoff analysis.
7. Impact quantification can provide a valuable basis for the assignment of impact ratings for different project actions and different environmental factors.
8. Color codes can be used to display or communicate information on anticipated impacts. Beneficial impacts could be displayed with green or shades of green; whereas, detrimental or adverse effects could be displayed with red or shades of red. Impact matrices can be used without incorporating number rating scales. For example, circles of varying size can be used to denote range of impacts.
9. One concern related to interaction matrices is that project actions or environmental factors are artificially separated when they should be considered together. Footnotes can be used in a matrix to identify groups of impacts which should be considered together. Footnote use allows the delineation of primary and secondary effects of projects.
10. The development of a preliminary interaction matrix does not mean that it must be included in a subsequent EIA report. The preliminary matrix can be used as an internal working document or tool in study planning and development.
11. Importance weighting for environmental factors and project actions can be used in a simple interaction matrix. If this approach is chosen, the rationale upon which differential importance weights are assigned must be carefully delineated.
12. One important advantage of a simple interaction matrix is that its use forces consideration of actions and impacts related to a proposed project within the context of other related actions and impacts. In other words, the matrix aids in preventing overriding attention being given to one action or environmental factor.

**TABLE 2.3.2 USDA CHECKLIST FOR ADDRESSING AND SUMMARIZING ENVIRONMENTAL IMPACTS (U.S. DEPARTMENT OF AGRICULTURE 1990)**

<i>Topical Issue</i>	<i>Yes</i>	<i>Maybe</i>	<i>No</i>	<i>Comments</i>
<b>Land Form</b>				
Will the project result in:				
Unstable slopes or embankments?				
Extensive disruption to or displacement of the soil?				
Impact to land classified as prime or unique farmland?				
Changes in ground contours, shorelines, stream channels, or river banks?				
Destruction, covering, or modification of unique physical features?				
Increased wind or water erosion of soils?				
Foreclosure on future uses of site on a long-term basis?				
<b>Air/Climatology</b>				
Will the project result in:				
Air pollutant emissions which will exceed federal or state standards or cause deterioration of ambient air quality (e.g., radon gas)?				
Objectionable odors?				
Alteration of air movements, humidity, or temperature?				
Emissions of hazardous air pollutants regulated under the Clean Air Act?				
<b>Water</b>				
Will the project result in:				
Discharge to a public water system?				
Changes in currents or water movements in marine or fresh water?				
Changes in absorption rates, drainage patterns, or the rate and amount of surface water runoff?				
Alterations to the course or flow of flood waters?				
Impoundment, control, or modifications of any body of water equal to or greater than ten acres in surface area?				
Discharges into surface waters or alteration of surface water quality including, but not limited to, temperature or turbidity?				
Alteration of the direction or rate of flow of groundwaters?				
Alterations in groundwater quality?				
Contamination of public water supplies?				
Violation of State Stream Quality Standards, if applicable?				
Location in a riverine or coastal floodplain?				
Exposure of people or property to water-related hazards such as flooding?				
Location in a state's coastal zone and subject to consistency with the State Coastal Zone Management Plan?				
Impact on or construction in a wetland or inland floodplain?				
<b>Solid Waste</b>				
Will the project:				
Generate significant solid waste or litter?				
<b>Noise</b>				
Will the project:				
Increase existing noise levels?				
Expose people to excessive noise?				
<b>Plant Life</b>				
Will the project:				
Change the diversity or productivity of species or number of any species of plants (including trees, shrubs, grass, crops, microflora, and aquatic plants)?				

*Continued on next page*

**TABLE 2.3.2** *Continued*

<i>Topical Issue</i>	<i>Yes</i>	<i>Maybe</i>	<i>No</i>	<i>Comments</i>
Reduce the numbers or affect the habitat of any state or federally designated unique, rare, or endangered species of plants? (Check state and federal lists of endangered species.)				
Introduce new species of plant into the area or create a barrier to the normal replenishment of existing species?				
Reduce acreage or create damage to any agricultural crop?				
<b>Animal Life</b>				
Will the project:				
Reduce the habitat or numbers of any state or federally designated unique, rare, or endangered species of animals? (Check state and federal lists and the Migratory Bird Treaty Act.)				
Introduce new species of animals into an area or create a barrier to the migration or movement of animals or fish?				
Cause attraction, entrapment, or impingement of animal life?				
Harm existing fish and wildlife habitats?				
Cause emigration resulting in human-wildlife interaction problems?				
<b>Land Use</b>				
Will the project:				
Substantially alter the present or planned use of an area?				
Impact a component of the National Park system, the National Wildlife Refuge system, the National Wild and Scenic River system, the National Wilderness system, or National Forest land?				
<b>Natural Resources</b>				
Will the project:				
Increase the use rate of any natural resource?				
Substantially deplete any nonreusable natural resource?				
Be located in an area designated as or being considered for wilderness, wild and scenic river, national park, or ecological preserve?				
<b>Energy</b>				
Will the project?				
Use substantial amounts of fuel or energy?				
Substantially increase the demand on existing sources of energy?				
<b>Transportation and Traffic Circulation</b>				
Will the project result in:				
Movement of additional vehicles?				
Effects on existing parking facilities or demands for new parking?				
Substantial impact on existing transportation system(s)?				
Alterations to present patterns of circulation or movement of people or goods?				
Increased traffic hazards to motor vehicles, bicyclists, or pedestrians?				
Construction of new roads?				
<b>Public Service</b>				
Will the project have an effect on, or result in, a need for new or altered governmental services in any of the following areas:				
Fire protection?				
Schools?				
Other governmental services?				

*Continued on next page*

**TABLE 2.3.2** *Continued*

<i>Topical Issue</i>	<i>Yes</i>	<i>Maybe</i>	<i>No</i>	<i>Comments</i>
<b>Utilities</b>				
Will the project result in a need for new systems or alterations to the following utilities:				
Power and natural gas?				
Communications systems?				
Water?				
Sewer or septic tanks?				
Storm sewers?				
<b>Population</b>				
Will the project:				
Alter the location or distribution of human population in the area?				
<b>Accident Risk</b>				
Does the project:				
Involve the risk of explosion or release of potentially hazardous substances including oil, pesticides, chemicals, radiation, or other toxic substances in the event of an accident or "upset" condition?				
<b>Human Health</b>				
Will the project:				
Create any health hazard or potential health hazard?				
Expose people to potential health hazards?				
<b>Economic</b>				
Will the project:				
Have any adverse effect on local or regional economic conditions, e.g., tourism, local income levels, land values, or employment?				
<b>Community Reaction</b>				
Is the project:				
Potentially controversial?				
In conflict with locally adopted environmental plans and goals?				
<b>Aesthetics</b>				
Will the project:				
Change any scenic vista or view open to the public?				
Create an aesthetically offensive site open to the public view (e.g., out of place with character or design of surrounding area)?				
Significantly change the visual scale or character of the vicinity?				
<b>Archaeological, Cultural, and Historical</b>				
Will the project:				
Alter archaeological, cultural, or historical sites, structures, objects, or buildings, either in or eligible for inclusion in the National Register (e.g., be subject to the Historic Preservation Act of 1974)?				
<b>Hazardous Waste</b>				
Will the project:				
Involve the generation, transport, storage or disposal of any regulated hazardous waste (e.g., asbestos, if demolition or building alterations is involved)?				

## Simple Checklists

Checklist methods range from listings of environmental factors to highly structured approaches. Structured approaches involve importance weightings for factors and the application of scaling techniques for the impact of each alternative on each factor. Simple checklists represent lists of environmental factors (or impacts) which should be addressed; however, no information is provided on specific data needs, methods for measurement, or impact prediction and assessment. Simple checklists were extensively used in the initial years of EIA studies, and they still represent a valid approach for providing systemization to an environmental impact study.

Table 2.3.2 shows a simple questionnaire checklist developed by the Cooperative Research Service of the U.S. Department of Agriculture (1990) for use related to projects that might impact agricultural lands. This extensive checklist can be used in both planning and summarizing an environmental impact study. It can also be used to identify environmental factors to be addressed in preparing a description of the affected (baseline) environment. Another example of a simple checklist is that developed by the Asian Development Bank (1987) for use on major dam, reservoir, and hydropower projects. This checklist also includes mitigation information. Other checklists have been developed: some focus on categories of impacts, such as health impacts (U.S. Agency for International Development 1980, World Bank 1982, and World Health Organization Regional Office for Europe 1983).

Simple checklists of environmental factors and impacts to consider are helpful in planning and conducting an environmental impact study, particularly if one or more checklists for the project type are used. The following summary comments are pertinent for simple checklists:

1. Because published checklists represent the collective professional knowledge and judgment of their developers, they have a certain level of professional credibility and useability.

2. Checklists provide a structured approach for identifying key impacts and pertinent environmental factors to consider in environmental impact studies.
3. Checklists stimulate and facilitate interdisciplinary team discussions during the planning, conduction, and summarization of environmental impact studies.
4. Checklists can be modified (items added or deleted) to make them more pertinent for particular project types in given locations.

## 2.4

# TECHNIQUES FOR IMPACT PREDICTION

---

---

A key technical element in the EIA process is the prediction of impacts (effects) for both the without-project and with-project conditions. Numerous technical approaches can be used. As an example, the principles and guidelines of the Water Resources Council (1983) delineate several approaches which can be used in the EIA process for water resources projects. These approaches include:

1. Adoption of forecasts made by other agencies or groups
2. Use of scenarios based on differing assumptions regarding resources and plans
3. Use of expert group judgment via the conduction of formalized Delphi studies or the use of the nominal group process
4. Extrapolation approaches based upon the use of trend analysis and simple models of environmental components
5. Analogy and comparative analyses which involve the use of look-alike resources and projects and the application of information from such look-alike conditions to the planning effort.

A criticism of many early EISs is that the impact predictions were not based on formalized and repeatable methods with predefined relationships, such as mathematical equations, physical models, and other structured approaches. Accordingly, many environmental impact studies have been criticized based on their lack of scientific approach and technical validity. This criticism is diminishing as more knowledge is gained based on the use of quantitatively based prediction techniques in environmental impact studies and the development of additional techniques through routine scientific research projects.

### Classification of Prediction Techniques

A study prepared for the Ministry of Environment in the Netherlands involved the examination of 140 case studies of EIAs and related studies (Environmental Resources Limited 1982). The objectives were to identify predictive techniques used in the practice of EIAs, prepare descriptions of the techniques, and classify the techniques in terms of the effect predicted and the method used. A total of 280 predictive techniques were identified and broadly classified for use in determining effects on the atmospheric environment, effects on the surface aquatic environment, effects on the subsurface environment (groundwater and soils), effects on the acoustic environment, direct effects on

plants and animals, direct effects on landscape, and accidental effects. Table 2.4.1 contains a summary of the different types of methods used in predictive techniques for each of the seven main effect groups (Environmental Resources Limited 1982). The identified methods can be divided into experimental methods, mathematical models, and survey techniques. Table 2.4.2 displays a systematic grouping of prediction techniques (Environmental Resources Limited 1982).

Experimental methods used for prediction include physical models, field experiments, and laboratory experiments. Physical models include scaled-down representations, in two or three dimensions, of the study area after an activity has been implemented. Field experiments refer to in situ tracer experiments where tracers are used to predict the behavior of releases to surface waters (usually marine) or to groundwater. Laboratory experiments refer to bioassay methods to determine the effect of pollution on a particular species. Standard toxicological methods are used to determine the effect of a pollutant (or mix of pollutants) in water on a species, usually fish. Laboratory experiments are useful where no data exist on the effect of a pollutant on plants or animals. An advantage is that these experiments can be set up to represent the environment in which the effect may occur by using, for example, water from the river to which a pollutant is discharged.

Mathematical models refer to predictive techniques which use mathematical relationships between system variables to describe the way an environmental system reacts to an external influence. Mathematical models can be divided into those models which are empirical or “black-box” models, where the relationships between inputs and outputs are established from analysis of observations in the environment; and those models which are internally descriptive, that is, where the mathematical relationships within the model are based on some understanding of the mechanisms of the processes occurring in the environment.

Survey techniques are based on the identification and quantification of existing or future aspects of the environment that might be affected, in terms of their sensitivity to change or of the importance of their loss or disturbance. The three main groups of survey techniques include inventory techniques, evaluation techniques, and visibility techniques.

Inventory techniques involve determining the distribution of things which may be affected by an activity (receptors) usually because of their proximity to an activity. Evaluation techniques refer to surveys to determine the

value of the environmental aspect that will be lost or disturbed as the result of an activity, and where possible its change in value after the activity is undertaken. The principle of evaluation techniques is that they place a value on an environmental aspect in some location where it will be affected by the activity. The evaluation is usually made in terms of an index based on several characteristics of the environment which are considered to contribute to or detract from the value of the environmental aspect in question. Visibility techniques form a group which cannot eas-

ily be categorized in either of the other types. These techniques are used in landscape assessment for determining the zone from which an activity will be visible.

### Current Use of Techniques

Currently the range of impact prediction techniques in the EIA process is broad and encompasses the use of analogies through sophisticated mathematical models. In a specific environmental impact study, several prediction tech-

niques may be required due to the availability of data and specific mathematical models (Stakhiv et al. 1981 and Stakhiv 1986). In addition, as greater attention is given to the global environment and to potential global consequences of large projects or activities, mesoscale environmental consequences must be considered.

### SIMPLE TECHNIQUES

Perhaps the simplest approach for impact prediction is to use analogies or comparisons to the experienced effects of existing projects or activities. This approach can be termed a "look-alike" approach in that information gathered from similar types of projects in similar environmental settings can be used to descriptively address the anticipated impacts of a proposed project or activity. Professional judgment is necessary when analogies are used for specific impacts on the environment.

Another approach is the inventory technique. In this approach, the environmental engineer compiles an inventory of environmental resources by assembling existing data or conducting baseline monitoring. With this approach, a presumption is that the resources in the existing environment, or portions of it, will be lost as a result of the proposed project or activity. This technique can be perceived as a worst-case prediction, and for certain types of resources it represents a reasonable approach for use in environmental impact studies. Again, professional judgment is necessary to interpret information related to the existing environment and the potential consequences of a proposed

project or activity. This approach can also be aided by the analogy approach.

An often used approach for impact prediction is to incorporate checklists or interaction matrices as a part of the impact study. Several types of checklists have been developed, ranging from simple listings of anticipated impacts by project type, to questionnaire checklists which incorporate a series of detailed questions and provide structure to the impact prediction activity. Some checklists include the use of scaling, rating, or ranking the impact of alternatives and incorporate relative-importance weights to the environmental factors. These checklists can aggregate the impacts of a project into a final index or score which can be used to compare alternatives. In this context, these checklists are similar to multicriteria decision-making techniques which are used in environmental planning and management.

Interaction matrices include simple  $x$ - $y$  matrices that identify impacts and provide a basis for categorization of impact magnitude and importance. In stepped matrices, secondary and tertiary consequences of project actions are delineated. The most sophisticated types of matrices are networks or impact trees in which systematic approaches trace the consequences of a given project or activity. A key point relative to both checklist and matrix methods is that they tend to be qualitative in terms of the predicted impacts; however, they do represent useful tools for impact prediction.

### INDICES AND EXPERIMENTAL METHODS

A fourth category of impact prediction approaches in environmental impact studies is environmental indices (Ott 1978). An environmental index is a mathematical or descriptive presentation of information factors used for classifying environmental quality and sensitivity and predicting the impacts of a proposed project or activity. The basic concept for impact prediction is to anticipate and quantify the change in the environmental index as a result of the project or activity, and then to consider the difference in the index from the with- and without-project conditions as a measure of impact. Numerous environmental indices have been developed for air quality, water quality, noise, visual quality, and quality of life (a socioeconomic index which can include a large number of specific factors). One widely used type of index is based on habitat considerations and uses the Habitat Evaluation Procedures developed by the U.S. Fish and Wildlife Service (1980) or a Habitat Evaluation System developed by the U.S. Army Corps of Engineers (1980). This system is based on the development of a numerical index to describe habitat quality and size. A key advantage of index approaches for impact prediction is that these approaches can be related to available information and they provide a systematic basis for considering the consequences of a project or activity.

The fifth category of impact prediction approaches is experimental methods. These methods encompass the conduction of laboratory experiments to develop factors or coefficients for mathematical models, and the conduction of large-scale field experiments to measure changes in environmental features as a result of system perturbations. In addition, physical models are used to examine impacts related to hydrodynamics and ecological changes within microcosms of environmental settings. Experimental methods are primarily useful in dealing with physical-chemical components and biological features of the environmental setting.

### MATHEMATICAL MODELS

The most sophisticated approach for impact prediction involves the use of mathematical models. Numerous types of mathematical models account for pollutant transport and fate within the environmental setting. Other models describe environmental features and the functioning of ecosystems. This review does not delineate the state-of-the-art of mathematical modeling with regard to environmental impact studies but discusses the availability of types of models which can be used in studies.

Stakhiv (1986) discusses several types of models used for forecasting in water resources planning. He notes the availability of predictive deterministic models for forecasting, including models addressing demographic, socioeconomic, and economic changes; and models for ecological, water quality, energy, hydraulics, hydrology, and land-use changes.

With regard to air quality dispersion, numerous models address point, line, and area sources of air pollution and the results of dispersion from these sources. In addition, within recent years, models are available for long-range transport of pollution and for atmospheric reactions leading to photochemical smog formation and acid rain. Many air quality models are available in software form for personal computers; they represent a usable technology for many studies.

Anderson and Burt (1985) note the following about hydrologic modeling:

All models seek to simplify the complexity of the real world by selectively exaggerating the fundamental aspects of a system at the expense of incidental detail. In presenting an approximate view of reality, a model must remain simple enough to understand and use, yet complex enough to be representative of the system being studied.

Anderson and Burt (1985) classify hydrological models into three types:

1. Black-box models: These models contain no physically based transfer function to relate input to output; they depend upon establishing a statistical correspondence between input and output.

2. Conceptual models: These models occupy an intermediate position between the deterministic approach and empirical black-box analysis. They are formulated on the basis of a simple arrangement of a small number of components, each of which is a simplified representation of one process element in the system being modeled; each element of the model consists of a nonlinear reservoir in which the relationship between outflow (Q) and storage (S) is given by

$$S = K \cdot Q^n \tag{2.4(1)}$$

where K and n represent constants.

3. Deterministic models: These models are based on complex physical theory. However, despite the simplifying assumptions to solve the flow equations, these models have huge demands in terms of computational time and data requirements and are therefore costly to develop and operate.

Figure 2.4.1 shows a generic method for selecting a mathematical hydrological model (Anderson and Burt 1985). The method emphasizes the dependence of the

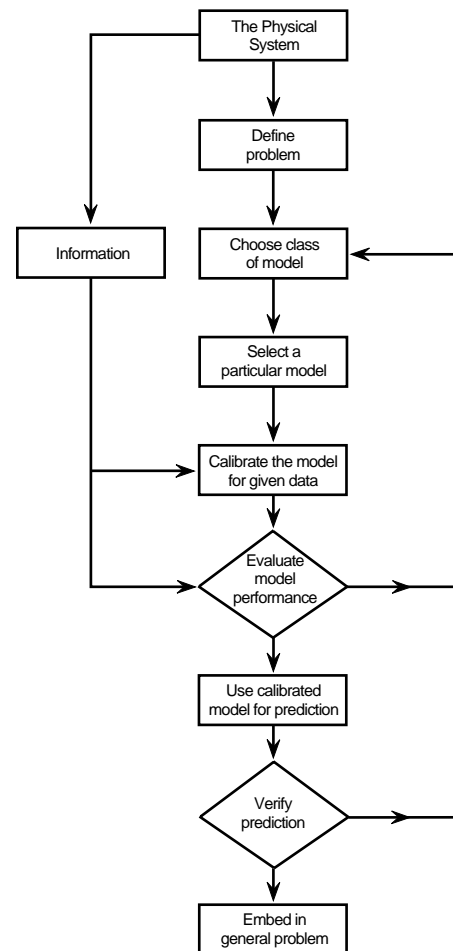

FIG. 2.4.1 Method for selecting a mathematical model (Anderson and Burt 1985).

modeling upon a clear definition of the problem to be solved, and upon the data base to describe the physical system.

Surface and groundwater quality and quantity models are also plentiful, with major research developments within the last decade occurring in solute transport in subsurface systems. Surface water quality and quantity models range from one-dimensional steady-state models to three-dimensional dynamic models which can be used for rivers, lakes, and estuarine systems (Anderson and Burt 1985). Groundwater flow models now include subsurface processes, such as adsorption and biological decomposition. The International Ground Water Modeling Center, along with the National Water Well Association, has hundreds of groundwater models in software form that address specific environmental consequences of projects or activities.

Noise impact prediction models are available for point, line, and area sources of noise generation. These models range in complexity from simple calculations involving the use of nomographs, to sophisticated computer modeling for airport operations. The technology for noise impact prediction is well developed as a result of numerous research studies related to highways and airports. Many noise impact prediction models are also available in software form for personal computers. Noise models can be used to address continuous or discontinuous noise sources, including instantaneous noise sources related to blasting.

Biological impact prediction models are characterized in the U.S. EIA practice as involving habitat approaches. Specifically, a widely used impact prediction approach involves the Habitat Evaluation Procedures developed by the U.S. Fish and Wildlife Service (1980). In addition, the Habitat Evaluation System developed by the U.S. Army Corps of Engineers (1980) has also been used in a number of impact studies. As noted earlier, these models involve calculating an index which incorporates both quality and quantity information. Prediction of impacts involves determining the index under baseline as well as future with- and without-project conditions. Other types of biological impact models include species population models which may be based on empirical approaches involving statistical correlations (Starfield and Bleloch 1986). The most sophisticated biological impact models are those involving energy system diagrams; these are used in some environmental impact studies.

Ad hoc models may be needed to address impact concerns associated with a proposed project, plan, program, or policy. Starfield and Bleloch (1986) address the building of models for conservation and wildlife management. Their topics include a simple single-species model, an exploratory stochastic model, a complex single-species model, and an ecosystem model, among others. Each topic begins with a management problem and describes how a model can be constructed to address that problem. They also describe modifications to the model in light of the

available (or unavailable) data, how the model can be exercised, and what can be learned from it. They presume that the problem that needs to be modeled is often poorly defined; the processes and mechanisms are not well understood, and the data are often scant and difficult to obtain. Their work also includes information on the development of expert systems, as well as for resource management.

Model building for biological systems is also addressed by Armour and Williamson (1988) in their procedure for organizing and simplifying complex information into a cause-and-effect model through an interdisciplinary exercise. Information includes prerequisites to help ensure model completion, applications of model information, diagnosing and correcting modeling problems when users encounter difficulties, and technical limitations of the approach.

Predictive modeling is also possible for ascertaining the potential for archaeological resources in geographical study areas. Such modeling is primarily based upon evaluating factors that indicate the likelihood of archaeological resources being found, relating the factors to existing information, evaluating the likelihood for early occupations in the area, and other environmental and sociological factors. This type of modeling is often used to determine the need for planning and conducting archaeological field surveys.

Visual quality is also a subject in selected impact studies. Visual impact modeling approaches have been developed by several federal agencies, including the U.S. Forest Service, U.S. Bureau of Land Management, U.S. Soil Conservation Service, and U.S. Army Corps of Engineers (Smardon, Palmer, and Felleman 1986). These visual impact models typically involve evaluating a series of factors, in some cases quantitatively and in other cases descriptively, and assembling the information into an overall visual quality index for the study area. In this context, these models are similar to the environmental indices approach described earlier.

Impact prediction related to the socioeconomic environment is often associated with the use of human population and econometric models. Population forecasting can range from simple projections of historical trends to complicated cohort analysis models. Econometric models relate the population and economic characteristics of study areas so that interrelationships can be depicted between population changes and changes in economic features within given study areas. In addition to the econometric models and models related to population change, other impact predictions for the socioeconomic environment are addressed by the use of multiplier factors applied to population changes. In this regard, several input-output models can be used in environmental impact studies.

Table 2.4.3 provides a noninclusive listing of state-of-the-art books or reports related to quantitative models useful for impact forecasting. A common ingredient in the ap-

proaches for impact prediction is that decisions for a project or activity must use the best available predictive technology in view of the location, size, and type of project or activity, as well as the budget available for the environmental impact study. In that regard, sophisticated mathematical models may not be used due to the need for extensive data input and model calibration. Accordingly, a range of approaches is usually necessary in conducting an environmental impact study for a project or activity.

## 2.5 DECISION-FOCUSED CHECKLISTS

Environmental impact studies typically address a minimum of two alternatives, and sometimes as many as ten, but usually three to five alternatives. The minimum number typically represents a choice between construction and operation of a project versus project nonapproval. The alternatives can encompass a range of considerations. Typical categories of alternatives, expressed generically, include:

1. Site location alternatives
2. Design alternatives for a site
3. Construction, operation, and decommissioning alternatives for a design
4. Project size alternatives
5. Phasing alternatives for size groupings
6. No-project or no-action alternatives
7. Timing alternatives relative to project construction, operation, and decommissioning

Decision-focused checklists are systematic methods for comparing and evaluating alternatives. Scaling, rating, or ranking-weighting checklists can be used in such comparisons and evaluations. In scaling checklists, an algebraic scale or letter scale is assigned to the impact of each alternative on each environmental factor. In ranking checklists, alternatives are ranked from best to worst in terms of their potential impacts on identified environmental factors, while rating uses a predefined rating approach. These checklists are useful for comparative evaluations of alternatives, thus they provide a basis for selecting the preferred alternative.

In weighting-scaling checklists, relative importance weights are assigned to environmental factors and impact scales are determined for each alternative relative to each factor. Weighting-ranking checklists involve importance weight assignments and the relative ranking of the alternatives from best to worst in terms of their impacts on each environmental factor. Numerous weighting-scaling and weighting-ranking checklists are available for environmental impact studies. These methods represent adaptations of routinely used multicriteria or multiattribute decision-making techniques; such techniques are also called decision-analysis techniques.

### Conceptual Basis for Tradeoff Analysis

To achieve systematic decision making among alternatives, tradeoff analysis should be used. Tradeoff analysis involves

the comparison of a set of alternatives relative to a series of decision factors. Petersen (1984) notes that in a trade-off analysis, the contributions of alternative plans are compared to determine what is gained or foregone in choosing one alternative over another. Table 2.5.1 displays a tradeoff matrix for systematically comparing the groups of alternatives or specific alternatives within a group relative to a series of decision factors (Canter, Atkinson, and Leistriz 1985).

The following approaches can be used to complete the tradeoff matrix in Table 2.5.1:

1. Qualitative approach: Descriptive, synthesized, and integrated information on each alternative relative to each decision factor is presented in the matrix.
2. Quantitative approach: Quantitative, synthesized, and integrated information on each alternative relative to each decision factor is displayed in the matrix.
3. Ranking, rating, or scaling approach: The qualitative or quantitative information on each alternative is summarized via the assignment of a rank, rating, or scale value relative to each decision factor (the rank or rating or scale value is presented in the matrix).
4. Weighting approach: The importance weight of each decision factor relative to each other decision factor is considered, with the resultant discussion of the information on each alternative (qualitative; quantitative; or ranking, rating, or scaling) being presented in view of the relative importance of the decision factors.
5. Weighting-ranking, -rating, or -scaling approach: The importance weight for each decision factor is multiplied

**TABLE 2.5.1 TRADEOFF ANALYSIS FOR DECISION MAKING (CANTER, ATKINSON, AND LEISTRITZ 1985)**

Decision Factors	Alternatives				
	1	2	3	4	5
Degree of Meeting Needs and Objectives					
Economic Efficiency					
Social Concerns (public preference)					
Environmental Impacts					
Biophysical					
Cultural					
Socioeconomic (includes health)					

by the ranking, rating, or scaling of each alternative, then the resulting products for each alternative are summed to develop an overall composite index or score for each alternative; the index may take the form of:

$$Index_j = \sum_i^n (IW)_i (R)_{ij} \quad 2.5(1)$$

where:

- Index j* = the composited index for the *j*th alternative
- n* = number of decision factors
- IW<sub>i</sub>* = importance weight of *i*th decision factor
- R<sub>ij</sub>* = ranking, rating, or scaling of *j*th alternative for *i*th decision factor

Decision making which involves the comparison of a set of alternatives relative to a series of decision factors is not unique to considering environmental impacts. This decision-making problem is classic and is often referred to as multiattribute or multicriteria decision making, or decision analysis.

## Importance Weighting for Decision Factors

If the qualitative or quantitative approach is used to complete the matrix as shown in Table 2.5.1, information for this approach related to the environmental impacts can be based on impact prediction. This information is also needed for the approaches involving importance weighting and ranking, rating, or scaling. If the importance weighting approach is used, the assignment of importance weights to decision factors, or at least the arrangement of them in a rank ordering of importance, is critical. Table 2.5.2 lists some structured importance weighting or ranking techniques which can be used to achieve this step. These techniques have been used in numerous environmental decision-making projects. Brief descriptions of several techniques from Table 2.5.2 are illustrated. In addition to the structured techniques, less formal approaches, such as reliance on scoping, can be used as a basis for importance weighting.

Ranking techniques for importance weighting basically involve the rank ordering of decision factors in their rela-

tive order of importance. If *n* decision factors exist, rank ordering involves assigning 1 to the most important factor, 2 to the second-most important factor, and so forth, until *n* is assigned to the least important factor. The rank order numbers can be reversed; that is, *n* can be assigned to the most important factor, *n* - 1 to the second-most important factor, and so forth, until 1 is assigned to the least important factor. The Nominal Group Process (NGP) technique (Voelker 1977) illustrates a ranking technique and is described next.

The NGP technique is an interactive group technique and was developed in 1968 (Voelker 1977). It was derived from social-psychological studies of decision conferences, management-science studies of aggregating group judgments, and social work studies of problems surrounding citizen participation in program planning. The NGP technique is widely used in health, social service, education, industry, and government organizations. For example, Voelker (1977) describes use of the NGP technique to rank decision factors in siting nuclear power plants. The following four steps are involved in the NGP technique for importance weighting:

1. Nominal (silent and independent) generation of ideas in writing by a panel of participants
2. Round-robin listing of ideas generated by participants on a flip chart in a serial discussion
3. Group discussion of each recorded idea for clarification and evaluation
4. Independent voting on priority ideas, with mathematical rank ordering determining the group decision

Rating techniques for importance weighting basically involve assigning importance numbers to decision factors and sometimes their subsequent normalization via a mathematical procedure. Two examples of rating techniques are the use of a predefined importance scale (Linstone and Turoff 1978) and the use of the multi-attribute utility measurement (MAUM) technique (Edwards 1976). The NGP technique can also be used for rating the importance of decision factors. Decision factors can be assigned numerical values based on predefined importance scales. Table 2.5.3 delineates five scales with definitions to consider in assigning numerical values to decision factors (Linstone and Turoff 1978). Use of the predefined scales can aid in systematizing importance weight assignments.

Paired comparison techniques (unranked and ranked) for importance weighting involve comparisons between decision factors and a systematic tabulation of the numerical results of the comparisons. These techniques are used extensively in decision-making efforts, including numerous examples related to environmental impact studies. One of the most useful techniques is the unranked paired comparison technique developed by Dean and Nishry (1965). This technique, which can be used by an individual or group, compares each decision factor to each other decision factor in a systematic manner.

**TABLE 2.5.3 EXAMPLE OF IMPORTANCE SCALE (LINSTONE AND TUROFF 1978)**

<i>Scale Reference</i>	<i>Definitions</i>
1. Very important	A most relevant point First order priority Has direct bearing on major issues Must be resolved, dealt with, or treated
2. Important	Is relevant to the issue Second order priority Significant impact, but not until other items are treated Does not have to be fully resolved
3. Moderately important	May be relevant to the issue Third order priority May have impact May be a determining factor to major issue
4. Unimportant	Insignificantly relevant Low priority Has little impact Not a determining factor to major issue
5. Most unimportant	No priority No relevance No measurable effect Should be dropped as an item to consider

## Scaling, Rating, or Ranking of Alternatives

Scaling, rating, or ranking of each alternative for each decision factor is the second major aspect in using the multicriteria decision-making approach. Rating and ranking concepts are described in the previous subsection on importance weighting. Several techniques can be used for this evaluation of alternatives in a decision. Examples of techniques include the use of the alternative profile concept, a reference alternative, linear scaling based on the maximum change, letter or number assignments designating impact categories, evaluation guidelines, unranked paired comparison techniques, and functional curves.

Bishop et al. (1970) discuss the alternative profile concept for impact scaling. This concept is represented by a graphic presentation of the effects of each alternative relative to each decision factor. Each profile scale is expressed on a percentage basis, ranging from a negative to a positive 100%, with 100% being the maximum absolute value of the impact measure adopted for each decision factor. The impact measure represents the maximum change, either plus or minus, associated with an alternative being evaluated. If the decision factors are displayed along with the impact scale from +100% to -100%, a dotted line can be used to connect the plotted points for each alternative and thus describe its profile. The alternative profile concept is useful for visually displaying the relative impacts of a series of alternatives.

Salomon (1974) describes a scaling technique for evaluating cooling system alternatives for nuclear power

plants. To determine scale values, his technique uses a reference cooling system, and each alternative system is compared with it. He assigned the following scale values to the alternatives based on the reference alternative: very superior (+8), superior (+4), moderately superior (+2), marginally superior (+1), no difference (0), marginally inferior (-1), moderately inferior (-2), inferior (-4), and very inferior (-8).

Odum et al. (1971) discuss a scaling technique in which the actual measures of the decision factor for each alternative plan are normalized and expressed as a decimal of the largest measure for that factor. This technique represents linear scaling based on the maximum change.

A letter scaling system is described by Voorhees and Associates (1975). This method incorporates eighty environmental factors oriented to the types of projects conducted by the U.S. Department of Housing and Urban Development. The scaling system assigns a letter grade from A+ to C- for the impacts, with A+ representing a major beneficial impact and C- an undesirable detrimental change.

Duke et al. (1977) describe a scaling checklist for the environmental quality (EQ) account for water resource projects. Scaling follows establishing an evaluation guideline for each environmental factor. An evaluation guideline is defined as the smallest change in the highest existing quality in the region that is considered significant. For example, assuming that the highest existing quality for dissolved oxygen in a region is 8 mg/l, if a reduction of 1.5 mg/l is considered as significant, then the evaluation guideline is 1.5 mg/l, irrespective of the existing quality in a

given regional stream. Scaling is accomplished by quantifying the impact of each alternative relative to each environmental factor, and if the net change is less than the evaluation guideline, it is insignificant. If the net change is greater and moves the environmental factor toward its highest quality, then it is considered a beneficial impact; the reverse exists for those impacts that move the measure of the environmental factor away from its highest existing quality.

One of the most useful techniques for scaling, rating, or ranking alternatives relative to each decision factor is the unranked paired comparison technique described by Dean and Nishry (1965). This technique was mentioned earlier relative to its use for importance weighting of decision factors. Again, this technique can be used by an individual or group for the scaling, rating, or ranking of alternatives.

Functional curves, also called value functions and parameter function graphs or curves, can also be used in environmental impact studies for scaling, rating, or ranking the impacts of alternatives relative to decision factors. Figure 2.5.1 shows an example of a functional curve for species diversity (Dee et al. 1972). Dee et al. (1972) describe the following seven steps used in developing a functional curve (relationship) for an environmental parameter (decision factor):

- Step 1.* Obtain scientific information on the relationship between the parameter and the quality of the environment. Also, obtain experts in the field to develop the value functions.
- Step 2.* Order the parameter scale so that the lowest value of the parameter is zero and it increases in the positive direction—no negative values.

**FIG. 2.5.1** Functional curve for species diversity (Dee et al. 1972).

- Step 3.* Divide the quality scale (0–1) into equal intervals, and express the relationship between an interval and the parameter. Continue this procedure until a curve exists.
- Step 4.* Average the curves over all experts in the experiment to obtain a group curve. (For parameters based solely on judgment, determine value functions by a representative population cross section.)
- Step 5.* Indicate to the experts estimating the value function the group curve and expected results of using the curves. Decide if a modification is needed; if needed, go to Step 3; if not, continue.
- Step 6.* Do Steps 1 through 5 until a curve exists for all parameters.
- Step 7.* Repeat the experiment with the same group or another group to increase the reliability of the functions.

## Development of a Decision Matrix

The final step in multicriteria decision making is to develop a decision matrix displaying the products of the importance weights (or ranks) and the alternative scales (or ranks). Table 2.5.4 shows a simple weighting-rating checklist used in an environmental impact study of sites for a wastewater treatment plant (Wilson 1980). Two groups of importance weights are used, with factors assigned an importance weight of 2 being more important than factors assigned an importance weight of 1. Each of the three sites in the study is rated on a scale from 1 to 3, with 1 denoting an undesirable site and 3 a desirable site relative to thirteen decision factors. The best overall site based on a composite evaluation is Site C.

## Examples of Decision-Focused Checklists

The Battelle Environmental Evaluation System (EES) is a weighting-scaling checklist developed for the U.S. Bureau of Reclamation. It contains seventy-eight environmental factors organized into seventeen components and four categories as shown in Figure 2.5.2 (Dee et al. 1972). An interdisciplinary team assigns importance weights to each of the categories, components, and factors based on use of the ranked paired comparison technique. Impact scaling in the Battelle EES uses functional relationships for each of the seventy-eight factors (Dee et al. 1972).

The basic concept of the Battelle EES is that an index expressed in environmental impact units (EIUs) can be developed for each alternative and baseline environmental condition. Mathematical formulation of this index is as follows:

$$EIU_j = \sum_{i=1}^n (EQ)_{ij} (PIU)_i \quad 2.5(2)$$

**TABLE 2.5.4 WEIGHTING-RATING CHECKLIST FOR WASTEWATER TREATMENT PLANT SITE EVALUATION (WILSON 1980)**

<i>Factors to be considered</i>	<i>Significance of factor</i>	<i>Importance to decision (2 = most)</i>	<i>Rating</i>		
			<i>scale: 1 = worst; 3 = best</i>		
			<i>Site A</i>	<i>Site B</i>	<i>Site C</i>
1. Construction cost	One-time cost with federal share	1	2	2.5	3
2. Operating cost	Ongoing cost, includes energy costs (all local share)	2	1	2	3
3. Nonpotable reuse	Safe, economic benefit; key is proximity to users	2	1	2	3
4. Potable reuse	More long-range than item 3 (above); best sites are near well field or water plant; industrial sewage should not be present	1	3	2.5	1
5. Odor potentials	Assumes good plant design and operation	2	2	1	3
6. Other land use conflicts	Potential to interfere with agricultural/residential land	1	2	1	3
7. Availability of site area	Future expansion capability, flexibility	2	3	2	1
8. Relationship to growth area	Assumes growth to state line (in fifty-year time frame)	1	3	2	1
9. Construction impacts	Reworking of lines	1	1	2	3
10. Health of workers	Air pollution	1	3	3	2
11. Implementation capability	Land acquisition problems	1	3	1	2
12. Operability	One plant is better than two	1	1	2	3
13. Performance reliability	Assumes equal treatment plants	1	2	2	2
14. TOTAL	Rating times Importance, totaled Highest number = best site		34	32	40

where:

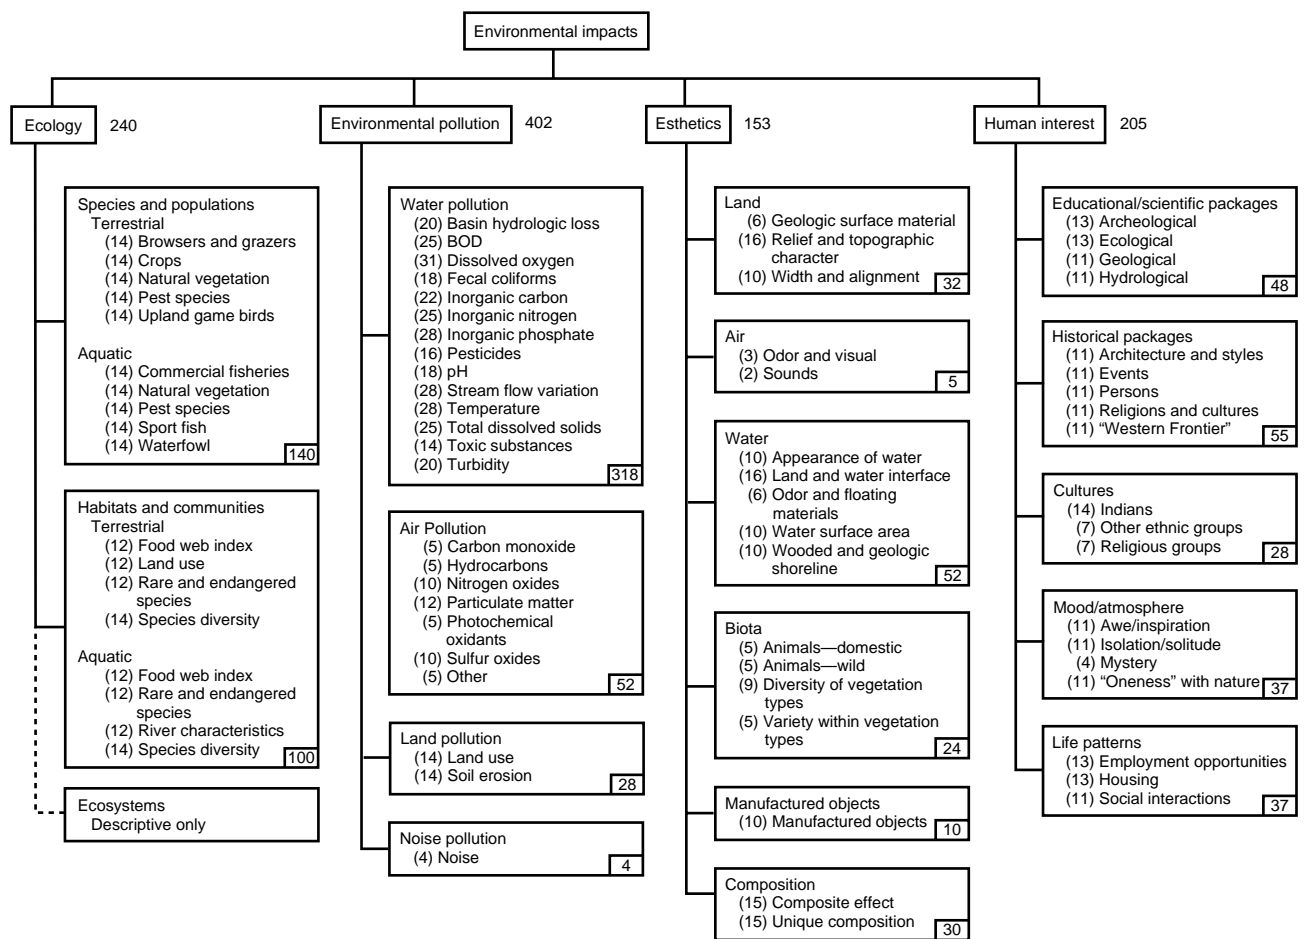

- $EIU_j$  = environmental impact units for  $j$ th alternative
- $EQ_{ij}$  = environmental quality scale value for  $i$ th factor and  $j$ th alternative
- $PIU_i$  = parameter importance units for  $i$ th factor

Use of the Battelle EES consists of obtaining baseline data on the seventy-eight environmental factors and, through use of their functional relationships, converting the data into EQ scale values. These scale values are then multiplied by the appropriate PIUs and aggregated to obtain a composite EIU score for the baseline setting. For each alternative being evaluated, the anticipated changes in the seventy-eight factors must be predicted. The predicted factor measurements are converted into EQ scale values using the appropriate functional relationships. The EQ scale values are then multiplied by the PIUs and aggregated to arrive at a composite EIU score for each alternative. This numerical system displays tradeoffs between the alternatives in terms of specific environmental factors, intermediate components, and categories. Profes-

sional judgment is necessary in the interpretation of the numerical results, with the focus on comparative analyses, rather than specific numerical values.

As noted earlier, the Battelle EES was developed for environmental impact considerations related to water resources projects. It has been used directly or in modified form in several water resources projects. For example, it was used on the Pa Mong Water Resources Project in South Thailand (Economic and Social Commission for Asia and the Pacific 1990) and in modified form for other water resources projects (Lohani and Halim 1990). The general approach of the EES can be applied to other project types through selection of pertinent environmental factors, assignment of importance weights, and the development of appropriate functional relationships for the factors. The approach used in the Battelle EES has been applied to a rapid transit system (Smith 1974), a waterway navigation project (School of Civil Engineering and Environmental Science and Oklahoma Biological Survey 1974), and to highway projects, pipeline projects, channel improvement projects, and wastewater treatment plants (Dee et al. 1973).

**FIG. 2.5.2** Battelle environmental evaluation system. Numbers in parentheses are parameter importance units. Numbers enclosed in boxes represent the total (Dee et al. 1972).

Another example of a weighting-scaling checklist for water resources projects is the Water Resources Assessment Methodology (WRAM) developed by the U.S. Army Corps of Engineers (Solomon et al. 1977). Table 2.5.5 lists the details of the methodology. Key elements include the selection of an interdisciplinary team; selection and inventory of assessment variables (environmental factors); impact prediction, assessment, and evaluation; and documentation of the results. Impact prediction, assessment, and evaluation is the element that includes weighting and scaling. The weighted ranking technique (unranked paired comparison technique) is used to determine the relative factor importance coefficient (FIC) for each assessment variable. Importance weight assignments are required for each study and should reflect the importance of the variables in the given geographical location. Impact scaling in the WRAM uses functional graphs (relationships), linear proportioning, or the development of alternative choice coefficients (ACCs).

In the late 1970s and early 1980s the concept of commensuration was introduced into the water resources planning vocabulary. Commensuration refers to measuring different things by a single standard or measure (Lord, Deane,

and Waterstone 1979). In essence, commensuration develops common units of measurement of various plans, with these units serving as the basis for tradeoff analysis among the plans. Lord, Deane, and Waterstone noted that the four components of commensuration are:

1. To identify the factors which are commensurable
2. To determine whose value judgments about those factors are to be considered
3. To discover what those value judgments are
4. To combine the judgments of all selected individuals into a single collective set of judgments

As a result of the emphasis on commensuration, several water resources methods were developed; the methods are basically weighting-scaling, -rating, or -ranking checklists. Four examples of these methods are discussed. Brown, Quinn, and Hammond (1980) address impact scaling for alternative water development plans, with particular emphasis on environmental and social impacts. Mumpower and Bollacker (1981) developed the Evaluation and Sensitivity Analysis Program (ESAP), which is a computerized environmental planning technique to evaluate alternative water resource management plans.

Reference Sources of Information</li> </ol>

Anderson (1981) also developed a multiple-objective, multiple-publics method for evaluating alternatives in water resources planning called the cascaded tradeoffs method. This method prepares an overall ranking of planning alternatives on the basis of public values. The key feature of the method is that it provides for tradeoffs across both issue dimensions (decision factors) and publics. Finally in terms of commensuration approaches, Brown and Valenti (1983) developed the Multiattribute Tradeoff System (MATS). MATS is a computer program that helps planners evaluate multiattribute alternatives to determine each alternative's relative worth or desirability. MATS leads the user through a series of questions (a tradeoff analysis) which focuses on the relative importance of various characteristics of the alternatives. The program documents the judgments which lead to developing a policy for evaluating alternatives. Importance weighting in MATS involves use of the unranked paired comparison technique, described earlier. Impact scaling is based on functional curves, also described earlier.

## **Current Trends in Decision-Making Tools**

A recent trend in decision making in environmental studies is the use of computer software. For example, Torno et al. (1988) developed a training manual to evaluate the environmental impacts of large-scale water resources development projects. Enough information is provided to enable the knowledgeable user to evaluate any water body of interest. The training primarily uses a multiobjective, multicriteria decision analysis approach. An interactive computer program simplifies application of the method described in the training manual and serves as a valuable learning aid.

A decision-support system computer model, called d-SSYS, can help determine the relative weights of evaluation parameters used to evaluate projects and the utility function for each of the attributes (Klee 1988). A unique feature of this model is that it incorporates three types of uncertainties: (1) those dealing with the factor (parameter) weights; (2) those dealing with the worth of each project with regard to each factor; and (3) those dealing with the utilities of the attributes. This model is applicable to any problem of competing alternatives.

## **Summary Observations on Decision-Focused Checklists**

Weighting-scaling, weighting-ranking, or weighting-rating checklists are valuable for displaying tradeoffs between alternatives and their associated environmental impacts; thus they are useful in selecting a proposed action. Computerization of these decision-focused checklists is a current

trend. The following observations pertain to this category of EIA methods:

1. Several approaches are available for assigning importance weights and for achieving scaling, rating, or ranking. These approaches have relative features and can be considered in choosing the approaches to be used in a study.
2. The process used for importance weighting of the individual decision factors and the rationale used in determining the relative importance weights of individual factors must be described. The rationale used for the scaling, rating, or ranking of individual alternatives relative to each decision factor must also be described. In fact, the description of the rationale is probably more important than the final numerical scores or classifications which result from them.
3. The most debatable point relative to weighting-scaling, -rating, or -ranking checklists is the assignment of importance weights to individual decision factors. Several approaches for importance weighting involve the use of public participation. Where this participation can be incorporated, it should legitimize the overall decision-making process.
4. The use of these checklists can structure the decision process in comparing alternatives and selecting the one to become the proposed action. The process of using these checklists can structure the decision process and provide a tradeoff basis for comparisons and evaluations of alternatives.
5. Due to the similarities between these decision-making approaches for environmental studies and other types of decision-making approaches, a wide range of computer software has become available within recent years to aid the process. This computer software is typically user friendly and can guide the assignment of importance weights and the scaling, rating, or ranking of alternatives. The software can then be used to calculate final index scores for each alternative. In addition, due to the availability of computer software, sensitivity analyses of the overall decision process can be easily conducted by examining the influence of changes in importance weights as well as impact scaling, rating, or ranking assignments to individual alternatives. Use of software for sensitivity analysis can indicate the relative sensitivity of the scores to individual changes.
6. The weighting-scaling, -rating, or -ranking checklist must be kept simple to facilitate the decision-making process. Additional alternatives and decision factors do not necessarily indicate that a better overall decision will be made.
7. These types of checklists can be used at several points in overall project planning and decision making. For example, they can be used early in a study to reduce the number of alternatives to allow a more detailed analysis of a smaller number of alternatives. In addi-

tion, using this process can reduce the number of decision factors so that in the final selection, a smaller number of alternatives is compared in relation to the key decision factors.

8. Use of these checklists forces decision making in context; that is, it keeps the decision maker from giving too much attention to a single issue in the decision-making process. It forces the decision maker to consider each issue and impact in relation to other issues and impacts.
9. These checklists can be used for several types of decision making, based on other considerations than environmental. They can also be used for decision making that evaluates and compares the environmental impacts as well as economic characteristics of different alternatives. Finally, such approaches can be used for systematic decision making considering environmental impacts, economic evaluations, and engineering feasibility. In other words, their use can range from considering only the environment to considering a composite of the three "Es" of decision making (environment, economics, and engineering).

## 2.6

# PREPARATION OF WRITTEN DOCUMENTATION

---

---

Perhaps the most important activity in the EIA process is preparing written reports which document the impact study findings. The resultant document or documents include EAs, EISs, environmental impact reports, environmental impact declarations, and FONSI. To illustrate the importance of written documentation in the EIA process, the CEQ regulations (1987) state in paragraph 1502.8:

Environmental impact statements shall be written in plain language and may use appropriate graphics so that decision makers and the public can readily understand them. Agencies should employ writers of clear prose or editors to write, review, or edit statements, which will be based upon the analysis and supporting data from the natural and social sciences and the environmental design arts.

The broad topics included in an EA prepared to meet the requirements of the CEQ (1987) are:

- Need for the proposal
- Description of alternatives
- Environmental impacts of proposed action and alternatives
- List of agencies and persons consulted

Table 2.6.1 shows a topical outline for an EIS (Council on Environmental Quality 1987).

Basic principles of technical writing must be applied in written documentation. These principles can be used in both planning the document and preparing written materials. Five such principles are delineated by Mills and Walter (1978):

1. Always have in mind a specific reader, and assume that this reader is intelligent, but uninformed.
2. Before you start to write, decide the purpose of your report; make sure that every paragraph, sentence, and word makes a clear contribution to that purpose, and makes it at the right time.
3. Use language that is simple, concrete, and familiar.
4. At the beginning and end of every section, check your writing according to this principle: First, tell your readers what you are going to tell them, then tell them, and then tell them what you have told them.
5. Make your report visually attractive.

The target audience of impact study documentation typically consists of two groups: (1) a nontechnical audience represented by decision makers and interested members of the public and (2) a technical audience represented by professional colleagues in government agencies and specific public groups who have interest in the study. Accordingly, written documentation on impact studies must address the information needs of both nontechnical and technical audiences.

—Larry W. Canter

**TABLE 2.6.1 ENVIRONMENTAL IMPACT STATEMENT OUTLINE (COUNCIL ON ENVIRONMENTAL QUALITY 1987)**

<i>Section</i>	<i>Comments</i>
Cover Sheet	The cover sheet shall not exceed one page. It shall include a list of the responsible agencies, including the lead agency and any cooperating agencies; the title of the proposed action; the name, address, and telephone number of the person at the agency who can supply further information; a designation of the statement as a draft, final, or draft or final supplement; a one-paragraph abstract of the statement; and the date by which comments must be received.
Summary	Each environmental impact statement shall contain a summary which adequately and accurately summarizes the statement. The summary shall stress the major conclusions, areas of controversy (including issues raised by agencies and the public), and the issues to be resolved (including the choice among alternatives). The summary will normally not exceed fifteen pages.
Purpose and Need	The statement shall briefly specify the underlying purpose and need to which the agency is responding in proposing the alternatives, including the proposed action.
Alternatives Including the Proposed Action	This section is the heart of the environmental impact statement. Based on the information and analysis presented in the sections on the Affected Environment and the Environmental Consequences, it should present the environmental impacts of the proposal and the alternatives in comparative form, thus sharply defining the issues and providing a clear basis for choice among options by the decision maker and the public.
Affected Environment	The environmental impact statement shall succinctly describe the environment of the area(s) to be affected or created by the alternatives under consideration. The descriptions shall be no longer than is necessary to understand the effects of the alternatives. Data and analyses in a statement shall be commensurate with the importance of the impact, with less important material summarized, consolidated, or simply referenced. Agencies shall avoid useless bulk in statements and shall concentrate effort and attention on important issues. Verbose descriptions of the affected environment are themselves no measure of the adequacy of an environmental impact statement.
Environmental Consequences	This section forms the scientific and analytic basis for the comparisons of alternatives. The discussion will include the environmental impacts of the alternatives, including the proposed action, any adverse environmental effects which cannot be avoided should the proposal be implemented, the relationship between short-term uses of man's environment and the maintenance and enhancement of long-term productivity, and any irreversible or irretrievable commitments of resources which would be involved in the proposal should it be implemented.
List of Preparers	The environmental impact statement shall list the names, together with their qualifications (expertise, experience, professional disciplines), of the persons who were primarily responsible for preparing the environmental impact statement or significant background papers, including basic components of the statement. Where possible, the persons who are responsible for a particular analysis, including analyses in background papers, shall be identified. Normally the list will not exceed two pages.
Appendices	If an agency prepares an appendix to an environmental impact statement, the appendix shall: (a) consist of material prepared in connection with the EIS; (b) normally consist of material which substantiates any analysis fundamental to the impact statement; (c) normally be analytic and relevant to the decision to be made; and (d) be circulated with the environmental impact statement or be readily available on request.

## 2.7

# ENVIRONMENTAL MONITORING

---

---

The CEQ regulations (1987) enunciate the principle of post-EIS environmental monitoring in sections 1505.3 and 1505.2(c). The CEQ regulations focus on monitoring in conjunction with implementing mitigation measures. Monitoring can also be used to determine the effectiveness of each of the types of mitigation measures.

Sadler and Davies (1988) delineate three types of environmental monitoring associated with the life cycle of a project, plan, or program; these include baseline monitoring, effects or impact monitoring, and compliance monitoring. Baseline monitoring refers to the measurement of environmental variables during a representative preproject period to determine existing conditions, ranges of variation, and processes of change. Effects or impact monitoring involves the measurement of environmental variables during project construction and operation to determine changes which may have resulted from the project. Finally, compliance monitoring is periodic sampling or continuous measurement of levels of waste discharge, noise, or similar emissions, to ensure that conditions are observed and standards are met. Pre-EIS monitoring includes baseline monitoring, while post-EIS monitoring encompasses effects or impact monitoring, and compliance monitoring.

Numerous purposes and implied benefits can be delineated for pre- and post-EIS environmental monitoring. For example, Marcus (1979) identifies the following six general purposes or uses of information from post-EIS monitoring:

1. Provides information for documentation of the impacts that result from a proposed federal action, with this information enabling more accurate prediction of impacts associated with similar federal actions.
2. Warns agencies of unanticipated adverse impacts or sudden changes in impact trends
3. Provides an immediate warning whenever a preselected impact indicator approaches a pre-selected critical level.
4. Provides information for agencies to control the timing, location, and level of impacts of a project. Control measures involve preliminary planning as well as the possible implementation of regulation and enforcement measures.
5. Provides information for evaluating the effectiveness of implemented mitigation measures.
6. Provides information to verify predicted impacts and thus validate impact prediction techniques. Based on these findings, techniques, such as mathematical models, can be modified or adjusted.

Environmental monitoring can serve as a basic component of a periodic environmental regulatory auditing program for a project (Allison 1988). In this context, auditing can be defined as a systematic, documented, periodic, and objective review by regulated entities of facility operations and practices related to environmental requirements (U.S. Environmental Protection Agency 1986). The purposes of environmental auditing are to verify compliance with environmental requirements, evaluate the effectiveness of in-place, environmental management systems, and assess risks from regulated and unregulated substances and practices. Some direct results of an auditing program include an increased environmental awareness by project employees, early detection and correction of problems and thus avoidance of environmental agency enforcement actions, and improved management control of environmental programs (Allison 1988). Several references are available describing protocols and experiences in auditing related to the EIA process (Canter 1985a; Munro, Bryant, and Matte-Baker 1986; PADC Environmental Impact Assessment and Planning Unit 1982; Sadler 1987; United Nations Environment Program, 1990).

Careful planning and implementation of an environmental monitoring program is necessary to meet the stated purposes of monitoring. Three premises relative to monitoring programs in the United States are:

1. An abundance of environmental monitoring data is routinely collected by various governmental agencies and the private sector. These data typically need to be identified, aggregated, and interpreted.
2. Environmental monitoring programs are expensive to plan and implement; therefore, every effort should be made to use extant monitoring programs or modify extant programs.
3. Due to overlapping environmental management and monitoring responsibilities of many local, state, and federal government agencies, environmental monitoring planning must be coordinated with several agencies.

Several fundamental books and articles are useful in the detailed planning and implementation of a monitoring program. References are available for air-quality monitoring (Noll and Miller 1977 and Lodge 1989), surface water quality monitoring (Canter 1985b and Loftis et al. 1989), groundwater quality monitoring (Aller et al. 1989), noise monitoring (Lipscomb and Taylor 1978), species and habitat monitoring (Brown and Dycus 1986; Gray 1988; Horner, Richey, and Thomas 1986; Ontario Ministry of

the Environment 1989; Roberts and Roberts 1984; and Spellerberg 1991), social impact assessment monitoring (Krawetz, MacDonald, and Nichols 1987), and health effects monitoring (Burtan 1991 and Schweitzer 1981). General references which encompass several types of environmental monitoring (Cheremisinoff and Manganiello 1990, Gilbert 1987, and Keith 1991) are also available.

## 2.8

# EMERGING ISSUES IN THE EIA PROCESS

---

---

After twenty-five years of experience in applying the EIA process in the United States, the process is maturing and the resultant procedures and documentation are becoming more technically sound and appropriate in including the environment in project planning and decision making. However, issues continue to emerge related to the process. These issues include new topical items and the application of new tools and techniques. Emerging items are related to cumulative impacts, focused activities related to the EIA process, the inclusion of risk assessment, the need to address impacts on biodiversity (Council on Environmental Quality 1993) and global issues, the importance of monitoring and environmental auditing, particularly as related to major projects, the need for environmentally responsible project management, and the emerging use of market-based approaches in project planning and evaluation.

Cumulative impact considerations in the EIA process are becoming increasingly important as projects are recognized as not being constructed and operated in isolation, but in the context of existing and other planned projects in the environs. Methods for identifying key cumulative impact concerns need to be developed and addressed in a responsible manner in the EIA process.

Risk assessment is a tool developed in the 1970s primarily for evaluating environmental regulatory strategies. In recent years, interest in the application of risk assessment within the EIA process (Canter 1993a) has increased. Risk assessment provides not only a focus on human health concerns, but can also be applied in ecological analyses. Risk assessment is anticipated to become more effectively integrated in the EIA process in the coming years.

As was noted earlier, the EIA process is being applied in a more focused manner to environmental permits and specific environmental remediation projects. In contrast, interest is increasing in considering regional and broader issues in the EIA process. One example is the delineated need for addressing the impacts of projects on biodiversity (Council on Environmental Quality 1993). This need results from the realization that projects can have implications on biodiversity, and this item should be considered, particularly for larger scale projects. A related item is the need to address project impacts in a transboundary context. This issue is particularly important as related to the impacts of a country's projects on other countries. Finally, the implications for some large-scale projects, in terms of acid rain as well as global warming, may have to be considered.

The need to consider the EIA process in relation to project management and follow-on is another topic on the EIA agenda. Follow-on monitoring to document experienced impacts, as well as auditing, was mentioned earlier. Monitoring and auditing can be used for project management decisions to minimize detrimental impacts (Canter 1993b).

Market-based approaches in environmental management include topics such as the use of mitigation banking for wetland losses and the application of emissions trading relative to both air pollutant and water pollutant emissions. The economic evaluation of potential environmental impacts is also of interest. This topic should receive more attention in the coming years, and soon such economic analyses may possibly be included with traditional cost-benefit analyses in project planning and decision making.

A number of new tools and techniques can be effectively used within the EIA process. The GIS represents an emerging technology that can facilitate resource identification and evaluation. GIS technology is already being used in larger scale projects.

Expert systems also represent an emerging tool which could find applicability within the EIA process. To date, most expert systems developed in environmental engineering focus on hazardous waste management and groundwater pollution evaluation, along with pollution control facilities. The development of expert systems for use in the EIA process is needed.

Public participation in the EIA process often leads to conflict. Several techniques are being developed in environmental mediation which have potential applicability in the EIA process. Examples include alternative dispute resolution and environmental dispute resolution techniques. A key feature of these techniques is the incorporation of a third-party intervener. The intervener negotiates between the project proponent and those interests who have raised opposition to the project on environmental grounds.

As increased information becomes available on environmental systems and processes, the associated development of mathematical models can be used for project impact quantification and evaluation. Such modeling is anticipated to increase, particularly for major projects that may have significant environmental impact issues.

In summary, the EIA process represents a young field within environmental engineering, while at the same time signs that it is a maturing field of practice are evident. Although many policy and social implications are associ-

ated with the EIA process, the process is fundamentally a technical or scientific process. Accordingly, the application of scientific approaches is fundamental to the effective implementation of this process in project planning and decision making.

—Larry W. Canter

## 2.9 INTERNATIONAL ACTIVITIES IN ENVIRONMENTAL IMPACT ASSESSMENT

---

---

The 1970 effective date of the NEPA in the United States signaled the beginning for many countries to adopt laws analogous to the NEPA. Over seventy-five countries now have laws requiring impact studies on proposed development projects. While the resultant reports are not always referred to as EISs, they do represent the documentation of studies similar in concept to those conducted in the United States. Terms other than EIS used by other countries include environmental impact assessment reports, environmental assessment reports, environmental impact documents, and environmental impact reports.

From a global perspective, the following observations relate to countries or portions of the world that have adopted EIA legislation. In North America, Canada, the United States, and Mexico have EIA laws. Some Central American countries have also adopted EIA legislation, and the majority of countries in South America have done similarly. Some larger countries with major development projects, such as Brazil, Argentina, and Venezuela, have active programs related to EIA.

In the European context, the European Community (EC) has a directive on EIA which must be met by all member countries. In addition, these countries also have their own EIA legislation which can be more stringent than the EC directive. The Scandinavian countries such as Sweden, Denmark, and Finland have EIA legislation and are active in the application of the EIA process. Many of the east European countries which were in the former Soviet Union are in the initial stages of adopting EIA legislation.

With regard to the African Continent, several countries in the northern tier, most notably Morocco and Egypt, have EIA legislation. South Africa also has such legislation. Other countries in the African Continent are in various stages of development of EIA legislation. In the Middle East, several countries have legislation or expressed inter-

## References

est in the EIA process; examples include Kuwait and Saudi Arabia.

In Asia and Southeast Asia, most countries have adopted EIA legislation; examples include India, Sri Lanka, Thailand, Malaysia, and Indonesia. Both Taiwan and the People's Republic of China have EIA legislation, as does Japan. Finally, Australia and New Zealand have active programs in planning and conducting impact studies.

For those countries that have not adopted their own EIA legislation, most are involved in some fashion in impact studies through the auspices of international lending agencies, such as the World Bank or Regional Development Banks, or through requirements of bilateral donor agencies providing funding for development projects. While the specific EIA requirements of donor countries may vary, the general concepts are applied throughout the developing world.

Both substantive and emphasis differences exist between the EIA processes of other countries and that in the United States. For example, in the United States, analyzing alternatives and choosing the one that balances environmental impacts and economic efficiency is emphasized. Most other countries emphasize alternatives analysis less than the EIA process in the United States does. In other words, detailed analysis in most other countries is for the proposed project.

A second difference is that many countries have highly structured land-use planning systems. In this context, the EIA process is often incorporated within the overall planning system. This incorporation causes procedural differences compared to the practice in the United States where an overall land-use planning system is absent.

A major difference between EIA practice in the United States and that in lesser developed countries is the limited availability of environmental data in the latter. Numerous

extant environmental monitoring systems exist in the United States, and this information can be used to describe the affected environment or baseline conditions. In many developing countries, such environmental data are either absent or only minimally available. Accordingly, monitoring baseline conditions in the EIA practice is emphasized in many countries.

EIA practice in the United States has typically focused on the preparation of an EA or an EIS. Follow-on activities are only minimally addressed. In contrast, post-EIS activities are emphasized in many countries. These activities include collecting monitoring data and using this information in project management to minimize negative environmental consequences.

As a final point of comparison, the United States practice is often characterized by litigation, wherein opponents

to projects can file a lawsuit against project sponsors on the basis of not satisfying the spirit and intent of the NEPA. This litigative concept is essentially absent in most other countries.

In summary, the international EIA practice throughout the world is largely patterned on the principles used in the United States. Future activities related to EIA suggest further coordination and integration of EIA requirements on a worldwide basis, with emphasis on both procedures and methodology. In addition, transboundary impacts, in which the impacts of development projects in one country may be manifested in other nearby countries, are being emphasized. These concerns will facilitate greater coordination between countries regarding the EIA process.

## 3.1 REGULATIONS AND DEFINITIONS

---

---

Pollution prevention, as defined under the Pollution Prevention Act of 1990, means source reduction and other practices that reduce or eliminate the creation of pollutants through (1) increased efficiency in the use of raw materials, energy, water, or other resources or (2) protection of natural resources by conservation. Under the Pollution Prevention Act, recycling, energy recovery, treatment, and disposal are not included within the definition of pollution prevention. Practices commonly described as in-process recycling may qualify as pollution prevention. Recycling conducted in an environmentally sound manner shares many of the advantages of pollution prevention—it can reduce the need for treatment or disposal and conserve energy and resources.

Pollution prevention (or source reduction) is an agency's first priority in the environmental management hierarchy for reducing risks to human health and the environment from pollution. This hierarchy includes (1) prevention, (2) recycling, (3) treatment, and (4) disposal or release. The second priority in the hierarchy is the responsible recycling of any waste that cannot be reduced at the source. Waste that cannot feasibly be recycled should be treated according to environmental standards that are designed to reduce both the hazard and volume of waste streams. Finally, any residues remaining from the treatment of waste should be disposed of safely to minimize their potential release into the environment. Pollution and related terms are defined in [Table 3.1.1](#).

### Regulatory Background

Three key federal programs have been implemented to address pollution production: the Pollution Prevention Act of 1990, the Environmental Protection Agency's (EPA's) 33/50 Voluntary Reduction Program, and the Clean Air Act Amendments' (CAAA's) Early Reduction Program for Maximum Achievable Control Technology (MACT). [Table 3.1.2](#) compares the features of these programs, from which the following key points are noted:

- Air toxics are used as a starting point for multimedia pollution prevention (that is consistent with two-thirds of the reported 3.6 billion lb released into the air).
- Reductions in hazardous air pollutants will occur incrementally during different years (1992, 1994, 1995, and beyond).
- Flexibility or variability in the definition of the base year, the definition of the source, and credits for reductions are possible.

The Pollution Prevention Strategy focuses on cooperative effort between the EPA, industry, and state and local governments as well as other departments and agencies to forge initiatives which address key environmental threats. Initially, the strategy focused on the manufacturing sector and the 33/50 program (formerly called the Industrial Toxics Project), under which the EPA sought substantial voluntary reduction of seventeen targeted high-risk industrial chemicals (see [Table 3.1.3](#)).

### Hazardous and Toxic Chemicals

The following five key laws specifically address hazardous and toxic chemicals.

*National Emission Standards for Hazardous Air Pollutants (NESHAP), Hazardous Air Emissions*—This law addresses six specific chemicals (asbestos, beryllium, mercury, vinyl chloride, benzene, and arsenic) and one generic category (radionuclides) released into the air.

*Clear Water Act, Priority Pollutants*—This act addresses 189 chemicals released into water including volatile substances such as benzene, chloroform, and vinyl chloride; acid compounds such as phenols and their derivatives; pesticides such as chlordane, dichlorodiphenyl trichloroethane (DDT), and toxaphene; heavy metals such as lead and mercury; polychlorinated biphenyls (PCBs); and other organic and inorganic compounds.

*Resource Conservation and Recovery Act (RCRA), Hazardous Wastes*—This act addresses more than 400 discarded commercial chemical products and specific chemical constituents of industrial chemical streams destined for disposal on land.

*Superfund Amendments and Reauthorization Act (SARA) Title III, Section 313: Toxic Substances*—This act addresses more than 320 chemicals and chemical categories released into all three environmental media. Under specified conditions, facilities must report releases of these chemicals to the EPA's annual Toxic Release Inventory (TRI).

*SARA Section 302: Extremely Hazardous Substances*—This act addresses more than 360 chemicals for which facilities must prepare emergency action plans if these chemicals are above certain threshold quantities. A release of these chemicals to air, land, or water requires a facility to report the release to the state emergency response committee (SERC) and the local emergency planning committee (LEPC) under SARA Section 304.

**TABLE 3.1.1 DEFINITIONS OF POLLUTION PREVENTION TERMS****Waste**

In theory, waste applies to nonproduct output of processes and discarded products, irrespective of the environmental medium affected.

In practice, since passage of the RCRA, most uses of waste refer exclusively to the hazardous and solid wastes regulated under RCRA and do not include air emissions or water discharges regulated by the Clean Air Act or the Clean Water Act.

**Pollution/Pollutants**

Pollution and pollutants refer to all nonproduct output, irrespective of any recycling or treatment that may prevent or mitigate releases to the environment (includes all media).

**Waste Minimization**

Waste minimization initially included both treating waste to minimize its volume or toxicity and preventing the generation of waste at the source. The distinction between treatment and prevention became important because some advocates of decreased waste generation believed that an emphasis on waste minimization would deflect resources away from prevention towards treatment. In the current RCRA biennial report, waste minimization refers to source reduction and recycling activities and now excludes treatment and energy recovery.

**Source Reduction**

Source reduction is defined in the *Pollution Prevention Act of 1990* as "any practice which (1) reduces the amount of any hazardous substance, pollutant, or contaminant entering any waste stream or otherwise released into the environment (including fugitive emissions) prior to recycling, treatment, and disposal; and (2) reduces the hazards to public health and the environment associated with the release of such substances, pollutants, or contaminants. The term includes equipment or technology modifications, process or procedure modifications, reformulations or design of products, substitution of raw materials, and improvements in housekeeping, maintenance, training, or inventory control." Source reduction does not entail any form of waste management (e.g., recycling and treatment). The act excludes from the definition of source reduction "any practice which alters the physical, chemical, or biological characteristics or the volume of a hazardous substance, pollutant, or contaminant through a process or activity which itself is not integral to and necessary for the production of a product or the providing of a service."

**Waste Reduction**

This term is used by the Congressional Office of Technology Assessment synonymously with source reduction. However, many groups use the term to refer to waste minimization. Therefore, determining the use of waste reduction is important when it is encountered.

**Toxic Chemical Use Substitution**

Toxic chemical use substitution or material substitution describes replacing toxic chemical with less harmful chemicals even though relative toxicities may not be fully known. Examples include substituting a toxic solvent in an industrial process with a less toxic chemical and reformulating a product to decrease the use of toxic raw materials or the generation of toxic by-products. This term also refers to efforts to reduce or eliminate the commercial use of chemicals associated with health or environmental risks, including substitution of less hazardous chemicals for comparable uses and the elimination of a particular process or product from the market without direct substitution.

**Toxics Use Reduction**

Toxics use reduction refers to the activities grouped under source reduction where the intent is to reduce, avoid, or eliminate the use of toxics in processes and products so that the overall risks to the health of workers, consumers, and the environment are reduced without shifting risks between workers, consumers, or parts of the environment.

**Pollution Prevention**

Pollution prevention refers to activities to reduce or eliminate pollution or waste at its source or to reduce its toxicity. It involves the use of processes, practices, or products that reduce or eliminate the generation of pollutants and waste or that protect natural resources through conservation or more efficient utilization. Pollution prevention does not include recycling, energy recovery, treatment, and disposal. Some practices commonly described as in-process recycling may qualify as pollution prevention.

**Resource Protection**

In the context of pollution prevention, resource protection refers to protecting natural resources by avoiding excessive levels of waste and residues, minimizing the depletion of resources, and assuring that the environment's capacity to absorb pollutants is not exceeded.

**Cleaner Products**

Cleaner products or clean products refers to consumer and industrial products that are less polluting and less harmful to the environment and less toxic and less harmful to human health.

**Environmentally Safe Products, Environmentally Preferable Products, or Green Products**

The terms environmentally safe products, environmentally preferable products, or green products refer to products that are less toxic and less harmful to human health and the environment when their polluting effects during their entire life cycle are considered.

**Life Cycle Analysis**

Life cycle analysis is a study of the pollution generation characteristics and the opportunities for pollution prevention associated with the entire life cycle of a product or process. Any change in the product or process has implications for upstream stages (extraction and processing of raw materials, production and distribution of process inputs) and for downstream stages (including the components of a product, its use, and its ultimate disposal).

**TABLE 3.1.2 SUMMARY OF POLLUTION PREVENTION REGULATORY INITIATIVES**

	<i>Pollution Prevention Act of 1990</i>	<i>CAAA Early Reduction Program</i>	<i>EPA 33/50 Voluntary Reduction Program</i>
Goals	Reporting requirements: Collect and disseminate information on pollution to all media and provide financial aid to states	For air only, reduction for source by 90% for gaseous hazardous air pollutants (HAPs) and 95% for particulate HAPs; uses hazard index for weighting reductions of highly toxic pollutants	Voluntary reduction of pollutants to all media by 33% by the end of 1992 and by 50% by the end of 1995
Number and Type of Chemicals	All SARA 313 chemicals	All 189 HAPs listed in the CAAs of which 35 are considered high-risk HAPs	17 chemicals, all of which are listed HAPs
Affected Sources	Facilities with ten or more employees, within standard industrial classification (SIC) 20-39, handling amounts greater than specified threshold limits for reporting	Facility-specific sources emitting more than 10 tn/yr of one HAP or more than 25 tn/yr of combined HAPs; flexible definition of source; credits for other reductions, including regulatory reductions, 33/50 reductions, or production shutdown or curtailment	Any SARA reporting companies; source can be all facilities operated by a company
Reporting Requirements	Annual, via new EPA Form R; report amounts of waste, recycle, and treated materials, amounts treated or disposed onsite and offsite, and treatment methods; project next two years	Six-year extension for implementing MACT; must enter into an enforceable commitment prior to EPA defining MACT in regulations; four submittal requirements: source identification, base-year HAP emissions, reduction plan, and statement of commitment	EPA Form R
Compliance Measurement or Baseline	For production throughput baseline production from prior year	Emissions in 1987 or later	Measured by annual EPA Form R relative to 1988 baseline year
Deadline(s)	7/1/92 for calendar year 1991 and every year thereafter	Achieve early reduction prior to MACT for the source or achieve reduction by 1/1/94 for sources with MACT prior to 1994	End of years 1992 and 1995
Enforcement	Penalties up to \$25,000 per day	The company may rescind prior to 12/1/93 without penalty; voluntary but enforceable once committed	None
For More Information	42 USCS § 13.01	Public Law 101-549, 11/15/90, 104 Stat. 2399-2712	The 33/50 program, U.S. EPA Office of Toxic Substances, Washington, DC, July 1991

## Source Reduction versus Discharge Reduction

The EPA has taken a strong position on pollution prevention by regarding source reduction as the only true pollution prevention activity and treating recycling as an option. Industry's position prior to the act (and effectively unchanged since) was to reduce the discharge of pollutant waste into the environment in the most cost-effective manner. This objective is achieved in some cases by source reduction, in others by recycling, in others by treatment and disposal, and usually in a combination of these methods. For this reason, this handbook examines all options in the pollution prevention hierarchy.

Traditionally, regulations change, with more stringent controls enacted over time. Therefore, source reduction and perhaps recycling and reuse (instead of treatment or disposal) may become more economically attractive in the future.

## State Programs

Many states have enacted legislation that is not voluntary, particularly those states with an aggressive ecological pres-

ence. Facilities should consult the pollution prevention legislation in their states on (1) goals, (2) affected chemicals, (3) affected sources, (4) reporting requirements, (5) exemptions, (6) performance measurement basis, (7) deadlines, and (8) other unique features.

Any company responding to the pollution prevention legislation in its state should consider a coordinated approach to satisfy the requirements of the federal programs as follows:

EPA Form R data and state emission data should be carefully reviewed, compared, and reported consistently. Scheduling activities for compliance should be integrated with the EPA's 33/50 program and the CAAA's Early Reduction Program prior to MACT for source reduction to be effective.

The Pollution Prevention Act contains new tracking and reporting provisions. These provisions require companies to file a toxic chemical source reduction and resource recycling report file for each used chemical listed under SARA 313 for TRI reporting under the Federal Emergency Planning and Community Right-to-Know Act (EPCRA). These reports, which do not replace SARA Form R, cover information for each reporting year including:

- The amount of the chemical entering the waste stream before recycling, treatment, or disposal
- The amount of the chemical that is recycled, the recycling method used, and the percentage change from the previous year
- The source reduction practice used for the chemical
- The amount of the chemical that the company expects to report for the two following calendar years
- A ratio of the current to the previous year's chemical production
- Techniques used to identify source reduction opportunities
- Any catastrophic releases
- The amount of the chemical that is treated onsite or offsite
- Optional information about source reduction, recycling, and other pollution control methods used in previous years

In addition, the appropriate state environmental protection agency should be contacted for detailed information on reporting requirements, including the pollution prevention plan (PPP) and PPP summary.

—David H.F. Liu

## 3.2 POLLUTION PREVENTION METHODOLOGY

In recent years, several waste reduction methodologies have been developed in government, industry, and academe. These methodologies prescribe a logical sequence of tasks at all organization levels, from the executive to the process area. Despite differences in emphasis and perspective, most stepwise methodologies share the following four common elements:

A *chartering phase*, in which an organization affirms its commitment to a waste reduction program; articulates policies, goals, and plans; and identifies program participants

An *assessment phase*, in which teams collect data, generate and evaluate options for waste reduction, and select options for implementation

An *implementation phase*, in which waste reduction projects are approved, funded, and initiated

An *ongoing auditing function*, in which waste reduction programs are monitored and reductions are measured. Usually feedback from the auditing function triggers a new iteration of the program.

### Model Methodologies

The EPA and the Chemical Manufacturers' Association have published their pollution prevention methodologies. These methodologies provide a model for companies to use in developing methodologies.

### EPA METHODOLOGY

The recent publication of the U.S. EPA's *Facility pollution prevention guide* (1992) represents a major upgrade to their methodology (see Figure 3.2.1). It places additional emphasis on the management of a continuous waste reduction program. For example, the single chartering step prescribed in the previous manual (U.S. EPA, 1988) was expanded to four iteration steps in the new guide. Also, where auditing was a constituent task of implementation in the previous manual, the new guide presents it as a discrete, ongoing step. The guide's inclusion of "maintain a pollution prevention program" as part of the methodology is also new.

The methodology prescribed in the new guide is a major step forward. The previous manual correctly assumed that assessments are the basis of a waste reduction program. However, the new methodology increases the likelihood that assessment is performed because it prescribes waste reduction roles at all levels of the organization.

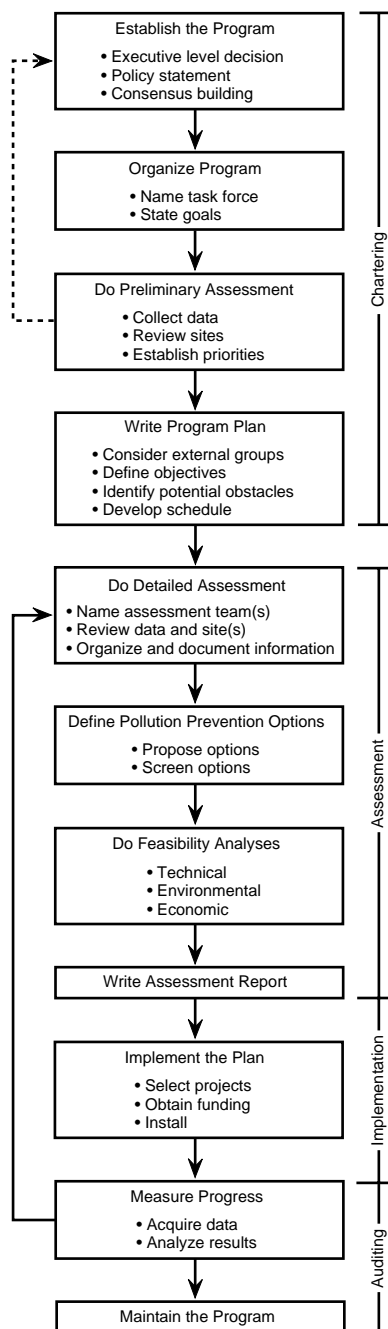

FIG. 3.2.1 EPA pollution prevention methodology. Chartering, assessment, implementation, and auditing elements are common to most methodologies.

## RESPONSIBLE CARE

The Chemical Manufacturers' Association (CMA) (1991) has published its *Responsible Care Code*, to which all member organizations have committed. The codes aim to improve the chemical industry's management of chemicals, safety, health, and environmental performance.

Figure 3.2.2 presents the responsible care codes for pollution prevention. The codes do not constitute a methodology in that they do not prescribe how any organization implements them. Rather, they describe hallmarks that successful pollution prevention programs share. The codes also provide a series of checkpoints for an organization to incorporate into its methodology.

## Determinants of Success

Today most corporations are committed to pollution prevention programs. Any lack of progress that exists represents the failure of a methodology to transfer corporate commitment into implementation at the production area. Area managers must meet multiple demands with limited amounts of time, people, and capital. Pollution prevention often competes for priority with ongoing demands of production, safety, maintenance, and employee relations. These competing demands for the area manager's attention present barriers to pollution prevention. A pollution prevention methodology can overcome these barriers in two ways:

By providing corporate enablers for the production areas  
By providing production areas with a set of tools to simplify and shorten the assessment phase

Pollution prevention policies are effective when they are developed to mesh with the firm's overall programs (Hamner 1993). Total quality management (TQM) complements and aids pollution prevention. In many aspects, the goals of safety and pollution prevention are compatible. However, some aspects, such as lengthened operating cycles to reduce waste generation, increase the likelihood of accidents. The optimal pollution prevention program requires balancing these two potentially contradictory requirements.

## CORPORATE ENABLERS

The output of the chartering step performed at the executive level can be viewed as a set of enablers designed to assist waste reduction at the process level. Enablers consist of both positive and negative inducements to reduce waste. They take a variety of forms, including the following:

- Policy statements and goals
- Capital for waste reduction projects
- People resources
- Training

<p><b>Code 1</b> A clear commitment by senior management through policy, communications, and resources to ongoing reductions at each of the company's facilities in releases to air, water, and land.</p>
<p><b>Code 2</b> A quantitative inventory at each facility of wastes generated and released to the air, water, and land measured or estimated at the point of generation or release.</p>
<p><b>Code 3</b> Evaluation, sufficient to assist in establishing reduction priorities, of the potential impact of releases on the environment and the health and safety of employees and the public.</p>
<p><b>Code 4</b> Education of and dialog with employees and members of the public about the inventory, impact evaluation, and risks to the community.</p>
<p><b>Code 5</b> Establishment of priorities, goals, and plans for waste and release reduction, taking into account both community concerns and the potential safety, health, and environmental impacts as determined under Codes 3 and 4.</p>
<p><b>Code 6</b> Ongoing reduction of wastes and releases, giving preference first to source reduction, second to recycling and reuse, and third to treatment.</p>
<p><b>Code 7</b> Measure progress at each facility in reducing the generation of wastes and in reducing releases to the air, water, and land by updating the quantitative inventory at least annually.</p>
<p><b>Code 8</b> Ongoing dialog with employees and members of the public regarding waste and release information, progress in achieving reductions, and future plans. This dialog should be at a personal, face-to-face level, where possible, and should emphasize listening to others and discussing their concerns and ideas.</p>
<p><b>Code 9</b> Inclusion of waste and release prevention objectives in research and in the design of new or modified facilities, processes, or products.</p>
<p><b>Code 10</b> An ongoing program for promotion and support of waste and release reduction by others.</p>
<p><b>Code 11</b> Periodic evaluation of waste management practices associated with operations and equipment at each member company facility, taking into account community concerns and health, safety, and environmental impacts, and implement ongoing improvements.</p>
<p><b>Code 12</b> Implementation of a process for selecting, retaining, and reviewing contractors and toll manufacturers, that takes into account sound waste management practices that protect the environment and the health and safety of employees and the public.</p>
<p><b>Code 13</b> Implementation of engineering and operating controls at each member company facility to improve prevention of and early detection of releases that may contaminate groundwater.</p>
<p><b>Code 14</b> Implementation of an ongoing program for addressing past operating and waste management practices and for working with others to resolve identified problems at each active or inactive facility owned by a member company taking into account community concerns and health, safety, and environmental impacts.</p>

FIG. 3.2.2 Responsible care codes for pollution prevention.

- Project accounting methods that favor waste reduction
- Awards and other forms of recognition
- Newsletters and other forms of communication
- Personnel evaluations based in part on progress in meeting waste reduction goals
- Requirements for incorporating waste reduction goals into business plans

Corporate managers can choose enablers to overcome barriers at the plant level.

## ASSESSMENT TOOLS

The procedures that a methodology recommends for performing assessment activities are assessment tools. For example, the weighted-sum method of rating is a tool for prioritizing a list of waste reduction implementations. Alternative tools include simple voting or assigning options to each category as do-now or do-later. An effective methodology avoids presenting a single tool for performing an assessment activity. Providing multiple tools from which a production area can choose imparts flexibility to a methodology and makes it suitable for a variety of processes and waste streams.

## Project Methodology

Proactive area managers need not wait for direction from the top to begin reducing waste. Each area can make its own commitment to waste reduction and develop its own vision of a waste-free process. Thus, chartering can occur at the area level. Establishing an area waste reduction program provides a degree of independence that can help bridge the differences between corporate commitment and implementation at the process area. Figure 3.2.3 is an example of what such a program may look like.

Some suggestions for enhancing the effectiveness of the program follow (Trebilcock, Finkle, and DiJulia 1993; Rittmeyer 1991).

## Chartering Activities

Selecting the waste streams for assessment is the first step in chartering a waste reduction program. This step is sometimes done at a high organizational level. Program planners should gather the minimum amount of data required to make their selections and use the fastest method possible to prioritize them. Methods such as weighted-sum ranking and weighting are not necessary for streams produced by a single area.

Other tools for prioritizing a waste stream can be considered. For example, Pareto diagrams are a simple way to rank waste streams by volume. Smaller waste volumes can be given high priority if they are toxic or if regulatory imperatives are anticipated. A Pareto analysis of a typical

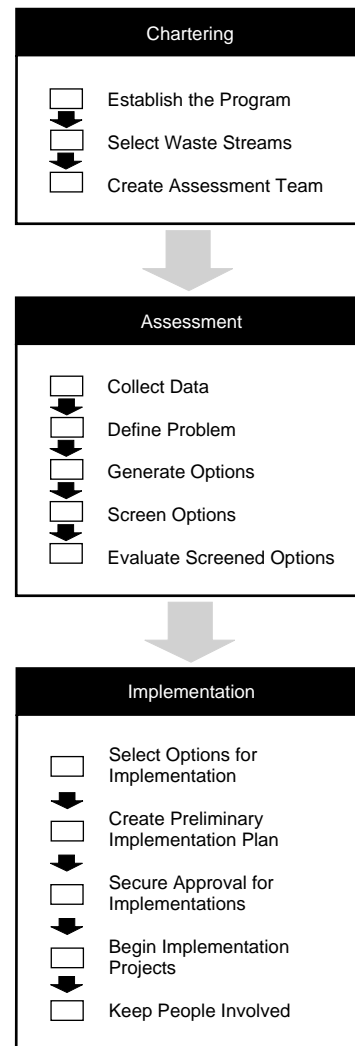

FIG. 3.2.3 A pollution prevention methodology for the production area.

chemical plant is likely to show that the top 20% of the waste stream accounts for more than 80% of the total waste volume.

In addition to selecting the major waste streams, planners should select a few small, easily reduced streams to reinforce the program with quick success.

## Assessment Phase

Some general observations from the assessment phase follow.

An assessment should be quick, uncomplicated, and structured to suit local conditions. Otherwise, it is viewed as an annoyance intruding on the day-to-day concern of running a production process.

Assessment teams should be small, about six to eight people, to encourage open discussion when options are generated.

Including at least one line worker on an assessment team provides insight into how the process operates.

Including at least one person from outside the process on an assessment team provides a fresh perspective.

Area inspections and brainstorming meetings are valuable tools during the assessment phase.

Determining the source of the waste stream, as opposed to the equipment that emits it, is important before the option generation step.

Overly structured methods of screening options do not overcome group biases and are regarded as time-wasters by most teams.

Particularly helpful is the inclusion of people from outside the process on each assessment team. Outsiders provide an objective view. Their presence promotes creative thinking because they do not know the process well enough to be bound by conventions. Appointing outsiders as the assessment team leaders can capitalize on the fresh perspectives they provide.

The following is a task-by-task analysis of the assessment phase of a project (Trebilcock, Finkle, and DiJulia 1993).

## DATA COLLECTION

Assessment teams should not collect exhaustive documentation, most of which is marginally useful. Material balances and process diagrams are minimum requirements, but many assessments require little more than that.

For each assessment, some combination of the following information is useful during the assessment phase:

- Operating procedures
- Flow rates
- Batch sizes
- Waste concentrations within streams
- Raw materials and finished product specifications
- Information about laboratory experiments or plant trials.

The project team may want to obtain or generate a material balance before the area inspection. The material balance is the most useful piece of documentation. In most cases, having sufficient data to compile a material balance is all that is required for an assessment. [Table 3.2.1](#) lists the potential sources of material balance information.

Energy balances are not considered useful because of their bias in the waste stream selection. Energy consumption is rated low as a criterion for selecting streams, and few of the options generated during an assessment have a significant impact on energy consumption. However, energy costs are included in the calculations for economic feasibility. Similarly, water balances are not considered useful, but water costs are included in the calculations for economic feasibility.

**TABLE 3.2.1 SOURCES OF MATERIAL BALANCE INFORMATION**

---

Samples, analyses, and flow measurements of feed stocks, products, and waste streams
Raw material purchase records
Material inventories
Emission inventories
Equipment cleaning and validation procedures
Batch make-up records
Product specifications
Design material balances
Production records
Operating logs
Standard operating procedures and operating manuals
Waste manifests

---

## AREA INSPECTION

An area inspection is a useful team-building exercise and provides team members with a common ground in the process. Without an inspection, outside participants may have trouble understanding discussions during subsequent brainstorming.

## PROBLEM DEFINITION

The sources and causes of waste generation should be well understood before option generation begins. A preassessment area inspection helps an assessment team understand the processes that generate pollution. [Table 3.2.2](#) presents guidelines for such a site inspection. The assessment team should follow the process from the point where raw material enters the area to the point where the products and waste leave the area.

Determining the true source of the waste stream before the option generation part of the assessment phase is important. Impurities from an upstream process, poor process control, and other factors may combine to contribute to waste. Unless these sources are identified and their relative importance established, option generation can focus on a piece of equipment that emits the waste stream and may only produce a small part of the waste. As [Figure 3.2.4](#) shows, the waste stream has four sources. Two of these sources are responsible for about 97% of the waste. However, because these sources were not identified beforehand, roughly equal numbers of options address all four sources. Fortunately, the causes of the waste stream were understood before the assessment was complete. But knowing the major sources of the waste beforehand would have saved time by allowing members to concentrate on them.

Several tools can help identify the source of the waste. A material balance is a good starting point. A cause-and-effect fishbone diagram, such as shown in [Figure 3.2.4](#), can identify the sources of the waste and indicate where to look for reductions. Sampling to identify components

**TABLE 3.2.2 GUIDELINES FOR SITE INSPECTION**

- Prepare an agenda in advance that covers all points that require clarification. Provide staff contacts in the area being assessed with the agenda several days before the inspection.
- Schedule the inspection to coincide with the operation of interest (e.g., make-up chemical addition, bath sampling, bath dumping, start up, and shutdown)
- Monitor the operation at different times during the shift, and, if needed, during all three shifts, especially when waste generation highly depends on human involvement (e.g., in painting or parts cleaning operations).
- Interview the operators, shift supervisors, and foremen in the assessed area. Do not hesitate to question more than one person if an answer is not forthcoming. Assess the operators' and their supervisors' awareness of the waste generation aspects of the operation. Note their familiarity (or lack of) with the impacts their operation may have on other operations.
- Photograph the area of interest, if warranted. Photographs are valuable in the absence of plant layout drawings. Many details are captured in photographs that otherwise may be forgotten or inaccurately recalled.
- Observe the housekeeping aspects of the operation. Check for signs of spills or leaks. Visit the maintenance shop and ask about any problems in keeping the equipment leak-free. Assess the overall cleanliness of the site. Pay attention to odors and fumes.
- Assess the organizational structure and level of coordination of environmental activities between various departments.
- Assess administrative controls, such as cost accounting procedures, material purchasing procedures, and waste collection procedures.

of the waste stream can provide clues to their sources. Control charts, histograms, and scatter diagrams can depict fluctuations in waste stream components and thus provide more clues.

### OPTIONS GENERATION

For all but the most obvious waste problems, brainstorming is the best tool for generating waste reduction options. The best format for these meetings is to freely col-

**FIG. 3.2.4** Sources of waste.

lect ideas and avoid discussing them beyond what is necessary to understand them. Team members are encouraged to suggest ideas regardless of their practicality. Scribes capture suggestions and record them on cause-and-effect fishbone charts. The fishbone charts enable grouping options into categories such as chemistry, equipment modification, and new technology.

Identifying potential options relies on both the expertise and creativity of the team members. Much of the requisite knowledge comes from members' education and on-the-job experience. However, the use of technical literature, contacts, and other information sources is helpful. Table 3.2.3 lists some sources of background information for waste minimization techniques.

### OPTIONS SCREENING

The EPA methodology offers several tools for screening options which vary in complexity from simple voting by the assessment team to more rigorous weighted-sum ranking and weighting.

**TABLE 3.2.3 SOURCES OF BACKGROUND INFORMATION ON WASTE MINIMIZATION OPTIONS**

#### *Trade associations*

As part of their overall function to assist companies within their industry, trade associations generally provide assistance and information about environmental regulations and various available techniques for complying with these regulations. The information provided is especially valuable since it is industry-specific.

#### *Plant engineers and operators*

The employees that are intimately familiar with a facility's operations are often the best source of suggestions for potential waste minimization options.

#### *Published literature*

Technical magazines, trade journals, government reports, and research briefs often contain information that can be used as waste minimization options.

#### *State and local environmental agencies*

A number of state and local agencies have or are developing programs that include technical assistance, information on industry-specific waste minimization techniques, and compiled bibliographies.

#### *Equipment vendors*

Meetings with equipment vendors, as well as vendor literature, are useful in identifying potential equipment-oriented options. Vendors are eager to assist companies in implementing projects. However, this information may be biased since the vendor's job is to sell equipment.

#### *Consultants*

Consultants can provide information about waste minimization techniques. A consultant with waste minimization experience in a particular industry is valuable.

In assessments using the weighted-sum method, follow-up meetings are held after brainstorming sessions. The meetings begin with an open discussion of the options. Sometimes, a team concludes that an option does not really reduce waste and removes it from the list. At other times, the team combines interdependent options into a single option or subdivides general options into more specific options.

After the team agrees on the final option list, they generate a set of criteria to evaluate the options. When the criteria are adopted, the team assigns each one a weight, usually between 0 and 10, to signify its relative importance. If the team feels that a criterion is not an important process or is adequately covered by another criterion, they can assign it a value of 0, essentially removing the criterion from the list.

After the weights are established, the team rates each option with a number from 0 to 10 according to how well it fulfills each criterion. Multiplying the weight by the rating provides a score for that criterion; the sum of all scores for all criteria yields the option's overall score.

The weighted-sum method has some potential pitfalls. An option can rank near the top of the list because it scores high in every criteria except probability of success or safety. However, an unsatisfactory score of these two criteria is enough to reject an option regardless of its other merits. High scores achieved by some impractical options probably indicate that the assessment team has used too many weighted criteria.

Another problem with ranking and weighting is that many options cannot be evaluated quickly. Some options must be better defined or require laboratory analysis, making ranking them at a meeting difficult.

Weighting and ranking meetings are not entirely fruitless. Often discussions about an option provide a basis for determining its technical and environmental feasibility.

One of the simpler tools offered by the EPA is to classify options into three categories: implement immediately, marginal or impractical, and more study required.

Other tools can be used to quickly screen options. These include cost-benefits analysis, simple voting, and listing options' pros and cons.

## FEASIBILITY ANALYSIS OR OPTION EVALUATION

The most difficult part of the feasibility evaluation is the economic analysis. This analysis requires estimating equipment costs, installation costs, the amount of waste reduction, cost saving to the process, and economic return.

For projects with significant capital costs, a more detailed profitability analysis is necessary. The three standard profitability measures are:

- Payback period
- Net present value (NPV)
- Internal rate of return (IRR)

The payback period is the amount of time needed to recover the initial cash outlay on the project. Payback periods in the range of three to four years are usually acceptable for a low-risk investment. This method is recommended for quick assessment of profitability.

The NPV and IRR are both discounted cash flow techniques for determining profitability. Many companies use these methods to rank capital projects that are competing for funds. Capital funding for a project may hinge on the ability of the project to generate positive cash flows well beyond the payback period and realize an acceptable return on investment. Both the NPV and IRR methods recognize the time value of money by discounting future net cash flows. For an investment with a low-risk level, an after-tax IRR of 12 to 15% is typically acceptable.

Most spreadsheet programs for personal computers automatically calculate the IRR and NPV for a series of cash flows. More information on determining the IRR or NPV is available in any financial management, cost accounting, or engineering economics text.

When the NPV is calculated, the waste reduction benefits are not the only benefits. Most good options offer other benefits such as improved quality, reduced cycle times, increased productivity, and reduced compliance costs (see [Table 3.2.4](#)). The value of these additional benefits is often more than the value derived from reducing waste.

## Implementation Phase

Waste reduction options that involve operational, procedural, or material changes (without additions or modifications to equipment) should be implemented as soon as the potential savings have been determined.

Some implementations consist of stepwise changes to the process, each incrementally reducing the amount of waste. Such changes can often be made without large capital expenditures and can be accomplished quickly. This approach is common in waste reduction. When expenditures are small, facilities are willing to make the changes without extensive study and testing. Several iterations of incremental improvement are often sufficient to eliminate the waste stream. Other implementations require large capital expenditures, laboratory testing, piloting, allocating resources, capital, installation, and testing.

Implementation resources should be selected that are as close to the process as possible. Engineers should not do what empowered personnel can do. External resources should not be solicited for a job that an area person can handle. A well-motivated facility can be self-reliant.

## AUDITING

Measuring the success of each implementation is important feedback for future iterations of the pollution prevention program. Waste streams are eliminated not by a

**TABLE 3.2.4 OPERATING COSTS AND SAVINGS ASSOCIATED WITH WASTE MINIMIZATION PROJECTS**

**Reduced waste management costs**

This reduction includes reductions in costs for:  
 Offsite treatment, storage, and disposal fees  
 State fees and taxes on hazardous waste generators  
 Transportation costs  
 Onsite treatment, storage, and handling costs  
 Permitting, reporting, and recordkeeping costs

**Input material cost savings**

An option that reduces waste usually decreases the demand for input materials.

**Insurance and liability savings**

A waste minimization option can be significant enough to reduce a company's insurance payments. It can also lower a company's potential liability associated with remedial clean-up of treatment, storage, and disposal facilities (TSDFs) and workplace safety. (The magnitude of liability savings is difficult to determine).

**Changes in costs associated with quality**

A waste minimization option may have a positive or negative effect on product quality. This effect can result in higher (or lower) costs for rework, scrap, or quality control functions.

**Changes in utility costs**

Utility costs may increase or decrease. This cost includes steam, electricity, process and cooling water, plant air, refrigeration, or inert gas.

**Changes in operating and maintenance labor, burden, and benefits**

An option can either increase or decrease labor requirements. This change may be reflected in changes in overtime hours or in changes in the number of employees. When direct labor costs change, the burden and benefit costs also change. In large projects, supervision costs also change.

**Changes in operating and maintenance supplies**

An option can increase or decrease the use of operating and maintenance supplies.

**Changes in overhead costs**

Large waste minimization projects can affect a facility's overhead costs.

**Changes in revenues from increased (or decreased) production**

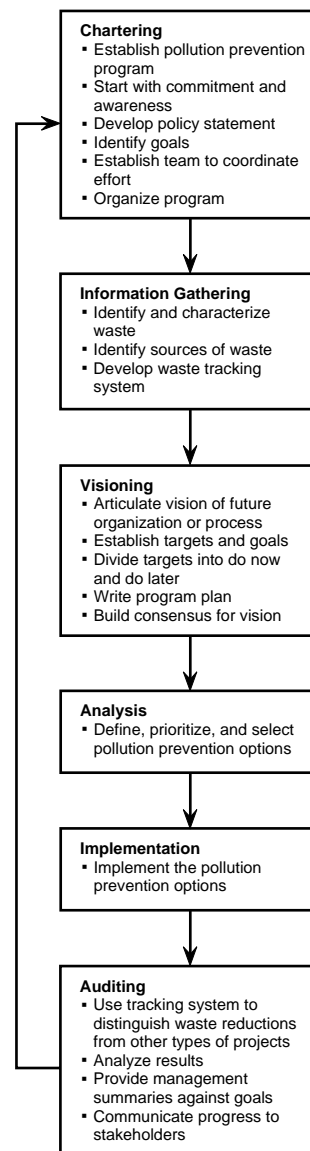

An option can result in an increase in the productivity of a unit. This increase results in a change in revenues. (Note that operating costs can also change accordingly.)

**Increased revenues from by-products**

A waste minimization option may produce a by-product that can be sold to a recycler or sold to another company as a raw material. This sale increases the company's revenues.

single, dramatic implementation, but by a series of small improvements implemented over time. Therefore, the last step is to renew the program.

Waste assessment should be documented as simply as possible. Capturing waste reduction ideas that were proposed and rejected may be useful in future iterations of the program. However, writing reports is not necessary.

**FIG. 3.2.5** Upgraded methodology.

Meeting minutes and worksheets used for analyses can be structured in such a way that merely collecting them in a folder is enough documentation.

**METHODOLOGY UPGRADE**

The EPA methodology has evolved from a method for conducting assessments to a comprehensive pollution prevention program. It will probably evolve again as experience with its application grows. Joint projects between the EPA and industry, such as the Chambers Works Project (U.S. EPA 1993), provide input to future iterations. The EPA is well-placed to develop an industry standard for pollution prevention methodologies.

An important strength of the current methodology is its recognition that pollution prevention requires participation from all levels of an organization. It contains well-articulated prescriptions about management commitment.

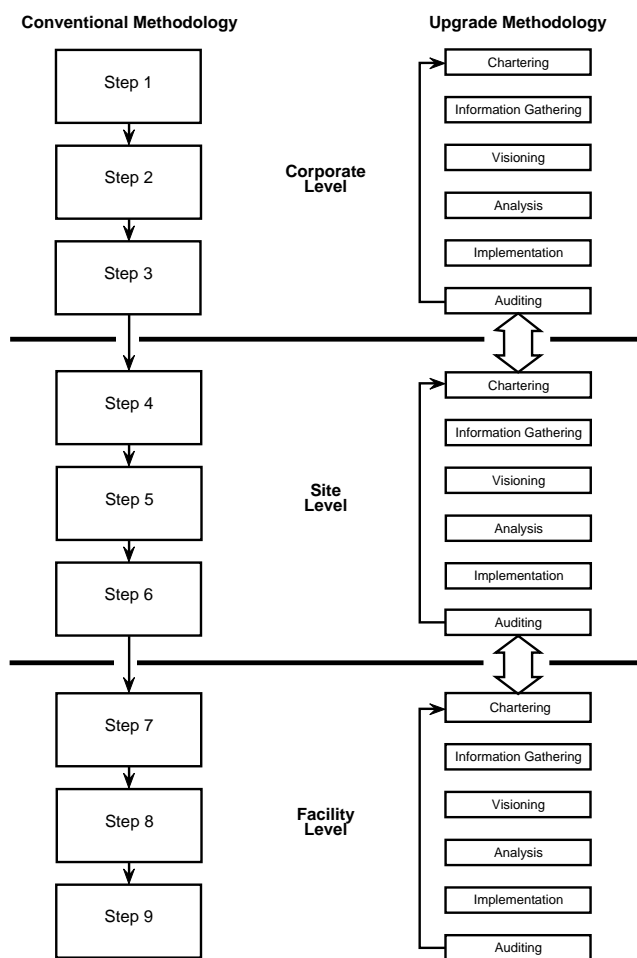

FIG. 3.2.6 Comparison of conventional and upgraded methodologies.

Figure 3.2.5 shows a suggested methodology update (U.S. EPA 1993). One unique feature is that all steps must be performed at all organization levels. This concept is illustrated in Figure 3.2.6. Most methodologies consist of a series of steps: the first few of which are performed at the highest organization levels, and the last of which are performed at the line organization. However, the new methodology prescribes that each step of the plan be performed at each level of the organization.

The activities recommended for each step consider the limited time and resources available for pollution prevention. Instead of prescribing “how-tos”, the methodology provides a variety of tools from which local sites can choose. The hope is that waste reduction opportunities can be identified quickly, leaving more time for people to perform the implementations that actually reduce waste.

## 3.3 POLLUTION PREVENTION TECHNIQUES

In the current working definition used by the EPA, source reduction and recycling are considered the most viable pollution prevention techniques, preceding treatment and disposal. A detailed flow diagram, providing an in-depth approach to pollution prevention, is shown in Figure 3.3.1.

Of the two approaches, source reduction is usually preferable to recycling from an environmental perspective. Source reduction and recycling are comprised of a number of practices and approaches which are shown in Figure 3.3.2.

A pollution prevention assessment involves three main steps as shown in Figure 3.3.3. This section focuses on defining the problem and developing pollution prevention strategies.

### Defining the Problem

Unlike other field assessments, the pollution prevention assessment focuses on determining the reasons for releases and discharges to all environmental media. These reasons

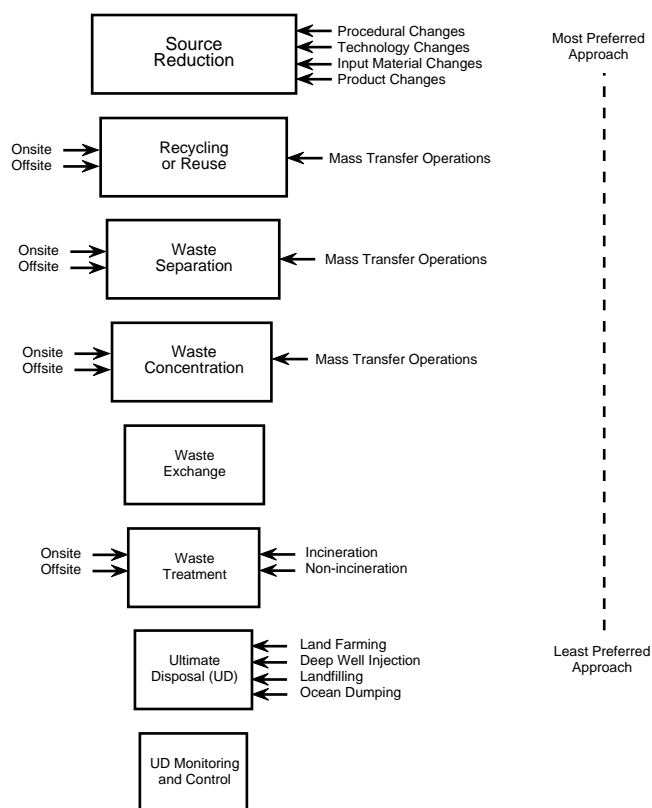

FIG. 3.3.1 Pollution prevention hierarchy.

can be identified based on the premise that the generation of emissions and waste follow recurring patterns independent of the manufacturing process (Chadha and Parmele, 1993).

Emissions and waste are generated due to process chemistry, engineering design, operating practices, or maintenance procedures. Classifying the causes into these four generic categories provides a simple but structured framework for developing pollution prevention solutions.

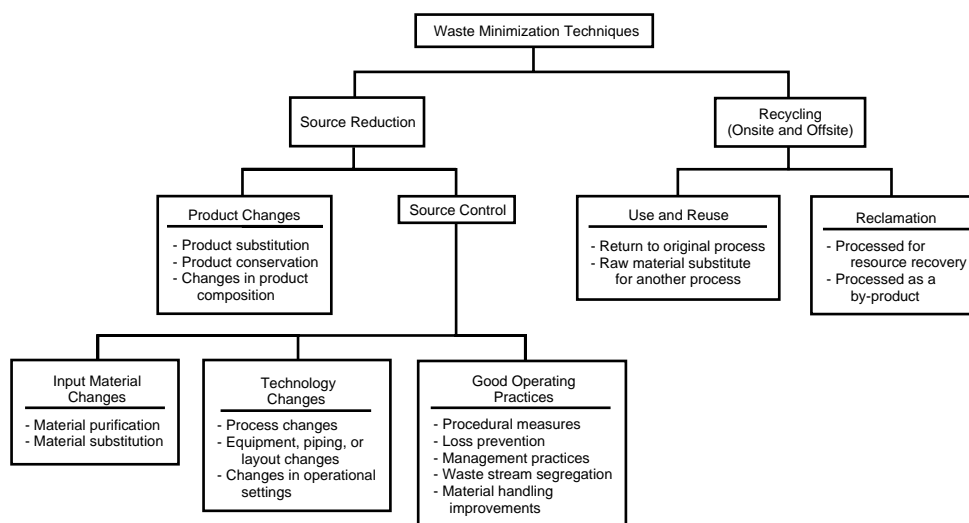

FIG. 3.3.2 Waste minimization techniques.

Data gathering, area inspections, and tools for identifying the source of waste are discussed in Section 3.2. In addition to the main chemical processing unit, the assessment team should also investigate the storage and handling of raw materials, solvent recovery, wastewater treatment, and other auxiliary units within the plant.

For many continuous processes, the source of an emission or waste may be an upstream unit operation, and a detailed investigation of the overall process scheme is necessary.

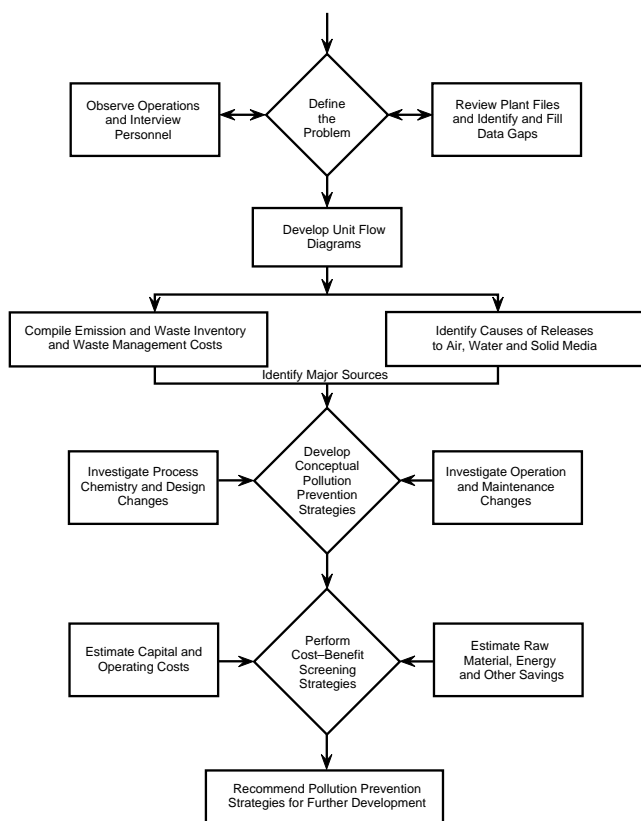

For example, impurities may be purged from a distillation column because of the quality of the raw materials used or undesirable products generated in upstream reaction steps.

Similarly, identifying and understanding the fundamental reasons for waste generation from a batch process requires evaluating all batch processing steps and product campaigns. This evaluation is especially important since batch operations typically generate emissions of varying characteristics on an intermittent basis.

Start up and shutdown and equipment cleaning and washing often play a key part in generating emissions waste, especially for batch processes. The related operations must be carefully observed and evaluated during problem analysis activities.

Emission sources and operations associated with batch processes are not always obvious and must be identified with the use of generic emission-generation mechanisms. In general, emissions are generated when a noncondensable such as nitrogen or air contacts a volatile organic compound (VOC) or when uncondensed material leaves a process.

Thus, for batch processes involving VOCs, processing steps such as charging the raw material powders, pressure transfer of the vessel's contents with nitrogen, solvent cleaning of the vessel's contents with nitrogen, and solvent cleaning of the vessels between batches should be closely

**FIG. 3.3.3** Methodology for multimedia pollution prevention assessments. (Reprinted, with permission, from N. Chadha, 1994, Develop multimedia pollution prevention strategies, *Chem. Eng. Progress* [November].)

observed. The operator may leave charging manholes open for a long period or use vessel cleaning procedures different from written procedures (if any), which can increase the generation of emissions and waste. The field inspection may also reveal in-plant modifications such as piping bypasses that are not reflected in the site drawings and should be assessed otherwise.

The unit flow diagram (UFD) shown in Figure 3.3.4 is a convenient way to represent the material conversion relationships between raw materials, solvents, products, by-products, and all environmental discharges. The UFD is a tool that systematically performs a unit-by-unit assessment of an entire production process from the perspective of discharges to sewers and vents. This visual summary focuses on major releases and discharges and prioritizes a facility's subsequent pollution prevention activities.

## Developing Conceptual Strategies

The next step is to develop conceptual strategies that specifically match the causes of emissions and waste generation. Addressing the fundamental causes helps to develop long-term solutions rather than simply addressing the symptoms.

A simple tool for brainstorming ideas and developing options is to use checklists based on practical experience. Tables 3.3.1 to 3.3.4 list 100 pollution prevention strategies based on changes in engineering design, process chemistry, operating procedures, and maintenance practices. These tables are based on the experiences of Chadha (1994), Chadha and Parmele (1993), Freeman (1989), Nelson (1989), and the U.S. EPA (1992) and are not comprehensive. The variety of technical areas covered by these checklists emphasizes the importance of a multimedia, multidisciplinary approach to pollution prevention.

## Source Reduction

Source reduction techniques include process chemistry modifications, engineering design modifications, vent condenser modifications, reducing nitrogen usage, additional automation, and operational modifications.

## PROCESS CHEMISTRY MODIFICATIONS

In some cases, the reasons for emissions are related to process chemistry, such as the reaction stoichiometry, kinetics, conversion, or yields. Emission generation is minimized by strategies varying from simply adjusting the order in which reactants are added to major changes that require significant process development work and capital expenditures.

### Changing the Order of Reactant Additions

A pharmaceutical plant made process chemistry modifications to minimize the emissions of an undesirable by-product, isobutylene, from a mature synthesis process. The process consisted of four batch operations (see Figure 3.3.5). Emissions of isobutylene were reduced when the process conditions that led to its formation in the third step of the process were identified.

In the first reaction of the process, tertiary butyl alcohol (TBA) was used to temporarily block a reactive site on the primary molecule. After the second reaction was complete, TBA was removed as tertiary butyl chloride (TBC) by hydrolysis with hydrochloric acid. To improve process economics, the final step involved the recovery of TBA by reacting TBC with sodium hydroxide. However, TBA recovery was incomplete because isobutylene was inadvertently formed during the TBA recovery step.

An investigation indicated that the addition of excess NaOH caused alkaline conditions in the reactor that favored the formation of isobutylene over TBA. When the order of adding the NaOH and TBC was reversed and the NaOH addition rate was controlled to maintain the pH between 1 and 2, the isobutylene formation was almost completely eliminated. Therefore, installing add-on emission controls was unnecessary, and the only capital expense was the installation of a pH control loop.

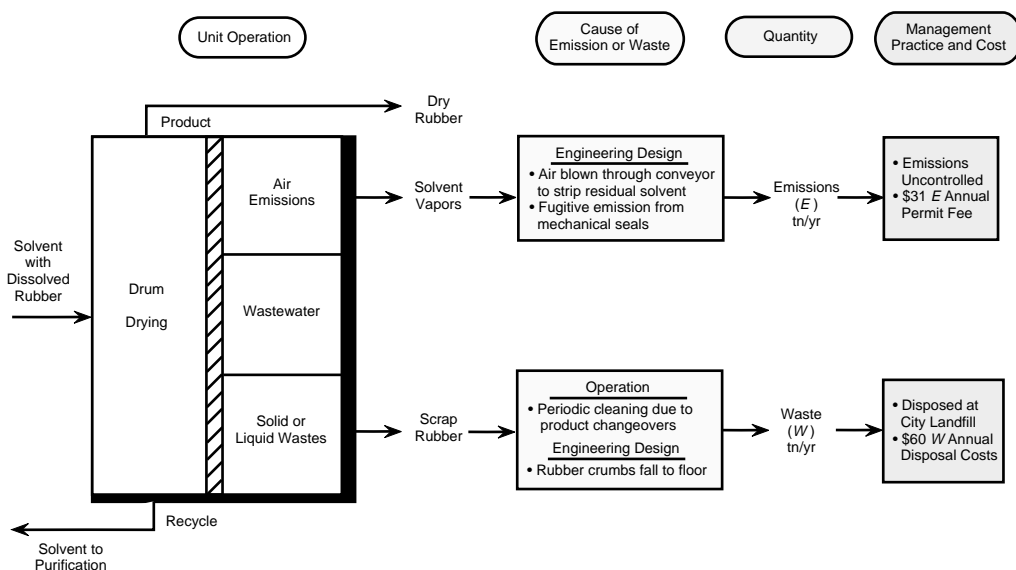

FIG. 3.3.4 Typical unit flow diagram for multimedia pollution prevention assessments. (Reprinted, with permission, from Chadha 1994.)

## Changing the Chemistry

In one plant, odorous emissions were observed for several years near a drum dryer line used for volatilizing an organic solvent from a reaction mixture. Although two dryer-product lines existed, the odors were observed only near one line.

The analysis and field testing indicated that the chemical compounds causing the odors were produced in upstream unit operations due to the hydrolysis of a chemical additive used in the process. The hydrolysis products were stripped out of the solution by the process solvent and appeared as odorous fumes at the dryer. Conditions for hydrolysis were favorable at upstream locations because of temperature and acidity conditions and the residence time available in the process. Also, the water for the hydrolysis was provided by another water-based chemical additive used in the dryer line that had the odor problem.

Because the cause of the odorous emission was the process chemistry, the plant had to evaluate ways to minimize hydrolysis and the resulting formation of odorous products. Ventilation modifications to mitigate the odor levels would not be a long-term solution to the odor problem.

## ENGINEERING DESIGN MODIFICATIONS

Emissions can be caused by equipment operating above its design capacity, pressure and temperature conditions, improper process controls, or faulty instrumentation. Strategies vary from troubleshooting and clearing obstructed equipment to designing and installing new hardware.

## Vent Condenser Modifications

In some plants, vent condensers are significant emission sources because of one or more of the following conditions:

Field modifications bypass vent condensers, but the associated changes are not documented in the engineering drawings.

The vent stream is too dilute to condense because of changes in process conditions.

The condenser is overloaded (e.g., the heat-transfer area is inadequate) due to gradual increases in production capacity over time.

The overall heat-transfer coefficient is much lower than design because of fouling by dirty components or condenser flooding with large quantities of noncondensable nitrogen gas.

The condenser's cooling capacity is limited by improper control schemes. In one case, only the coolant return temperature was controlled.

In each case, design modifications are needed to reduce emissions.

## REDUCING NITROGEN USAGE

Identifying ways to reduce nitrogen usage helps to minimize solvent emissions from a process. For example, every 1000 cu ft of nitrogen vents approximately 970 lb of methylene chloride with it at 20°C and 132 lb of methylene chloride with it at -10°C. The problem is aggravated if fine mists or aerosols are created due to pressure transfer or entrainment and the nitrogen becomes supersaturated with the solvent.

**TABLE 3.3.1 ENGINEERING DESIGN-BASED POLLUTION PREVENTION STRATEGIES**

---

**Storage and Handling Systems**

- Install geodesic domes for external floating-roof tanks.
- Store VOCs in floating-roof tanks instead of fixed-roof tanks.
- Store VOCs in low-pressure vessels instead of atmospheric storage tanks.
- Use onsite boilers instead of wet scrubbers for air pollution control.
- Select vessels with smooth internals for batch tanks requiring frequent cleaning.
- Install curbs around tank truck unloading racks and other equipment located outdoors.
- Load VOC-containing vessels via dip pipes instead of splash loading.
- Install closed-loop vapor recycling systems for loading and unloading operations.

**Process Equipment**

- Use rotary-vane vacuum pumps instead of steam ejectors.
- Use explosion-proof pumps for transferring VOCs instead of nitrogen or air pressure transfer.
- Install canned or magnetic-drive sealless pumps.
- Install hard-faced double or tandem mechanical seals or flexible face seals.
- Use shell-and-tube heat exchangers instead of barometric condensers.
- Install welded piping instead of flanges and screwed connections.
- Install lining in pipes or use different materials of construction.
- Install removable or reusable insulation instead of fixed insulation.
- Select new design valves that minimize fugitive emissions.
- Use reboilers instead of live steam for providing heat in distillation columns.
- Cool VOC-containing vessels via external jackets instead of direct-contact liquid nitrogen.
- Install high-pressure rotary nozzles inside tanks that require frequent washing.

**Process Controls and Instrumentation**

- Install variable-speed electric motors for agitators and pumps.
- Install automatic high-level shutoffs on storage and process tanks.
- Install advanced process control schemes for key process parameters.
- Install programmable logic controllers to automate batch processes.
- Install instrumentation for inline sampling and analysis.
- Install alarms and other instrumentation to help avoid runaway reactions, trips, and shutdowns.
- Install timers to automatically shut off nitrogen used for blowing VOC-containing lines.

**Recycle and Recovery Equipment**

- Install inplant distillation stills for recycling and reusing solvent.
- Install thin-film evaporators to recover additional product from distillation bottoms and residues.
- Recover volatile organics in steam strippers upstream of wastewater treatment lagoons.
- Selectively recover by-products from waste using solvent extraction, membrane separation, or other operations.
- Install equipment and piping to reuse noncontact cooling water.
- Install new oil-water separation equipment with improved designs.
- Install static mixers upstream of reactor vessels to improve mixing characteristics.
- Use a high-pressure filter press or sludge dryer for reducing the volume of hazardous sludge.
- Use reusable bag filters instead of cartridge filters for liquid streams.

---

*Source:* N. Chadha, 1994, Develop multimedia pollution prevention strategies, *Chem. Eng. Progress* (November).

Some plants can monitor and reduce nitrogen consumption by installing flow rotameters in the nitrogen supply lines to each building. Within each building, simple engineering changes such as installing rotameters, programmable timers, and automatic shutoff valves can minimize solvent emissions.

**ADDITIONAL AUTOMATION**

Sometimes simply adding advanced process control can produce dramatic results. For example, an ion-exchange resin manufacturer improved the particle size uniformity

of resin beads by installing a computerized process control. This improvement reduced the waste of off-spec resins by 40%.

**OPERATIONAL MODIFICATIONS**

Operational factors that impact emissions include the operating rate, scheduling of product campaigns, and the plant's standard operating procedures. Implementing operational modifications often requires the least capital compared to other strategies.

**TABLE 3.3.2 PROCESS CHEMISTRY AND TECHNOLOGY-BASED STRATEGIES**

**Raw Materials**

- Use different types or physical forms of catalysts.
- Use water-based coatings instead of VOC-based coatings.
- Use pure oxygen instead of air for oxidation reactions.
- Use pigments, fluxes, solders, and biocides without heavy metals or other hazardous components.
- Use terpene or citric-acid-based solvents instead of chlorinated or flammable solvents.
- Use supercritical carbon dioxide instead of chlorinated or flammable solvents.
- Use plastic blasting media or dry ice pellets instead of sand blasting.
- Use dry developers instead of wet developers for nondestructive testing.
- Use hot air drying instead of solvent drying for components.
- Use no-clean or low-solids fluxes for soldering applications.

**Plant Unit Operations**

- Optimize the relative location of unit operations within a process.
- Investigate consolidation of unit operations where feasible.
- Optimize existing reactor design based on reaction kinetics, mixing characteristics, and other parameters.
- Investigate reactor design alternatives to the continuously stirred tank reactor.
- Investigate a separate reactor for processing recycling and waste streams.
- Investigate different ways of adding reactants (*e.g.*, slurries versus solid powders).
- Investigate changing the order of adding reaction raw materials.
- Investigate chemical synthesis methods based on renewable resources rather than petrochemical feedstocks.
- Investigate conversion of batch operations to continuous operations.
- Change process conditions and avoid the hydrolysis of raw materials to unwanted by-products.
- Use chemical additives to oxidize odorous compounds.
- Use chemical emulsion breakers to improve organic-water separation in decanters.

Source: Chadha, 1994.

Market-driven product scheduling and inventory considerations often play an important part in the generation of waste and emissions. A computerized material inventory system and other administrative controls can address these constraints. Another common constraint for pollution prevention projects is conformance with product quality and other customer requirements (Chadha 1994).

An example of reducing emissions through operational modifications is a synthetic organic chemical manufacturing industry (SOCMI) plant that wanted to reduce emissions of a cyclohexane solvent from storage and loading and unloading operations. The tank farms had organic liquid storage tanks with both fixed-roof and floating-roof

storage tanks. The major source of cyclohexane emissions was the liquid displacement due to periodic filling of fixed-roof storage tanks. Standard operating procedures were modified so that the fixed-roof storage tanks were always kept full and the cyclohexane liquid volume varied only in the floating-roof tanks. This simple operational modification reduced cyclohexane emissions from the tank farm by more than 20 tn/yr.

Another example is a pharmaceutical manufacturer who wanted to reduce emissions of a methylene chloride solvent from a process consisting of a batch reaction step followed by vacuum distillation to strip off the solvent. The batch distillation involved piping the reactor to a receiver vessel evacuated via a vacuum pump. The following changes were made in the operating procedures to minimize emissions:

The initial methylene chloride charge was added at a reactor temperature of  $-10^{\circ}\text{C}$  rather than at room temperature. Providing cooling on the reactor jacket lowered the methylene chloride vapor pressure and minimized its losses when the reactor hatch was opened for charging solid reactants later in the batch cycle.

The nitrogen purge to the reactor was shut off during the vacuum distillation step. The continuous purge had been overloading the downstream vacuum pump system and was unnecessary because methylene chloride is not flammable. This change reduced losses due to the stripping of methylene chloride from the reaction mix. The temperature of the evacuated receiving vessel was lowered during the vacuum distillation step. Providing maximum cooling on the receiving vessel minimized methylene chloride losses due to revaporization at the lower pressure of the receiving vessel.

Table 3.3.5 shows another checklist that can be integrated into an analysis structured like a hazard and operability (HAZOP) study but focuses on pollution prevention.

## Recycling

Reuse and recycling (waste recovery) can provide a cost-effective waste management approach. This technique can help reduce costs for raw materials and waste disposal and possibly provide income from a salable waste. However, waste recovery should be considered in conjunction with source control options.

Waste reuse and recycling entail one or a combination of the following options:

- Use in a process
- Use in another process
- Processing for reuse
- Use as a fuel
- Exchange or sale

**TABLE 3.3.3 OPERATIONS-BASED POLLUTION PREVENTION STRATEGIES****Inventory Management**

- Implement a computerized raw material inventory tracking system.
- Maintain product inventory to minimize changeovers for batch operations.
- Purchase raw materials in totes and other reusable containers.
- Purchase raw materials with lower impurity levels.
- Practice first-in/first-out inventory control.

**Housekeeping Practices**

- Recycle and reuse wooden pallets used to store drums.
- Implement procedures to segregate solid waste from aqueous discharges.
- Implement procedures to segregate hazardous waste from nonhazardous waste.
- Segregate and weigh waste generated by individual production areas.
- Drain contents of unloading and loading hoses into collection sumps.

**Operating Practices**

- Change filters based on pressure-drop measurements rather than operator preferences.
- Increase relief valve set pressure to avoid premature lifting and loss of vessel contents.
- Optimize reflux ratio for distillation columns to improve separation.
- Optimize batch reaction operating procedures to minimize venting to process flares.
- Optimize electrostatic spray booth coater stroke and processing line speed to conserve coating.
- Implement a nitrogen conservation program for processes that commonly use VOCs.
- Minimize the duration for which charging hatches are opened on VOC-containing vessels.
- Use vent condensers to recover solvents when boiling solvents for vessel cleaning purposes.
- Reduce the number or volume of samples collected for quality control purposes.
- Develop and test new markets for off-spec products and other waste.
- Blend small quantities of off-spec product into the salable product.

**Cleaning Procedures**

- Use mechanical cleaning methods instead of organic solvents.
- Operate solvent baths at lower temperatures and cover when not in use.
- Reduce the depth of the solvent layer used in immersion baths.
- Reduce the frequency of the solvent bath change-out.
- Use deionized water to prepare cleaning and washing solutions.
- Develop written operating procedures for cleaning and washing operations.

*Source:* Chadha, 1994.

The metal finishing industry uses a variety of physical, chemical, and electrochemical processes to clean, etch, and plate metallic and nonmetallic substrates. Chemical and electrochemical processes are performed in numerous chemical baths, which are following by a rinsing operation.

Various techniques for recovering metals and metal salts, such as electrolysis, electrodialysis, and ion exchange, can be used to recycle rinse water in a closed-loop or open-loop system. In a closed-loop system, the treated effluent is returned to the rinse system. In an open-loop, the treated effluent is reused in the rinse system, but the final rinse is accomplished with fresh water. An example of a closed-loop system is shown in [Figure 3.3.6](#).

Due to the cost associated with purchasing virgin solvents and the subsequent disposal of solvent waste, onsite recycling is a favorable option. Recycling back to the generating process is favored for solvents used in large volumes in one or more processes.

Some companies have developed ingenious techniques for recycling waste streams that greatly reduced water consumption and waste regeneration. At a refinery, hydrocarbon-contaminated wastewater and steam condensate are first reused as washwater in compressor aftercoolers to prevent salt buildup. The washwater is then pumped to a fluid catalytic cracker column to absorb ammonium salts from the vapor. The washwater, now laden with phenol, hydrogen sulfide, and ammonia, is pumped to a crude column vapor line, where organics extract the phenol from the wastewater. This step reduces the organic load to the downstream end-of-pipe wastewater treatment process which includes steam stripping and a biological system (Yen 1994).

A general pollution prevention option in the paper and pulp industry is to use closed-cycle mill processes. An example of a closed-cycle bleached kraft pulp mill is shown in [Figure 3.3.7](#). This system is completely closed, and water is added only to the bleached pulp decker or to the last

**TABLE 3.3.4 MAINTENANCE-BASED STRATEGIES**

**Existing Preventive Maintenance (PM) Program**

- Include centrifuges, dryers, and other process equipment in the PM program.
- Include conveyors and other material handling equipment in the PM program.
- Minimize pipe and connector stresses caused by vibration of pumps and compressors.
- Minimize air leaks into VOC-containing equipment operating under vacuum.
- Minimize steam leaks into process equipment.
- Adjust burners to optimize the air-to-fuel ratio.
- Implement a computerized inventory tracking system for maintenance chemicals.
- Use terpene or citric-acid-based maintenance chemicals instead of chlorinated solvents.

**Proactive PM Strategies**

- Monitor fugitive emissions from pumps, valves, agitators, and instrument connections.
- Monitor fouling and leaks in heat exchangers and other process equipment.
- Monitor vibration in rotating machinery.
- Inspect and test interlocks, trips, and alarms.
- Inspect and calibrate pH, flow, temperature, and other process control instruments.
- Inspect and test relief valves and rupture disks for leaks.
- Inspect and periodically replace seals and gaskets.

Source: Chadha, 1994.

dioxide stage washer of the bleach plant. The bleach plant is countercurrent, and a major portion of the filtrate from this plant is recycled to the stock washers, after which it flows to the black liquor evaporators and then to the recovery furnace. The evaporator condensate is steam stripped and used as a major water source at various points in the pulp mill. A white liquor evaporator is used to sep-

**TABLE 3.3.5 EXAMPLE CHECKLIST OF POLLUTION REDUCTION METHODS**

**Material Handling**

- Recycling, in-process or external
- Reuse or alternative use of the waste or chemical
- Change in sources from batch operations (for example, heel reuse, change in bottom design of vessel, vapor space controls, dead-space controls)
- Installation of isolation or containment systems
- Installation of rework systems for treating off-spec materials
- Change in practices for managing residuals (consolidation, recirculation, packaged amounts, reuse and purification)
- Use of practices or equipment leading to segregated material streams
- Recovery or rework of waste streams generated by maintenance or inspection activities

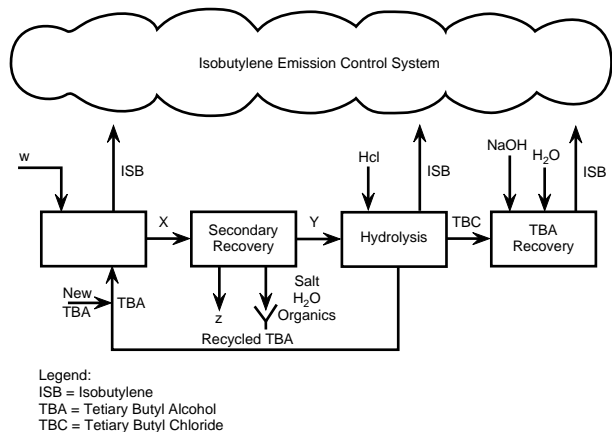

**Chemical or Process Changes**

- Treatment or conversion of the chemical
- Chemical substitution
- Process change via change in thermodynamic parameters (temperature, pressure, chemical concentration, or phase) or installation of phase-separation equipment (such as vapor suppression systems, vessels with reduced vapor spaces, and filtration or extraction equipment)
- Altering line or vessel length or diameter to make changes in the amount of product contained in lines or equipment that are purged
- Installation of recirculation systems for process, water, gas inerting, or discharge streams as a substitute for single-pass streams

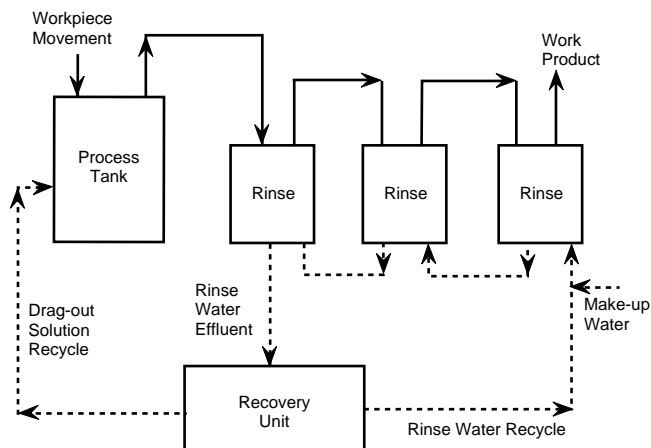

**Time-Related Issues**

- Change in frequency of operation, cleaning, release, or use
- Change in sequence of batch operations

## 3.4 LIFE CYCLE ASSESSMENT (LCA)

Life cycle refers to the cradle-to-grave stages associated with the production, use, and disposal of any product. A complete life cycle assessment (LCA), or ecobalance, consists of three complementary components:

- Inventory analysis, which is a technical, data-based process of quantifying energy and resource use, atmospheric emissions, waterborne emissions, and solid waste
- Impact analysis, which is a technical, quantitative, and qualitative process to characterize and assess the effects

of the resource use and environmental loadings identified in the inventory state

Improvement analysis, which is the evaluation and implementation of opportunities to effect environmental improvement

Scoping is one of the first activities in any LCA and is considered by some as a fourth component. The scoping process links the goal of the analysis with the extent, or scope, of the study (i.e., that will or will not be included).

The following factors should also be considered when the scope is determined: basis, temporal boundaries (time scale), and spatial boundaries (geographic).

## Inventory Analysis

The goal of a life cycle inventory (LCI) is to create a mass balance which accounts for all input and output to the overall system. It emphasizes that changes within the system may result in transferring a pollutant between media or may create upstream or downstream effects.

The LCI is the best understood part of the LCA. The LCA has had substantial methodology development and now most practitioners conduct their analyses in similar ways. The research activities of the EPA's Pollution Research Branch at Cincinnati have resulted in a guidance manual for the LCA (Keoleian, Menerey, and Curran 1993).

The EPA manual presents the following nine steps for performing a comprehensive inventory along with general issues to be addressed:

- Define the purpose
- Define the system boundaries
- Devise a checklist
- Gather data
- Develop stand-alone data
- Construct a model
- Present the results
- Conduct a peer review
- Interpret the results

### DEFINING THE PURPOSE

The decision to perform an LCI is usually based on one or more of the following objectives:

To establish a baseline of information on a system's overall resource use, energy consumption, and environmental loading

To identify the stages within the life cycle of a product or process where a reduction in resource use and emissions can be achieved

To compare the system's input and output associated with alternative products, processes, or activities

To guide the development of new products, processes, or activities toward a net reduction of resource requirements and emissions

To identify areas to be addressed during life cycle impact analysis.

### SYSTEM BOUNDARIES

Once the purposes for preparing an LCI are determined, the analyst should specifically define the system. (A *system* is a collection of operations that together perform some clearly defined functions.) In defining the system, the

analysts must first set the system boundaries. A complete LCI sets the boundaries of the total system broadly to quantify resources, energy use, and environmental releases throughout the entire cycle of a product or process, as shown in Figure 3.4.1. For example, the three steps of manufacturing are shown in Figure 3.4.2.

As shown in Figure 3.4.1, a life cycle comprises the four stages described next.

### Raw Materials Acquisition Stage

This stage includes all activities required to gather or obtain raw materials or energy sources from the earth. This stage includes transporting the raw materials to the point of manufacture but does not include material processing activities.

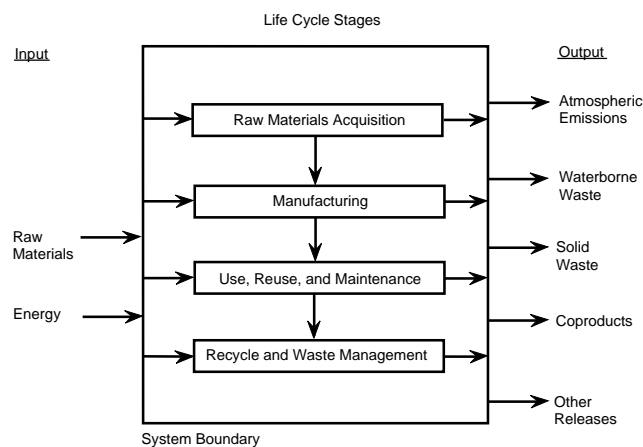

### Manufacturing Stage

This stage includes the following three steps shown in Figure 3.4.2:

Materials manufacture—The activities required to process a raw material into a form that can be used to fabricate a product or package. Normally, the production of many intermediate chemicals or materials is included in this category. The transport of intermediate materials is also included.

Product fabrication—the process step that uses raw or manufactured materials to fabricate a product ready to be filled or packaged. This step often involves a consumer product that is distributed for use by other industries.

Filling, packaging, and distribution—processes that prepare the final products for shipment and transport the

FIG. 3.4.2 Steps in the manufacturing stage. (Reprinted from Keoleian, Menerey, and Curran, 1993.)

products to retail outlets. In addition to primary packaging, some products require secondary and tertiary packaging and refrigeration to keep a product fresh, all of which should be accounted for in the inventory.

### Use, Reuse, and Maintenance Stage

This stage begins after the product or material is distributed for use and includes any activity in which the product or package is reconditioned, maintained, or serviced to extend its useful life.

### Recycling and Waste Management Stage

This stage begins after the product, package, or material has served its intended purpose and either enters a new system through recycling or enters the environment through the waste management system.

### Examples of System Boundaries

Figure 3.4.3 shows an example of setting system boundaries for a product baseline analysis of a bar soap system. Tallow is the major material in soap production, and its primary raw material source is the grain fed to cattle. The production of paper for packaging the soap is also included. The fate of both the soap and its packaging end the life cycle of this system. Minor input could include the energy required to fabricate the tires on the combine that plants and harvests the grain.

The following analysis compares the life cycles of bar soap made from tallow and liquid hand soap made from synthetic ingredients. Because the two products have different raw material sources (cattle and petroleum), the analysis begins with the raw material acquisition steps. Because the two products are packaged differently and have different formulas, the materials manufacture and packaging steps must be included. Consumer use and waste management options should also be examined because the different formulas can result in varying usage patterns. Thus, for this comparative analysis, an analyst would have to inventory the entire life cycle of the two products.

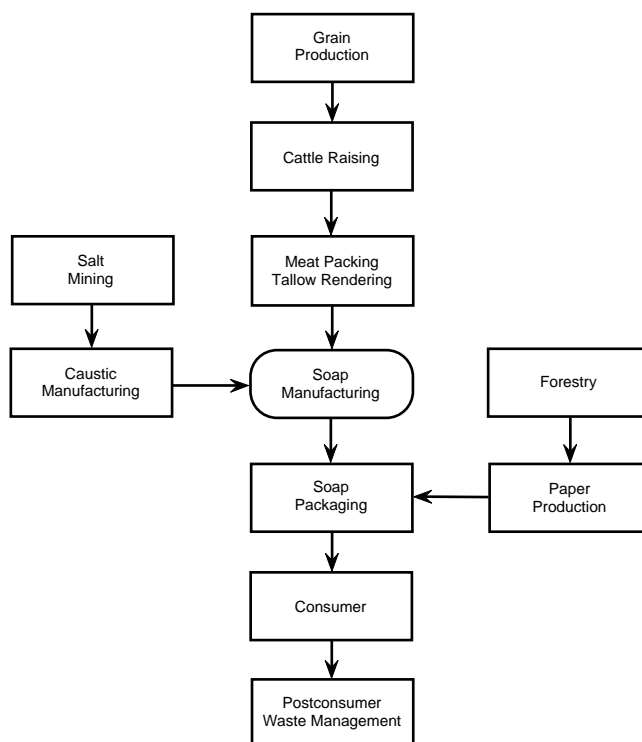

FIG. 3.4.3 Example system flow diagram for bar soap. (Reprinted from Keoleian, Menerey, and Curran, 1993.)

Again, the analyst must determine the basis of comparison between the systems. Because one soap is a solid and the other is a liquid, each with different densities and cleaning abilities per unit amount, comparing them on equal weights or volumes does not make sense. The key factor is how much of each is used in one hand-washing to provide an equal level of function or service.

A company comparing alternative processes for producing one petrochemical product may not need to consider the use and disposal of the product if the final composition is identical.

A company interested in using alternative material for its bottles while maintaining the same size and shape may not need filling the bottle as part of its inventory system. However, if the original bottles are compared to boxes of a different size and shape, the filling step must be included.

After the boundaries of each system are determined, a flow diagram as shown in Figure 3.4.3 can be developed to depict the system. Each system should be represented individually in the diagram, including production steps for ancillary input or output such as chemicals and packaging.

### INVENTORY CHECKLIST

After inventory purposes and boundaries are defined, the analyst can prepare an inventory checklist to guide data collection and validation and to enable the computational model. Figure 3.4.4 shows a generic example of an in-

<b>LIFE CYCLE INVENTORY CHECKLIST PART I—SCOPE AND PROCEDURES</b>

ventory checklist and an accompanying data worksheet. The LCA analyst may tailor this checklist for a given product or material.

**PEER REVIEW PROCESS**

Overall a peer review process addresses the four following areas:

- Scope and boundaries methodology
- Data acquisition and compilation

- Validity of key assumptions and results
- Communication of results

This peer review panel could participate at several points in the study: reviewing the purpose, system boundaries, assumptions, and data collection approach; reviewing the compiled data and the associated quality measures; and reviewing the draft inventory report, including the intended communication strategy.

## GATHER DATA

Data for a process at a specific facility are often the most useful for analysis. Development teams may be able to generate their own data for in-house activities, but detailed information from outside sources is necessary for other life cycle stages. Sources of data for inventory analysis include:

Predominately In-House Data:

- Purchasing records
- Utility bills
- Regulatory records
- Accident reports
- Test data and material or product specifications

Public Data:

- Industry statistics
- Government reports including statistical summaries and regulatory reports and summaries
- Material, product, or industry studies
- Publicly available LCAs
- Material and product specifications
- Test data from public laboratories

Analysts must be careful in gathering data. The data presented in government reports may be outdated. Also, data in such reports are often presented as an average. Broad averages may not be suitable for accurate analysis. Journal articles, textbooks, and proceedings from technical conferences are other sources of information for an inventory analysis but may also be too general or outdated. Other useful sources include trade associations and testing laboratories. Many public laboratories publish their results. These reports cover such issues as consumer product safety, occupational health issues, or aspects of material performance and specifications.

## Develop Stand-Alone Data

Stand-alone data is a term that describes the set of information developed to standardize or normalize the subsystem module input and output for the product, process, or activity being analyzed. (A *subsystem* is an individual step or process that is part of the defined system.) Stand-alone data must be developed for each subsystem to fit the subsystems into a single system. Two goals are necessary to achieve in this step:

Presenting data for each subsystem consistently by reporting the same product output from each subsystem  
 Developing the data in terms of the life cycle of only the product being examined in the inventory

A standard unit of output must be determined for each subsystem. All data could be reported in terms of producing a certain number of pounds, kilograms, or tons of a subsystem product.

Once the data are at a consistent reporting level, the analyst must determine the energy and material requirements

and the environmental releases attributed to the production of each coproduct using a technique called coproduct allocation. One commonly used allocation method is based on relative weight. Figure 3.4.5 illustrates this technique.

Once the input and output of each subsystem are allocated, the analyst can establish the numerical relationships of the subsystems within the entire system flow diagram. This process starts at the finished product of the system and works backward; it uses the relationships of the material input and product output of each subsystem to compute the input requirements from each of the preceding subsystems.

## CONSTRUCT A COMPUTATION MODEL

The next step in an LCI is model construction. This step consists of incorporating the normalized data and material flows into a computational framework using a computer spreadsheet or other accounting technique. The sys-

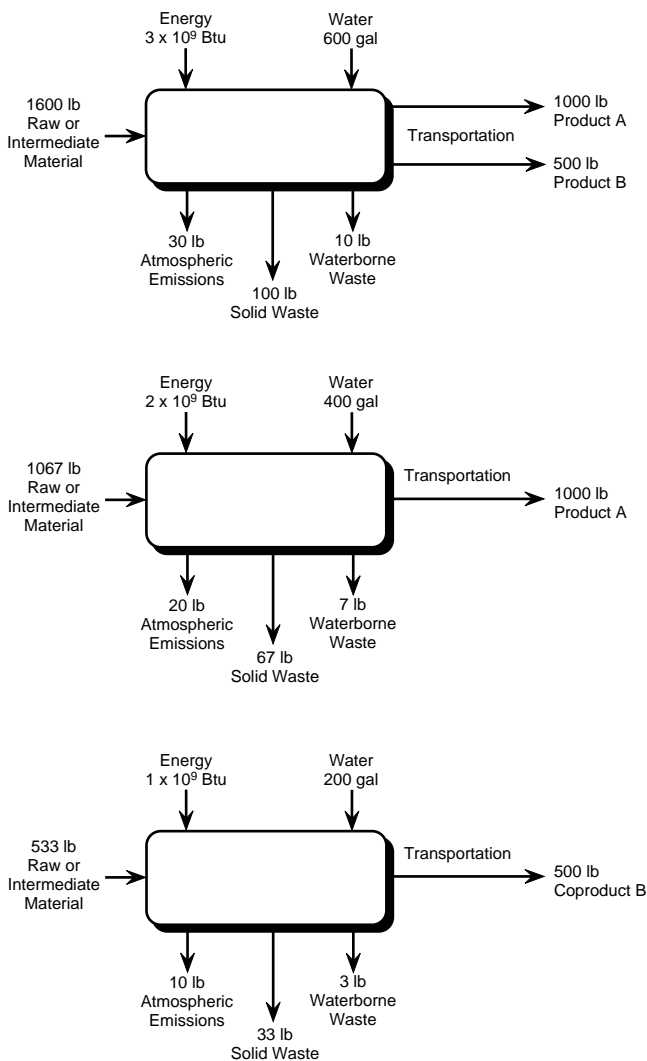

FIG. 3.4.5 Example coproduct allocation based on relative weight. (Reprinted from Keoleian, Menerey, and Curran, 1993.)

tem accounting data that result from the model computations give the total results for energy and resource use and environmental releases from the overall system.

The overall system flow diagram, derived in the previous step, is important in constructing the computational model because it numerically defines the relationships of the individual subsystems to each other in the production of the final product. These numerical relationships become the source of *proportionality factors*, which are quantitative relationships that reflect the relative subsystem contributions to the total system. The computational model can also be used to perform sensitivity analysis calculations.

## PRESENT THE RESULTS

The results of the LCI should be presented in a report that explicitly defines the systems analyzed and the boundaries that were set. The report should explain all assumptions made, give the basis for comparison among the systems, and explain the equivalent usage ratio used. Using a checklist or worksheet as shown in Figure 3.4.4 provides a process for communicating this information.

A graphic presentation of information augments tabular data and aids interpretation. Both bar charts (either individual bars or stacked bars) and pie charts help the reader to visualize and assimilate the information from the perspective of gaining ownership or participation in the LCA.

For internal industrial use by product manufacturers, pie charts showing a breakout by raw materials, process, and use or disposal have been useful in identifying waste reduction opportunities.

## Interpret and Communicate the Results

The interpretation of the results of the LCI depends on the purpose for which the analysis was performed. Before any statements regarding the results of the analysis are published, the analyst should review how the assumptions and boundaries were defined, the quality of the data used, and the representativeness of the data (e.g., whether the data were specific to one facility or representative of the entire industry).

The assumptions in analysis should be clearly documented. The significance of these assumptions should also be tested. For LCIs, sensitivity analysis can reveal how large the uncertainty in the input data can be before the results can no longer be used for the intended purpose.

The boundaries and data for many internal LCAs require that the results be interpreted for use within a particular corporation. The data used may be specific to a company and may not represent any typical or particular product on the market. However, because the data used in this type of analysis are frequently highly specific, ana-

lysts can assume a fairly high degree of accuracy in interpreting the results. Product design and process development groups often benefit from this level of interpretation.

The analyst should present the results of externally published studies comparing products, practices, or materials cautiously and consider the assumptions, boundaries, and data quality in drawing and presenting conclusions. Studies with different boundary conditions can have different results, yet both can be accurate. These limitations should be communicated to the reader along with all other results. Final conclusions about results from LCIs can involve value judgments about the relative importance of air and water quality, solid waste issues, resource depletion, and energy use. Based on the locale, background, and life style, different analysts make different value judgments.

## LIMITATIONS AND TRENDS

Data quality is an ongoing concern in LCA due in part to the newness of the field. Additional difficulties include:

- Lack of data or inaccessible data
- Time and cost constraints for compiling data

Performing an LCA is complex, but the time and expense required for this task may be reduced in the future. The methodology has advanced furthest in Europe where it is becoming part of public policy-making and environmental initiatives (C&E News 1994).

The discipline has produced the two following organizations dedicated to the methodology:

The Society of Environmental Toxicology and Chemistry (SETAC), founded in 1979 and currently based in Pensacola, Florida and in Brussels. Its members are individuals working to develop LCA into a rigorous science.

The Society for the Promotion of LCA Development (SPOLD), founded in 1992 and based in Brussels. Its members are companies who support LCA as a decision making tool.

SPOLD is conducting a feasibility study on creating a database of lifetime inventories for commodities such as basic chemical feedstocks, electricity, packaging, water, and services.

Another public information source is the Norwegian database on LCA and clean production technology, which is operated by the World Industries Committee for the Environment (WICE) in Frederickstad, Norway. Although it does not inventory data, the database lists LCAs with information on product type, functional units, and system boundaries. The database already contains fifty LCAs and can be accessed by computer modem (telephone: 47 69 186618). According to project coordinator Ole Hanssen (1993), WICE's long term objective is to integrate LCA with pollution prevention and process innovation.

## Impact Analysis

The impact analysis component of the LCA is a technical, quantitative, and qualitative process to characterize and assess the effects of the resource requirements and environmental loading (atmospheric and waterborne emissions and solid waste) identified in the inventory stage. Methods for impact analysis under development follow those presented at a SETAC workshop in 1992. The EPA's Office of Air Quality Planning has two documents which address life cycle impact analysis. (See also Chapter 2.)

The key concept in the impact analysis component is that of stressors. The stressor concept links the inventory and impact analysis by associating resource consumption and the releases documented in the inventory with potential impact. Thus, a *stressor* is a set of conditions that may lead to an impact. For example, a typical inventory quantifies the amount of SO<sub>2</sub> releases per product unit, which may then produce acid rain and then in turn affect the acidification of a lake. The resultant acidification might change the species composition and eventually create a loss of biodiversity.

Impact analysis is one of the most challenging aspects of LCA. Current methods for evaluating environmental impact are incomplete. Even when models exist, they can be based on many assumptions or require considerable data. The following sections describe several aspects of impact assessment and their limitations when applied to each of the major categories of environmental impact.

### RESOURCE DEPLETION

The quantity of resources extracted and eventually consumed can be measured fairly accurately. However, the environmental and social costs of resource depletion are more difficult to assess. Depletion of nonrenewable resources limits their availability to future generations. Also, renewable resources used faster than they can be replaced are actually nonrenewable.

Another aspect of resource depletion important for impact assessment is resource quality. Resource quality is a measurement of the concentration of a primary material in a resource. In general, as resources become depleted, their quality declines. Using low-quality resources requires more energy and other input while producing more waste.

### ECOLOGICAL EFFECTS

Ecological risk assessment is patterned after human health risk assessment but is more complex. As a first step in the analysis, the ecological stressors are identified; then the ecosystem potentially impacted is determined. Ecological stressors can be categorized as chemical (e.g., toxic chemicals released into the atmosphere), physical (e.g., habitat

destruction through logging), or biological (e.g., the introduction of an exotic species).

The Ecology and Welfare Subcommittee of the U.S. EPA Science Advisory Board has developed a method for ranking ecological problems (Science Advisory Board 1990). The subcommittee's approach is based on a matrix of ecological stressors and ecosystem types (Harwell and Kelly 1986). Risks are classified according to the following:

- Type of ecological response
- Intensity of the potential effect
- Time scale for recovery following stress removal
- Spatial scale (local or regional biosphere)
- Transport media (air, water, or terrestrial)

The recovery rate of an ecosystem to a stressor is a critical part of risk assessment. In an extreme case, an ecological stress leads to permanent changes in the community structure or species extinction. The subcommittee classifies ecosystem responses to stressors by changes in the following:

- Biotic community structure (alteration in the food chain and species diversity)
- Ecosystem function (changes in the rate of production and nutrient cycling)
- Species population of aesthetic or economic value
- Potential for the ecosystem to act as a route of exposure to humans (bioaccumulation)

Determining potential risks and their likely effects is the first step in ecological assessment. Many stressors can be cumulative, finally resulting in large-scale problems. Both habitat degradation and atmospheric change are examples of ecological impact that gain attention.

### Habitat Degradation

Human activities affect many ecosystems by destroying the habitat. When a habitat is degraded, the survival of many interrelated species is threatened. The most drastic effect is species extinction. Habitat degradation is measured by losses in biodiversity, decreased population size and range, and decreased productivity and biomass accumulation.

Standard methods of assessing habitat degradation focus on those species of direct human interest: game fish and animals, songbirds, or valuable crops (Suter 1990).

Ecological degradation does not result from industrial activity alone. Rapid human growth creates larger residential areas and converts natural areas to agriculture. Both are major sources of habitat degradation.

### Atmospheric Change

A full impact assessment includes all scales of ecological impact. Impact can occur in local, regional, or global scales. Regional and local effects of pollution on atmosphere include acid rain and smog. Large-scale effects in-

clude global climate change caused by releases of greenhouse gases and increased ultraviolet (UV) radiation from ozone-depletion gases.

A relative scale is a useful method for characterizing the impact of emissions that deplete ozone or lead to global warming. For example, the heat-trapping ability of many gases can be compared to carbon dioxide, which is the main greenhouse gas. Similarly, the ozone-depleting effects of emissions can be compared to chlorofluorocarbons such as CFC-12. Using this common scale makes interpreting the results easier.

### Environmental Fate Modeling

The specific ecological impact caused by pollution depends on its toxicity, degradation rate, and mobility in air, water, or land. Atmospheric, surface water, and groundwater transport models help to predict the fate of chemical releases, but these models can be complex. Although crude, equilibrium partitioning models offer a simple approach for predicting the environmental fate of releases. Factors useful for predicting the environmental fate include:

- Bioconcentration factor (BCF)—the chemical concentration in fish divided by the chemical concentration in water
- Vapor pressure
- Water solubility
- Octanol/water partition coefficient—the equilibrium concentration in octanol divided by the equilibrium chemical concentration in the aqueous phase
- Soil/water partition coefficient—the chemical concentration in soil divided by the chemical concentration in the aqueous phase

Once pathways through the environment and final fate are determined, impact assessment focuses on the effects. For example, impact depends on the persistence of releases and whether these pollutants degrade into further hazardous by-products.

### HUMAN HEALTH AND SAFETY EFFECTS

Impact can be assessed for individuals and small populations or whole systems. The analyst usually uses the following steps to determine the impact on human health and safety: (1) hazard identification, (2) risk assessment, (3) exposure assessment, and (4) risk characterization. (See Section 11.8.)

Determining health risks from many design activities can be difficult. Experts, including toxicologists, industrial hygienists, and physicians, should be consulted in this process. Data sources for health risk assessment include biological monitoring reports, epidemiological studies, and bioassays. Morbidity and mortality data are available from

sources such as the National Institute of Health, the Center for Disease Control, and the National Institute of Occupational Safety and Health.

The following ways are available to assess health impact: the threshold limited value–time-weighted average (TLV–TWA), the medium lethal dose (LD), the medium lethal concentration (LC), the no observed effect level (NOEL), and the no observed adverse effect level (NOAEL). (See Section 11.8.)

Other methods are used to compare the health impact of residuals. One approach divides emissions by regulatory standards to arrive at a simple index (Assies 1991). This normalized value can be added and compared when the emission standard for each pollutant is based on the same level of risk. However, this situation is rare. In addition, such an index reveals neither the severity nor whether the effects are acute or chronic. Properly assessing the impact of various releases on human health usually requires more sophistication than a simple index.

Impact on humans also includes safety. Unsafe activities cause particular types of health problems. Safety usually refers to physical injury caused by a chemical or mechanical force. Sources of safety-related accidents include malfunctioning equipment or products, explosions, fires, and spills. Safety statistics are compiled on incidences of accidents, including hours of lost work and types of injuries. Accident data are available from industry and insurance companies.

Health and safety risks to workers or users also depend on ergonomic factors. For tools and similar products, biomechanical features, such as grip, weight, and field of movement influence user safety and health.

### ASSESSING SYSTEM RISK

Human error, poor maintenance, and interactions of products or systems with the environment produce consequences that should not be overlooked. Although useful for determining human health and safety effects, system risk assessment applies to all other categories of impact. For example, breakdowns or accidents waste resources and produce pollution that can lead to ecological damage. Large, catastrophic releases have a different impact than continual, smaller releases of pollutants.

In risk assessment, predicting how something can be misused is often as important as determining how it is supposed to function. Methods of risk assessment can be either relatively simple or quite complex. The most rigorous methods are usually employed to predict the potential for high-risk events in complex systems. Risk assessment models can be used in design to achieve inherently safe products. Inherently safe designs result from identifying and removing potential dangers rather than just reducing possible risks (Greenberg and Cramer 1991). A brief outline of popular risk assessment methods follows.

## Simple Risk Assessment Procedures

These procedures include the following:

- Preliminary hazard analysis
- Checklists
- What-if analysis

A preliminary hazard analysis is suited for the earliest phases of design. This procedure identifies possible hazardous processes or substances during the conceptual stage of design and seeks to eliminate them, thereby avoiding the costly and time-consuming delays caused by later design changes.

Checklists ensure that the requirements addressing risks have not been overlooked or neglected. Design verification should be performed by a multidisciplinary team with expertise in appropriate areas.

A what-if analysis predicts the likelihood of possible events and determines their consequences through simple, qualitative means. Members of the development team prepare a list of questions that are answered and summarized in a table (Doerr 1991).

## Mid-Level Risk Assessment Procedures

These procedures include the following:

- Failure mode and effects analysis (FEMA)
- HAZOP study

The FEMA is also a qualitative method. It is usually applied to individual components to assess the effect of their failure on the system. The level of detail is greater than in a what-if analysis (O'Mara 1991). HAZOPs systematically examine designs to determine where potential hazards exist and assign priorities. HAZOPs usually focus on process design.

## Relatively Complex Risk Assessment Procedures

These procedures include the following:

- Faulty tree analysis (FTA)
- Event tree analysis (ETA)
- Human reliability analysis (HRA)

FTA is a structured, logical modeling tool that examines risks and hazards to precisely determine unwanted consequences. FTA graphically represents the actions leading to each event. Analysis is generally confined to a single system and produces a single number for the probability of that system's failure. FTA does not have to be used to generate numbers; it can also be used qualitatively to improve the understanding of how a system works and fails (Stoop 1990).

ETA studies the interaction of multiple systems or multiple events. ETA is frequently used with FTA to provide

quantitative risk assessment. Event trees are also used to assess the probability of human errors occurring in a system.

HRA can be a key factor in determining risks and hazards and in evaluating the ergonomics of a design. HRA can take a variety of forms to provide proactive design recommendations.

## LIMITATIONS

LCA analysts face other fundamental dilemmas. How to examine a comprehensive range of effects to reach a decision? How to compare different categories of impact? Assessment across categories is highly subjective and value laden. Thus, impact analysis must account for both scientific judgment and societal values. Decision theory and other approaches can help LCA practitioners make these complex and value-laden decisions.

Impact assessment inherits all the problems of inventory analysis. These problems include lack of data and time and cost constraints. Although many impact assessment models are available, their ability to predict environmental effects varies. Fundamental knowledge in some areas of this field is still lacking.

In addition to basic inventory data, impact analysis requires more information. The often complex and time-consuming task of making further measurements also creates barriers for impact analysis.

Even so, impact analysis is an important part of life cycle design. For now, development teams must rely on simplified methods. LCA analysts should keep abreast of developments in impact analysis so that they can apply the best available tools that meet time and cost constraints.

## Improvement Analysis

The improvement analysis component of LCA is a systematic evaluation of the need and opportunities to reduce the environmental burden associated with energy and raw material use and waste emissions throughout the life cycle of a product, process, or activity. Improvement analysis has not received the immediate attention of the LCA methodology development community. Improvement analysis is usually conducted informally throughout an LCA evaluation as a series of what-if questions and discussions. To date, no rigorous or even conceptual framework of this component exists. Ironically, this component of the LCA is the reason to perform these analyses in the first place. SETAC has tentative plans to convene a workshop in 1994 (Consoil 1993).

## 3.5

# SUSTAINABLE MANUFACTURING (SM)

---

---

In the report, *Our Common Future, sustainable development* is defined as “meets the needs of the current generation without compromising the needs of future generations” (United Nations World Commission on the Environment and Development 1987). The concept of sustainability is illustrated by natural ecosystems, such as the hydrologic cycle and the food cycle involving plants and animals. These systems function as semi-closed loops that change slowly, at a rate that allows time for natural adaptation.

In contrast to nature, material flows through our economy in one direction only—from raw material toward eventual disposal as industrial or municipal waste (see part (a) in [Figure 3.5.1](#)). Sustainable development demands change. When a product’s design and manufacturing process are changed, the overall environmental impact can be reduced. Green design emphasizes the efficient use of materials and energy, reduction of waste toxicity, and reuse and recycling of materials (see part (b) in [Figure 3.5.1](#)).

SM seeks to meet consumer demands for products without compromising the resource and energy supply of future generations. SM is a comprehensive business strategy that maximizes the economic and environmental returns on a variety of innovative pollution prevention techniques (Kennedy 1993). These techniques including the following:

Design for environment (DFE) directs research and development (R&D) teams to develop products that are environmentally responsible. This effort revolves on product design.

Toxics use reduction (TUR) considers the internal chemical risks and potential external pollution risks at the process and worker level.

LCA defines the material usage and environmental impact over the life of a product.

SM embeds corporate environmental responsibility into material selection, process and facility design, marketing, strategic planning, cost accounting, and waste disposal.

## Product Design and Material Selection

By following the design strategies described next, designers can meet environmental requirements.

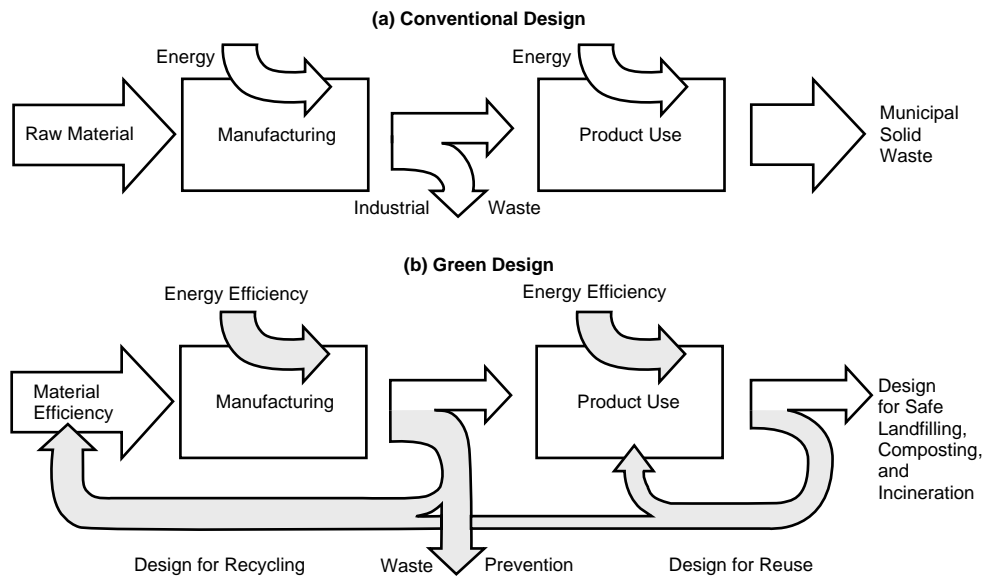

### PRODUCT SYSTEM LIFE EXTENSION

Extending the life of a product can directly reduce environmental impact. In many cases, longer-lived products save resources and generate less waste because fewer units are needed to satisfy the same need. Doubling the life of a product translates into a pollution prevention of 50% in process transportation and distribution and a waste reduction of 50% at the end of the product’s life.

Understanding why products are retired helps designers to extend the product system life. Reasons why products are no longer in use include:

- Technical obsolescence
- Fashion obsolescence
- Degraded performance or structural fatigue caused by normal wear over repeated use
- Environmental or chemical degradation
- Damage caused by accident or inappropriate use

To achieve a longer service life, designers must address issues beyond simple wear. A discussion of specific strategies for product life extension follows.

**FIG. 3.5.1** How product design affects material flows. Making changes in a product's design reduces overall environmental impact. The green design emphasizes the efficient use of material and energy, reduction of waste toxicity, and reuse and recycling of materials. (Reprinted from U.S. Congress Office of Technology Assessment 1992, *Green products by design: Choices for a cleaner environment* [U.S. Government Printing Office].)

### Appropriate Durability

Durable items can withstand wear, stress, and environmental degradation over a long useful life. Development teams should enhance durability only when appropriate. Designs that allow a product or component to last beyond its expected useful life are usually wasteful.

Enhanced durability can be part of a broader strategy focused on marketing and sales. Durability is an integral part of all profitable leasing. Original equipment manufacturers who lease their products usually gain the most from durable design.

For example, a European company leases all the photocopiers it manufactures. The company designs drums and other key components of their photocopiers for maximum durability to reduce the need for replacement or repair. Because the company maintains control of the machines, they select materials to reduce the cost and impact of disposal.

### Adaptability

Adaptability can extend the useful life of a product that quickly becomes obsolete. To reduce the overall environmental impact, designers should design a product so that a sufficient portion of it remains after obsolete parts are replaced.

Adaptable designs rely on interchangeable components. For example, an adaptable strategy for a new razor blade design ensures that the new blade mounts on the old handle so that the handle does not become part of the waste stream.

A large American company designed a telecommunication control center using a modular work station approach. Consumers can upgrade components as needed to maintain state-of-the-art performance. Some system components change rapidly, while others stay in service for ten years or more.

### Reliability

Reliability is often expressed as a probability. It measures the ability of a system to accomplish its design mission in the intended environment for a certain period of time.

The number of components, the individual reliability of each component, and the configuration are important aspects of reliability. Parts reduction and simplified design can increase both reliability and manufacturability. A simple design may also be easier to service. All these factors can reduce resource use and waste.

Designers cannot always achieve reliability by reducing parts or making designs simple. In some cases, they must add redundant systems to provide backup. When a reliable product system requires parallel systems or fail-safe components, the cost can rise significantly. Reliable designs must also meet all other project requirements.

Reliability should be designed into products rather than achieved through later inspection. Screening out potentially unreliable products after they are made is wasteful because such products must be repaired or discarded. Both environmental impact and cost increase.

For example, a large American electronics firm discovered that the plug-in boards on the digital scopes it designs

failed in use. However, when the boards were returned for testing, 30% showed no defects and were sent back to customers. Some boards were returned repeatedly, only to pass tests every time. Finally, the company discovered that a bit of insulation on each of the problem boards' capacitors was missing, producing a short when they were installed in the scope. The cause was insufficient clearance between the board and the chassis of the scope; each time the board was installed it scraped against the side of the instrument. Finding the problem was difficult and expensive. Preventing it during design with a more thorough examination of fit and clearance would have been simpler and less costly.

### **Remanufacturability**

Remanufacturing is an industrial process that restores worn products to like-new condition. In a factory, a retired product is first completely disassembled. Its usable parts are then cleaned, refurbished, and put into inventory. Finally, a new product is reassembled from both old and new parts, creating a unit equal in performance and expected life to the original or currently available alternative. In contrast, a repaired or rebuilt product usually retains its identity, and only those parts that have failed or are badly worn are replaced.

Industrial equipment or other expensive products not subject to rapid change are the best candidates for remanufacturing.

Designs must be easy to take apart if they are to be remanufactured. Adhesives, welding, and some fasteners can make this process impossible. Critical parts must be designed to survive normal wear. Extra material should be present on used parts to allow refinishing. Care in selecting materials and arranging parts also helps to reduce excessive damage during use. Design continuity increases the number of interchangeable parts between different models in the same product line. Common parts make remanufacturing products easier.

For example, a midwestern manufacturer could not afford to replace its thirteen aging plastic molding machines with new models, so it chose to remanufacture eight molders for one-third the cost of new machines. The company also bought one new machine at the same time. The remanufactured machines increased efficiency by 10 to 20% and decreased scrap output by 9% compared to the old equipment; performance was equal to the new molder. Even with updated controls, operator familiarity with the remanufactured machines and use of existing foundations and plumbing further reduced the cost of the remanufactured molders.

### **Reusability**

Reuse is the additional use of an item after it is retired from a defined duty. Reformulation is not reuse. However,

repair, cleaning, or refurbishing to maintain integrity can be done in the transition from one use to the next. When applied to products, reuse is a purely comparative term. Products with no single-use analogs are considered to be in service until discarded.

For example, a large supplier of industrial solvents designed a back-flush filter that could be reused many times. The new design replaced the single-use filters for some of their onsite equipment. Installing the back-flush filter caused an immediate reduction in waste generation, but further information about the environmental impact associated with the entire multiuse filter system is necessary to compare it to the impact of the single-use filters (Kusz 1990).

### **MATERIAL LIFE EXTENSION**

Recycling is the reformation or reprocessing of a recovered material. The EPA defines recycling as "the series of activities, including collection, separation, and processing, by which products or other materials are recovered from or otherwise diverted from [the] solid waste stream for use in the form of raw materials in the manufacture of new products other than fuel" (U.S. EPA 1991a).

Recycled material can follow two major pathways: closed loop and open loop. In closed-loop systems, recovered material and products are suitable substitutes for virgin material. In theory a closed-loop model can operate for an extended period of time without virgin material. Of course, energy, and in some cases process material, is required for each recycling. Solvents and other industrial process ingredients are the most common materials recycled in a closed loop.

Open-loop recycling occurs when the recovered material is recycled one or more times before disposal. Most postconsumer material is recycled in an open loop. The slight variations or unknown composition of such material usually cause it to be downgraded to a less demanding use.

Some material also enters a cascade open-loop model in which it is degraded several times before the final discard. For example, used white paper can be recycled into additional ledger or computer paper. If this product is then dyed and not de-inked, it can be recycled as mixed grade after use. In this form, it can be used for paper board or packing, such as trays in produce boxes. Currently, the fiber in these products is not valuable enough to recover. Ledger paper also enters an open-loop system when it is recycled into facial tissue or other products that are disposed of after use.

Recycling can be an effective resource management tool. Under ideal circumstances, most material can be recovered many times until it becomes too degraded for further use. Even so, designing for recyclability is not the strategy for meeting all environmental requirements. As an example, studies show that refillable glass bottles use less life cycle

energy than single-use recycled glass to deliver the same amount of beverages (Sellers and Sellers 1989).

When a suitable infrastructure is in place, recycling is enhanced by:

- Ease of disassembly
- Ease of material identification
- Simplification and parts consolidation
- Material selection and compatibility

In most projects, the material selection is not coordinated with environmental strategies. For instance, a passenger car currently uses 50 to 150 different materials. Separating this mixture from a used car is impossible. Designers can aid recycling by reducing the number of incompatible materials in a product. For example, a component containing parts of different materials could be designed with parts made from the same material.

Some polymers and other materials are broadly incompatible. If such materials are to be recycled for similar use, they must be meticulously separated for high purity.

Some new models in a personal system/2 product line are specifically designed with the environment in mind. These models use a single polymer for all plastic parts. The polymer has a molded-in finish, eliminating the need for additional finishes, and molded-in identification symbols. In addition, the parts snap together, avoiding the use of metal pieces such as hinges and brackets. These design features facilitate recycling, principally through easy disassembly, the elimination of costly plastic parts sorting, and the easy identification of polymer composition (Dillon 1993).

## **MATERIAL SELECTION**

Because material selection is a fundamental part of design, it offers many opportunities for reducing environmental impact. In life cycle design, designers begin material selection by identifying the nature and source of raw materials. Then, they estimate the environmental impact caused by resource acquisition, processing, use, and retirement. The depth of the analysis and the number of life cycle stages varies with the project scope. Finally, they compare the proposed materials to determine the best choices.

Minimizing the use of virgin material means maximizing the incorporation of recycled material. Sources of recycled feedstock include in-house process scrap, waste material from another industry, or reclaimed postconsumer material.

The quality of incoming material determines the amount of unusable feedstock and the amount of time required to prepare the material. Therefore, product design dimensions should closely match incoming feedstock dimensions to minimize machining, milling, and scrap generation.

## **Material Substitution**

Material substitutions can be made for product as well as process materials, such as solvents and catalysts. For example, water-based solvents or coatings can sometimes be substituted for high-VOC alternatives during processing. Also, materials that do not require coating, such as some metals or polymers, can be substituted in the product.

For example, an American company replaced its five-layer finish on some products with a new three-layer substitute. The original finish contained nickel (first layer), cadmium, copper, nickel, and black organic paint (final layer). The new finish contains nickel, a zinc-nickel alloy, and black organic paint. This substitution eliminates cadmium, a toxic heavy metal, and the use of a cyanide bath solution for plating the cadmium. The new finish is equally corrosion resistant. It is also cheaper to produce, saving the company 25% in operating costs (U.S. EPA 1991b).

A large textile dye house in Chelsea, Massachusetts, complied with local sewer limits by working with its imported fabric suppliers and clients to select only those fabrics with the lowest zinc content. The company thus avoided installing a \$150,000 treatment plant. (Kennedy 1993).

Finally, reducing the use of toxic chemicals results in fewer regulatory concerns associated with handling and disposing hazardous material and less exposure to corporate liability and worker health risks. For example, a water-based machining coolant can reduce the quantity of petroleum oils generated onsite and allow parts to be cleaned more effectively using a non-chlorinated or water-based solvent.

## **Reformulation**

Reformulation is an appropriate strategy when a high degree of continuity must be maintained with the original product. Rather than replacing one material with another, the designer alters the percentages to achieve the same result. Some material may be added or deleted if the original product characteristics are preserved.

## **REDUCED MATERIAL INTENSIVENESS**

Resource conservation can reduce waste and directly lower environmental impact. A less material-intensive product may also be lighter, thus saving energy in distribution or use. When reduction is simple, benefits can be determined with a vigorous LCA.

For example, a fast-food franchise reduced material input and solid waste generation by decreasing the paper napkin weight by 21%. Two store tests revealed no change in the number of new napkins used compared to the old design. Attempts to reduce the gage of plastic straws, however, caused customer complaints. The redesigned straws were too flimsy and did not draw well with milkshakes

(Environmental Defense Fund and McDonalds' Corporation 1991).

## ENERGY-EFFICIENT PRODUCTS

Energy-efficient products reduce energy consumption and greenhouse gas emissions. For example, the EPA's Energy Star Program initiates a voluntary program to reduce the power consumption of laser printers when inactive. The EPA's Green Lights Program is aimed at persuading companies to upgrade their lighting systems to be more efficient.

## Process Management

Although process design is an integral part of product development, process improvement can be pursued outside of product development.

## PROCESS SUBSTITUTION

Processes that create major environmental impact should be replaced with more benign ones. This simple approach to impact reduction can be effective. For example, copper sheeting for electronic products was previously cleaned with ammonium persulfate, phosphoric acid, and sulfuric acid at one large American company's facility. The solvent system was replaced by a mechanical process that cleaned the sheeting with rotating brushes and pumice. The new process produces a nonhazardous residue that is disposed in a municipal solid waste landfill.

A large American chemical and consumer products company switched from organic solvent-based systems for coating pharmaceutical pills to a water-based system. The substitution was motivated by the need to comply with regulations limiting emissions of VOCs. To prevent the pills from becoming soggy, a new sprayer system was designed to precisely control the amount of coating dispensed. A dryer was installed as an additional process step. The heating requirements increased when the water-based coatings were used. However, for a total cost of \$60,000, the new system saved \$15,000 in solvent costs annually and avoided the expense of \$180,000 in end-of-the-pipe emission controls that would have been required if the old solvent system had been retained (Binger 1988).

Process redesign directed toward plant employees can also yield health and safety benefits, as well as reduce cost. In addition, through certain process changes, a facility can reduce its resource demands to a range where closing the loop or completely eliminating waste discharges from the facility is economically feasible. Unless a company fine tunes each process first, however, the waste volume may overwhelm the equipment's capacity to recycle or reuse it. For example, an electroplating process that does not have an optimized rinsing operation must purchase metal re-

covery equipment with a capacity of five to ten times that needed under optimal rinsing conditions.

The EPA has published several pollution prevention manuals for specific industries. Each manual reviews strategies for waste reduction and provides a checklist.

## PROCESS ENERGY EFFICIENCY

Process designers should always consider energy conservation including:

- Using waste heat to preheat process streams or do other useful work

- Reducing the energy requirement for pumping by using larger diameter pipes or cutting down frictional losses

- Reducing the energy use in buildings through more efficient heating, cooling, ventilation, and lighting systems

- Saving energy by using more efficient equipment. Both electric motors and refrigeration systems can be improved through modernization and optimized control technology.

- Conserving process energy through the insulation of process tanks, monitoring, and regulating temperatures to reduce energy cost and resource use in energy generation

- Using high-efficiency motors and adjustable-speed drives for pumps and fans to reduce energy consumption

- Reducing energy use through proper maintenance and sizing of motors

Renewable energy sources such as the sun, wind, and water offer electricity for the cost of the generating equipment. Surplus electricity can often be sold back to the utilities to offset electrical demand. A decrease in the demand for electricity resulting from the use of renewable resources increases the environmental quality.

## PROCESS MATERIAL EFFICIENCY

A process designed to use material in the most efficient manner reduces both material input and waste. For example, new paint equipment can reduce overspray, which contains VOCs.

Environmental strategies for product design are also applicable to facilities and equipment. Designers can extend the useful life of facilities and processes by making them appropriately durable. Flexible manufacturing can be an effective life extension for facilities. Through its Green Light Program, the EPA educates companies about new lighting techniques and helps them conserve energy.

For example, a large American electronics company designed a flux dispensing machine for use on printed circuit boards. This low solid flux (LSF) produces virtually no excess residue when it is applied, thus eliminating a cleaning step with CFCs and simplifying operations. Performance of the boards produced with the new LSF was maintained, and the LSF helped this manufacturer reduce CFC emissions by 50% (Guth 1990).

## INVENTORY CONTROL AND MATERIAL HANDLING

Improved inventory control and material handling reduces waste from oversupply, spills, or deterioration of old stock. This reduction increases efficiency and prevents pollution. Proper inventory control also ensures that materials with limited shelf lives have not degraded. Processes can thus run at peak efficiency while directly reducing the waste caused by reprocessing.

On-demand generation of hazardous materials needed for certain processes is an example of innovative material handling that can reduce impact.

Storage facilities are also an important element of inventory and handling systems. These facilities must be properly designed to ensure safe containment of material. They should be adequately sized for current and projected needs.

A large American electronics firm developed an on-demand generation system for producing essentially toxic chemicals that had no substitutes. Less harmful precursors were reacted to form toxic chemicals for immediate consumption. The company now produces arsine, an acutely toxic chemical essential for semiconductor production, as it is needed. This system avoids transporting arsine to manufacturing sites in compressed cylinders and using specially designed containment facilities to store the arsine. The company no longer must own three special storage facilities which cost \$1 million each to build and maintain (Ember 1991).

## Efficient Distribution

Efficient distribution includes improving transportation and packaging.

## TRANSPORTATION

The environmental impact caused by transportation can be reduced by several means including:

- Choosing an energy-efficient route
- Reducing air pollutant emissions from transportation
- Using the maximum vehicle capacity where appropriate
- Backhauling materials
- Ensuring proper containment of hazardous material
- Choosing routes carefully to reduce potential exposure from spills and explosions

Table 3.5.1 shows transportation efficiencies. Time and cost considerations, as well as convenience and access, determine the best choice for transportation. When selecting a transportation system, designers should also consider infrastructure requirements and their potential impacts.

## PACKAGING

As a first step, products should be designed to withstand both shock and vibration.

Designers can use the strategies that follow to design packaging for efficient distribution.

### Packaging Reduction

Packaging reduction includes elimination, reusable packaging, product modifications, and material reduction.

In elimination, appropriate products are distributed unpackaged. In the past, many consumer goods such as screw drivers, fasteners, and other items were offered unpackaged. Wholesale packaging can be eliminated. For example, furniture manufacturers commonly ship furniture uncartoned.

With reusable packaging, wholesale items that require packaging are commonly shipped in reusable containers. Tanks of all sizes, wire baskets, plastic boxes, and wooden hooks are frequently used for this purpose.

Even when products require primary or secondary packaging to ensure their integrity during delivery, product modifications can decrease packaging needs. Designers can further reduce the amount of packaging by avoiding unusual product features or shapes that are difficult to protect.

In material reduction, products that contain an ingredient in dilute form can be distributed as concentrates. In some cases, customers can simply use concentrates in reduced quantities. A larger, reusable container can also be sold in conjunction with concentrates. This method allows customers to dilute the products if appropriate. Examples of product concentrates include frozen juice concentrates and concentrated versions of liquid and powdered detergent. Material reduction can also be pursued in packaging design. Many packaging designers have reduced material use while maintaining performance. Reduced thickness of corrugated containers (board grade reduction) is one example. In addition, aluminum, glass, plastic, and steel containers have continually been redesigned to require less material to deliver the same volume.

TABLE 3.5.1 TRANSPORTATION EFFICIENCIES

Mode	Btu/tn-mi
Waterborne	365
Class 1 Railroad	465
All Pipelines <sup>1</sup>	886
Crude oil pipeline	259
Truck	2671–3460
Air <sup>2</sup>	18,809

<sup>1</sup>Average figure; ranges from 236 Btu/tn-mi for petroleum to approximately 2550 Btu/tn-mi for coal slurry and natural gas.

<sup>2</sup>All-cargo aircraft only. Belly freight carried on passenger airlines is considered free because the energy used to transport it is credited to the passengers. Thus, the efficiency figure for all air freight is a misleading 9548 Btu/tn-mi.

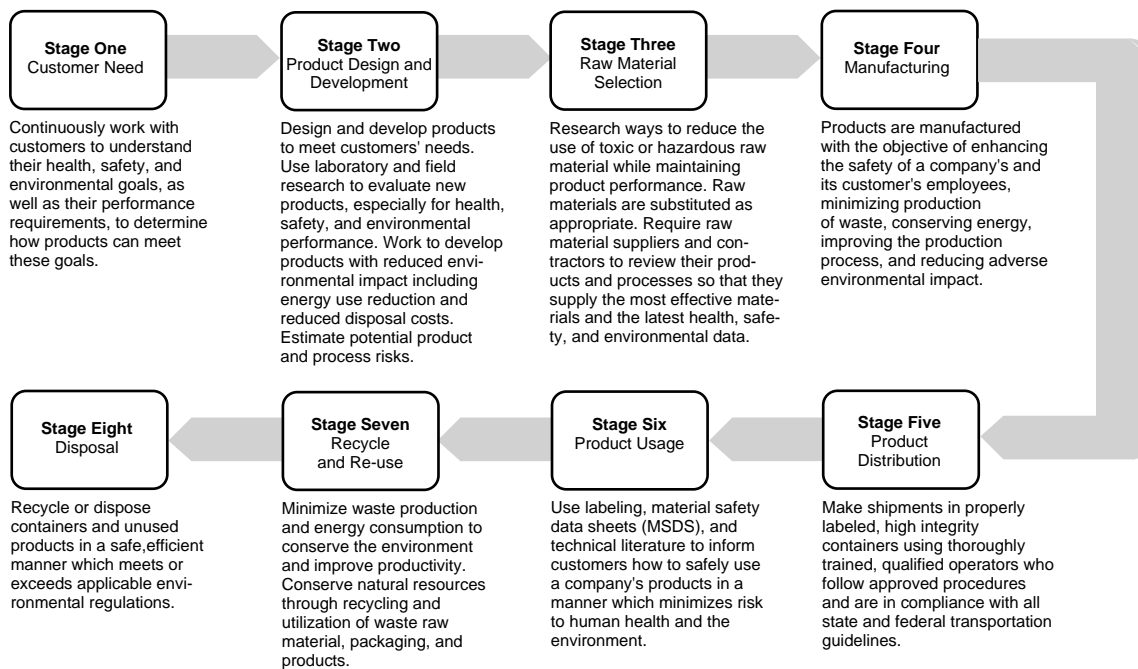

FIG. 3.5.2 XYZ Product stewardship.

### Material Substitution

One common example of this strategy is to substitute more benign printing inks and pigments for those containing toxic heavy metals or solvents. Also, whenever possible, designers can create packaging with a high recycled content. The necessary design elements for most reusable packaging systems include:

- a collection or return infrastructure
- procedures for inspecting items for defects or contamination
- repair, cleaning, and refurbishing capabilities
- storage and handling systems

### Degradable Materials

Degradable materials can be broken down by biological or chemical processes or exposure to sunlight. Degradability is a desirable trait for litter deposited in aesthetically pleasing natural areas. However, a number of challenging problems must be resolved before the use of degradable packaging becomes a commonly accepted strategy.

### Improved Management Practices

Designing new business procedures and improving existing methods also play a role in reducing environmental impact. Business management strategies apply to both manufacturing and service activities. For example, forcing aircraft to use a plug-in system at an airport rather than using their own auxiliary power systems results in a re-

duction of air pollution, especially in countries with clean hydroelectricity.

Figure 3.5.2 shows a product steward's program covering each part of the product's stages, including design, manufacturing, marketing, distribution, use, recycling, and disposal.

## 3.6 R & D FOR CLEANER PROCESSES

From the inception of any process, pollution prevention should be a fundamental objective. That objective should be pursued aggressively through process development, process design, engineering to construction, startup, and operation. It should also be a continuing objective of plant engineers and operators once the unit begins production (see Figure 3.6.1).

The best time to consider pollution prevention is when the process is first conceived. Research should explore the possibility of alternate pathways for chemical synthesis. Once the process has undergone significant development at the pilot plant, making major process changes or modifications is generally difficult and costly. For instance, the pharmaceutical industry is restricted from process modifications once the clinical efficacy of the drug is established.

An international consensus is growing on the need to use pollution prevention and clean production principles for the following:

- Changing industrial raw materials to less toxic chemicals

- Improving the materials' efficiency of manufacturing processes
- Designing products to increase environmental performance over their entire life cycles

Some of the research opportunities being explored include (Illman 1993):

- Aqueous, solvent-based reactions
- Ambient-temperature reactions
- Just-in-time in situ generation of toxic intermediates
- Chiral catalysts
- Artificial enzymes
- Built-in recyclability

### Environmental Load Indicator

ICI uses a rough indicator of environmental impact called the environmental load factor (ELF) to choose the reaction route that is best for the environment. The ELF equals the net weight of raw materials, solvents, catalysts, and

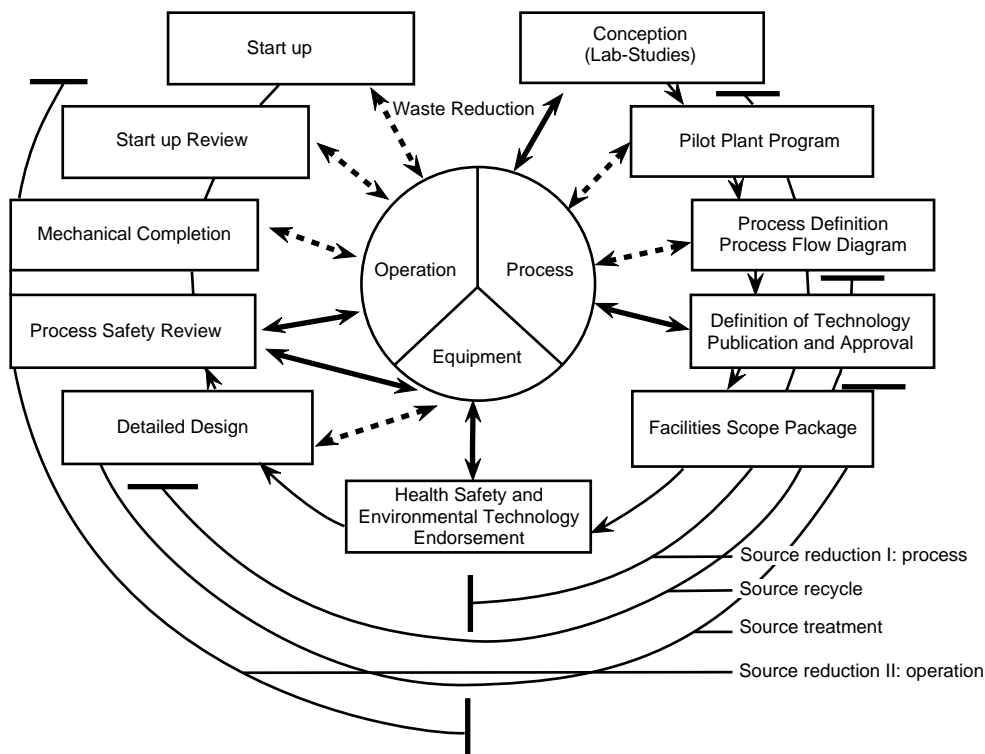

FIG. 3.6.1 Waste reduction and new technology development. (Reprinted, with permission, from Ronald L. Berglund and Glenn E. Snyder, 1990, Waste minimization: The sooner the better, *Chemtech* [December].)

other chemicals used to make a unit weight of product. Subtracting the weight of the finished product from the weight of all material fed to the process and dividing that difference by the weight of the finished product calculates the ELF. Therefore, pollution prevention dictates that researchers minimize the use of additives. Additives must be separated from a product, and at some point, they too become waste. In addition, installations designed to protect the environment are also invariably sources of waste (Hileman 1992).

The waste ratio is an indicator used at the 3M Company to measure the progress of the waste-reduction strategies. This ratio is defined rather simply as:

$$\text{Waste ratio(\%)} = (\text{Waste}/\text{total output})(100) \quad \mathbf{3.6(1)}$$

The quantities are measured by weight. Total output includes good output plus waste. Good output includes finished goods, semifinished goods, and by-products (however, by-product material that is beneficially burned for fuel counts as waste). Waste is the residual from the manufacturing site before it is subjected to any treatment process. The material that is recycled is not included as waste (Benforado, Riddlehover, and Gores 1991).

At 3M, the waste ratio varies from 10 to 20% for batch polymerizations to 99% for products that are not favored by reaction kinetics or that require multistep purification operations. New products undergo special screening if the initial waste ratio exceeds 50%. This screening is important not only for meeting waste-reduction targets but also for assessing the economic viability of the product as treatment and disposal costs escalate.

## Process Chemistry

Preventing pollution in process chemistry includes the choice of the reaction route, catalyst technology, the choice of the reagents, and the choice of the solvents.

### CHOICE OF REACTION ROUTE

One major way to reduce waste in the manufacture of complex organic substances is to reduce the number of steps required from raw materials to the final product. Every intermediate must usually be purified after each step, and nearly all purification processes produce waste. For example, a new ICI route to a fungicide process reduces the number of reaction steps from six to three while using fewer solvents and other chemicals. The total effect decreases the amount of waste to only 10% of that generated in the previous process (Hileman 1992). In addition, reducing steps means decreasing capital and operating costs.

Figure 3.6.2 compares the six-step ibuprofen process with the three-step process. Both processes start with the Friedel-Crafts conversion of sec-butylbenzene to p-sec-butylacetophenone. The six-step process also uses alu-

minum chloride as a catalyst with potential problems of water quench, emulsions, difficult extractions or filtration, and a large volume of water-borne waste. The three-step process uses the cleaner hydrogen fluoride as a catalyst and reduces the need for treatment of the water effluent and eliminates the formation of HCl.

Molecular Design in Basel, Switzerland has reaction retrieval systems that can be used to design improved processes to clients' target compounds (Stinson 1993). These reaction retrieval systems allow the design of a sequence that has only four steps, begins from more easily accessible substituted phthalimides to spirosuccinimides, and eliminates the generation of toxic by-products (see Figure 3.6.3). One of the steps uses trimethylsilyl cyanide which could be added to the company's catalog for sales to others.

In various forms, such computer software has been under development around the country for about twenty-five years. Its purpose is to help chemists identify new syntheses for target molecules from the myriad of potential routes and to suggest novel chemical reactions that might be investigated.

Most of these programs are retrosynthetic—that is they generate syntheses for target molecules by working back-

FIG. 3.6.2 Hoechst route to ibuprofen versus conventional route.

FIG. 3.6.3 Databases to improve synthetic schemes. (Reprinted, with permission, from Molecular Design.)

ward from the target to the candidate starting materials. Other programs are synthetic—that is they identify side reactions, by-products, and the effect of various conditions on reaction outcomes. However, none of these programs are built with environmentally benign synthesis in mind.

Out of about twenty software tools examined by J. Dirk Nies (Chemical Information Services, Oakville, Maryland) and colleagues, three programs appear to be useful for providing theoretical alternative synthesis pathways in support of EPA pollution prevention initiatives: Cameo, which operates synthetically, and Syngen and Lhasa, which both operate retrosynthetically. The user, however, must decide which pathways are environmentally safer by considering

the health and environmental hazards of the starting reagents (Illman 1993).

## CATALYST TECHNOLOGY

Catalytic technologies offer great potential for reducing waste and energy consumption, minimizing the use and transportation storage of hazardous materials, and developing products that are safer for the environment. Some examples of catalyst-based products and processes that reduce pollutant emissions follow.

### Production of Environmentally Safer Products

This example describes a process with negligible side reactions in which 1,1-dichloro-1-fluoroethane (HCFC-141b) is a replacement for stratospheric-ozone-depleting fluorotrichloromethane (CFC-11).

Low yields are obtained when 1,1 dichloroethylene ( $\text{CH}_2=\text{CCl}_2$ ) is reacted with hydrogen fluoride using conventional catalysts because the reaction favors trichloroethane (HFC-143a) as follows:

However, when a specially prepared aluminum fluoride catalyst is used, nearly all the reactant is converted to HCFC-141b, and less than 500 ppm of the reactant remain in the product. The HCFC-141b does not even need to be purified (see Figure 3.6.4).

### Management of Hazardous and Toxic Materials

The DuPont company has a catalytic process for making methylisocyanate (MIC), starting from materials far less hazardous than the traditional phosgene. The MIC is produced only moments before it is converted to a pesticide so that only small quantities of MIC exist at any one time. This pathway is safer for both the environment and worker health and safety. The catalytic process does not produce hydrochloric acid.

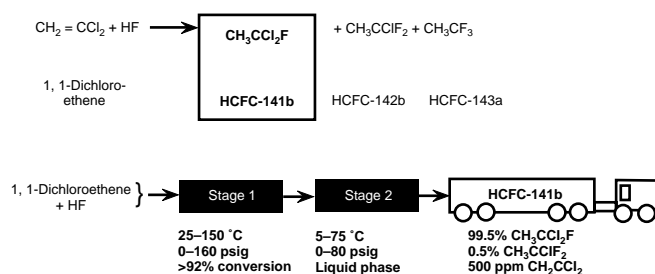

FIG. 3.6.4 High-yield catalytic hydrochlorofluorocarbon process.

In the traditional process, the following reaction occurs:

In the DuPont catalytic process, the following reactions occur:

### Environmentally Benign Reagent for Carbonylation or Methylation

Dimethylcarbonate (DMC) is an alternative to toxic and dangerous phosgene, dimethyl sulphate, or methyl chloride. DMC is easy to handle, offers economic advantages, and is a versatile derivatives performer. It uses readily available, low-cost raw material, a clean technology, and a clean product. The result is a route based on the oxidation of carbon monoxide with oxygen in methanol as follows:

This process operates at medium pressure using a copper chloride catalyst (see Figure 3.6.5).

### Environmentally Safer Route to Aromatic Amines

The conventional industrial reaction involves activating the C–H bond by chloride oxidation. A variety of commercial processes use the resulting chlorobenzenes to produce substituted aromatic amines. Since neither chlorine atom ultimately resides in the final product, the ratio of the by-product produced per pound of product generated in these processes is unfavorable.

In addition, these processes typically generate waste streams that contain high levels of inorganic salts which are expensive and difficult to treat.

Michael K. Stern, of Monsanto, uses nucleophilic substitution for hydrogen to generate intermediates for manufacturing 4-amino-diphenylamine, eliminating the need for halogen oxidation (see Figure 3.6.6). Stern and coworkers synthesize *p*-nitroaniline (PNA) and *p*-phenylenediamine (PPD) using nucleophilic aromatic substitution for

FIG. 3.6.5 Block diagram of the EniChem Synthesis process for DMC.

hydrogen instead of a pathway using chlorine oxidation. Benzamide and nitrobenzene react in the presence of a base under aerobic conditions to give 4-nitrobenzamide in high yield. Further treatment with methanolic ammonia gives PNA and regenerates benzamide.

### Minimizing Waste Disposal Using Solid Catalysts

This example includes processes for producing ethylbenzene, methyl tert-butyl ether (MTBE), and ethyl tert-butyl ether (ETBE), and many other processes.

Historically, the  $\text{AlCl}_3$  catalyst system has been the technology for ethylbenzene synthesis. However, the disposal of the waste stream presented an environmental problem. The Mobil ZSM-5 catalyst permits a solid-catalyst, vapor-phase system which gives yields comparable to the  $\text{AlCl}_3$ , catalyzed system but without the environmental problems associated with  $\text{AlCl}_3$ .

A new, strongly acidic, ion-exchange catalyst is replacing more acid catalyst applications for producing MTBE, ETBE, olefin hydration, and esterification. The high-temperature catalyst, Amberlyst 36, can tolerate temperatures up to  $150^\circ\text{C}$ . Compared to sulfuric acid, the selectivity of the acidic resins is higher, product purity is better, and unlike acid, separating the product from the catalyst is not a problem.

### Petrochemicals from Renewable Resources

This example describes making alpha-olefins from carboxylic acids.

A catalytic technique (the Henkel process) offers a green alternative for making alpha-olefins because it can produce them from fatty acids instead of from petroleum. In the reaction, an equimolar mixture of a carboxylic acid and acetic anhydride is heated to  $250^\circ\text{C}$  in the presence of a palladium or rhodium catalyst as follows:

This reaction causes the carboxylic acid to undergo decarbonylation and dehydration to a 1-alkene having one

FIG. 3.6.6 Environmentally safer route to aromatic amines. (Reprinted, with permission, from D.L. Illman, 1993, Green technology presents challenge to chemists, *C&E News* [6 September].)

less carbon atom. The catalyst lives are long. The spent catalyst can be recovered for reuse (Borman 1993). Only minute quantities of by-products are generated.

### Avoiding Toxic Catalysts, Toxic Acids, and Solvents

These examples include using a dye and a light in green oxidations and an alternate to the Friedel–Crafts reaction.

The use of nontoxic dyes as catalysts in oxidation reactions that were previously carried out with toxic compounds of metals such as cadmium, lead, mercury, nickel, and chromium are being explored by Epling. His strategy uses a dye to absorb visible light and then transfer an electron efficiently and selectively to cause a reaction. Some of these reactions are shown in Figure 3.6.7.

In this figure, with light as a reagent and dye as a catalyst, deprotection of organic functional groups proceeds under neutral conditions without the use of heavy metals or chemical oxidants. The reaction at the top of the figure shows deprotection of dithianes. Shown in the middle, the benzyl ether protecting group is often used to protect an alcohol during organic synthesis. The usual ways to remove this blocking group—catalytic hydrogenation or alkalimetal reduction—involve conditions that can result in additional, unwanted reductions in the alcohol molecule. Using visible light and a dye catalyst, Epling has achieved excellent yields of alcohol. The bottom reaction shows 1,3-oxathianes, used in stereo-controlled synthesis routes, which often are deprotected by oxidative methods that involve mercuric chloride in acetic acid, mercuric chloride with alkaline ethanolic water, or silver nitrate with *N*-chlorosuccinimide. In addition to the carbonyl product, Epling obtains the nonoxidized thioalcohol, allowing the chiral starting material to be recovered while avoiding the generation of toxic pollutants. Eosins (yellow), erthrosin (red), and methylene blue are examples of dyes that have worked well (Illman 1993).

Kraus is studying a photochemical alternative to the Friedel–Crafts reaction. The Friedel–Crafts reaction uses Lewis acids such as aluminum chloride and tin chloride, as well as corrosive, air-sensitive, and toxic acid chlorides and solvents such as nitrobenzene, carbon disulfide, or halogenated hydrocarbons. Kraus' photochemical alterna-

FIG. 3.6.7 Dye and light used in green oxidations.

tive exploits the reaction between a quinone and an aldehyde and is initiated by a simple lamp. Some of the products produced with this alternative are shown in Figure 3.6.8.

This figure shows that no restrictions appear to exist for functional groups meta and para to the formyl group of the benzaldehyde. Ortho groups that are compatible with the reaction conditions include alkoxy groups, alkyl groups, esters, and halogens. Many substituted benzoquinones react with aromatic and aliphatic aldehydes according to this scheme.

### Organic Chemicals from Renewable Resources

This example discusses processes that use genetically engineered organisms as synthetic catalysts.

D-glucose can be derived from numerous agricultural products as well as waste streams from processing food products. Frost has developed a technology using genetically engineered microbes as synthetic catalysts to convert D-glucose to hydroquinone, benzoquinone, catechol, and adipic acid used in nylon production (see Figure 3.6.9).

The technology shown in this figure presents two challenges: directing the largest possible percentage of the consumed D-glucose into the common pathway of aromatic amino acid synthesis and assembling new biosynthetic pathways inside the organism to siphon carbon flow away from those amino acids and into the synthesis of the industrial chemicals. To synthesize hydroquinone and benzoquinone, 3-dehydroquinone (DHQ) is siphoned from the common pathway by the action of quinic acid dehydrogenase. Catechol and adipic acid synthesis rely on siphoning off 3-dehydroshikimate (DHS).

Until recently, enzymes have been used largely for degradative processes in the food and detergent industries.

FIG. 3.6.8 Alternative to Friedel–Crafts reaction. (Reprinted, with permission, from D.L. Illman, 1993, Green technology presents challenge to chemists, *C&E News* [6 September].)

FIG. 3.6.9 Industrial chemicals produced from D-glucose by engineered bacteria.

However, in the future, they will be used increasingly for synthesis. The advantages are that enzymes are selective, they are nonhazardous, and operating conditions are moderate. For example, *S. aureus*, a naturally occurring protease (enzyme), is used in a route to convert aspartic acid and phenylalanine methyl ester into aspartame. This use avoids the pretreatment needed to block a side reaction that forms a nonsweet product (Parkinson and Johnson 1989).

### CHOICE OF REAGENTS

In oxidations, potassium dichromate or permanganate, or lead tetraacetate, is used in the laboratory. However, these stoichiometric reactions involve mole-for-mole amounts of high-molecular-weight oxidants. Therefore, the oxidants must be used in large, absolute quantities. Such reactions are costly and generate large volumes of an effluent, pos-

sibly containing toxic metal salts that must be treated in the scaled-up process (Stinson 1993).

Hydrogen peroxide, peracetic acid, or tert-butyl hydroperoxide should be investigated as alternatives in oxidations catalyzed by trace amounts of transition metals. Such reactions could be easily worked up and result in only water, acetic acid, or tert-butanol as by-products. (Stinson 1993).

DMC can replace phosgene in carbonylation reactions and dimethyl sulfate and methyl chloride in methylation reactions. Oxalyl chloride is another alternative to phosgene.

Phosgene is a valuable agent for converting acids to acid chlorides, amides to nitriles, primary amines to isocyanates, and alcohols to chloroformates. The more tractable diphosgene (trichloromethyl chloroformate,  $\text{ClCO}_2\text{Cl}_3$ ) can be used as a phosgene substitute in small-scale reactions (Stinson 1993).

An alternative to the highly toxic and potentially explosive fluorinating reagents (such as HF,  $\text{FClO}_3$ , and  $\text{CF}_3\text{OF}$ ) and the reagent called Selectfluor (or F-TEDA-BF4) is 1-chloromethyl-4-fluoro-1,4-diazonia[2,2,2] bicyclooctane bis(tetrafluoroborate). Selectfluor provides a tool for developing and producing high-performance fluorine-containing drugs (Illman 1993).

Carbon dioxide has advantages over traditional pH-control chemicals, such as sulfuric acid. The savings come from both the favorable cost of carbon dioxide and the elimination of the costs of handling, storing, and disposing sulfuric acid. Charging a sodium nitrile solution with carbon dioxide under high pressure drops the pH low enough to diazotize p-anisidine. Releasing the pressure afterward raises the pH so that the coupled product precipitates out.

### CHOICE OF SOLVENTS

The principal functions of a solvent are to (1) provide a practical homogeneous reaction mass, (2) act as a heat-transfer agent, and (3) cause products or by-products to precipitate out, thereby improving the yield.

Chemicals under the 33/50 program started by the EPA in February 1991 should be avoided. The solvent should be chosen based on environmental grounds (ease of workup and solvent recovery) and then on optimizing in that solvent.

Less-hazardous organic solvents, such as ethyl acetate and isopropylacetate, should be used in place of more toxic (or more rigidly controlled by the EPA) solvents, such as methylene chloride and benzene. The current trend is to replace chlorinated solvents with nonchlorinated solvents.

Table 3.6.1 provides a set of general rules for the biodegradability of some organic molecules.

The use of polar solvents such as dimethyl sulfoxide (DMSO) or dimethylformamide (DMF) should be minimized. These solvents speed up many reaction rates, but

**TABLE 3.6.1 GENERAL RULES FOR BIODEGRADABILITY**

<i>Chemical Structure</i>	<i>Factors</i>
Branched structures	Highly branched compounds are more resistant to biodegradation. <ol style="list-style-type: none"> <li>1. Unbranched side chains on phenolic and phenoxy compounds are more easily metabolized than branch alkyl moieties.</li> <li>2. Branched alkyl benzene sulfonates degrade more slowly than straight chains.</li> </ol>
Chain length	Short chains are not as quickly degraded as long chains. <ol style="list-style-type: none"> <li>1. The rate of oxidation of straight-chain aliphatic hydrocarbons is correlated to length of the chain.</li> <li>2. Soil microbes attack long-chain mononuclear aromatics faster than short chains.</li> <li>3. Sulfate-reducing bacteria more rapidly degrade long-length carbon chains than short-length carbon chains.</li> <li>4. ABS detergents increase in degradability with an increase in chain length from C<sub>6</sub> to C<sub>12</sub> but not &gt;C<sub>12</sub>.</li> </ol>
Oxidized compounds	Highly oxidized compounds, like halogenated compounds, can resist further oxidation under aerobic conditions but can be more rapidly degraded under anaerobic conditions.
Nonionic compounds	With active halogens present, nonionic compounds are likely to be degraded by nucleophilic displacement reactions like hydrolysis.
Saturated and unsaturated compounds	Unsaturated aliphatics are more easily degraded than corresponding saturated hydrocarbons.
Substituents on simple organic molecules	<ol style="list-style-type: none"> <li>1. Alcohols, aldehydes, acids, esters, amides, and amino acids are more susceptible for biodegradation than the corresponding alkanes, olefins, ketones, dicarboxylic acids, amines, and chloroalkanes.</li> <li>2. Increased substitution, higher chlorine content, and more than three cyclic rings hinder or greatly reduce biodegradation.</li> <li>3. The more chlorine on the aromatic ring, the more resistant the compound is to biodegradation.</li> <li>4. Aromatics with substituents are not available for bacterial utilization. Para substituents are more utilized than the meta or ortho substituents.</li> <li>5. Mono- and dicarboxylic acids, aliphatic alcohols, and ABS are decreasingly degraded when H is replaced by the CH<sub>3</sub> group.</li> <li>6. Ether functions are sometimes resistant to biodegradation.</li> </ol>

the reaction mixtures then need dilution with water, extraction, and evaporation and cause difficulties in solvent recovery and generate contaminated effluent water for treatment. However, using a 10% solution of DMF or DMSO in toluene might be worthwhile because the increased reaction rates can be combined with easier solvent recovery.

DeSimone and colleagues demonstrated the use of supercritical CO<sub>2</sub> as a medium for dispersion polymerizations. They used CO<sub>2</sub> and a specially engineered, free-radical initiator and polymeric stabilizer to effect the polymerization of methyl methacrylate.

The stabilizer contains a carbon-dioxide-phobic background, which attaches to the growing polymer particle, and a carbon-dioxide-philic side-chain, which is soluble in the supercritical medium and stabilizes the polymer colloid as the reaction proceeds. Use of the stabilizer allows high degrees of polymerization, leading to micrometer-size particles with a narrow size distribution.

Carbon dioxide can be easily separated from the reaction mixture since the pressure can be released and the gas vented to the atmosphere. This scheme offers the possibility of avoiding the generation of hazardous waste streams, including aqueous streams contaminated with leftover monomer and initiator, which is one of the plastic industry's greatest cleanup problems.

## Physical Factors

In addition to the preceding chemical factors, a number of physical factors have an important bearing on the chemical reaction. The most important of these are:

- Reaction pressure
- Reaction temperature
- Ratio of reactants
- Product workup

Most reactions occur under atmospheric pressure; while oxidation, hydrogenation, and some polymerization occur at higher pressures. The effects of pressure and temperature on equilibrium and the reaction rate are discussed in Section 3.7.

For capacity, feeding the reactants in their stoichiometric ratio and at a maximum concentration is advantageous. However, if one of the reactants is relatively expensive, using the other, less expensive, reactant in excess produces a higher yield with respect to the former reactant. This method is especially effective when recovering the more expensive reactant from the product stream is difficult.

## Process Optimization

In process optimization, the chemical engineer uses statistical, factorial experiments while simultaneously varying the reaction parameters such as temperature and stoichiometry. Computer programs are then used to generate contour maps of yield versus temperature and stoichiometry, revealing the global maximum yield. Finally, the engineer optimizes for the overall process cost but not necessarily for yields. Although certain stoichiometry gives the highest yields, the costs of indicated molar excesses of reagents may be higher for it than other stoichiometries, raising the process cost overall.

The workup is a separate phase of optimization because the workup of a reaction mixture differs depending on the ratio of product to other substances. The workup is different in a reaction that gives a 60% yield than in another that gives a 95% yield.

The yields to be maximized in a workup should be chromatographically determined yields and not isolated ones. Thus, with the yield maximized, the workup can be optimized.

Whenever feasible, distillation provides the most convenient and cheapest workup procedure. On a workup of reaction mixtures, quenching with water to precipitate an organic product or extract the aqueous layer with organic solvents should be avoided. When the organic product is precipitated by water, it is usually not in the best crystalline form. Thus, the solid is hard to filter and takes a long time to dry, which results in a long production time. Water precipitation also results in the water being contaminated with organics, which must be treated (Benforado, Riddlehover, and Gores 1991).

The organic solvent extraction of a water-quenched reaction mixture is also messy. The extraction is slow and inefficient. Things tend to be extracted nonselectively. Also, several water washings of organic phases produce a large amount of water effluent.

Instead of water quenching, chemical engineers can usually induce a solid product to crystallize by adjusting the solvent concentration and temperature (Stinson 1993). These adjustments result in a purer product, easier solvent

recovery by distillation of the filtrate, and less effluent to treat.

## Process Development

Once the process has been defined in the laboratory, expected yields are known, and the waste streams that are most likely to be produced are quantified, the chemical engineer's next step is to verify these data on a scale that can be used to design the commercial manufacturing process. This step is done in a pilot plant.

## PILOT PLANT STUDIES

Obviously, some waste reduction work must be done. In addition to verifying the chemistry proven in the laboratory, an effective waste elimination strategy dictates that the pilot plant be used to quantify the nonproductive activities which include:

- Start up and shutdown losses
- Reactor washings between operations
- Sampling and analytical losses
- Catalyst usage and losses
- Incidental losses from spills and equipment cleanings
- Packaging requirements for raw materials and products

The key parameters to evaluate during a pilot plant study include:

- Flexibility in the selection of raw materials to minimize waste volume and toxicity
- Methods of improving process reliability to minimize spills and off-spec production
- The ability to track and control all waste streams
- The potential impacts of the process on the public, including odor generation, visible emissions, fear generated by the handling of toxic materials, emergency considerations, and so on

Process reliability is generally considered from the health and safety perspective. Reliability also affects waste generation by preventing situations that might result in releases or off-spec products. Sequencing operations to reduce equipment cleaning and reactor washing between steps also reduces the amount of nonproduction waste associated with the process.

A major problem that interferes with the ability of many operating plants to minimize their waste is a lack of adequate process measurement. Thus, the installation of point-of-generation measurement systems should be incorporated into the process and plant design.

## INTEGRATED PROCESS DEVELOPMENT

The aim of pollution prevention R&D is to modify processes or test alternate routes to minimize waste streams

in the first place. For waste that is unavoidable, this goal involves integrating recovery or waste destruction into the process. In this procedure, the chemical engineer must evaluate the type and quality of the starting materials, the optimal recycling options, and improved treatment or elimination of process waste as a whole at the development stage. Thus for each process, optimum chemical and physical conditions must first be established in the laboratory and then at the pilot plant. The engineer must establish process balances and develop technologies for the optimal treatment of waste streams.

The decision tree approach (see Figure 3.6.10) relates a production plant and its waste streams, with emphasis on process safety. Integrated process development allows a dynamic search for the optimum process conditions by iterative use of the established tools of process chemists and engineers. The described approach for an environmentally sound chemical process applies to both individual process steps and complete, complex, multistage processes.

Figure 3.6.11 shows the process balances of letter acid production before and after the development work (Laing 1992). The upgraded process requires about sixty man-years' work for chemists, chemical engineers, and other engineers. The cost of the new plant is several hundred millions of dollars. Large production volumes, similarities in products, and the possibility of building a new plant at a new site facilitated a near perfect solution.

The following benefits were achieved:

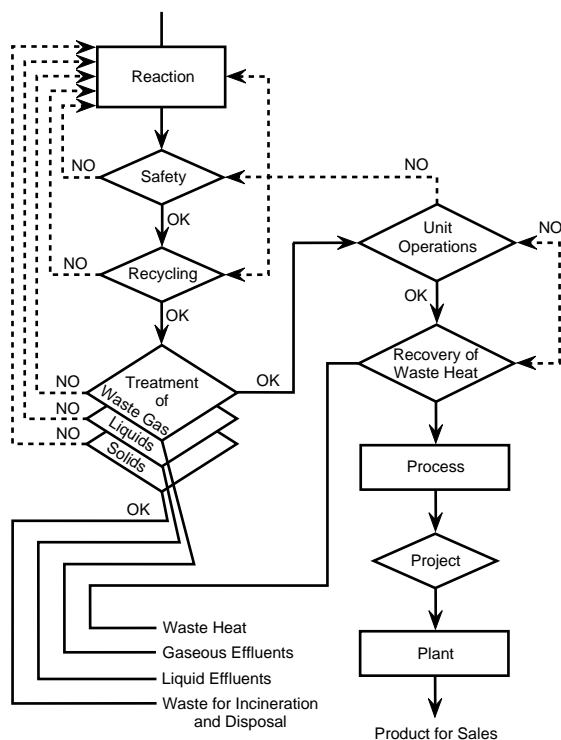

FIG. 3.6.10 Integrated process development.

FIG. 3.6.11 Letter acid production. (Reprinted, with permission, from Ian G. Laing, 1992, Waste minimisation: The role of process development, *Chemistry & Industry* [21 September].

Raw material consumption reduced from 13.3 tn to 7.5 tn per ton of product—a decrease of 44%.

The solvents were recycled, and the hydrochloric acid (gas) was converted back to chlorosulphonic acid and recycled in the process.

Sulfur dioxide gas was purified, liquified, and sold for external recycling (no sulfur dioxide emissions).

All waste was reduced by about half and the aqueous effluent by about 80%.

The organic load in the aqueous effluent was reduced by more than 97% through the integration of wet air oxidation, and waste gas was reduced to zero through the inclusion of waste air incineration.

As in another plant, the waste was drastically reduced but not totally eliminated. Even with ever increasing automation and processing technologies, the optimization between the input and output streams of a production process is never complete. The potential for improving efficiency always exists.

—David H.F. Liu

## 3.7 REACTION ENGINEERING

---

---

A pollution prevention strategy is to begin at the reactor, which is the heart of the process. The reactor is where raw materials are converted into products and waste by products. Reactor design is therefore a vital step in the overall design of a process. Here, the chemical engineer must regard two things as being fixed beforehand: the scale of operation and the thermodynamics and kinetics of the given reaction.

### Batch and Continuous Operations

For batch operations, the physical properties such as temperature, concentration, pressure, and reaction rate change at any point within the reactor as the reaction proceeds. In continuous operations, these properties are subject to only small, if any, local fluctuations. Two key differences on waste regeneration between batch and continuous processes are:

Waste streams from batch processes are generally intermittent, whereas those from continuous processes are continuous.

The composition and flow rates of waste streams leaving batch processes typically vary, whereas those of continuous processes are fairly constant.

The variability of waste from batch processes creates more difficult waste management problems. For example, if the total volume of waste must be handled, the instantaneous maximum flow is higher in a batch plant, and larger equipment is required to handle this waste. Also, waste generation rates are often high during start up and shutdown periods, and these periods occur most frequently in batch units. Therefore, waste reduction factors generally favor continuous rather than batch processing (Rossiter, Spriggs, and Klee 1993).

The main factors and heuristics usually considered in a decision between batch and continuous operations are (Rossiter, Spriggs, and Klee 1993):

Production rate: Under 500,000 lb/yr, batch processing is invariably used; between 500,000 and 5,000,000 lb/yr, batch processing is common; at higher rates, continuous processing is preferred.

Product life: Batch plants are better suited to products with short life spans where a rapid response to the market is required.

Multiproduct capabilities: If the unit must make several similar products using the same equipment, batch processing is usually preferred.

Process reasons: A number of process-related factors can lead to batch processing being preferred; for example, cleaning requirements that need frequent shutdowns, difficulties in scaling up laboratory data, or complicated process recipes.

If potentially serious environmental problems are anticipated with a process, the selection of a continuous unit is favored. Batch operations are preferred for reactions where rapid fouling occurs or contamination is feared.

In practice, some of the other factors mentioned previously can dictate that a batch operation is preferred. Then, the chemical engineer should consider smoothing intermittent or variable flow streams (for example, by adding buffer storage capacity) to simplify processing and recovery of waste material.

The capital cost for a batch operation is often less than for a corresponding continuous process. Therefore, it is frequently favored for new and untried processes which will be changed to a continuous operation at a more advanced stage of development.

As a final observation on the use of heuristics, Haseltine (1992) notes that the inherent flexibility of batch plants often makes raw material and product substitution simpler in these processes.

### Waste Production in Reactors

Under normal operating conditions, five sources of waste production exist in reactors (Smith and Petela 1991):

If unreacted feed material cannot be recycled back to the reactor, then low conversion in the reactor leads to waste for that unreacted feed.

The primary reaction can produce waste by products; for example:

Secondary reactions can produce waste by products; for example:

Impurities in the feed material become waste or can react to produce additional waste by products.

The catalyst is either degraded and requires changing or is lost and cannot be recycled.

## REDUCING WASTE FROM SINGLE REACTIONS

If the reaction forms a waste by-product, as in Equation 3.7(1), the chemical engineer can only avoid the waste by product by using a different reaction path, e.g., a change in feedstock, different reaction chemistry, and ultimately a different process.

### Increasing Conversion for Single Irreversible Reactions

If separating and recycling unreacted feed material is difficult, a high conversion in the reactor is necessary. For an irreversible reaction, a low conversion can be forced to a higher conversion by a longer residence time in the reactor, a higher temperature, or higher pressure. A longer residence time is usually the most effective means.

For continuous reactors, this increase in residence time means adding extra volume to the reactor. For batch reactors, higher conversion can mean a longer cycle time, a bigger reactor, or a new reactor in parallel. Sometimes, the chemical engineer can increase the residence time in the existing reactor without increasing the cycle time simply by rescheduling other operations in the process.

### Increasing Conversion for Single Reversible Reactions

Maximum conversion is the equilibrium conversion, which cannot be exceeded even with a long residence time. However, options are available for increasing conversion.

#### EXCESS REACTANTS

Using an excess of one of the reactants is a well-known technique (see part (a) in Figure 3.7.1).

(a) The effect of the Feed Ratio on Equilibrium Conversion

(b) The Effect of a Concentration of Inerts on both Gas- and Liquid-Phase Reactions

(c) The Effect of Temperature on Equilibrium Conversion

(d) The Effect of Pressure on Equilibrium Conversion of Gas-Phase Reactions

FIG. 3.7.1 How reactor conditions affect equilibrium conversion for reversible reactions.

#### PRODUCT REMOVAL DURING REACTION

Sometimes the product (or one of the products) can be removed continuously from the reactor as the reaction progresses; for example, the product can be allowed to vaporize from a liquid-phase reaction mixture. Another way is to carry out the reaction in stages with intermediate separation of the products between each stage.

#### INERT CONCENTRATION

Sometimes an inert is present in the reactor. This inert might be a solvent in a liquid-phase reaction or an inert gas in a gas-phase reaction. If the total number of moles increases as the reaction proceeds, adding inert material increases the equilibrium conversion (see part (b) in Figure 3.7.1). If the number of moles decreases, decreasing the concentration of the inert increases the equilibrium conversion. If the number of moles remains the same, the inert material has no effect on the equilibrium conversion.

## REACTION TEMPERATURE

Sometimes the chemical engineer can change the temperature to force a higher equilibrium conversion (see part (c) in Figure 3.7.1). For endothermic reactions, the temperature should be as high as possible without exceeding the limitations on construction materials, catalyst life, and safety. For exothermic reactions, the ideal temperature decreases continuously as conversion increases.

## REACTION PRESSURE

Changing the reactor pressure can also force a higher equilibrium conversion in gas-phase reactions (see part (d) in Figure 3.7.1). Reactions involving a decrease in the number of moles should operate at the highest possible pressure. For reactions involving an increase in the number of moles, the ideal pressure should decrease continuously as conversion increases. The chemical engineer can reduce the pressure by either operating at a lower absolute pressure or adding an inert diluent.

Note that forcing a high conversion reduces the load on the separation system and may allow it to operate more effectively. Thus changes to the reactor reduce waste from the separation system.

## REDUCING WASTE FROM MULTIPLE REACTION SYSTEMS

All of the arguments presented for a single reaction apply to the primary reaction in a multiple reaction system. Besides suffering the losses described for single reactions, multiple reaction systems also form waste by-products in secondary reactions.

### Reactor Type

The correct type of reactor must be selected. The CPI uses a variety of reactor types, but most emulate one of three ideal models used in reaction kinetic design theory: the ideal-batch, continuous well-mixed, and plug-flow models (see Figure 3.7.2). In ideal-batch and plug-flow reactors, material spends the same time in the reactor. By contrast, in the continuous well-mixed reactor, the residence time is widely distributed. A series of continuous well-mixed reactors approaches the plug-flow reactor in behavior.

The differences in mixing characteristics between ideal-batch and plug-flow reactors and ideal-batch and continuous well-mixed reactors can significantly effect waste minimization in multiple reaction systems.

In the continuous well-mixed reactor, the incoming feed is instantly diluted by the product which has been formed. Thus, an ideal-batch or plug-flow reactor maintains a higher average concentration of feed than a continuous well-mixed reactor.

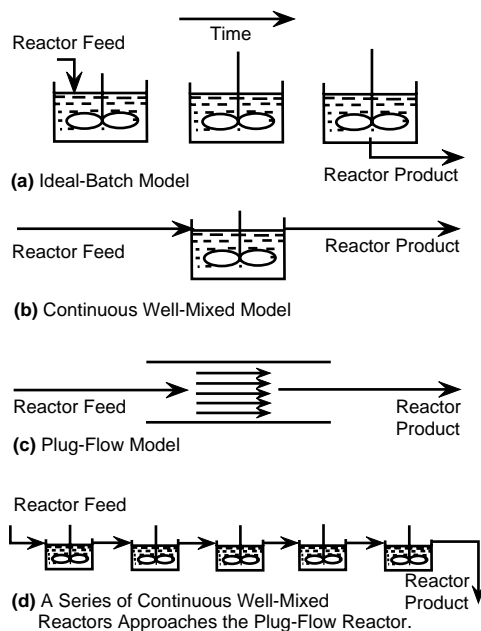

FIG. 3.7.2 Models for reactor design. (Reprinted, with permission, from Robin Smith and E. Petela, 1991, Waste minimization in the process industries, Part 2: Reactors, *The Chemical Engineer* [12 December].)

### Reactor Selection

As shown in the two sets of parallel reactions in Table 3.7.1, the feed material can react either to the PRODUCT or in parallel to the WASTE BY-PRODUCT. By looking at the ratio of the rates of the secondary and primary reactions in Table 3.7.1, the chemical engineer can choose conditions to minimize that ratio.

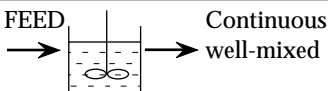

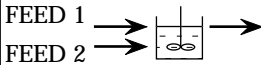

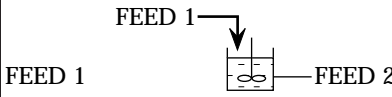

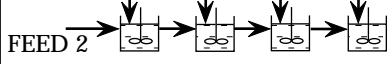

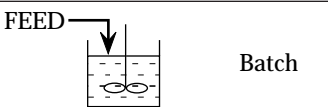

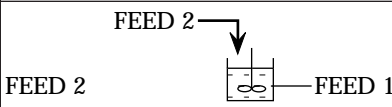

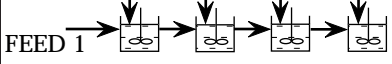

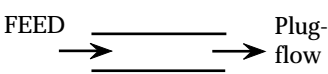

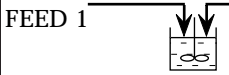

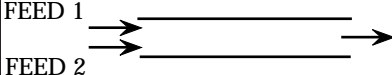

For some two-feed reaction systems (as shown in Table 3.7.1), semibatch and semiplug-flow processes can be used. In a semibatch process, the reactor is charged with one of the feeds at the start of the reaction, and the other feed is added gradually. The semiplug-flow scheme uses a series of well-mixed reactors, and one of the feeds is charged gradually as the reaction progresses.

Instead of the parallel reactions shown in Table 3.7.1, reactions can also be in series. This reaction system with its corresponding rate equations is as follows:

In this reaction system, the FEED reacts to the PRODUCT without any parallel reactions, but the PRODUCT continues to react in series to the WASTE BY-PRODUCT. If the FEED's residence time in the reactor is too short, insufficient PRODUCT is formed. However, if the FEED remains in the reactor too long, this excess time increases its chances of becoming WASTE BY-PRODUCT. Thus, the FEED should ideally have a fixed, well-defined residence

**TABLE 3.7.1 CHOOSING THE CORRECT REACTOR TYPE TO MINIMIZE WASTE FOR PARALLEL REACTIONS**

Reaction system	FEED --> PRODUCT FEED --> WASTE PRODUCT	FEED 1 + FEED 2 ---> PRODUCT FEED 1 + FEED 2 ---> WASTE BY-PRODUCT	
Rate equations	$r_1 = k_1 [C_{FEED}]^{a_1}$ $r_2 = k_2 [C_{FEED}]^{a_2}$	$r_1 = k_1 [C_{FEED, 1}]^{a_1} [C_{FEED, 2}]^{b_1}$ $r_2 = k_2 [C_{FEED, 1}]^{a_2} [C_{FEED, 2}]^{b_2}$	
Ratio to minimize	$\frac{r_2}{r_1} = \frac{k_2}{k_1} [C_{FEED}]^{a_2-a_1}$	$\frac{r_2}{r_1} = \frac{k_2}{k_1} [C_{FEED, 1}]^{a_2-a_1} [C_{FEED, 2}]^{b_2-b_1}$	
$a_2 > a_1$	$b_2 > b_1$ 	$b_2 > b_1$ 	Continuous well-mixed
	$b_2 < b_1$	 	Semibatch Semiplug flow
$a_2 < a_1$	$b_2 > b_1$ 	$b_2 > b_1$  	Semibatch Semiplug flow
	$b_2 < b_1$ 	$b_2 < b_1$  	Batch Plug-flow

Source: Smith and Petela, 1991.

time in the reactor. This requirement implies that to minimize waste from multiple reactions in series, an ideal-batch or plug-flow reactor performs better than a continuous well-mixed reactor.

### Reactor Conversion

For the series reaction of Equations 3.7(3) and 3.7(4), a low concentration of PRODUCT in the reactor minimizes the formation of WASTE BY-PRODUCT. This reduction can be achieved by low conversion in the reactor.

If the reaction involves more than one feed, operating with the same low conversion on all feeds is not necessary. By using an excess of one feed, the chemical engineer can operate with relatively high conversion of other feed material and still inhibit series waste by-product formation.

Unfortunately, low conversion in the reactor (whether on one or all of the feeds) can increase both energy use and the cost of separation and recycling. However, if an existing separation system has spare capacity, reducing conversion to reduce waste by-product formation via series reaction is still worth considering.

Whereas increasing conversion always increases the formation of waste by-products via series reactions, the same is not always true of parallel reactions. Whether waste by-product formation via parallel reactions increases or decreases with increasing conversion depends on the order of the primary and secondary reactions.

### Reactor Concentration

One or more of the following actions improves selectivity:

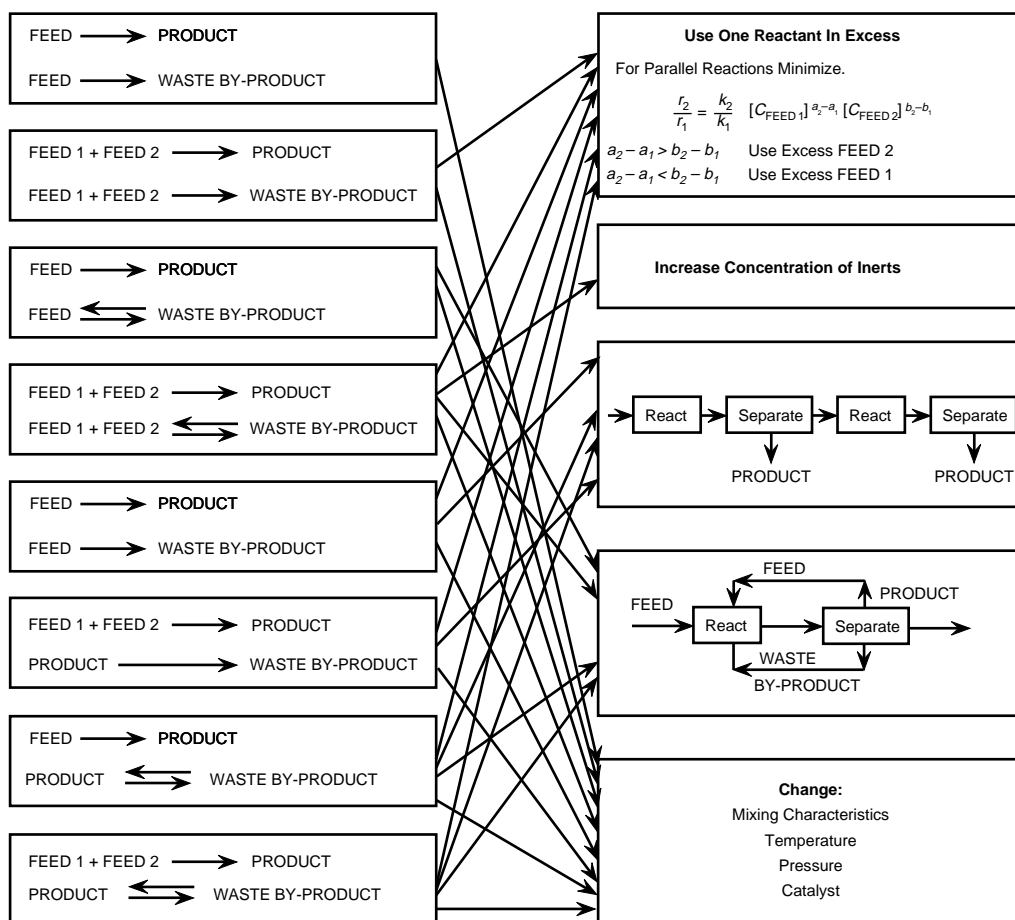

For a given reactor design, use an excess of one of the feeds when more than one feed is involved.

If the by-product reaction is reversible and involves a decrease in the number of moles, increase the concentration of inerts.

If the by-product reaction is reversible and involves an increase in the number of moles, decrease the concentration of inerts.

Separate the product during the reaction before continuing further reaction and separation.

Recycle waste by-products to the reactor. Where this recycling is possible, the waste by-products should be recovered and recycled to extinction.

**FIG. 3.7.3** Overall strategy for minimizing waste from secondary reactions. (Reprinted, with permission, from Smith and Petela, 1991.)

Each of these measures, in appropriate circumstances, minimizes waste. The effectiveness of these techniques depends on the reaction system. Figure 3.7.3 shows where each technique is appropriate for a number of reaction systems.

### Temperature, Pressure, and Catalysts

In a system of multiple reactions, a significant difference can exist between the primary and secondary reactions in the way they are affected by changes in temperatures or pressure. Temperature and pressure should be manipulated to minimize waste (see Figure 3.7.3).

Catalysts also have a significant influence on the waste production with multiple reactions. Changing a catalyst is a complex problem which can ultimately mean a new process.

### Impurities and Catalyst Loss

When feed impurities react, this reaction wastes feed material, products, or both. Avoiding such waste is usually only possible by purifying the feed. Thus, higher feed pu-

rification costs must be evaluated against lower cost for raw materials, product separation, and waste disposal.

Using heterogeneous rather than homogeneous catalysts can also reduce waste from catalyst loss. Homogeneous catalysts can be difficult to separate and recycle, and this difficulty leads to waste. Heterogeneous catalysts are more common, but they degrade and need replacement. If contaminants in the feed material or recycling shortens the catalyst life, extra separation to remove those contaminants before they enter the reactor might be justified. If the catalyst is sensitive to extreme conditions such as high temperature, the following measures can help avoid local hot spots and extend the catalyst life:

- Better flow distribution
- Better heat transfer
- A catalyst diluent
- Better instrumentation and control

Fluid-bed catalytic reactors tend to lose the catalyst through attrition of the solid particles generating fines which are then lost. More effective separation and recycling of fines reduce catalyst waste to a point. Improving the mechanical strength of the catalyst is probably the best solution in the long run.

## Kinetic Data

The three types of laboratory and pilot plant data on which reactor designs are based are:

1. Measurements of composition as a function of time in a batch reactor of constant volume at a substantially constant temperature
2. Measurements of composition as a function of feed rate to a flow reactor of constant volume operated at constant pressure and substantially constant temperature
3. Measurements of composition as a function of time in a variable-volume batch reactor operated at constant temperature and substantially constant pressure.

The third type of data is less common than the other two, and the experimental technique is more difficult. A variable-volume reactor generally depends on varying the level of a confining liquid such as molten metal to maintain constant pressure. This method works well where the volume of the reacting system is difficult to calculate such as when a change of phase accompanies the reaction. It has the advantage of yielding positive rate measurements and data on the specific volume of the reacting system at the same time.

Data of the second type are generally the most dependable and simple to obtain. This method is directly applicable to the flow-type reactor. Data of the first type at constant volume are satisfactory except where added moles of gas result from the reaction. In such cases, the varying pressures make the data more difficult to interpret for complex systems (Hougen and Watson 1947).

Levenspiel (1972) provides more information about the methods for analysis of experimental kinetic data of complex reactions.

## 3.8

# SEPARATION AND RECYCLING SYSTEMS

---

---

Waste minimization within industry is synonymous with increasing the efficiency of separation systems. Efficiency means both the sharpness of the separation (i.e., how well the components are separated from each other) and the amount of energy required to effect the separation. If separation systems can be made more efficient so that the reactant and the intermediate in the reactor effluent can be separated and recycled more effectively, this efficiency can reduce waste.

This section discusses the use of schemes that minimize waste from separation and recycling systems and the use of new separation technologies for waste reduction.

### Minimizing Waste

Figure 3.8.1 illustrates the basic approach for reducing waste from separation and recycling systems. The best sequence to consider the four actions depends on the process. The magnitude of effect that each action has on waste minimization varies for different processes.

### RECYCLING WASTE STREAMS DIRECTLY

If waste streams can be recycled directly, this way is clearly the simplest to reduce waste and should be considered first. Most often, the waste streams that can be recycled directly are aqueous streams which, although contaminated, can be substituted for part of the freshwater feed to the process.

Figure 3.8.2 is a flowsheet for the production of isopropyl alcohol by the direct hydration of propylene. Propylene containing propane as an impurity is reacted with water to give a mixture which contains propylene, propane, water, and isopropyl alcohol. A small amount of by-products, principally di-isopropyl ether, is formed. Unreacted propylene is recycled to the reactor, and a purge is taken so that the propane does not build-up. The first distillation column (C1) removes the light ends (including di-isopropyl ether). The second distillation column (C2) removes as much as water as possible to approach the azeotropic composition of the isopropyl alcohol-water mixture. The final column (C3) performs an azeotropic distillation using di-isopropyl ether as an entrainer.

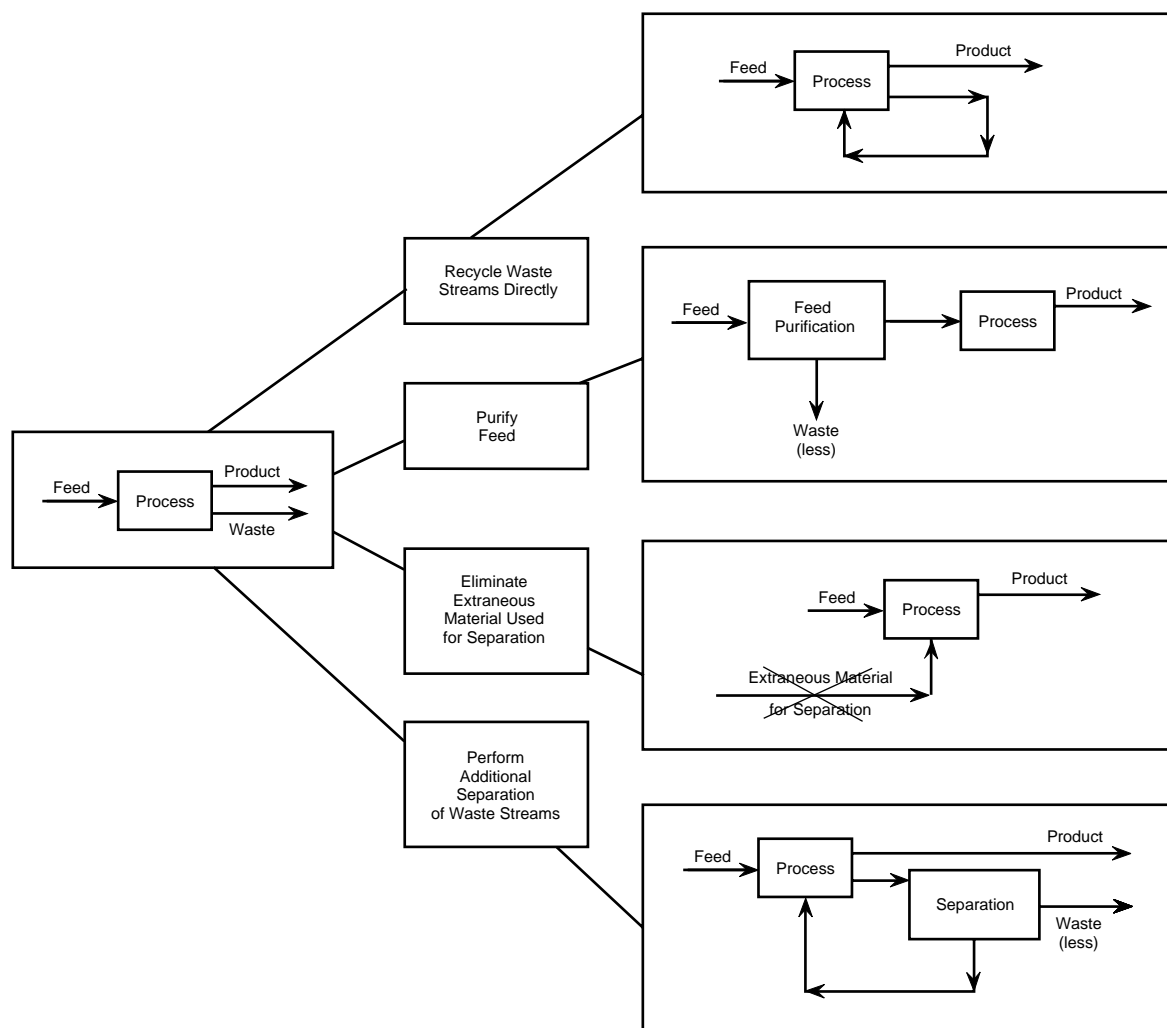

FIG. 3.8.1 Four general ways in which waste from the separation and recycling systems can be minimized.

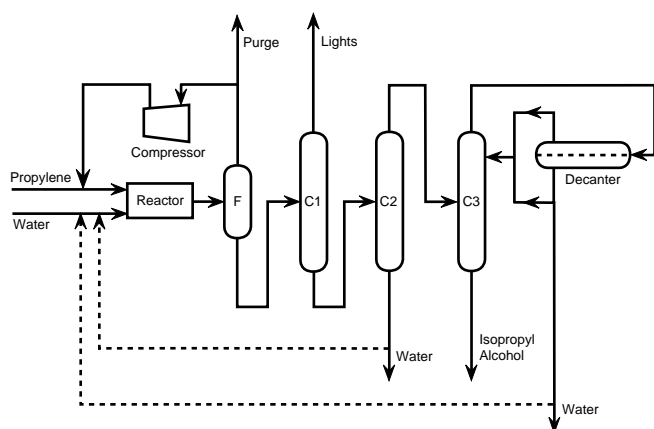

FIG. 3.8.2 Flowsheet for the production of isopropyl alcohol by direct hydration of propylene. (Reprinted, with permission, from R. Smith and Eric Patela, 1992, Waste minimization in the process industries, Part 3: Separation and recycle systems, *The Chemical Engineer* [13 February].)

Waste water leaves the process from the bottom of the second column (C2) and the decanter of the azeotropic distillation column (C3). These streams contain small quantities of organics which must be treated before the final discharge. The chemical engineer can avoid this treatment by recycling the wastewater to the reactor inlet and substituting it for part of the fresh water feed (dotted line in Figure 3.8.2).

Sometimes waste streams can be recycled directly but between different processes. The waste streams from one process may become the feedstock for another.

### FEED PURIFICATION

Impurities that enter with the feed inevitably cause waste.

Figure 3.8.3 shows a number of ways to deal with feed impurities including:

If the impurities react, they should be removed before they enter the process (see part a in Figure 3.8.3).

If the impurities are inert, are present in fairly large amounts, and can be easily separated by distillation,

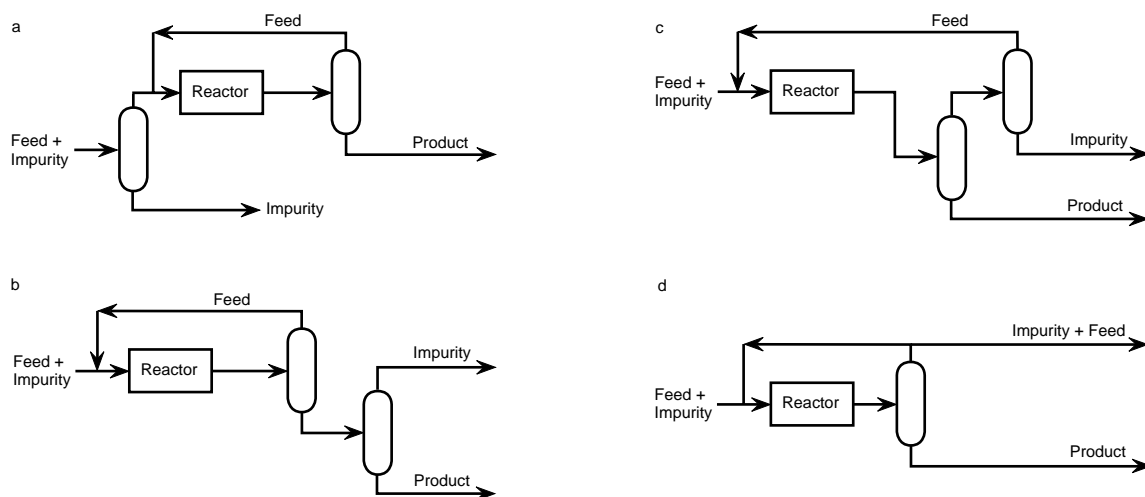

FIG. 3.8.3 Ways of dealing with feed impurities. (Reprinted, with permission, from Smith and Patela, 1992.)

they should be removed before processing. No heuristic seems to be available in enough quantity to handle the amount of the inerts.

If the impurities do not undergo reactions, they can be separated out after the reaction (see parts b and c in Figure 3.8.3).

If the impurities do not undergo reactions, a purge can be used (see part d in Figure 3.8.3). This way saves the cost of a separator but wastes useful feed material in the purge stream.

Of the preceding options, the greatest source of waste occurs when a purge is used. Impurities build up in recycling and building up a high concentration minimizes the waste of feed material and product in the purge. However, two factors limit the extent to which feed impurities can be allowed to build up:

High concentrations of inert material can have an adverse effect on the reactor performance.

As more and more feed impurities are recycled, the recycling cost increases (e.g., through increased recycling gas compression costs) to the point where that increase outweighs the savings in raw material lost in the purge.

In general, the best way to deal with a feed impurity is to purify the feed before it enters the process. In the isopropyl alcohol process (see Figure 3.8.2), the propane, an impurity in propylene, is removed from the process via a purge. This removal wastes some propylene together with a small amount of isopropyl alcohol. The purge can be virtually eliminated if the propylene is purified by distillation before entering the process.

Many processes are based on an oxidation step for which air is the first obvious source of oxygen. Clearly, because the nitrogen in air is not required by the reaction, it must be separated at some point. Because gaseous separations are difficult, nitrogen is normally separated using a purge, or the reactor is forced to as high a conversion

as possible to avoid recycling. If a purge is used, the nitrogen carries process materials with it and probably requires treatment before the final discharge. When pure oxygen is used for oxidation, at worst, the purge is much smaller; at best, it can be eliminated altogether.

In the oxychlorination reaction in vinyl chloride production, ethylene, hydrogen chloride, and oxygen react to form dichloroethane as follows:

If air is used, a single pass for each feedstock is used, and nothing is recycled to the reactor (see Figure 3.8.4). The process operates at near stoichiometric feedrates to reach high conversions. Typically, 0.7 to 1.0 kg of vent gases are emitted per kilogram of dichloroethane produced.

When pure oxygen is used, the problem of the large flow of inert gas is eliminated (see Figure 3.8.5). Unreacted gases can be recycled to the reactor. This recycling allows oxygen-based processes to operate with an excess of ethylene thereby enhancing the hydrogen chloride conversion without sacrificing the ethylene yield. Unfortunately, this

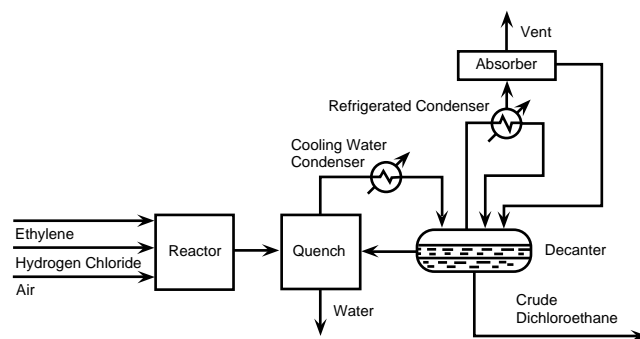

FIG. 3.8.4 The oxychlorination step of the vinyl chloride process with air feed. (Reprinted, with permission, from Smith and Patela, 1992.)

**FIG. 3.8.5** The oxychlorination step of the vinyl chloride process with oxygen feed. (Reprinted, with permission, from Smith and Patela, 1992.)

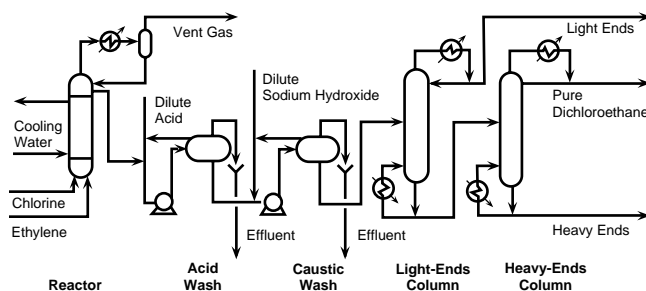

processing introduces a safety problem downstream of the reactor; unconverted ethylene can create explosive mixtures with oxygen.

This problem can be avoided when a small bleed of nitrogen is introduced. Since nitrogen is drastically reduced in the feed and essentially all ethylene is recycled, only a small purge must be vented. This method results in a 20- to-100-fold reduction in the size of the purge compared to a process that uses air as the oxidant (Reich 1976).

### ELIMINATION OF EXTRANEOUS SEPARATION MATERIALS

The most obvious example of an extraneous material used for separation is a solvent, either aqueous or organic. An acid or alkali can be used to precipitate other materials from a solution. When these extraneous materials used for separation can be recycled with high efficiency, no major problem exists. Sometimes, however, they cannot, and the discharge of that material creates waste. Reducing this waste involves using an alternative method of separation, such as evaporation instead of precipitation.

A flowsheet for a liquid-phase, vinyl chloride process is shown in Figure 3.8.6. The reactants, ethylene and chlorine dissolved in recirculating dichloroethane, are reacted to form more dichloroethane. The temperature is maintained between 45 and 65°C, and a small amount of ferric chloride is present to catalyze the reaction. The reaction generates considerable heat.

**FIG. 3.8.6** The direct chlorination step of the vinyl chloride process using a liquid-phase reactor. (Reprinted, with permission, from Smith and Patela, 1992.)

In early designs, the reaction heat was typically removed by means of heat transfer to cooling water. Crude dichloroethane was withdrawn from the reactor as a liquid, acid-washed to remove ferric chloride, then neutralized with a dilute caustic, and purified by distillation. The material used for separating the ferric chloride could be recycled to a point, but a purge had to be taken. This process created waste streams contaminated with chlorinated hydrocarbons which had to be treated before disposal.

The problem with the process shown in Figure 3.8.6 is that the ferric chloride is carried from the reactor with the product and must be separated by washing. A reactor design that prevents the ferric chloride from leaving the reactor would avoid the effluent problems created by the washing and neutralization. Because the ferric chloride is nonvolatile, one way to prevent ferric chloride from leaving the reactor is to allow the heat of the reaction to rise to the boiling point and remove the product as a vapor, leaving the ferric chloride in the reactor. Unfortunately, if the reaction is allowed to boil, two problems result:

Ethylene and chlorine are stripped from the liquid phase, giving a low conversion.

Excessive by-product formation occurs.

This problem is solved in the reactor shown in Figure 3.8.7. Ethylene and chlorine are introduced into circulating liquid dichloroethane. They dissolve and react to form more dichloroethane. No boiling takes place in the zone where the reactants are introduced or in the zone of reaction. As shown in Figure 3.8.7, the reactor has a U-leg in which dichloroethane circulates as a result of the gas lift and thermosiphon effects. Ethylene and chlorine are introduced at the bottom of the up-leg, which is under sufficient hydrostatic head to prevent boiling.

The reactants dissolve and immediately begin to react to form further dichloroethane. The reaction is essentially complete at a point two-thirds of the way up the rising leg. As the liquid continues to rise, boiling begins, and finally the vapor-liquid mixture enters the disengagement

**FIG. 3.8.7** A boiling reactor used to separate the dichloroethane from the ferric chloride catalyst. (Reprinted, with permission, from Smith and Patela, 1992.)

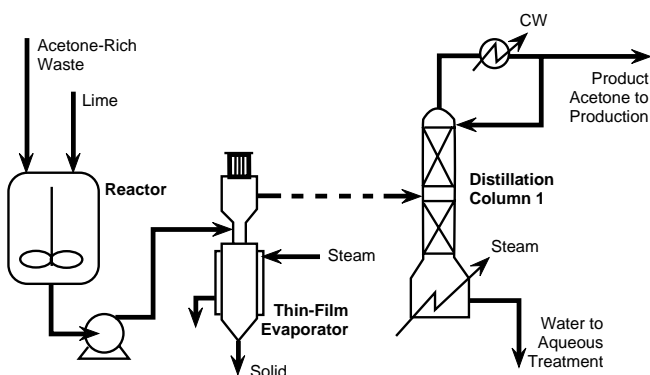

**FIG. 3.8.8** The direct chlorination step of the vinyl chloride process using a boiling reactor. This design eliminates the washing and neutralization steps and the resulting effluents. (Reprinted, with permission, from Smith and Patela, 1992.)

drum. A slight excess of ethylene ensures essentially 100% conversion of the chlorine.

As shown in Figure 3.8.8, the vapor from the reactor flows into the bottom of a distillation column, and high-purity dichloroethane is withdrawn as a sidestream, several trays from the column top. The design shown in Figure 3.8.8 is elegant in that the reaction heat is conserved to run the separation, and no washing of the reactor products is required. This design eliminates two aqueous streams which inevitably carry organics with them, require treatment, and cause loss of materials.

With improved heat recovery, using the energy system inherent in the process can often drive the separation system and operate at little or no increase in operating costs.

Figure 3.8.9 is a schematic for the recovery of acetone in a liquid waste containing hydrofluoric acid. This stream originates in the manufacture of an antibiotic precursor. It is pumped to a holding tank. Next, the hydrofluoric acid is neutralized with calcium hydroxide in a stirred reactor. The calcium fluorides that precipitate are difficult to filter. A totally enclosed, high-press filter press was tested. The filter cake had to be washed, generating large quan-

**FIG. 3.8.9** Acetone recovery. The thin-film evaporator provides a solution for hard-to-filter calcium fluorides. (Reprinted, with permission, from Smith and Patela, 1992.)

ties of aqueous waste, and then dried—another high capital cost item.

A more elegant solution involves a thin-film evaporator. In this design, the neutralized slurry is fed continuously to a thin-film evaporator. The acetone and water evaporate and are condensed, and the calcium fluorides fall from the base of the evaporator as a free-flowing, fine, dry powder. The acetone and water are fed continuously to a distillation column. The water leaves the bottom of the column and is sent to a water treatment plant. The acetone is upgraded to a sufficiently high purity to be reused directly in the production.

### ADDITIONAL SEPARATION AND RECYCLING

Perhaps the most extreme examples of separation and recycling are purge streams. Purges deal with both feed impurities and the by-products of the reaction. Purifying the feed can reduce the size of some purges. However, if purification is not practical or the purge must remove a by-product of the reaction, additional separation is necessary.

Figure 3.8.10 shows the recovery of acetone from an aqueous waste stream by distillation. As the fractional recovery of acetone increases when the reflux ratio is fixed, the cost of column and auxiliary equipment increases. Alternately, fixing the number of plates in the column eliminates additional column cost, and increasing recovery by increasing the reflux ratio increases the energy consumption for separation.

For each fractional recovery, a tradeoff exists between the capital and the energy required to obtain the optimum reflux ratio. The result is that the cost of separation (capital and energy) increases with increasing recovery (see Figure 3.8.11). On the other hand, increasing recovery saves the cost of some of the lost acetone. Adding the cost of raw materials to the cost of separation and recycling

**FIG. 3.8.10** Process improved by recycling the excess reactant and solvent used in the reaction.

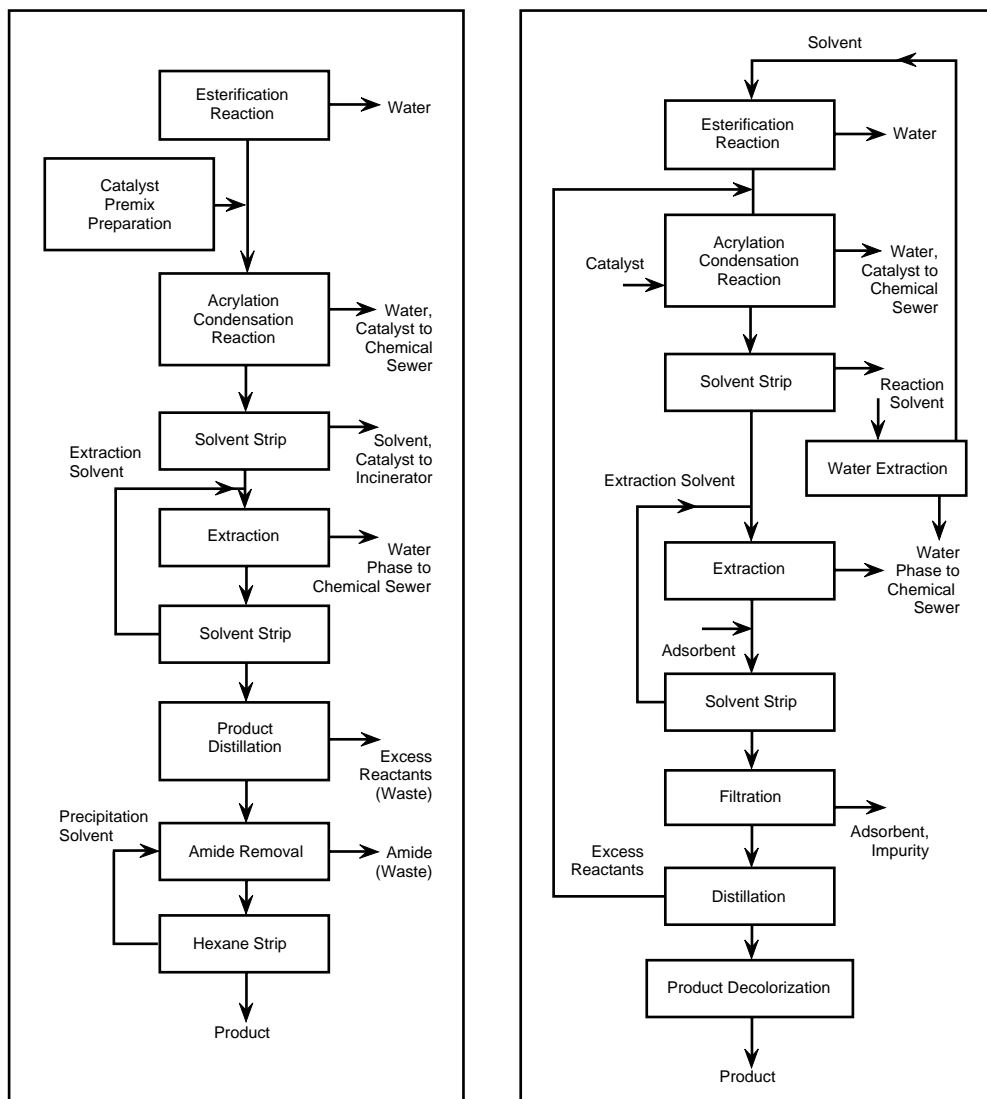

**FIG. 3.8.11** Optimum recovery determined by trading-off the effluent treatment costs and raw materials costs against the costs of separation.

gives a curve which shows the minimum cost at a particular acetone recovery.

Again, the unrecovered material from the separation becomes an effluent that requires treatment before it can be discharged to the environment. Thus, adjusting the raw material cost to the net value involves adding the cost of waste treatment of the unrecovered material. In fact with some separations, such as that between acetone and water, separation is possible to a level that is low enough for discharge without biological treatment.

Figure 3.8.12 shows an example of improving a process by recycling the excess reactant and solvent used in the reaction. Initially, the total waste generated from this process amounts to 0.8 lb/lb of product produced. After the changes, this figure drops to 0.1 lb/lb of product produced, and manufacturing costs drop by more than 20%.

**FIG. 3.8.12** Changing a process to recycle excess reactants. The change from the process on the left to the process on the right not only slashed the outlet of waste, but also lowered the manufacturing costs significantly.

## Separation Technology

In the CPI, separation processes account for a large part of the investment and a significant portion of the total energy consumption. The dominant separation process in the chemical industry (for liquids) is distillation. In terms of cleaner engineering, a goal is to find methods that provide a sharper separation than distillation, thus reducing the amount of contaminated product streams (i.e., waste), improving the use of raw materials, and yielding better energy economy. For this purpose, this section discusses some unconventional techniques that offer the potential for high separation efficiency and selectively.

### EXTRACTION

Distillation is used predominately in the process industries for separating the components of a liquid mixture. Liquid-liquid extraction (LLE) has some similarities to distillation; but whereas distillation employs differences in the boiling point to make a separation, extraction relies on the differences in chemical structure. LLE applications have a broad range and are growing.

LLE is seldom a stand-alone operation. It nearly always requires at least one distillation step as an adjunct because the extract stream contains not only the component but also some solvent. Most LLE processes distill this stream to purify the component and recover the solvent.

If a liquid-liquid separation problem can be conveniently handled by distillation alone, that option is simpler and better than LLE. Extraction becomes necessary in the separation of components that are either difficult or im-

**TABLE 3.8.1 EXTRACTION USES**

Pharmaceuticals	Recovery of active materials from fermentation broths
	Purification of vitamin products
Chemicals	Separation of olefins and paraffins
	Separation of structured isomers
Metals Industry	Copper production
	Recovery of rare-earth elements
Polymer Processing	Recovery of caprolactam for nylon manufacture
	Separation of catalyst from reaction products

	Recovery of acetic acid from dilute solutions
Foods	Decaffeination of coffee and tea
	Separation of essential oils (flavors and fragrances)
Petroleum	Lube oil quality improvement
	Separation of aromatics and aliphatics (e.g., benzene, toluene, xylenes)

possible to handle by ordinary distillation. Key examples are:

- The separation of close-boiling mixtures such as isomers
- The separation of heat-sensitive materials such as antibiotics
- The recovery of nonvolatile components as in extractive metallurgy
- The removal of organics from aqueous streams, e.g., phenol removal from wastewater

Table 3.8.1 shows some of the more common industrial extraction processes.

### SUPERCRITICAL EXTRACTION

Supercritical extraction is essentially a liquid extraction process employing compressed gases under supercritical conditions instead of solvents. The extraction characteristics are based on the solvent properties of the compressed gases or mixtures.

From an environmental point of view, the choice of the extraction gas is critical, and, to date, only the use of CO<sub>2</sub> qualifies as an environmentally benign solution. CO<sub>2</sub> is easy to handle and requires few safety precautions. Table 3.8.2 summarizes the applications of the supercritical extraction of natural products.

The advantage offered by supercritical extraction is that it combines the positive properties of both gases and liquids, i.e., low viscosity with high density, which results in good transport properties and high solvent capacity. Also, under critical conditions, changing the pressure and temperature varies the solvent characteristics over a range.

Figure 3.8.13 is a flow diagram of a typical supercritical extraction process using supercritical CO<sub>2</sub>. Mixing organic components into CO<sub>2</sub> generally enhances their solvent power while inert gases (Ar, N<sub>2</sub>) reduce the solvent power. Supercritical extraction is developing rapidly and may become an alternative worth considering not only for fine chemical separation but also for bulk processes.

## MEMBRANES

Membrane processes constitute a well-established branch of separation techniques (see Table 3.8.3). They work on continuous flows, are easily automated, and can be adapted to work on several physical parameters such as:

- Molecular size
- Ionic character of compounds
- Polarity
- Hydrophilic or hydrophobic character of components

Microfiltration, ultrafiltration, and reverse osmosis differ mainly in the size of the particles that the membrane can separate as follows:

Microfiltration uses membranes having pore diameters of 0.1 to 10 μm for filtering suspended particles, bacteria, or large colloids from solutions.

Ultrafiltration uses membranes having pore diameters in the range of 22,000 Å for filtering dissolved macromolecules, such as proteins from solutions.

Reverse osmosis membranes have pores so small that they are in the range of the thermal motion of polymer chains, e.g., 5 to 20 Å.

Electrodialysis membranes separate ions from an aqueous solution under the driving force of an electrostatic potential difference.

The membrane is also used in pervaporation that permits the fractionation of liquid mixtures by partial vaporization through a membrane, one side of which is under reduced pressure or flushed by a gas stream. Currently, the only industrial application of pervaporation is the dehydration of organic solvents, particularly dehydration of 90% plus ethanol solutions.

## LIQUID MEMBRANES

Liquid membrane technology offers a novel membrane separation method in which the separation is affected by the solubility of the component to be separated rather than by its permeation through pores, as in conventional membrane processes. The component to be separated is extracted from the continuous phase to the surface of the liquid membrane, through which it diffuses into the interior liquid phase.

The liquid membrane can be created in an emulsion or on a stabilizing surface of a permeable support (e.g., polymer, glass, or clay) as shown in Figure 3.8.14. The advantage of an emulsion is the large specific surface.

Figure 3.8.15 is a simplified diagram of a continuous emulsion liquid extraction process. The emulsion is prepared in the first stage of the process (water in oil [W/O] emulsion) by the emulgation of the inner liquid phase I in an organic phase II. In the permeation stage, the emulsion is dispersed into the continuous phase to be treated to form a water/oil/water (W/O/W) emulsion in which the mater-

ial transfer takes place. In the sedimentation stage, the continuous phase is separated from the emulsion by gravity. In the emulsion-breaking stage, the W/O emulsion is broken, and the organic inner phase is separated.

Compared to LLE, liquid membrane extraction, has the following advantages:

- Requires less solvent
- Is more compact because the extraction and stripping are performed simultaneously

Currently, the main areas of development are in increasing the emulsion stability and in the possibility of including catalyst reactions in the inner phase. Although liquid membrane extraction is not yet widely available, promising results have been reported for a variety of applications, and it appears to offer distinct advantages over alternative methods.

## BIOSORBERS

A number of selected, nonliving, inactivated materials of biological origin, such as algae, bacteria, and their products, have been screened for their ability to adsorb metals from a solution. Different biomass types exhibited different performance for the metal species tested. The pH for the test solutions also influenced biomass adsorption performance (see [Table 3.8.4](#)).

The biosorptive uptake of chromium and gold was rather specific. It was not affected by the presence of other cations such as  $\text{Cu}^{2+}$ ,  $\text{UO}_2^{2+}$ ,  $\text{Ca}^{2+}$ , and  $\text{Ni}^{2+}$  or anions

**TABLE 3.8.4** NEW BIOSORBENTS FOR NONWASTE TECHNOLOGY

such as  $\text{NO}^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{PO}_4^{3-}$ . The kinetics of metal uptake, except for gold, was generally rapid.

Sequestered metals could be eluted from the biomass, and the biosorbent material could be reused many times. This work demonstrates the potential of a new group of biosorbent materials of microbial origin which can be effectively used in novel processes of metal recovery from dilute solutions.

## REACTIVE DISTILLATION

Also known as catalytic distillation, this technique involves the use of a catalyst within a distillation column (see [Figure 3.8.16](#)). When the reaction and distillation occur in one step, a separate reaction step is eliminated.

The chemical reactions best suited for reactive distillation are those characterized by unfavorable reaction equilibria, high reaction heat, and significant reaction rates at distillation temperatures. For example, reactions with unfavorable equilibria are those in which the reaction products contain high concentrations of unconverted reactants. For these reactions, continuously removing one or more products from the reacting mixture substantially increases product conversion. A recently introduced structured packing that incorporates a catalyst may have significant benefits with this application.

A commercial process that uses catalytic distillation is the production of methyl-*tert*-butyl ether (MTBE), an octane enhancer made from methanol and isobutylene. Other

applications under testing include cumene from benzene and propylene; *tert*-amyl methyl ether (TAME); and ETBE, an octane enhancer similar to MTBE, made by reactive distillation from C<sub>4</sub> and C<sub>5</sub> feedstocks.

## 3.9 ENGINEERING REVIEW

---

---

During the early stages of a new facility's design, ample opportunity exists to implement design modifications that reduce waste treatment via source reduction or reuse. Incorporating waste elimination during process design is less complicated than modifying operations at an existing plant (Jacobs 1991).

This section discusses two aspects of pollution prevention from the early stage of engineering; these aspects are plant configuration and layout (Berglund and Lawson 1991). Then, it details a ten-step procedure and checklist that identifies and analyzes all environmental issues and pollution prevention opportunities during the plant design stage (Kraft 1992).

### Plant Configuration

In the context of pollution prevention, two aspects of plant configuration and layout are especially important: process integration and safety.

### PROCESS INTEGRATION

An integrated plant uses all by-products and co-products within the plant itself. This use minimizes the interplant transportation of raw materials, by-products, and wastes. Such a facility is likely to be large and complex. Thus, pollution prevention can supplement or replace the economics of scale for planning large, integrated facilities.

The importance of considering pollution prevention from the early design stage cannot be overemphasized. This consideration is critical for avoiding intrinsic wastes including unreacted raw materials, impurities in the reactants, unwanted by-products, and spent auxiliary materials (catalysts, oils, solvents, and others).

### THE SAFETY LINK

Chemical plants today are designed and operated to minimize chances of the worst possible outcome, such as ex-

## Reference

Reich, P. 1976. *Hydrocarbon processing*. (March).

plosions, fires, and operator exposure to toxic material. On the other hand, the pollution prevention perspective tries to maximize chances of the best possible outcome, namely zero emissions.

Reducing storage, monitoring for fugitive leaks, and using more integrated facilities are compatible objectives of both those operating goals. However, in other aspects, such as lengthened operating cycles to reduce waste generation during maintenance, efforts to achieve zero emissions can increase the likelihood of unsafe incidents, such as process upsets or the episodic (as opposed to continual) release of a toxic material. The optimal pollution prevention program balances the objectives between these potentially contradictory goals.

### Ten-Step Procedure

The ten-step procedure is summarized in [Table 3.9.1](#). Completing these steps ensures that all environmental issues are addressed and all opportunities to reduce waste are effectively defined and analyzed. This technique has been successfully applied in the design of a grassroots plant (Kraft 1992).

**TABLE 3.9.1 ENVIRONMENTAL REVIEW  
PROCEDURE TO EVALUATE NEW  
PLANT DESIGNS**

- 
1. Conduct initial screening and predesign assessments.
  2. Assign project environmental leadership responsibility.
  3. Define the project's environmental objectives.
  4. Identify the need for any permits.
  5. Determine the environmental compliance requirements.
  6. Perform an overall waste minimization analysis.
  7. Apply best environmental practices for emission-free and discharge-free facilities.
  8. Determine waste treatment and disposal requirements.
  9. Perform engineering evaluations of waste management options.
  10. Complete project environmental overview.
-

## STEP 1—PERFORM INITIAL ASSESSMENTS

The initial screening of the project is performed to:

- See if any environmental issues exist
- Perform an environmental site assessment evaluation
- Define and evaluate environmental baseline information

The initial screening answers the following questions:

- Does the project involve the use of chemical ingredients?
- Does the project involve equipment containing fuels, lubricants, or greases?
- Does the potential exist for reducing or eliminating waste, internally recycling materials, or reusing by-products?
- Do potential problems exist with the existing site conditions, such as the presence of contaminated soil or groundwater?
- Does the project have the potential to contaminate or impair groundwater or soil?
- Does the project involve the storage or transport of secondary waste?

If the responses to all of these questions are negative, then the responses are documented, and no further review is required. However, if the answer to any of these questions is yes, then environmental leadership responsibility for the project is assigned (Step 2), and the remaining steps are followed.

Many projects suffer delays and unforecasted expense due to site contamination. Therefore, the site should be checked for potential contamination as soon as possible. The site assessment should do the following:

- Determine whether site remediation is needed before construction
- Define the proper health and safety plans for construction activities
- Determine the appropriate disposal options for any excavated soil
- Identify the regulatory requirements that apply

Environmental site assessments include a review of the files about past site operations, an examination of aerial photographs, tests for potential soil and groundwater contamination, and the identification of the environmental constraints that can delay or prevent construction. The time and expense for the assessment should be incorporated into the project time-line and cost estimates.

Environmental baseline information usually includes:

- Background air quality prior to project start up
- Current emissions at existing sites and potential impact of these emissions on a new project
- Monitoring equipment needed to verify environmental compliance after start up

Impact of the construction and operation of a new facility on existing waste treatment facilities and current air, land, and water permits

Determination of whether an environmental impact analysis (EIA) should be performed. EIAs are common at greenfield sites, especially in Europe, and are generally performed by outside consultants.

## STEP 2—ASSIGN LEADERSHIP RESPONSIBILITY

The leader's role is to identify and coordinate all resources and ensure that the environmental analysis steps outlined in this procedure are followed. This role should be assigned as early as possible.

## STEP 3—DEFINE ENVIRONMENTAL OBJECTIVES

Environmental objectives include a statement supporting government regulations and company policy, a list of specific goals for emissions and discharges or reduction of emissions and discharges, and other project-specific objectives. These objectives focus preferentially on source reduction and recycling rather than waste treatment.

Table 3.9.2 is an example of an environmental charter. Table 3.9.3 presents a hierarchy (prioritized list) of emissions and discharges, and Table 3.9.4 lists the types of emissions and discharges. The charter and these lists serve as a starting point and should be modified to suit the project. The hierarchy of emissions and discharges varies depending on the geographical location (for example, CO<sub>2</sub> can rank higher in the hierarchy in Europe than in the United States).

## STEP 4—IDENTIFY PERMIT NEEDS

Obtaining permits to construct and operate a new facility is often the most critical and time-limiting step in a project schedule. Therefore, this step should be started as early as possible in the project.

Permit requirements or limits are not always clearly defined and can often be negotiated with government regulatory agencies. The types of permits required depend on the process involved, the location of the facility, the types of existing permits at an existing facility, and whether new permits or modifications to the existing permits are needed. Typically, permits are required for any part of a process that impacts the environment, such as:

- Any treatment, storage, or disposal system for solid or hazardous waste
- The exhaust of anything other than air, nitrogen, oxygen, water, or carbon dioxide (Carbon dioxide may require a permit in the future.)
- The use of pesticides or herbicides
- Incineration or burning

**TABLE 3.9.2 ENVIRONMENTAL CHARTER****TO**

Design facilities that operate as close to emission- or discharge-free as technically and economically feasible

**IN A WAY THAT**

Complies with existing and anticipated regulations as well as the established standards, policies, and company practices. Emission- and discharge-reduction priorities are based on a hierarchy of emissions and discharges (see Table 3.9.3) and include various types of emissions and discharges (see Table 3.9.4)

Develops investment options to reduce and eliminate all liquid, gaseous, and solid discharges based on best environmental practices. These options are implemented if they yield returns greater than capital costs. Failing to meet this standard, options may still be implemented subject to nonobjection of the business, production, and research and development functions.

Considers waste management options in the following priority order:

1. Process modifications to prevent waste generation
2. Process modifications to be able to
  - a. Recycle
  - b. Sell as co-product
  - c. Return to vendor for reclamation or reuse. Where materials are sold or returned to the vendor, the project team should ensure that customers and vendors operate in an environmentally acceptable manner.
3. Treatment to generate material with no impact on the environment.

Considers all potential continuous and fugitive emissions in the basic design data as well as all noncontinuous events such as maintenance and clean-out, start-up, and routine or emergency shutdowns.

Allows no hazardous waste to be permanently retained onsite unless the site has a regulated hazardous landfill.

Documents all emissions prior to and after waste minimization efforts.

Interacts with other internal or external processes or facilities to generate a combined net reduction in emissions. Interaction that leads to a net decrease in emissions is considered in compliance with this charter, while that leading to a net increase in emissions is considered not in compliance.

Where decisions are made to delay the installation of emission reduction facilities or to not eliminate specific emissions, considers providing for the future addition of such facilities at minimal cost and operating disruption.

Lists, where possible, specific goals for emissions and discharges or emission and discharge reductions, especially with regard to hazardous and toxic substances.

**SO THAT**

New facilities provide a competitive advantage in the marketplace based on their environmental performance.

**TABLE 3.9.3 HIERARCHY OF EMISSIONS AND DISCHARGES**

Carcinogens  
 Hazardous and Toxic Substances  
   Air emissions  
     Locally regulated pollutants  
     Nonregulated pollutants  
   Liquid and solid discharges  
     Heavy metals  
     Locally regulated pollutants  
     Nonregulated pollutants  
 Nonhazardous Substances  
   Low concentrations of toxic materials  
   Air emissions  
   Liquid and solid emissions  
   Inorganic salts  
 Nonhazardous Waste  
   Packaging, sanitary, biotreatment wastewater and sludge  
 Carbon dioxide  
 Water and Air (oxygen and nitrogen)  
   Drinking and breathing standards

*Note:* Odor, visible plumes, thermal pollution, and noise should also be considered and may rank high on the hierarchy, depending on the project.

**TABLE 3.9.4 TYPES OF EMISSIONS AND DISCHARGES**

Direct process streams (including after treatment)  
 Fugitive emissions  
 Oils, lubricants, fuels, chlorofluorocarbons, heat transfer fluids  
 Noncontact process water (e.g., cooling tower water and steam)  
 Batch process waste (e.g., dirty filters, fly ash, and water washes)  
 Packaging materials  
 Old equipment disposal  
 Office and cafeteria waste  
 Contaminated soil  
 Contaminated groundwater  
 Sediment and erosion control  
 Stormwater runoff discharges  
 Construction debris

**TABLE 3.9.5 STREAM-BY-STREAM INVENTORY (CHECKLIST A)**

Stream Type	Stream Name and Number	State (Vapor, Liquid, Solid)	Quantity (Volume)	Potential Environmental Issue(s)
-------------	------------------------	------------------------------	-------------------	----------------------------------

- Dredging in a water body or any activity that impacts wetlands
- Erosion and sedimentation control
- Monitoring or dewatering wells
- Any action that constructs or alters landfills or land-treatment sites
- Any system that constructs or alters water systems
- Any system that constructs or alters sanitary wastewater collection or treatment systems
- Stormwater runoff

**STEP 5—DETERMINE COMPLIANCE REQUIREMENTS**

Compliance is determined from the emission and discharge limits specified in the application permit. Going beyond the regulatory requirements and company goals can im-

prove goodwill or image, proactively address possible future regulations, and enhance the company’s competitive advantage. If a company decides to go beyond the regulatory requirements, it should do so via waste reduction or reuse rather than waste treatment.

**STEP 6—ANALYZE WASTE MINIMIZATION OVERALL**

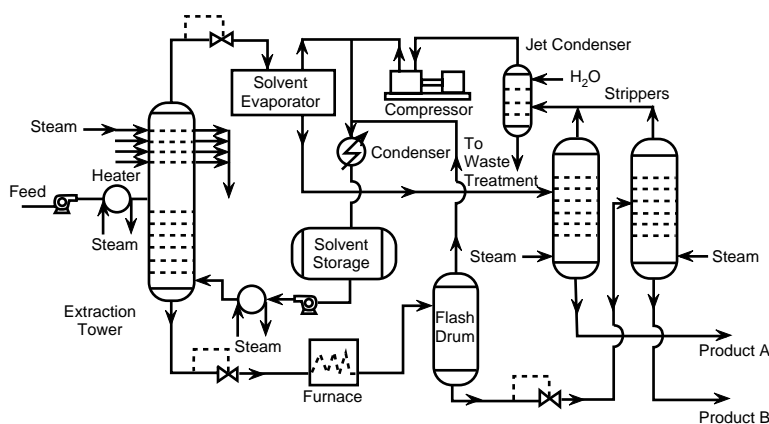

An accurate flow sheet that identifies all major process streams and their composition is important for meaningful waste minimization results.

First, all process streams should be classified into one of the four categories—nonuseful (waste), feed, intermediate, and recyclable—with potential environmental issues noted. Checklist A shown in Table 3.9.5 can be used for this analysis.

**TABLE 3.9.6 STREAM-BY-STREAM WASTE MINIMIZATION ANALYSIS (CHECKLIST B)**

1. Name of project (process step, production unit, plant)
2. Operating unit
3. Person completing this analysis
4. Stream information (see Nonuseful Streams on Checklist A, Question #5)
Stream Number
Stream Name
State (Vapor, Liquid, Solid)
5. What technologies, operating conditions, and process changes are being evaluated to:
a. Minimize this stream at the source?
b. Reuse, recover, or recycle this stream further than originally planned?
c. Process this stream into a useful product not originally planned?
d. Reduce the pollution potential, toxicity, or hazardous nature of this stream?
6. What other technologies, operating conditions, and process changes must be evaluated to:
a. Totally eliminate this stream at the source?
b. Allow reuse, recovery, or recycling of the stream?
c. Develop a useful product?
d. Reduce the pollution potential, toxicity, and hazardous nature of this stream?
7. How could raw material changes eliminate or reduce this nonuseful stream (See Checklist A, Question #4)?
8. What considerations are being given to combining or segregating streams to enhance recycling and reuse or optimize treatment?
9. Does this stream have fuel value? If so, what is being done to recover this fuel value?
10. What consideration is being given to using this stream as a raw material in other company production lines?
11. How does the way in which this stream is handled meet or exceed corporate, operating unit, and site waste elimination or minimization goals?
12. What is the regulatory inventory status (if any) of the chemical components of this stream? Do any premanufacture regulatory requirements exist for these components?

Fill out a separate form for each Nonuseful Stream (prior to treatment or abatement) that is not recycled internally in the manufacturing process via hard piping.

**FIG. 3.9.1** Two-phase separators in a chemical process setup. (Reprinted, with permission, from S.G. Woinsky, 1994, Help cut pollution with vapor/liquid and liquid/liquid separators, *CEP* [October].)

Next, the focus is on the nonuseful streams. Checklist B (see Table 3.9.6) should be completed for each nonuseful stream. Each nonuseful stream should be analyzed as follows:

- Can it be eliminated or minimized at the source?
- If not, can the need for waste treatment be avoided or minimized via reuse, recycling, or co-product sale?
- If not, the stream must be treated or rendered as nonhazardous to the environment. (Waste treatment is discussed in Step 8.)

The first two routes often result in attractive economic returns in addition to the environmental benefits. Treatment, while having environmental benefits, seldom has an economic return. For example, separating a gaseous raw material from a reactor purge stream for recycling or reuse may be advantageous. Removing VOCs from the air leaving the dryer involves passing the air through a carbon bed and recirculating it to the heater and dryer.

Reactors can be redesigned to minimize the buildup of latex with a polished interior surface.

Vapor-liquid and liquid-liquid separators can reduce pollution in a plant. Figure 3.9.1 shows a process flowsheet before the detailed engineering phase. Table 3.9.7 summarizes the points in Figure 3.9.1 where separation devices need to be considered. Since the quantities of the recovered material are small, high-value products are the most likely targets for separators, especially from liquid-liquid separators. However, for vapor-liquid separators, the cost is usually low since only the cost of a separator pad is normally involved, and moderately valued products can be targets for these separators (Woinsky 1994).

A major problem that interferes with the ability of operating plants to minimize their waste is a lack of adequate process measurements, such as flows and pH. Installing measurement devices where the waste is generated allows individual streams with waste-reduction potential to be identified and controlled (Jacobs 1991).

**TABLE 3.9.7** USE OF LIQUID-LIQUID AND VAPOR-LIQUID SEPARATORS IN FIGURE 3.9.1

Type of Device	Location	Reason
1. Liquid-liquid	In bottom of extraction tower.	Reduces utilities and size of furnace and flash drum.
2. Liquid-liquid	Above feed in extraction tower.	Avoids contamination of Product A with Product B and loss of Product B.
3. Vapor-liquid	In solvent evaporator.	Reduces utilities, avoids fouling of heat exchange equipment, and reduces size of heat exchangers.
4. Vapor-liquid	In flash drum.	Same as above.
5. Vapor-liquid	In top of jet condenser.	Protects compressor.
6. Vapor-liquid	In top of Product A stripper.	Avoids loss of Product A and reduces wastewater hydrocarbon load.
7. Vapor-liquid	In top of Product B stripper	Avoids loss of Product B and reduces wastewater hydrocarbons load.

**TABLE 3.9.8 BEST PRACTICES FOR EMISSION- AND DISCHARGE-FREE FACILITIES (CHECKLIST C)**

- 
1. Name of project (process step, production unit, plant)
  2. Operating unit
  3. Person completing this analysis
  4. What waste or emission is being generated from nonroutine operations (such as changeovers, clean-outs, start ups and shutdowns, spills, and sampling)? List the waste, its major constituents, frequency, and quantity.
  5. What techniques or hardware are being used to eliminate or minimize waste from nonroutine operations?
  6. What design practices are being used to eliminate fugitive emissions (e.g., from valves, pumps, flanges, and maintenance practices)?
  7. Where is closed-loop piping used to eliminate emissions (e.g., interconnections of vents)?
  8. What provisions are being made to contain process materials while other steps are in process or are taken offline (e.g., keeping materials within pipes or reactors or going to total recycling)?
  9. Where is emission-free equipment specified (e.g., pumps and compressors)?
  10. Where does the slope of lines change to eliminate waste via proper draining back to the process?
  11. Where are special materials of construction selected to eliminate waste (e.g., so conservation vents do not rust and stick open, cooling coils do not leak, metals do not leach from tanks, and sewers do not leak)?
  12. Where are equipment or unit operations close-coupled to eliminate waste?
  13. What is being done to eliminate or minimize putting waste in drums?
  14. What is being done to eliminate or minimize the amount of excess empty drums to dispose (e.g., changes to receive raw materials in returnable packages or bulk shipment)?
  15. What design practices are being used to prevent, through containment and early detection, soil and groundwater contamination due to leaks and spills (e.g., aboveground piping, secondary containment, and no inground facilities)?
  16. Where is secondary containment not provided and why?
  17. Where are chemicals stored or transported inground and why?
  18. What measures are being taken to ensure the control, recovery, and proper disposal of any accidental release of raw materials, intermediates, products, or waste?
- 

**TABLE 3.9.9 STREAM-BY-STREAM TREATMENT DISPOSAL ANALYSIS (CHECKLIST D)**

- 
1. Name of project (process step, production unit, plant)
  2. Operating unit
  3. Person completing this analysis
  4. Stream information (see Nonuseful Streams on Checklist A, Question #5)
    - Stream number
    - Stream name
    - State (Vapor, Liquid, Solid)
  5. Does this stream:
    - a. Contain toxic chemicals on any regulatory list? If yes, which ones?
    - b. Become a hazardous waste under any regulations? If yes, is it a listed or a characteristic waste?
  6. What permitting requirements are triggered if this stream is to enter the environment?
    - Water:
    - Land:
    - Air:
    - Local:
    - Other:
  7. Is treatment of this stream required before release to the environment? If no, what is the basis for this decision?
  8. How is this stream, or waste derived from treating it, to be disposed?
  9. If flaring of this stream is proposed, what alternatives to flaring were considered?
  10. If landfilling of this stream, or waste derived from it, is proposed:
    - a. What can be done to eliminate the landfilling?
    - b. Must this stream be stabilized before landfilling?
    - c. Must this waste be disposed in a secure Class I hazardous waste landfill?
  11. Is offsite treatment, storage, or disposal of this waste proposed? If yes, what could be done to dispose of this waste onsite?
- 

Fill out a separate form for each Nonuseful Stream listed in Checklist A and being discharged or emitted into the environment from this process step, production unit, or plant.

---

**TABLE 3.9.10 PROJECT DESIGN ENVIRONMENTAL SUMMARY (CHECKLIST E)**

Date				12. Environmental results:					
1. Project name		Project number		Emission/ Discharge	Before <sup>1</sup> (thousand lb/yr)	After (thousand lb/yr)	Waste Mgmt Hierarchy Method <sup>2</sup>	Reason for Not Zero Discharge <sup>3</sup>	Included in Company Env. Plan?

				Waste treatment					
				Investment					
				IRR (%)					
				For company compliance					
				For regulatory compliance					

**Explanations:**

- For stand-alone projects, before is the amount of waste generated and after is the amount emitted or discharged to the environment. For other projects, before and after refer to the amounts emitted or discharged to the environment before and after the project.
- Indicate A, B, C, or D; A = Source reduction; B = Recycling or Reuse; C = Treatment, D = Disposal.
- Indicate A, B, C, or D; A = Costs, B = Technology not available; C = Time schedule precluded; D = Other (explain).
- Use SARA 313 for U.S. and countries that have no equivalent regulation; use equivalent for countries that have a SARA 313 equivalent.
- Includes NO, SO, CO, NH<sub>3</sub>, nonSARA or equivalent VOCs, and particulates.
- Indicates CO<sub>2</sub>, N<sub>2</sub>O, CCl<sub>4</sub>, methyl chloroform, and nonSARA CFCs.
- Can include (for example) TOD, BOD, TSS, and pH.

Finally, the operating conditions (e.g., temperature and pressure) and procedures, equipment selection and design, and process control schemes must be evaluated. Some minor alterations to operating conditions, equipment design, and process control may afford significant opportunities for waste minimization at the source.

**STEP 7—APPLY BEST ENVIRONMENTAL PRACTICES**

The designer should review the entire process to minimize or eliminate unplanned releases, spills, and fugitive emis-

sions. (For example, recycle loops are used to sample batches. The use of reusable tote tanks should be promoted, and small refrigerated condensers should be installed on selected units to cut the emissions of costly volatile materials). This review should include all equipment pieces, seals, operating procedures, and so on.

The following hierarchy lists ways to eliminate or minimize fugitive emissions:

Prevent or minimize leaks at the source by eliminating equipment pieces or connections where possible and upgrading or replacing standard equipment with equipment that leaks less or does not leak at all.

Capture and recycle or reuse to prevent or minimize the need for abatement.

Abate emissions to have no impact on the environment.

Use the checklist shown in [Table 3.9.8](#) in this analysis.

### STEP 8—DETERMINE TREATMENT AND DISPOSAL OPTIONS

This step defines the waste treatment for nonuseful streams that cannot be reused or eliminated at the source. The goal here is to define the most cost-effective treatment method to render emissions and discharges nonharmful to the environment.

Waste treatment seldom has attractive economics. Waste treatment is used only as the last resort after all options to eliminate waste at the source or reuse waste are exhausted. The checklist shown in [Table 3.9.9](#) can be used to analyze waste treatment.

### STEP 9—EVALUATE OPTIONS

Performing engineering evaluations for Steps 6, 7, and 8 is the next step and is especially important when more than one option is available to achieve the same result. Choosing between options based on economic considerations re-

quires information such as capital investment, operating costs, and the cost of capital. The net present value calculations and internal rate of return can economically justify one alternative over another.

### STEP 10—SUMMARIZE RESULTS

Checklist E shown in [Table 3.9.10](#) is a suggested form for this report. If projects follow a formal approval procedure, this form shows that appropriate environmental reviews were conducted.

Finally, auditing the construction and start up ensures that the environmental recommendations are implemented.

## 3.10 PROCESS MODIFICATIONS

---

---

The ideal way to reduce or eliminate waste products is to avoid making them in the first place. Almost every part of a process presents an opportunity for waste reduction. Pollutant generation follows repeating patterns that are independent of an industry. Specific improvements involve raw materials, reactors, distillation columns, heat exchangers, pumps, piping, solid processors, and process equipment cleaning.

This section describes several practical ideas and options for preventing polluting generation. When these options are not practical, a second technique is used: recycling waste products back to the process. This section is not an exhaustive compilation of all possibilities. This information is intended to serve as a basis for discussion and brainstorming. Each organization must evaluate the suitability of these and other options for their own needs and circumstances.

Understanding the sources and causes of pollutant or waste generation is a prerequisite to brainstorming for the

equipment and process improvement options. For example, when confronted with a tar stream leaving a distillation column, an investigator can formulate the problem as reducing the tar stream. This formulation could lead the investigator to consider measures for optimizing the column. However, further investigation of the problem may show that the distillation is responsible for only a small portion of the tar and that variable raw material quality is responsible for some percentage of the by-product formation. Therefore, the most effective route for reducing the tar stream may not involve the distillation column at all (U.S. EPA 1993).

### Raw Materials

Raw materials are usually purchased from an outside source or transferred from an onsite plant. Studying each raw material determines how it affects the amount of waste produced. Also, the specification of each raw material en-

tering the plant should be closely examined. The options described next can prevent pollution generated from raw materials.

### Improving Feed Quality

Although the percentage of impurities in a feed stream may be low, it can be a major contributor to the total waste produced by a plant. Reducing the level of impurities involves working with the supplier of a purchased raw material, working with onsite plants that supply feed streams, or installing new purification equipment. Sometimes the effects are indirect (e.g., water gradually kills the reactor catalyst causing formation of by-product, so a drying bed is added).

### Using Off-Spec Materials

Occasionally, a process uses off-spec materials (that would otherwise be burned or landfilled) because the quality that makes a material off-spec is not important to the process.

### Improving Product Quality

Impurities in a company's products can create waste in their customers' plants. Not only is this waste costly, it can cause some customers to look elsewhere for higher quality raw materials. A company should take the initiative to discuss the effects of impurities with their customers.

### Using Inhibitors

Inhibitors prevent unwanted side reactions or polymer formation. A variety of inhibitors are commercially available. If inhibitors are already being used, a company should check with suppliers for improved formulations and new products.

### Changing Shipping Containers

If the containers for raw materials being received cannot be reused and must be burned or landfilled, they should be changed to reusable containers or bulk shipments. Similarly, a company should discuss the use of alternative containers for shipping plant products with customers.

### Reexamining the Need for Each Raw Material

Sometimes a company can reduce or eliminate the need for a raw material (especially one which ends up as waste) by modifying the process or improving control. For example, one company cut in half the need for algae inhibitors in a cross-flow cooling tower by shielding the water distribution decks from sunlight.

## Reactors

The reactor is the center of a process and can be a primary source of waste. The quality of mixing in a reactor is crucial. Unexpected flow patterns and mixing limitations cause problems in commercial reactors designed from bench-scale research data.

The three classes of mixing are defined as follows:

*Macro scale mixing* refers to blending the feed so that every gallon in a reactor has the same average composition.

Mixing on the macro scale is controlled through the use of agitators, educators, and chargers.

*Micro scale mixing* refers to interdispersing the feed to give uniform composition to the 10–100 m $\mu$  scale. Mixing on the micro scale is controlled by eddies and is not affected much by agitation.

*Molecular scale mixing* is complete when every molecule in the reactor is surrounded by exactly the same molecules at least on a time-averaged basis. This mixing is almost totally driven by diffusion.

A completely well-stirred-tank reactor implies good mixing in all these levels. Many agitated vessels are well mixed on the macro scale, however, no commercial reactor is perfectly well mixed or thoroughly plug-flow. This incomplete mixing may be unimportant if the reaction is dominant or all reactions are slow. In many applications, the reaction and mixing times are often similar and must be carefully studied.

Sometimes one level of mixing controls the reaction rates in a bench reactor, and another level controls them in the plant. For example, in the following commercial reaction:

where A, B, and D are reactants; P is the product; and Q and X are by-products; a major discrepancy in yields between laboratory and plant reactors was found. The scale of mixing regimes was determined to be the source of the difference. The reaction in Equation 3.10(1) was fast, the reaction in Equation 3.10(2) was the slow-rate determining step and the reaction in Equation 3.10(3) was intermediate in speed. In the laboratory reactor, A reacted with B before it could form X. In the plant, it took a few seconds to get A and B together. During this mixing time, enough A was lost to X to seriously reduce the yield. A 1-mm-diameter stream disperses much faster than a 50-mm one.

The vessel flow patterns, feed introduction methods, and mixing at all levels can create waste and operational problems. Companies should consider the following options to prevent pollution generated in reactors.

**FIG. 3.10.1** Feed distribution systems. (a) Poor feed distribution in a fixed-catalyst bed causes poor conversion and poor yield. (b) Uniform feed flow improves both yield and conversion.

### Improving Physical Mixing in the Reactor

Modifications to the reactor such as adding or improving baffles, installing a higher revolutions-per-minute motor on the agitator, or using a different mixer blade design (or multiple impellers) improves mixing. Pumped recirculation can be added or increased. Two fluids going through a pump, however, do not necessarily mix well, and an inline static mixer may be needed to ensure good contacting.

### Distributing Feed Better

Part (a) in Figure 3.10.1 shows the importance of distributing feeds. The reactants enter at the top of a fixed-catalyst bed. Part of the feed short-circuits through the center of the reactor having inadequate time to convert to the product. Conversely, the feed closer to the walls remains in the reactor too long and overreacts creating by-products that become waste. Although the average residence time in the reactor is correct, inadequate feed distribution causes poor conversion and poor yield.

One solution is to add a distributor that causes the feed to move uniformly through all parts of the reactor (see part (b) in Figure 3.10.1). Some form of collector may also be necessary at the bottom to prevent the flow from necking down to the outlet.

### Improving Methods of Adding Reactants

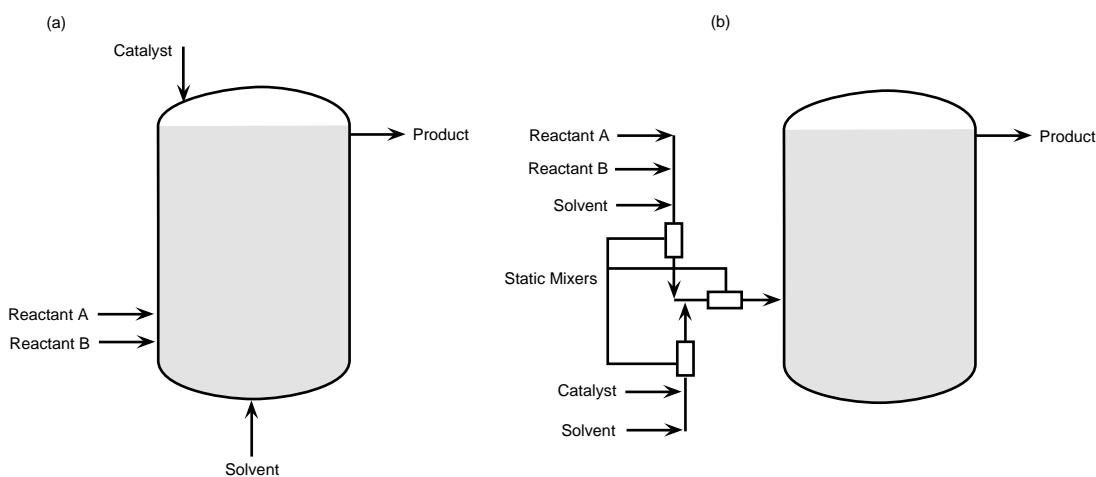

The purpose of this option is to make the reactant concentrations closer to the ideal before the feed enters the reactor. This change helps avoid the secondary reactions which form unwanted by-products. Part (a) in Figure 3.10.2 shows the wrong way to add reactants. The ideal concentration probably does not exist anywhere in this reactor. A consumable catalyst should be diluted in one of the feed streams (one which does not react in the presence of the catalyst). Part (b) in Figure 3.10.2 shows one approach of improving the addition of reactants using three inline static mixers.

### Improve Catalysts

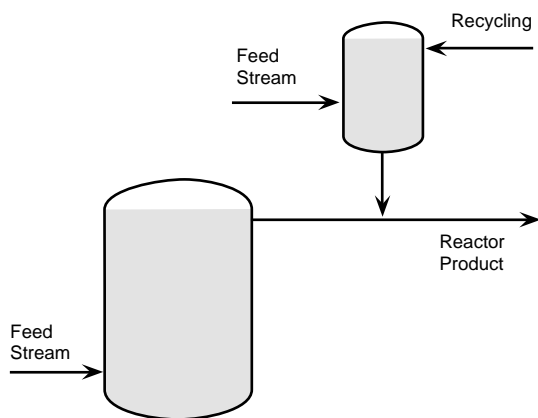

Searching for better catalysts should be an ongoing activity because of the significant effect a catalyst has on the reactor conversion and product mix. Changes in the chemical makeup of a catalyst, the method of preparation, or its physical characteristics (such as size, shape, and porosity) can lead to substantial improvements in the catalyst life and effectiveness (Nelson 1990).

### Providing Separate Reactors for the Recycling Stream

Recycling by-product and waste streams is an excellent way of reducing waste, but often the ideal reactor conditions for converting recycling streams to usable products are different from conditions in the primary reactors. One solution is to provide a separate, smaller reactor for handling recycling and waste streams (see Figure 3.10.3). The temperatures, pressures, and concentrations can then be optimized in both reactors to take maximum advantage of reaction kinetics and equilibrium.

**FIG. 3.10.2** Adding feed to a reactor. (a) This method results in poor mixing. (b) Inline static mixers improve reactor performance.

**FIG. 3.10.3** A separate, small reactor for recycling waste streams.

### Examining Heating and Cooling Techniques

A company should examine the techniques for heating and cooling the reactor to avoid hot or cold spots in a fixed-bed reactor or overheated feed streams, both of which usually give unwanted by-products.

### Providing Online Analysis

Online analysis and control of process parameters, raw material feed rates, or reaction conversion rates can significantly reduce by-products and waste.

### Implementing Routine Calibration

Routine calibration of process measurement and control equipment can minimize inaccurate parameter set points and faulty control.

### Upgrading Process Controls

Upgrading process parameter measurement and control equipment to ensure more accurate control within a narrow range can reduce process conditions that contribute to by-product formation.

### Considering a Different Reactor Design

The classic stirred-tank, back-mix reactor is not necessarily the best choice. A plug reactor has the advantage that it can be staged and each stage can run at different conditions, with close control of the reaction for optimum product mix (minimum waste). Many hybrid innovative designs are possible.

### Converting to a Continuous Process

The start ups and shutdowns associated with batch processes are a common source of waste and by-product

formation. Converting a process from batch to continuous mode reduces this waste. This option may require modification of piping and equipment.

### Optimizing Operating Procedures

This option includes investigating different ways of adding the reactant (e.g., slurry or solid powders), changing process conditions and avoiding the hydrolysis of raw materials to unwanted by-products, and using chemical emulsion breakers to improve organic-water separation in decanters. A common cause of by-product formation is a reaction time that is either too short or too long. In such cases, increasing or decreasing the feed rate can reduce by-products. Optimization of the reactant ratio can reduce excess constituents that may be involved in side, by-product-forming reactions.

### Distillation Columns

Distillation columns typical produce waste as follows:

- By allowing impurities that ultimately become waste to remain in a product. The solution is better separation. In some cases, normal product specifications must be exceeded.
- By forming waste within the column itself usually because of high reboiler temperatures which cause polymerization. The solution is lower column temperatures.
- By having inadequate condensation, which results in vented or flared products. The solution is improved condensing.

Some column and process modifications that reduce waste by attacking one or more of these three problems are outlined next.

### Increasing the Reflux Ratio

The most common way of improving separation is to increase the reflux ratio. The use of a higher reflux ratio raises the pressure drop across the column and increases the reboiler temperature (using additional energy). This solution is probably the simplest if column capacity is adequate.

### Adding Sections to the Column

If the column is operating close to flooding, adding a new section increases capacity and separation. The new section can have a different diameter and use trays, regular packing, or high-efficiency packing. It does not have to be consistent with the original column.

### Retraying or Repacking the Column

Another method of increasing separation is to retrain or repack part or all of a column. Both regular packing and

high-efficiency packing lower the pressure drop through a column, decreasing the reboiler temperature. Packing is no longer limited to a small column; large-diameter columns have been successfully packed.

### **Changing the Feed Tray**

Many columns are built with multiple feed trays, but valving is seldom changed. In general, the closer the feed conditions are to the top of the column (high concentration of lights and low temperature), the higher the feed tray; the closer the feed conditions are to the bottom of the column (high concentration of heavies and high temperature), the lower the feed tray. Experimentation is easy if the valving exists.

### **Insulating the Column or Reboiler**

Insulation is necessary to prevent heat loss. Poor insulation requires higher reboiler temperatures and also allows column conditions to fluctuate with weather conditions (Nelson 1990).

### **Improving the Feed Distribution**

A company should analyze the effectiveness of feed distributors (particularly in packed columns) to be sure that distribution anomalies are not lowering the overall column efficiency (Nelson 1990).

### **Preheating the Column Feed**

Preheating the feed should improve column efficiency. Supplying heat in the feed requires lower temperatures than supplying the same amount of heat to the reboiler, and it reduces the reboiler load. Often, the feed is preheated by a cross-exchange with other process streams.

### **Removing Overhead Products**

If the overhead contains light impurities, obtaining a higher purity product may be possible from one of the trays close to the top of the column. A bleed stream from the overhead accumulator can be recycled back to the process to purge the column lights. Another solution is to install a second column to remove small amounts of lights from the overheads.

### **Increasing the Size of the Vapor Line**

In a low-pressure or vacuum column, the pressure drop is critical. A larger vapor line reduces the pressure drop and decreases the reboiler temperature (Nelson 1990).

### **Modifying Reboiler Design**

A conventional thermosiphon reboiler is not always the best choice, especially for heat-sensitive fluids. A falling-film reboiler, a pumped recirculation reboiler, or high-heat flux tubes may be preferable to minimize product degradation.

### **Using Spare Reboilers**

Shutting down the column because of reboiler fouling can generate waste, e.g., the material in the column (the hold up) can become an off-spec product. A company should evaluate the economics of using a spare reboiler.

### **Reducing Reboiler Temperature**

Temperature reduction techniques such as using lower pressure steam, desuperheating steam, installing a thermocompressor, or using an intermediate heat-transfer fluid also apply to the reboiler of a distillation column.

### **Lowering the Column Pressure**

Reducing the column pressure also decreases the reboiler temperature and can favorably load the trays or packing as long as the column stays below the flood level. The overhead temperature, however, is also reduced, which may create a condensing problem. If the overhead stream is lost because of an undersized condenser, a company can consider retubing, replacing the condenser, or adding a supplementary vent condenser to minimize losses. The vent can also be rerouted back to the process if the process pressure is stable. If a refrigerated condenser is used, the tubes must be kept above 32°F if any moisture is in the stream.

### **Forwarding Vapor Overhead Streams**

If the overhead stream is sent to another column for further separation, using partial condensers and introducing the vapor to the downstream column may be possible.

### **Upgrading Stabilizers or Inhibitors**

Many distillation processes use stabilizers that reduce the formation of tars as well as minimize unfavorable or side reactions. However, the stabilizers not only become large components of the tar waste stream but also make the waste more viscous. The more viscous the waste stream, the more salable product the waste stream carries with it. Upgrading the stabilizer addition system requires less stabilizer in the process.

The upgrade can include the continuous versus batch addition of a stabilizer or the continuous or more frequent analysis of a stabilizer's presence coupled with the automatic addition or enhanced manual addition of the stabilizer. Another option is to optimize the point of addition,

the column versus the reboiler, along with the method of addition.

A stabilizer typically consists of a solid material slurried in a solvent used as a carrier. Options for waste reduction also focus on the selection of one of these two components. The addition of a stabilizer in powder form eliminates the solvent. The use of the product as a carrier component is one of the best options.

### Improving the Tar Purge Rate

Continuous distillation processes require a means of removing tar waste from the column bottoms. Optimizing the rate at which tars are purged can reduce waste. An automatic purge that controls the lowest possible purge rate is probably best. If an automatic purge is not possible, other ways exist to improve a manually controlled or batch-operated tar purge. If a batch purge is used, more frequent purges of smaller quantities can reduce overall waste (EPA 1993).

Some processes that purge continuously are purged at excessively high rates to prevent valve plugging. More frequent cleaning or installing a new purge system (perhaps with antisticking interior surfaces) permits lower purge rates.

### Treating the Column Bottoms to Further Concentrate Tars

Treating the tar stream from the bottom of a distillation column for further removal of the product by a wipe-film evaporator may be a viable option.

### Automating Column Control

For a distillation process, one set of operating conditions is optimum at any given time. Automated control systems respond to process fluctuations and product changes swiftly and smoothly, minimizing waste production.

### Converting to a Continuous Process

The start ups and shutdowns associated with batch processes are a common source of waste and by product formation. Converting a process from batch to continuous mode reduces this waste. This option may require modifications to piping and equipment. Before any equipment modification is undertaken, a company should do a computer simulation and examine a variety of conditions. If the column temperature and pressure change, equipment ratings should also be reexamined.

## Heat Exchangers

A heat exchanger can be a source of waste, especially with products that are temperature-sensitive. A number of techniques can minimize the formation of waste products in

heat exchangers. Most techniques are associated with reducing tube-wall temperatures.

### Using a Lower Pressure Steam

When plant steam is at fixed-pressure levels, a quick option is to switch to steam at a lower pressure, reducing the tube-wall temperatures.

### Desuperheating Plant Steam

High-pressure plant steam can contain several hundred degrees of superheat. Desuperheating steam when it enters a process (or just upstream of an exchanger) reduces tube-wall temperatures and increases the effective area of heat transfer because the heat transfer coefficient of condensing steam is about ten times greater than that of superheated steam.

### Installing a Thermocompressor

Another way of reducing the tube-wall temperature is to install a thermocompressor. These relatively inexpensive units work on an ejector principle, combining high- and low-pressure steams to produce an intermediate-pressure steam.

Figure 3.10.4 illustrates the principle of thermocompression. The plant steam at 235 psig upgrades 30-psig steam to 50 psig. Before a thermocompressor was installed, only 235-psig steam was used to supply the required heat.

### Using Staged Heating

If a heat-sensitive fluid must be heated, staged heating minimizes degradation. For example, the process can begin with waste heat, then use low-pressure steam, and finally use superheated, high-pressure steam (see Figure 3.10.5).

FIG. 3.10.4 Thermocompressor to upgrade 30-psig steam.

FIG. 3.10.5 Staged heating to reduce product degradation.

### Using Air-Fin Coolers

This option reduces the use of cooling water.

### Using Online Cleaning Techniques

Online cleaning devices such as recirculated sponge balls or reversing brushes keep tube surfaces clean so that lower temperature heat sources can be used.

### Using Scraped-Wall Exchangers

A scraped-wall exchanger consists of a set of rotating blades inside a vertical, cylindrical, jacketed column. They can be used to recover salable products from viscous streams. A typical application is to recover a monomer from polymer tars.

### Monitoring Exchanger Fouling

Exchanger fouling does not always occur steadily. Sometimes an exchanger fouls rapidly when plant operating conditions change too fast or when a process upset occurs. Other actions, such as switching pumps, unloading tank cars, adding new catalysts, or any routine action, can influence fouling. However, estimating the effect is possible.

The first step in reducing or eliminating the fouling causes is for the company to identify the causes by continuously monitoring the exchanger and correlating any rapid changes with plant events.

### Using Noncorroding Tubes

Corroded tube surfaces foul more quickly than noncorroded tube surfaces. Changing to noncorroding tubes can significantly reduce fouling.

### Controlling the Cooling Water Temperature

Excessive cooling water temperature can cause scale on the cooling water side.

## Pumps

Two options can prevent the pollution generated by pumps.

### Recovering Seal Flushes and Purges

A company should examine each seal flush and purge for a possible source of waste. Most can be recycled to the process with little difficulty.

### Using Seal-less Pumps

Leaking pump seals lose product and create environmental problems. Using can-type, sealless pumps or magnetically driven sealless pumps eliminates these losses.

## Piping

Even plant piping can cause waste, and simple piping changes can result in major reductions. The process changes described next are options for preventing pollution from piping.

### Recovering Individual Waste Streams

In many plants, various streams are combined and sent to a waste treatment facility as shown in Figure 3.10.6. A company should consider each waste stream individually. The nature of the impurities may make recycling or otherwise reusing a stream possible before it is mixed with other waste streams and becomes unrecoverable. Stripping, filtration, drying, or some type of treatment may be necessary before the stream can be reused.

### Avoiding Overheating Lines

If a process stream contains temperature-sensitive materials, a company should review both the amount and temperature level of line and vessel tracing and jacketing. If plant steam levels are too hot, a recirculated warm fluid can prevent the process stream from freezing. A company should choose a fluid that does not freeze if the system is shut down in winter. Electric tracing is also an option.

### Avoiding Sending Hot Material to Storage

Before a temperature-sensitive material is sent to storage, it should be cooled. If this coding is uneconomical because the stream from the storage must be heated when used, hot steam can be piped directly into the suction line of the storage tank pump as shown in Figure 3.10.7. The storage tank pump must be able to handle hot material without cavitating.

FIG. 3.10.6 Typical plant mixing of waste streams.

**FIG. 3.10.7** Hot stream piped directly into the suction line of the storage tank pump.

### Eliminating Leaks

Leaks are a major contributor to a plant's overall waste, especially if the products cannot be seen or smelled. A good way to document leaks is to measure the quantity of raw materials that must be purchased to replace lost stream (e.g., the amount of refrigerant purchased).

### Changing the Material of Construction

The type of metal used for vessels or piping can cause color problems or act as a catalyst in the formation of by-products. If this problem occurs, an option is to change to more inert metals. Using lined pipes or vessels is often a less expensive alternative to complex metallurgy. Several coatings are available for different applications.

### Monitoring Major Vents and Flare Systems

Flow measurements need not be highly accurate but should give a reasonable estimate of how much product is lost and when those losses occur. Intermittent losses, such as equipment purges, can be particularly elusive. Corrective action depends on the situation. Frequently, a company can reduce or eliminate venting or flaring by installing piping to recover products that are vented or flared and reuse them in the process. Storage tanks, tank cars, and tank trucks are common sources of a vented product. A condenser or small vent compressor may be all that is needed in these sources. Additional purification may be required before the recovered streams can be reused.

### Solid Processing

The options described next can prevent pollution generated in solid processing.

#### Optimizing Crystallization Conditions

A company should optimize crystallization conditions to (1) reduce the amount of product lost to the mother liquor and cake wash and (2) obtain the necessary crystal size. A crystal size that is too small needs recrystallization; a crystal size that is too large needs milling. A common practice is to add small crystals known as seeds into the solution immediately before incipient crystallization.

### Using Multiprocessors

New reactor-filter-dryer systems can handle more than one operation in the same vessel, thus minimizing transfer losses.

### Coupling the Centrifuge and Dryer

With this option, the solid is separated, washed, and dropped into the dryer to minimize transfer losses. A company can also use an easily emptied, bottom-discharge centrifuge.

### Using Bag Filters

A company should consider the use of bag filters instead of cartridge filters. Products can be recovered, and the bags can be washed and reused, while used filter cartridges must be disposed.

### Installing a Dedicated Vacuum System

This option can be used to clean spilled powders for companies producing dry formulations.

### Minimizing Wetting Losses

To minimize wetting losses, a company can modify the tank and vessel dimensions to reduce contact (e.g., the use of conical vessels).

### Process Equipment Cleaning

Equipment cleaning is one of the most common areas of waste generation. The reduction of solvent wash waste from metal cleaning and degreasing operations as well as various applications in the paint industries is well documented. This section focuses on the options used in the chemical industry's reduction of solvent wash waste (i.e., vessels and associated piping required in the clean-out).

#### Cleaning Equipment Manually

Manual cleaning reduces the amount of solvent used because: manual washing can be more efficient than an automated wash system; and personnel can vary the amount of solvent needed from wash to wash depending on the condition of the equipment (cleanliness).

A variation of this option involves personnel entering the equipment and wiping the product residue off the equipment interior walls with hand-held wipers or spatulas which would minimize or eliminate the need for a subsequent solvent wash. A company should thoroughly review the safety aspect of this option, particularly the nature and extent of personnel exposure, before implementation.

### Draining Equipment Between Campaigns

Better draining can reduce the amount of product residue on equipment walls and thereby minimizes or eliminates the solvent needed in a subsequent wash. A company can improve its draining simply by lengthening the time between the end of a production batch or cycle and the start of the washout procedure. For a packed distillation column, maintaining a slight positive pressure (with nitrogen) on the column for twenty-four to forty-eight hours facilitates draining. The residue product is thereby swept off the packing and accumulates in the bottom of the column.

### Prewashing Equipment with a Detergent and Water Solution

Prewashing contaminated equipment with a soap and water solution minimizes or eliminates the solvent needed in a subsequent wash step.

### Flushing the Equipment with the Product and Recycling It Back to the Process

This option applies when more than one product is produced with the same equipment. Prior to processing another product, a company can withhold a small reserve of a product from a previous similar process and then use it to flush the equipment. The contaminated product (used as a flush) can then be reworked or reprocessed to make it acceptable for use.

### Flushing with Waste Solvent from Another Process

Instead of using fresh solvent, a company can use the waste solvent from another process in the plant for the equipment flush. This option reduces the plant's total waste load.

### Minimizing the Amount of Solvent Used to Wash Equipment

Often, a company can minimize the amount of solvent used for a flush without changing the resulting cleanliness of the equipment.

### Increasing Campaign Lengths

With careful scheduling and planning, a company can increase product campaign lengths and thereby reduce the number of equipment washings needed.

### Optimizing the Order of Product Changeovers

Often the specifications for products produced in the same equipment are different. One set of specifications may be

more stringent than another. Through careful planning and inventory control, a company can make product changeovers from products with tighter specifications to those with looser specifications.

### Washing Vessels Immediately to Avoid Solidification

Often, product residue dries, thickens, and hardens in the equipment between solvent washouts. Immediately washing out vessels between campaigns makes the residue easier to remove when it does not set on the equipment interior walls.

### Replacing the Solvent with a Nonhazardous Waste

The solvent wash can be replaced with a less hazardous or nonhazardous (i.e., water) flush material. Another variation is to replace the solvent with a less volatile solvent thus reducing fugitive emissions. The solvent can then be recovered and recycled.

### Using a High-Pressure Water Jet

A new cleaning system uses a special nozzle and lance assembly which is connected to a high-pressure water source and inserted through a flange at the vessel bottom (see Figure 3.10.8).

As shown in the figure, a chain-drive moves the lance up and down the carriage as needed. A swivel joint at the base of the lance permits free rotation. The nozzle at the tip of the spinning lance has two apertures, which emit

FIG. 3.10.8 High-pressure water system.

cone-shaped sprays of water at 10,000 psi with a combined flow rate of 16 gpm. The operation of the lance is controlled from a panel well removed from the vessel. The process is designed so that no high-pressure spray leaves the interior of the vessel. These precautions assure operator safety during vessel washout.

All solvent waste is eliminated. The product removed from the equipment walls can be separated from the water and recovered for further waste reduction. Even in processes where water cannot be introduced into a vessel, an alternative exists. Vessels can be cleaned with solid carbon dioxide (dry ice) particles suspended in a nitrogen gas carrier. The solid CO<sub>2</sub> cleans in a manner similar to that of sand blasting, leaving only the material removed from the equipment (U.S. EPA 1993).

### **Using a Rotating Spray Head**

A rotating spray head can be used to clean vessel interiors. This system minimizes solvent use by allowing the solvent to contact all contaminated surfaces in an efficient manner (U.S. EPA 1993).

### **Using Pipe-Cleaning Pigs**

Pigs are pipe-cleaning mechanisms made of various materials. They are actuated by high-pressure water, product, or air. Pigs remove the residual build-up on pipe walls thereby minimizing or eliminating subsequent washing.

### **Using a Wiping or Brushing System**

This option uses a system of wipers or brushes that cleans off residual product. (This system is somewhat analogous to a car wash except that it washes the interior vessel walls as opposed to the outside of a car.) This system is appropriate for processes where the product hardens on the vessel walls. The wipers or brushes dislodge the material which subsequently falls to the vessel bottom. This system is not appropriate for a viscous material that would adhere to the brushes or wipers and have to be washed out; this situation would create as much, if not more, waste than the original process.

### **Using Antistick Coatings on Equipment Walls**

The application of anti-stick agent, such as Teflon, to the equipment interior walls enables the easy removal of left-over residue. Then, a subsequent flush can be accomplished with less solvent resulting in less waste (U.S. EPA 1993).

### **Using Distillation or Other Technology to Recover the Solvent**

The recycling and reuse of a solvent can reduce waste significantly.

### **Using Dedicated Equipment to Make Products**

This option eliminates the necessity of washing out equipment between production campaigns thus eliminating the flush solvent stream.

### **Installing Better Draining Equipment**

During the design of a new process, a company can minimize flush solvent waste by designing equipment to facilitate draining. This equipment includes vessels with sloping interior bottoms and piping arrangements with valve low points or valves that drain back to the main vessels. After a product campaign, the residue is drained from each equipment section into a movable, insulated collection vessel. The collected material is then reintroduced into the process during the next campaign.

### **Other Improvements**

A company can make a number of other improvements to reduce waste. These options are described next.

#### **Avoiding Unexpected Trips and Shutdowns**

A good preventive maintenance program and adequate spare equipment are two ways to minimize trips and unplanned shutdowns. Another way is to provide early warning systems for critical equipment (e.g., vibration monitors). When plant operators report unusual conditions, minor maintenance problems are corrected before they become major and cause a plant trip.

#### **Reducing the Number and Quantity of Samples**

Taking frequent and large samples can generate a large amount of waste. The quantity and frequency of sampling should be reduced, and the samples returned to the process after analysis.

#### **Recovering Products from Tank Cars and Trucks**

The product drained from tank cars and trucks (especially those dedicated to a single service) can often be recovered and reused.

#### **Reclaiming Waste Products**

Sometimes waste products—not all of which are chemical streams—can be reclaimed. Rather than sending waste products to a burner or landfill, some companies have

found ways to reuse them. This reuse can involve physical cleaning, special treating, filtering, or other reclamation techniques. Also, converting a waste product into a salable product may require additional processing or creative salesmanship, but it can be an effective means of reducing waste.

### Installing Reusable Insulation

When conventional insulation is removed from equipment, it is typically scrapped and sent to a landfill. A number of companies manufacture reusable insulation which is particularly effective on equipment where the insulation is removed regularly for maintenance (e.g., head exchanger heads, manways, valves, and transmitters).

### Maintaining External Painted Surfaces

Even in plants handling highly corrosive material, external corrosion can cause pipe deterioration. Piping and valves should be painted before being insulated, and all painted surfaces should be well maintained.

—David H.F. Liu

## 3.11 PROCESS INTEGRATION

---

---

*Process integration* is defined as the act of putting together (or integrating) the various chemical reactors, physical separations, and heating and cooling operations that constitute a manufacturing process in such a way that the net production cost is minimized. *Pinch technology* is the term used for the series of principles and design rules developed around the concept of a process pinch within the general framework of process integration. Pinch technology is a methodology for the systematic application of the first and second laws of thermodynamics to process and utility systems.

Pinch technology is a versatile tool for process design. Originally pioneered as a technique for reducing the capital and energy costs of a new plant, pinch technology is readily adaptable to identifying the potential for energy savings in an existing plant. Most recently, it has become established as a tool for debottlenecking, yield improvement, capital cost reduction, and enhanced flexibility. With the concern for the environment, design engineers can use the power of pinch technology to solve environmental problems.

This section addresses the following three areas in which pinch technology has been identified as having an important role (Spriggs, Smith, and Petela 1990):

- Flue gas emissions
- Waste minimization
- Evaluation of waste treatment options

Before these areas are described, a brief review of pinch technology is necessary.

### Pinch Technology

Pinch technology provides a clear picture of the energy flows in a process. It identifies the most constrained part of the process—the process pinch. By correctly constructing composite heating and cooling curves, a design engineer can quantitatively determine the minimum hot and cold utility requirements. This tool is called *targeting*. Another tool, the *grand composite curve*, determines the correct types, levels, and quantities of all utilities needed to drive a process.

Once targets are set, the design engineer can design the equipment configuration that accomplishes the targeted minimum utilities. A key feature of pinch technology is that energy and capital targets for the process are established before the design of the energy recovery network and utility systems begins.

### FUNDAMENTALS

Part a in Figure 3.11.1 shows two streams plotted in the temperature–enthalpy (T/H) diagram, one hot (i.e., requiring cooling) and one cool. The hot stream is represented by the line with an arrow pointing to the left, and the cold stream by the line with an arrow pointing to the right.

For feasible heat exchange between the two streams, the hot stream must be hotter than the cool stream at all points. However, because of the relative temperatures of the two streams, the construction of the heating and cooling curves shown in part a of Figure 3.11.1 represents a

limiting case illustrated by the flow diagram shown in part b of the figure. The heat exchange between the hot stream countercurrent to the cold stream cannot be increased because the temperature difference between the hot and cold streams at the cold end of the exchanger is zero. This difference means that the heat available in the hot stream below 100°C must be rejected to the cooling water, and the balance of the heat required by the cold stream must be made up from steam heating.

In part c of Figure 3.11.1, the cold stream is shifted on the H-axis relative to the hot stream so that the minimum temperature difference,  $\Delta T_{\min}$ , is no longer zero but positive and finite. The effect of this shift increases utility heating and cooling by equal amounts and reduces the load on the heat exchanger by the same amount. The arrangement, which is now practical because  $\Delta T_{\min}$  is nonzero, is shown in the flow diagram in part d of Figure 3.11.1. Clearly, further shifting implies larger  $\Delta T_{\min}$  values and larger utility consumption.

### COMPOSITE CURVES

A design engineer can analyze the heat exchanges between several hot and cold streams in the same way as in the preceding two-stream, heat exchange example. A single composite of all hot and a single composite of all cold streams

can be produced in the T/H diagram and handled in the same way as the two-stream problem.

The first step in constructing composite curves is to correctly identify the streams that undergo enthalpy changes as hot or cold. A *hot stream* is defined as one that requires cooling; a *cold stream* is defined as one that requires heating. The objective is to determine the minimum amount of residual heating or cooling necessary after the heat interchange between the process streams has been fully exploited.

The design engineer extracts stream data from the process flowsheet which contains heat and material balance information. The items of interest are mass flow rates, specific heat capacity (CP), and supply and target temperatures. This procedure is called *data extraction*.

Starting from the individual streams, the design engineer can construct one composite curve of all hot streams in the process and another of all cold streams by simply adding the heat contents over the temperature range.

In part a of Figure 3.11.2, three hot streams are plotted separately, with their supply and target temperatures defining a series of interval temperatures  $T_1$  to  $T_5$ . Between  $T_1$  and  $T_2$ , only stream B exists, so the heat available in this interval is given by  $CP_B (T_1 - T_2)$ . However, between  $T_2$  and  $T_3$ , all three streams exist, so the heat available in this interval is  $(CP_A + CP_B + CP_C) \times (T_2 - T_3)$ . A series

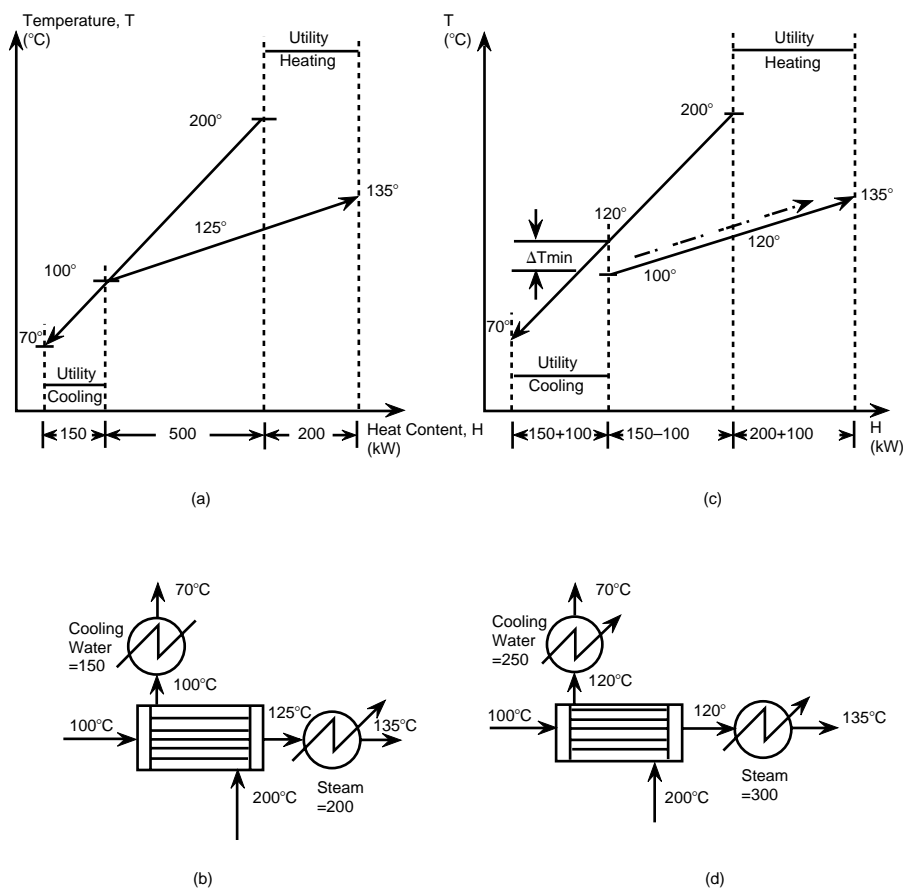

FIG. 3.11.1 Two-stream heat exchange in the T/H diagram.

of values of  $\Delta H$  for each interval can be obtained in this way, and the result can be replotted against the interval temperatures as shown in part **b** of Figure 3.11.2. The resulting T/H plot is a single curve representing all hot streams. A similar procedure gives a composite of all cold streams in the problem.

Figure 3.11.3 shows a typical pair of composite curves. Shifting the curves leads to behavior similar to that shown in the two-stream problem. However, the kinked nature of the composites means that  $\Delta T_{\min}$  can occur anywhere in the interchange region and not just at one end. For a given value of  $\Delta T_{\min}$ , the utility quantities predicted are the minimum required to solve the heat recovery problem. Although many streams are in the problem, in general,  $\Delta T_{\min}$  occurs at only one point termed the pinch. Therefore, a network can be designed which uses the minimum utility requirement, where only the heat exchangers at the pinch must operate at  $\Delta T$  values down to  $\Delta T_{\min}$ .

Figure 3.11.4 shows that the pinch divides the overall system into two thermodynamically separate systems, each of which is in enthalpy balance with its utility target. This example shows that utility targets can only be achieved if no heat transfers across the pinch. To guarantee minimum energy consumption, the design engineer must ensure that heat is not transferred across the pinch in developing a structure. The following design rules must be followed:

FIG. 3.11.3 Energy targets and the pinch with composite curves.

- Heat must not be transferred from hot streams above the pinch to cold streams below the pinch.
- Utility cooling cannot be used above the pinch.
- Utility heating cannot be used below the pinch.

FIG. 3.11.2 Construction of composite curves.

### GRAND COMPOSITE CURVE

Composite curves show the scope for energy recovery and the hot and cold utility targets. Generally, several utilities at different temperature levels and of different costs are available to a design engineer. Another pinch technology tool, the grand composite curve, helps the design engineer to select the best individual utility or utility mix.

The grand composite curve presents the profile of the horizontal (enthalpy) separation between the composite curves with a built-in allowance for  $\Delta T_{\min}$ . As shown in Figure 3.11.5, its construction involves bringing the composite curves together vertically (to allow for  $\Delta T_{\min}$ ) and then plotting the horizontal separation ( $\alpha$  in Figure 3.11.5).

Figure 3.11.6 shows how the grand composite curve reveals where heat is transferred between utilities and process and where the process can satisfy its own heat demand (Linnhoff, Polley, and Sahdev 1988).

### Applications in Pollution Prevention

This section describes the application of pinch technology in pollution prevention in flue gas emissions and waste minimization.

### FLUE GAS EMISSIONS

The relationship between energy efficiency and flue gas emissions is clear. The more inefficient the use of energy,

FIG. 3.11.4 Division of a process into two thermodynamically separate systems.

the more fuel burned and the greater the flue gas emissions. Pinch technology can be used to improve energy efficiency through better integration and thus reduce flue gas emissions.

In addition, a design engineer can systematically direct basic modifications to a process to reduce flue gas emissions. For example, part a of Figure 3.11.7 shows a process grand composite. Because the process requires a high temperature, a furnace is required. Part a in Figure 3.11.7 shows the steepest flue gas line which can be drawn against

the existing process. This line corresponds with the smallest flue gas flowrate, the smallest fuel consumption, and hence the smallest flue gas emissions.

Part b in Figure 3.11.7 shows the grand composite curve of the same process which has been modified specifically to open the temperature-driving forces in the high-temperature part of the process. The overall process duty is unchanged. However, the systematic modification of the process shown in part b of the figure allows a steeper flue gas line to be drawn leading to reduced flue gas emissions.

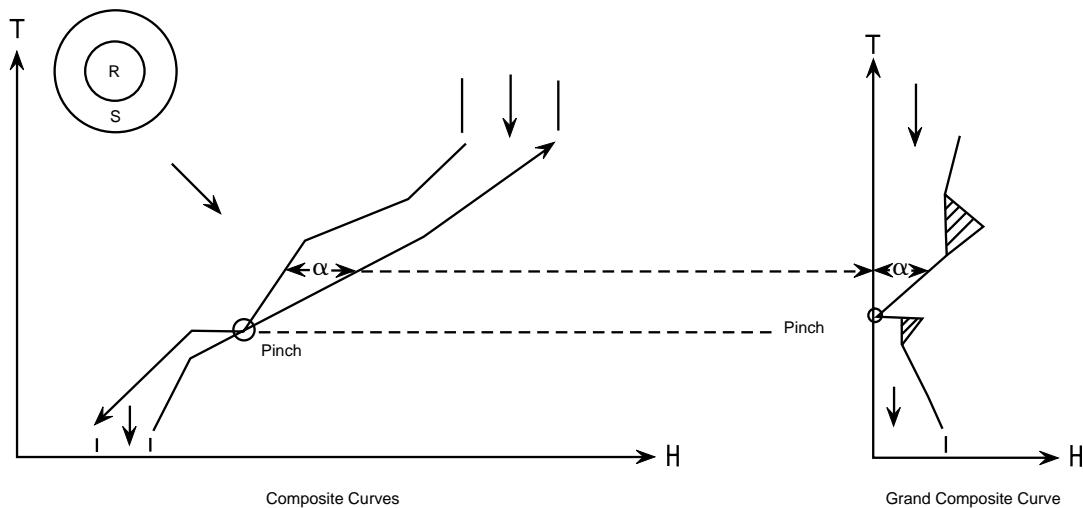

FIG. 3.11.5 Grand composite curve presenting the profile of the horizontal separation between the composite curves with a built-in allowance for  $\Delta T_{\min}$ .

**FIG. 3.11.6** Grand composite curve revealing where heat is transferred between utilities and the process.

### WASTE MINIMIZATION

In waste minimization, the objective is to make a process more efficient in its use of raw materials. This objective is achieved through improvements in the reaction and separation systems within the process. Because these systems often require the addition or removal of heat, a design engineer can use pinch technology to identify the cost-effective process modifications. The following example from a fine chemical plant illustrates this use (Rossiter, Rutkowski, and McMullen 1991).

Figure 3.11.8 shows the process, which is a batch operation. The stirred-tank reactor is filled with two feeds (F1 and F2) and is heated to the reaction temperature with the steam in the reactor jacket. The temperature is then maintained at this level to allow the reaction to proceed to the required extent, after which the vessel is cooled by water passing through the reactor jacket. This cooling causes the product to crystallize out of the solution. The solid product is then separated from the liquid by filtration, and the filtrate is rejected as an effluent.

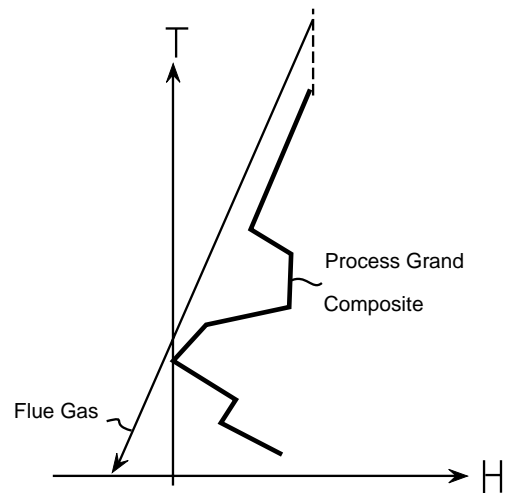

Because of the high effluent treatment costs, the company sought means to improve product recovery and thereby reduce the effluent treatment requirements. They considered the following two options:

Cooling of the effluent with refrigeration to reduce the product solubility, thereby increasing product recovery  
 Evaporating the effluent to reduce the volume of the liquid and thus increase the amount of solid products formed

Both of these options required capital expenditure and additional energy to reduce the effluent and improve the raw material efficiency. However, pinch analysis high-

(a) Flue gas matched against the process limited by the process above the pinch

(b) Modified process allowing a steeper flue gas line which reduces fuel and emissions even though the process duty has not changed.

**FIG. 3.11.7** Grand composite curve allowing the minimum flue gas to be drawn leading to reduced flue gas emissions. (a) Flue gas matched against the process limited by the process above the pinch. (b) Modified process allowing a steeper flue gas line which reduces fuel and emissions even though the process duty has not changed.

lighted an opportunity to totally eliminate the effluent without increasing the energy costs.

Steam to the original process shown in part a of Figure 3.11.8 was supplied at 10 bars. However, the grand composite curve for the process (see Figure 3.11.9), which plots the net heat flow against the actual, required processing temperatures rather than the existing practice, clearly shows that steam at only 2 bars is hot enough for the reactor requirements.

This observation led to the modified design (see part b in Figure 3.11.8), in which 10-bar steam drives an evap-

a

b

FIG. 3.11.8 Example process.

orator which operates at 2 bars. The 2-bar steam produced in the evaporator can then be used to heat the reactor. Thus, the company could use the evaporator to increase product recovery and eliminate the effluent without any increase in energy costs.

Of course, to make this design work in a batch plant the operations must be sequenced in such a way that the evaporator is running at the same time that the reactor is being heated. In practice, this sequencing is easily achieved. The resulting process modification is a more cost-effective means of waste minimization than those developed without pinch technology and has the added benefit of enhanced product recovery.

## Designing a Heat Exchange Network

After targeting is complete, the remaining task is to design a heat exchange network that meets energy and capital targets. The following design aids are available to accomplish this task (Linnhoff et al. 1982):

Grid representations, which provide a convenient way to

represent heat exchanger networks

Pinch rules

Matching sequence, in which the design engineer starts by placing HX matches at the process pinch and works away

CP inequality, which states that for any given heat exchanger match, the CP for the stream coming out the pinch must be greater than that of the stream entering the pinch

Using these rules, a design engineer can systematically design a network that uses the minimum amount of utilities. Pinch technology software is available from Linnhoff March Inc., 107 Loudoun Street S.E., Leesburg, VA 22075.

## Waste Minimization

Figure 3.11.10 summarizes a suggested approach for applying pinch technology to environmental problems (Spriggs, Smith, and Petela 1990). Waste minimization is clearly the place to start. Solving environmental problems at the source is not always the simplest solution, but it is usually the most satisfactory solution in the long term. Reducing the problem at the source by modifications to the process reaction and separation technology has the dual benefit of reducing raw material and effluent treatment costs.

Once the design engineer has exhausted the possibilities for waste minimization by process modifications, the

FIG. 3.11.9 Grand composite of example process.

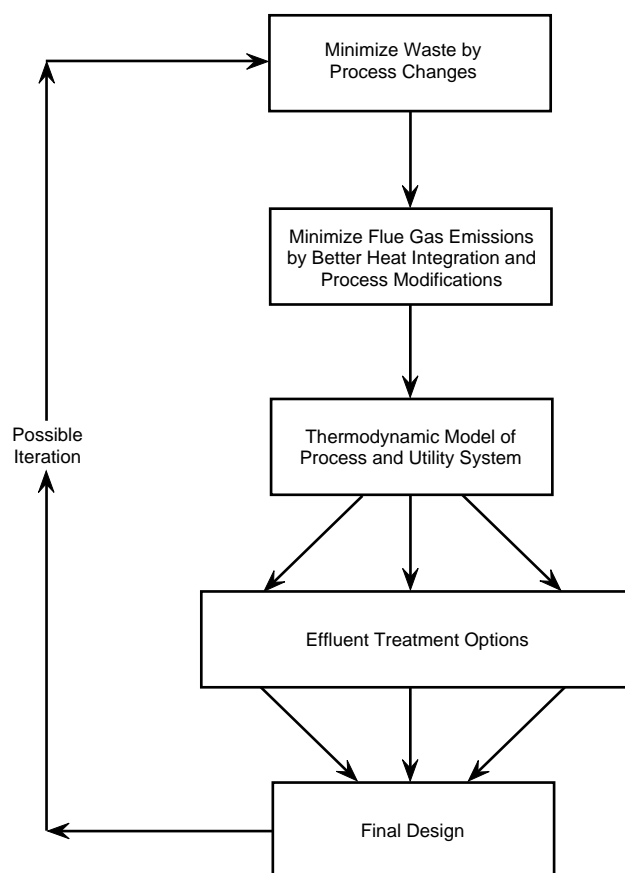

FIG. 3.11.10 A suggested approach for applying pinch technology to environmental problems.

minimum flue gas emissions can be established (see Figure 3.11.10). This stage establishes the thermodynamic model for the process and utility system.

Next, the design engineer assesses the alternative waste treatment options (see Figure 3.11.10). The design engineer must assess these options by considering the process and its waste treatment systems together and any possibilities for integration between them.

Figure 3.11.10 also shows that some earlier decisions may need to be readdressed after the waste treatment options and considered. At each stage, pinch technology establishes the economic tradeoffs.

## 3.12 PROCESS ANALYSIS

Online analysis of the physical properties or chemical composition in dynamic processes allows for realtime control. Thus, a company can detect potentially harmful by-products in process streams immediately, especially in a continuous stream, to prevent the production of large quantities of off-spec products. In addition, online analyzers cut down product variation and raw material waste and help plants minimize energy use.

Onsite data gathering is becoming increasingly important as waste streams become more complex. A waste treatment facility benefits from the ability to identify a change in the waste profile. Multiple sensor and instrumentation systems serve this need in generating realtime data. On-demand interrogation coupled with limit alarms announce changing conditions and facilitate a response action (Breen and Dellarco 1992).

Several analytical methods, including gas chromatography, liquid chromatography, infrared and near-infrared (NIR) spectroscopy, and wet chemistry analyzer, have successfully transferred from the laboratory to the process line. Each method has its own price, accuracy, complexity, and maintenance requirements. A thorough knowledge of this information is required to install an economic and effective system.

The major parts of an online process analyzer are the sampling apparatus; the analyzer; and the methods used for data correlation, reporting, and communication.

### Sampling

In online analysis, as in all analytical chemistry, sampling is the most critical and least accurate step. In addition, 80

to 90% of all maintenance problems experienced by an online analyzer occur during sampling. Filtration and dilution may be required when the sample arrives at the analyzer; the more equipment used, the greater the potential for malfunctions.

All sampling techniques for online analysis fall into one of the three following general categories:

Direct insertion of the sampler into the process (*inline or in situ analysis*)

Continuous extraction of process material for delivery to the analyzer via transfer lines (*ex situ or extractive analysis*)

Discrete or grab sampling (*atline or nearline analysis*)

### INLINE OR IN SITU ANALYSIS

In inline or in situ systems, the sample is not transported from the sampling point to the analyzer because the analyzer is at the sampling point. Probe-type analyzers have been used for a long time. One of the newer probes is the fiber-optic probe (FOP), which uses fiber-optic waveguides to return process-modified light from the probe to the spectrum analyzer usually located in a control room (see Figure 3.12.1). No transfer time or sample waste occurs because the measurement is made on the moving process material.

Another advantage of inline analyzers is that they can be multiplexed; that is, installed at many points in the

process. The analyzer's controller oversees the frequency of analysis at each point and directs switching between them.

However, inline systems usually use a window through which light is transmitted and reflected, and this window can cause measurement errors. Process liquids can make the window dirty and cause measurement errors. In addition, the extreme temperatures and safety considerations at the sampling point may not allow for installation of the sensitive electronics that inline systems generally require.

### EXTRACTIVE OR EX SITU ANALYSIS

In extractive or ex situ systems, process material is transferred from the sample point to an external analyzer. Because the analyzer (e.g., process gas chromatograph) is installed away from the process, maintenance is more manageable than for inline devices (see Figure 3.12.2).

Like inline analyzers, extractive samplers can be located at several different points in a process. However, calibration and reference streams can also be routed to the analyzer with the process samples, something not possible with inline systems. If more detailed analyses on specific materials are needed later, users can divert the sample to a collection vessel.

The disadvantages of extractive systems are that they can be bulky and slow and generate a lot of waste. For

FIG. 3.12.1 FOPs providing data on absorbance, diffuse reflectance, fluorescence, and scattering. (Reprinted, with permission, from Guided Wave Inc.)

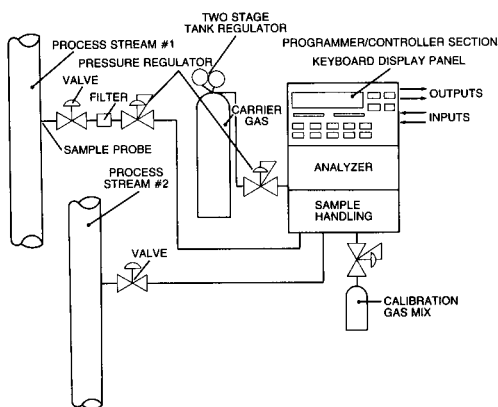

FIG. 3.12.2 Basic elements of a multistream, process gas chromatograph system.

example, an analyzer sampling six different streams requires an enclosure at the process to house the related machinery. Depending on the distance that the sample must travel to the analyzer, times ranging from 20 to 60 sec are common. Filtration, dilution, or concentration may also be required when the sample arrives at the analyzer. When heated samplers and transfer lines are required to keep a sample at a particular temperature, installation and maintenance costs can also be significant.

### DISCRETE OR GRAB SAMPLING

In discrete or grab sampling, aliquots of process material are simply collected by hand and delivered to the analyzer, which is located at the process (atline) or in a lab (offline). While this type of sampling can be sufficient for some analytical requirements, it is not a true online analysis method.

### Analyzers

Analyzers range from property- or compound-specific sensors, such as pH probes and oxygen detectors, to chemical and optical analyzers, chromatographs, and spectrophotometers.

### SPECIFIC SENSORS

*Specific sensors* are the simplest type of online analyzers. They are generally used to measure either the physical parameters of a gas or liquid stream, such as pH, temperature, turbidity, or oxidation-reduction potential, or easily detected compounds, such as oxygen, cyanide, or chlorine. In most cases, these sensors have continuous output.

Sensors are relatively inexpensive and easy to install and require little or no maintenance. While they can be selective and sensitive, specific sensors can become fouled by constant contact with process materials, particularly those with high particulate concentration.

While the output from specific sensors is considered to be in real time, all process analyzers, including sensors, experience lag times and stabilization times. The lag time is the time required for the process material to pass through the sensor's sampling element. The stabilization time, called  $T_{90}$ , is the time required for the sensor to reach 90% of its final output. Typical  $T_{90}$  times are about 20 to 60 sec.

### GAS CHROMATOGRAPHY (GC)

GC is one of the most widely used analyzers in the petrochemical and refining industry. It offers flexibility of applications, high sensitivity analysis, and multicomponent analysis. The widespread use of GC is a result of its versatility. If a sample can be vaporized, an effective separation is often possible.

Process GC sampling is extractive. A small sample of process material is obtained with a sample valve and vaporized in a preheater. The sample is pushed by an inert carrier through a packed solid capillary tube. Components within the sample have varying degrees of affinity for the column packing. The more the component is attracted to the column packing, the slower it moves. As the components come out of the column (that is, are eluted), they are recorded as a function of time by a detector. Depending upon the sensitivity of the detector (see Figure 3.12.3) and separation quality of the instrument, GCs routinely achieve accuracy within 0.25 to 2%. The accuracy of most analyzers is a fixed percentage of their full-scale range.

GC offers continuous results, but the retention time of the sample (i.e., the time taken for the separated components to pass down the column) must be considered. Typical retention times range between 1 and 20 min, depending on the number of components and their vaporization temperatures. A retention longer than 20 min is impractical and generally unacceptable for online analysis.

A big drawback of GC is maintenance. Instruments generally have many electrical and mechanical components. Preventive maintenance is a must. Repairs are not always fast or easy. Repairing a chromatograph can take hours or even days.

FIG. 3.12.3 Basic schematic of a chromatograph.

## LIQUID CHROMATOGRAPHY (HPLC)

HPLC is similar to gas chromatography. HPLCs also use carriers (mobile phase), columns, and detectors. The sample is passed through the column under high pressure. However, because the HPLC column is much smaller in diameter than the process GC column, plugging results if the liquid sample is not free of particulates. Not many process streams can be conditioned to provide the necessary clean sample. To date, HPLCs have not been used with great success in liquid component process analysis.

## WET CHEMISTRY ANALYZERS

*Wet chemistry analyzers* all work similarly. A sample-handling system extracts a clean sample from the process (to prevent plugging). The sample is injected into a chemically treated solution, and a chemical reaction takes place. The reaction can be a change in color, pH, or conductivity. The change is proportional to the concentration of a single component of interest in the process stream (Lang 1991).

The fastest wet chemistry technique is process flow injection analysis (PFIA). Here, a clean process sample flows continuously through a sample injection valve. At user-selected intervals, a fixed volume of sample, usually in microliters, is injected into a constantly flowing liquid carrier stream. Precise mixing generates a specific chemical reaction, and an appropriate detector (UV or visible, pH, or conductivity) gives a signal proportional to the concentration in the sample of the component of interest. The response time is usually fast so that one or two determinations can be made per minute.

## MASS SPECTROMETERS

*Mass spectrometers* offer performance, versatility, and flexibility, sometimes exceeding that of GC. They are applicable for quantitative analysis of organic and inorganic compounds. A small vapor sample is drawn into the instrument through an inlet leak. A mass spectrometer works by ionizing a sample and then propelling the ions into a magnetic field. This field deflects each ion in proportion to its charge/mass ratio and causes it to strike one of a number of collectors. The signal from each collector is directly proportional to the concentration of ions having a particular mass. Ahlstrom in the *Instrument engineers' handbook* provides a detailed description of quadrupole mass-filter and multicollector, magnetic-sector instruments.

Typical instruments can sample multiple streams with a concentration of eight to twelve components in less than 5 sec. Depending on the vendor and applications, a variety of configurations are possible to maximize sensitivity and utility.

## SPECTROSCOPY

*Spectroscopy* is an optical technique in which UV, visible, or infrared radiation is passed through a sample. Filters isolate discrete bands of light that are absorbed by the specific component. Basically, a spectrophotometer consists of a light source, an optical filter, a flow cell, and a detector sensitive to a particular wave length. If only one component absorbs light in the wavelength region, a simple photometer provides accurate measurements. The amount of absorbed light is proportional to the concentration of each component. The technique is most useful where the concentration of a particular molecular group such as hydroxyls, paraffins, olefins, naphthenes, and aromatics must be determined (see Figure 3.12.4).

Spectroscopy is faster and mechanically simpler than chromatography, and either direct-insertion or extractive sampling can be used. Spectroscopy is not precise when multicomponent mixtures are measured because a chemical's absorbances at individual wavelengths often interfere with each other. Multiple filters or a scanning instrument must be used in these solutions.

System computers are now equipped with data reduction programs called chemometrics. These programs compare sample spectra to known spectra stored in a database as a learning or training set. Establishing such a database requires examining and storing the spectral properties and reference methods for a significant number of calibration samples before the unit goes online.

For GCs controlled by external computers, the calibration requires only one sample, or six at most, to establish linearity in the expected concentration range. However, the chemometric models used by online spectrophotometers become more reliable as more samples are added to the learning set (Crandall 1993).

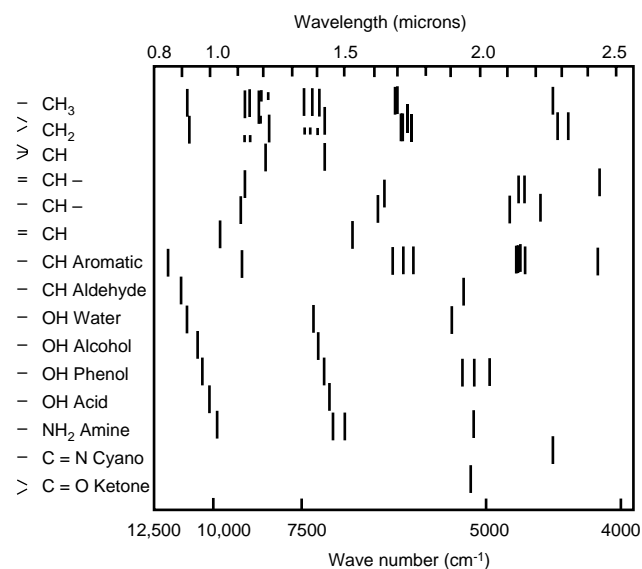

FIG. 3.12.4 An example of how the location of absorption bands shows functional groups in the NIR.

The precision of spectroscopic methods can be 0.1% of the full-scale reading. A system's accuracy is a reflection of its learning set. The accuracy of an online spectrophotometer is only as good as the accuracy of the reference method used to calibrate it.

## NEAR INFRARED ANALYSIS

Near infrared (NIR) analysis is a new process liquid measurement technology that is growing. NIR spectroscopy is an optical scanning technique that operates in a range of wavelengths between 800 and 2400 nm. The primary advantage of NIR analysis is that because the sample probe is placed directly in the process stream, an extractive sample handling system is not needed. More importantly, process NIR analysis addresses applications that have not been tried by other technologies.

Traditionally, the measurement of liquid components using NIR analysis has been done by analyzers that operate at only one wavelength. Recently, analyzers using gratings, filter wheels, and other moving parts have been developed to vary the infrared wavelengths, making measurements of multiple liquid components possible. However, when these moving parts are in the process environment, they require frequent maintenance.

Traditionally, NIR analysis has been used to measure moisture in the process industry. However, its ability to perform scanning and the advent of fast computers with sophisticated computer software (e.g., chemometric) have expanded its applications, particularly in polymers.

A summary of proven and potential applications of spectroscopy follows. Table 3.12.1 summarizes a proven, closed-loop control application for NIR spectroscopy. Any molecule containing a carbon-hydrogen, hydroxyl (O-H), carboxyl (C=O), or amine (N-H) bond and

many inorganic species adsorbs NIR radiation. Water allows NIR radiation to pass through. Thus, NIR analysis can perform water analysis or determine the concentration of the materials that are mixed with it. Table 3.12.2 lists online NIR projects that are in development for processes which have not been amenable to the technique in the past. The NIR analyzer can monitor alkylation, reforming, blending, and isomerization in addition to distillation.

With the advent of fiber optics, online spectroscopy has become safer and more flexible. Fiber-optic cable allows the analyzer and online probes to be separated up to 1000 m. The incident light travels along the cable to the probe, where sample absorption occurs. The reflected signal travels back to the detector through the cable, where it is analyzed (see Figure 3.12.1).

If process safety is a high priority, fiber optics may be the best technique to use because only the probe is in contact with the process material; the analyzer is in a safe location. The tradeoff is that the spectral quality of such systems can suffer and they can be expensive.

The maintenance of online spectrophotometers is equipment- and application-oriented. The maintenance of the equipment is fairly simple. Application maintenance consists of the scientific and engineering work required to validate the system's results and generate the learning set as process formulations and the associated feedstocks change. Application maintenance is often overlooked by users, but it is critical to the reliability of online analysis.

Even today's simplest analyzer has a microprocessor that refines raw data, does calculations, and displays results. Analyzers can have graphic interfaces and can be networked with other analyzers and data systems.

Every analyzer should be linked to a plant's distributed control system (DCS). Thus, process analytical data can

be shared along a network just like data from input-output devices of the DCS. Users along the network with either a DCS interface or engineering work can access the process data. Many suppliers of chromatography systems offer such networks (see Figure 3.12.5).

### System Design and Support

The objective of system design and support is to install an online analyzer that measures physical properties and chemical compositions in dynamic processes. This objective means selecting the right equipment, making sure it is

**FIG. 3.12.5** A typical multiprocess GC interface to the DCS. In this configuration, only process GC data, validation, system alarms, and stream sequence control are available to the DCS operator. All control and data communication is available to the AMS operator. (Reprinted, with permission, from The Foxboro Co.)

reliable, and making sure it provides the proper analytical data to the users.

The goals of a project are determined by the analytical requirements of the plant. These requirements include the chemical components or properties to be determined, as well as the ranges, precision, accuracies, and response times. The analyst must define the minimum analytical requirements, the optimum requirements, and the degree of flexibility between them.

Technologies compete. One method of analysis can overlap another in capability which means that more than one technology can give satisfactory results and the analyst must choose between technologies.

The analyst should test equipment before installation to verify its reliability and define the probable maintenance

requirements. Regardless of how simple or complex the online systems is, every system requires constant validation and maintenance.

## 3.13 PROCESS CONTROL

---

---

### Benefits in Waste Reduction

Modern technology allows the installation of sophisticated computer control systems that respond more quickly and accurately than human beings. That capability can be used to reduce waste as follows.

#### IMPROVING ONLINE CONTROL

Good process control reduces waste by minimizing cycling and improving a plant's ability to handle normal changes in flow, flow temperatures, pressures, and composition. Statistical quality control techniques help analyze process variations and document improvements. Additional instrumentation or online monitors are necessary, but good control optimizes process conditions and reduces a plant's trips, a major source of waste (Nelson 1990).

#### OPTIMIZING DAILY OPERATIONS

If a computer is incorporated into the control scheme, it can be programmed to analyze the process continuously and optimize operating conditions. If a computer is not an integral part of the control scheme, a company can per-

form offline analysis and use it as a guide for setting process conditions (Nelson 1990).

### AUTOMATING START UPS, SHUTDOWNS, AND PRODUCT CHANGEOVERS

Large quantities of waste are produced during plant start ups, shutdowns, and product changeovers, even when these events are well planned. Programming a computer to control these events brings the plant to stable operating conditions quickly and minimizes the time spent generating off-spec products. In addition, since minimum time is spent in unwanted running modes, equipment fouling and damage are reduced.

### UNEXPECTED UPSETS AND TRIPS

Even with the best control systems, upsets and trips occur. Not all upsets and trips can be anticipated, but operators who have years of plant experience probably remember the important ones and know the best ways to respond. With computer control, optimum responses can be pre-programmed. Then, when upsets and trips occur, the computer takes over, minimizing downtime, spills, equipment damage, product loss, and waste generation.

## Distributed Control Systems

The DCS is the dominant form of instrumentation used for process control (Liptak 1994). The equipment in a DCS is separated by function and is installed in two different working areas of a process installation. The equipment that an operator uses to monitor process conditions and manipulate the set points of the process operation is located in a central control room. From this location, the operator can (1) view the information transmitted from the processing areas on a CRT and (2) change control conditions from a keyboard. The controlling portions of the system, which are distributed at various locations throughout the processing area, perform the following two functions at each location:

- Measure analog variable and discrete input
- Generate output signals to actuators that change process conditions

Input and output signals can be analog or digital. By means of electric transmission, the system communicates information between the central location and the remote controller locations.

Figure 3.13.1 shows a generic arrangement for the components in a DCS. The operator's console in the control room is called the high-level operator's interface (HLOI). It can be connected through a shared communication facility (data highway) to several distributed system components. These components can be located either in rooms adjacent to the control room or in the field. Such distributed local control units (LCUs) can also have a limited amount of display capability and are called the low-level operator's interface (LLOI).

FIG. 3.13.1 A typical DCS. The panel boards and consoles are eliminated, and the communications are over a shared data highway, which minimizes the quantity of wiring while allowing unlimited reconfiguration flexibility. (Reprinted, with permission, from M.P. Lukas, 1986, *Distributed control systems*, Van Nostrand Reinhold Co.)

The console or HLOI is the work center for an operator. In this area, the operator follows a process and uses the fast and accurate translation of raw data into useful trends and patterns to decide the required actions. One CRT is usually dedicated to each section of a plant; each of these CRTs requires an operator's continuous attention. The HLOI also includes keyboards, usually one for each CRT, which allow the operator to enter set points or other parameters or to closely examine particular portions of the process for further information. The HLOI peripherals include disks, tapes or other recorders, and printer units.

The DCS operator depends on the CRT displays for plant information. Three principal types of displays are the group display, the overview display, and the detailed display. A graphic display capacity shows a picture on the screen so that the operator can look at a portion of the process more realistically than by watching a row of bar graphs. Figure 3.13.2 is a graphic display representation of a fractionation column. The display includes process and operation information, and it can be interactive, dynamically changing as real-time information changes.

Trend displays are the DCS equivalents of chart records. They are a profile of the values of process variables showing the changes that occur over a period of time. Some detail displays (see Figure 3.13.3) include a real-time trend graph of the process variable values during a selected period. In some displays, several trend graphs can be displayed at the same time, allowing a comparison of the history of several variables. Trends over longer periods (up to a week) can be saved on floppy-disk memory and displayed on command.

A single best distributed control solution does not exist. The right control system for an application is a function of the process to be controlled (Funk and McAllister 1989).

In the broadest sense, manufacturing processes are either continuous (e.g., a petroleum refinery or an ethylene plant), or batch (e.g., specialty chemicals or pharmaceuti-

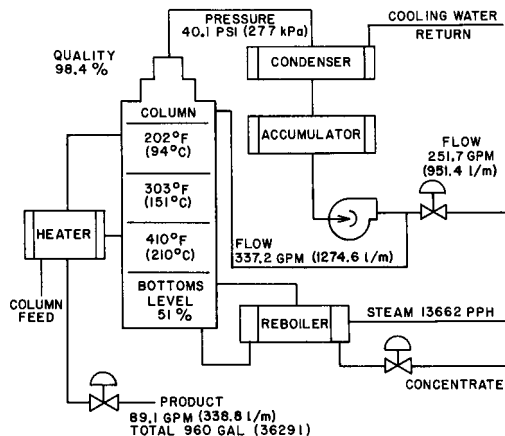

FIG. 3.13.2 Graphic display.

CONFIGURATION WORD  
 ALGORITHM TYPE  
 HIGHWAY AND STATION ADDRESS

FIG. 3.13.3 Detail display.

cal). In reality, few plants are purely batch or continuous. Instead, they often fall in between and blend some aspects of both.

## MASS FLOW

In batch flow, some physical mass of materials is processed together as a unit. Recipe management is essential. Predetermined quantities of raw materials are added to the vessel and blended and reacted with the entire batch being completed at one time. A plant can keep records by batch and, if necessary, troubleshoot by batch.

In a continuous process, the product is comingled continuously. The process is either on or off; material flow never stops while the process is running. Raw materials enter at the beginning of the process, and the final product comes out continuously.

### Control Information Requirements

In a batch process, 5-min averages of process values are seldom meaningful. Chemicals can be added to the batch at various times, at which point the temperature may drop. Then, the batch can be heated for a period of time, held at a particular temperature for a while, and then allowed to cool. In this process, the average temperature for the whole cycle offers no real information about the batch properties. A different type of data gathering and archiving is needed that is more event-oriented.

Continuous processes rely heavily on regulatory controls. In these processes, the control system can be set to read a temperature data point every 5 sec, average it for 5 min, and present the resulting data as a representative sample of the process temperature.

In batch systems, linkage to product specifications and the daily shipping schedule are commonly needed and can be provided by DCS. In continuous processes, recipe management is less of a concern, and shipments are typically in bulk.

## CONTROL HARDWARE

Batch systems use a greater number of digital devices. Ranges of 65 to 85% digital and only 15 to 35% analog signals are typical. On-off valves and limit switches comprise the majority of digital devices although alarms, interlocks, and emergency shutdown equipment are also important (Procyk 1991).

In general, the analog PID controller is less prominent in batch operations because a batch process operates on a changing state instead of the steady-state environment maintained by the proportional integral and derivative (PID)-loop set point.

Batch processes are usually operated with more modularity and flexibility than are continuous processes. Thus, design engineers must anticipate and plan for what will be needed for future recipes and batches.

## SAFETY SYSTEMS

Safety systems on continuous processes aim to minimize shutdowns due to the expense associated with a shutdown or an interruption in production. This issue may have little relevance for batch processes.

## BATCH AUTOMATION

The justification for a DCS to control a batch process focuses on maintaining on-spec quality or minimizing the

dead time between batches. Cost is important, but that is not the overriding factor. The operator controls the process to make various products to their individual specifications (Funk and McAllister 1989).

## Sensors

Sensors represent both the basis and the most critical part of automating a batch process. The center of a batch process is the reactor. Often a glass-lined vessel to withstand corrosive agents, the reactor is equipped with an agitator and a jacket for cooling or heating. The reaction temperature and pressure, the jacket temperature, and the fluid level within the reactor are the variables which are often sensed.

### TEMPERATURE MEASUREMENTS

The mostly commonly used instrument is a resistance temperature detector (RTD) with an electronic temperature transmitter. The RTD provides high accuracy.

### LEVEL MEASUREMENTS

Level measurements can present challenging problems. First, the properties from which the level can be inferred usually vary. Further, mechanical and electrical complications exist, such as swirling, swishing, and frothing at the top layer. No single level sensor fits all applications. Every level measurement situation must be evaluated separately. The design engineer must consider the metallurgy and configuration of the vessel, the temperature and pressure ranges, the chemical and physical characteristics of the liquid, the nature of the agitation, the electrical area classification, maintenance practices, and perhaps other factors.

### PRESSURE AND VACUUM MEASUREMENTS

A range of conventional sensors can be used for pressure and vacuum measurements. The presence of corrosive vapors may require the use of diaphragms and pancake flange designs linked to the main body of the sensor by a capillary.

### FLOW MEASUREMENTS

An array of flow sensors is suitable for batch processes, ranging from a rotameter to a mass flowmeter. However, careful evaluation is required of the phase (solid, liquid, or powder), viscosity, flow range, corrosivity, required accuracy, and other parameters in special cases.

### ANALYZERS

The online analyzer is becoming more prevalent. This trend is stimulated by the technological advances and corre-

sponding price reductions for analyzers and by the growing insistence on real-time analysis for processors (Procyk 1991).

For batch processing, analyzers that do not require elaborate sampling systems or the constant attention of a maintenance crew are recommended. Analyzers for pH, conductivity, and resistance generally meet those criteria. However, if measuring color, moisture, spectroscopic properties, or the presence of ions is necessary, the analyzer is more likely to require a sampling system with some stream conditioning, such as filtering to remove suspended particles.

Some or all of these analyzers may be needed in any typical processing step. However, many process industries need a special analyzer. For example, the fermentation batches in pharmaceutical or other plants using biotechnology must monitor the oxygen content and cell density and growth. In many cases, analyzers for qualitative properties do not exist, and a plant must try to correlate those properties with ones that can be measured using DCS.

## Step-by-Step Batch DCS

Table 3.13.1 shows the control activities of an entire batch in a hierarchical manner from the sensors and elements to the business planning level. Level 1 activities involve process and product management and production management; Level 2 activities involve a batch and unit management; and Level 3 activities involve sequential, regulatory, and discrete control and safety interlocking.

### PROCESS AND PRODUCT MANAGEMENT

Production management consists of three control activities: recipe management, production scheduling, and batch history management.

#### Recipe Management

A recipe is the complete set of data and operations that defines the control requirements of a type or grade of product. A recipe is composed of (1) the header, (2) equipment requirements, (3) the formula, and (4) the procedure.

The procedure defines the generic strategy for producing a batch product. A procedure consists of subprocedures, subprocedures of operations, operations of phases, phases of control steps, and control steps of control instructions. Figure 3.13.4 diagrams this relationship.

The recipe management function maintains a database of site recipes for various products, formulas, and procedures. The control recipe contains specific information on the batch equipment and units that can run each operation within the procedure. A master recipe is constructed from the site recipes using the formulas, procedures, and equipment-specific information. The master recipe is se-

**TABLE 3.13.1 CONTROL ACTIVITY MODEL**

<i>Level</i>	<i>Function</i>	<i>Activity</i>
Level 1	Process/product management Production management	Production planning, inventory planning, and general recipe management Recipe management, production scheduling, and batch history management
Level 2	Batch management	Recipe generation and selection, batch execution supervision, unit activities coordination, and log and report generation
Level 3	Unit management Sequential/regulatory/ discrete control Safety interlocking	Unit supervision, allocation management, and unit coordination Device, loop, and equipment module control, predictive control, model-based control, and process interlocking —

lected and accessed by the batch management activity which converts it to a control recipe. The control recipe is the batch-specific recipe that is ready to run. Figure 3.13.5 shows the recipe hierarchy.

Using process and product knowledge, the recipe management function analyzes a process and determines the basic phases. These basic phases, along with product knowledge from the laboratory chemist, are used to construct the general (corporate-wide) recipe. Plant knowledge (for example, raw material availability) from the plant site engineer is used to transform the general recipe into a site-specific recipe. Equipment knowledge (for example, what vessels and piping are available in the plant) is used to transform this site-specific recipe into a master recipe. This master recipe is used as the basis for a control recipe when a batch is ready to be produced. Figure 3.13.6 summarizes the activities involved during recipe management.

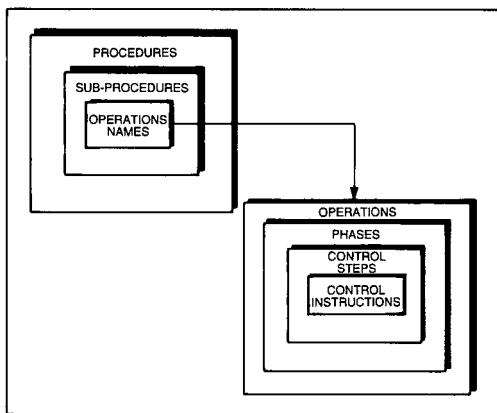

**Production Scheduling**

Schedules serve as a guide for the production requirements in terms of the availability of equipment, personnel, raw materials, facilities, equipment, and process capacity. The schedule should have many of the following objectives:

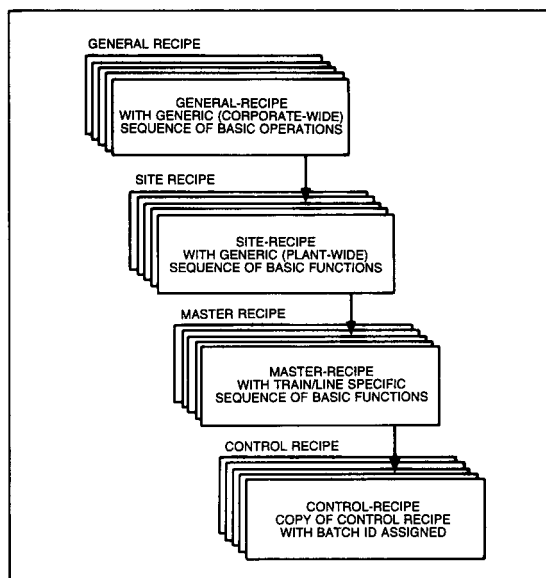

- To minimize the processing time
- To minimize the deviation from a master plan
- To optimize the production of the product within quality guidelines
- To minimize energy costs
- To minimize the use of raw materials

The responsibility of the production scheduler is to develop a detailed, time-based plan of the activities necessary to achieve the production targets set by the production plan. The production scheduler must be able to dynamically allocate a new schedule at any time. Reallocating or creating a schedule automatically via some algorithm or manually via user intervention should be feasible.

Schedulers can be implemented in several ways. Linear programs, expert systems, or other multivariable techniques have been used successfully. The scheduler must provide a procedure and method for batch sizing and is the logical place where lot assignments are made. Figure 3.13.7 presents the production scheduling model currently defined by ISA standards committee (Jensen 1994).

**FIG. 3.13.4** Procedure model.

**FIG. 3.13.5** Recipe model.

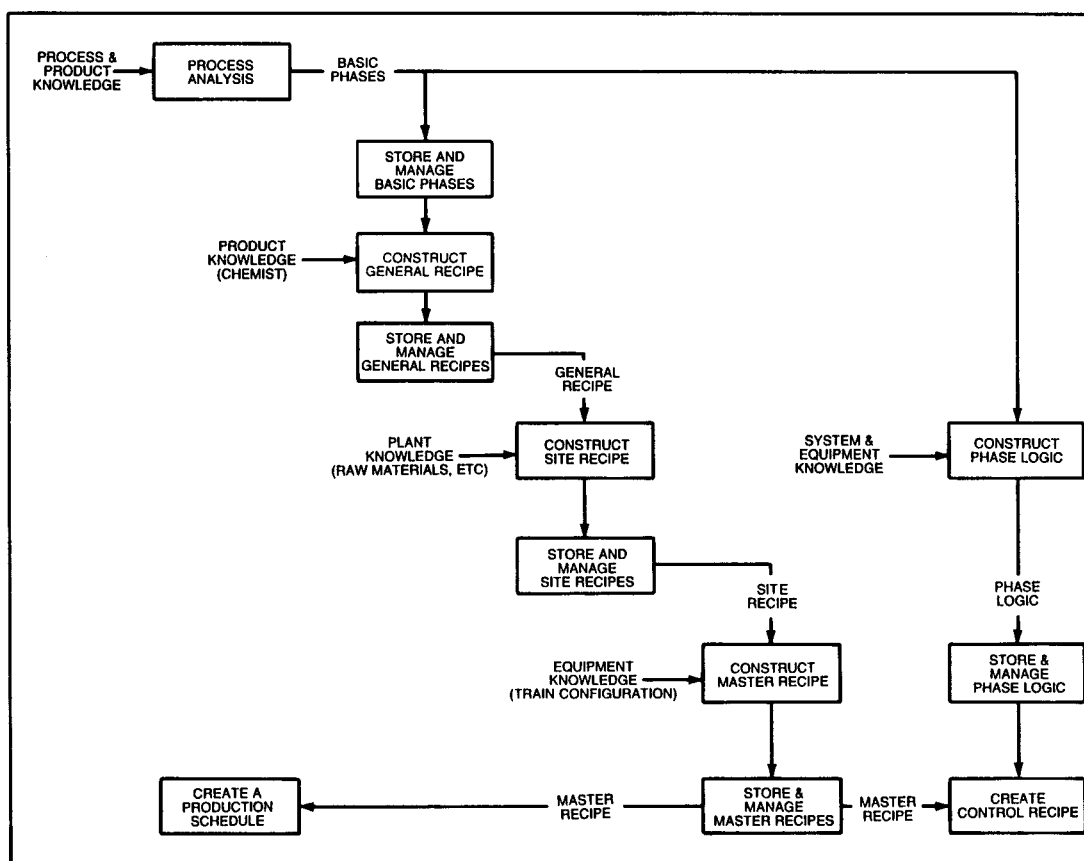

FIG. 3.13.6 Recipe activities.

As shown by the model, the production plan is input to the scheduling model. The plan is first transformed to an area plan. Knowledge about the process equipment is required at this time. The area plan is a listing of the end items which are to be produced, how many of each item are to be produced, and when the items are to be produced for the specific plant area. The area plan is a disaggregation of the production plan specific to the plant site and directly drives the production schedule. The transformation to an area plan occurs each time the production plan is sent to the production scheduling function.

The area plan, along with information from the site recipe from the recipe management activity, is used to create the master schedule. The master schedule is a list of the recipes in the order that they are to be run. Lot numbers are optionally assigned, the train or line is determined, and the batches are sized. The master schedule is prioritized according to the production constraints found via the site recipe and is passed to the queue manager. The master schedule can be filed away and is a copy of the best schedule for that area.

### Batch History Management

Batch history management involves collecting and maintaining integrated, identifiable sets of dissimilar data. Batch

tracking is the collection of this data. It is generally event triggered and contains the following related data:

- Continuous process data (flow, temperatures, and pressures)
- Event data (operator actions, alarms, and notes)
- Recipe formula data (set points and times)
- Calculated data (totalization, material usage, and accounting data)
- Manual entries with an audit trail (location of change and operator of record)
- Stage, batch, and lot identification
- Time and date stamps on all data

The batch end report typically includes a copy of the recipe used to make the batch. Events such as alarms, operator instructions, and equipment status should also be logged. A trend chart can also be retained. Batch management records and collects batch end reports, which are then archived to some other medium. Batch reports are statutory requirements in some applications (e.g., in the pharmaceutical industry). Figure 3.13.8 shows a simplified batch history management model.

Advances in relational databases allow data for the process control of current batches to be linked to the histories of previous batches. Using standard query language (SQL) calls to access batch history provides new ways to

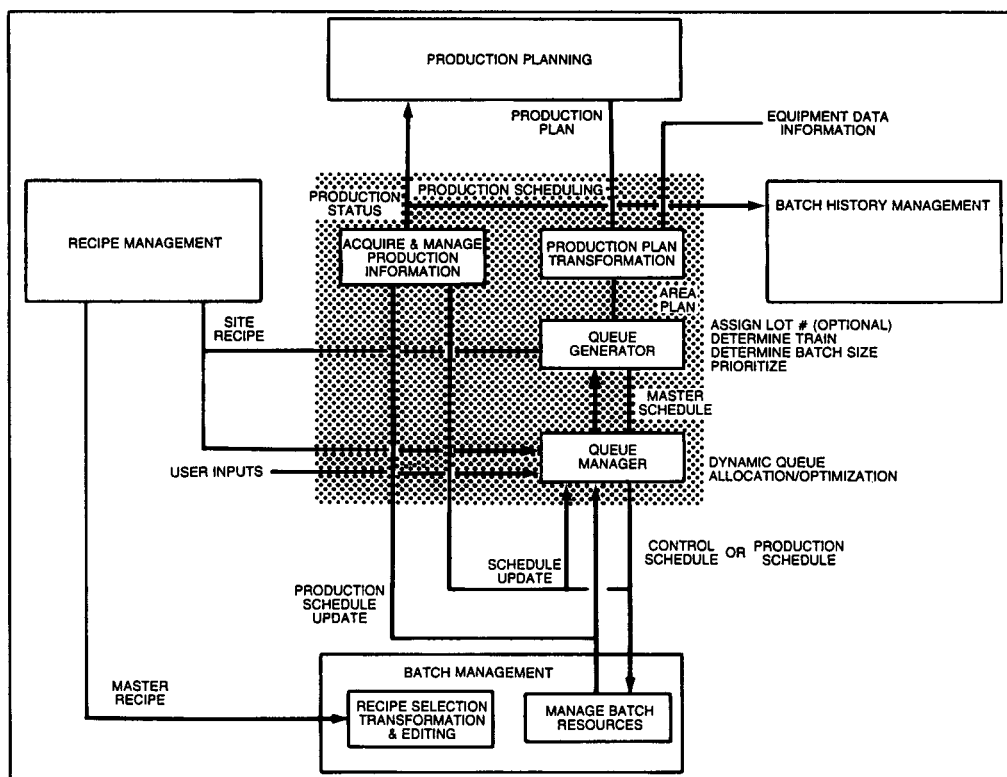

FIG. 3.13.7 Production scheduling model.

analyze and report batch histories. Other analysis techniques, such as statistical process control (SPC) and statistical quality control (SQC), can be applied at this level.

### MANAGEMENT INTERFACES

Batch management interfaces with the user, recipe management, production scheduling, unit management, sequential control, and regulatory and discrete control. Its functions include (1) recipe selection, transformation, and editing; (2) initiation and supervision of batch processes; (3) management of batch resources; and (4) acquisition and management of batch information. Figure 3.13.9 shows the batch management model currently defined by the ISA standards committee.

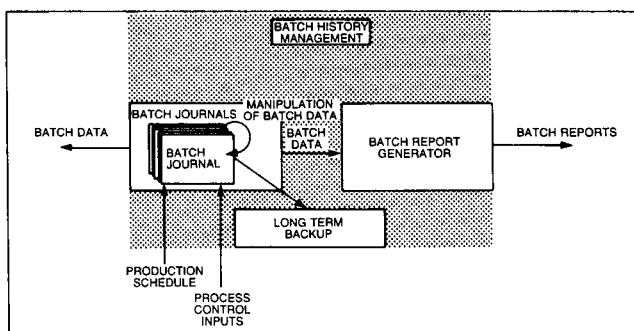

FIG. 3.13.8 Batch history management.

### UNIT MANAGEMENT

A unit is a physical grouping of equipment and the unit control functions required to execute a batch. A process unit is a group of mechanical equipment, with each piece performing, somewhat independently, a portion of the chemical process. Examples of process units are filters, batch reactors, heat exchangers, and distillation columns. Control consists of the process states, known as phases, required to perform the unit operations. Examples are charging, heating, cooling, agitation, reacting, discharging, and washing.

Unit management interfaces with the user, batch management, sequential control, regulatory control, and discrete control in performing its function of (1) communicating with other unit equipment modules, loops, devices, and elements; (2) acquiring resources; (3) executing phases; and (4) handling phase exceptions. (In a batch program, the basic action is called a statement; several statements make up a step; a number of steps comprise a phase; phases can be combined into an operation; and a sequence of operations makes up a batch.) Figure 3.13.10 shows the unit management model defined by the ISA.

### CONTROL FUNCTIONS

Sequential, regulatory, and discrete control functions interface directly with elements and actuators to change the process. These control functions are defined as:

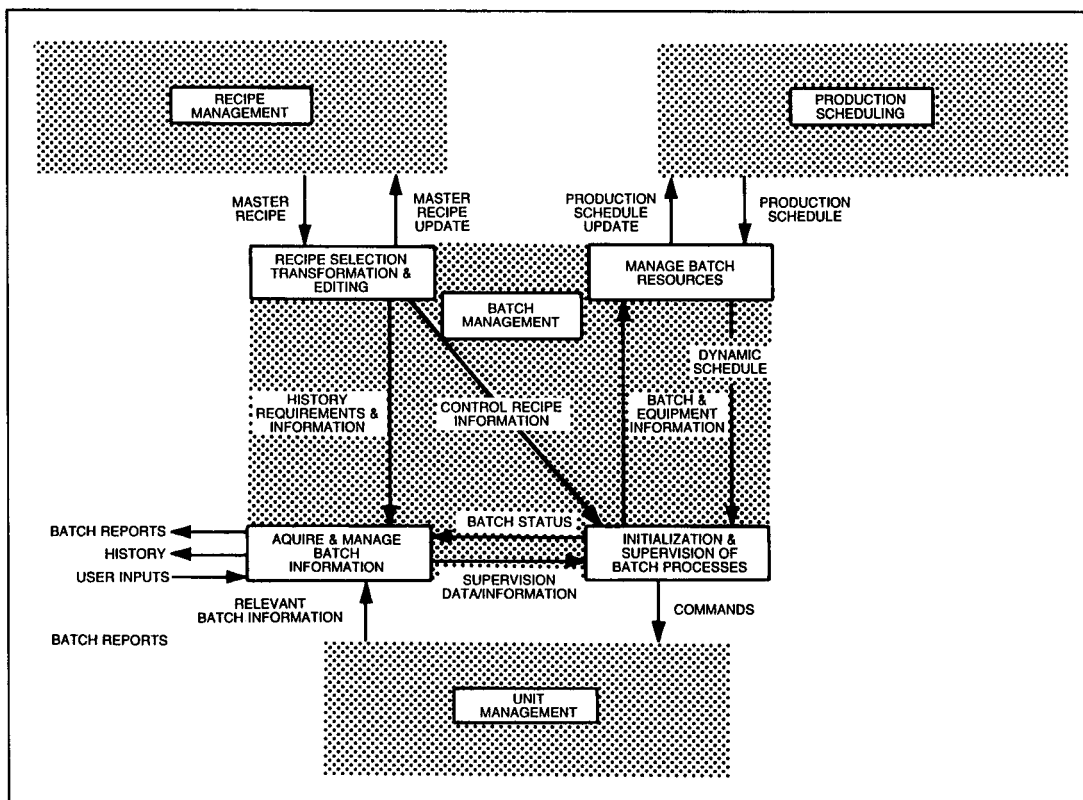

FIG. 3.13.9 Batch management model.

Discrete control maintains the process states at target values chosen from a set of stable states.

Regulatory control maintains the measurements of a process as close as possible to their set-point values during all events, including set-point changes and disturbances.

Sequential control sequences the process through a series of states as a function of time.

The user implements these control functions using devices, loops, and equipment modules, which are defined as:

A *device* is an item of process equipment that is operated as a single entity and can have multiple states or values. The user initiates discrete states (using hardware and software) to control discrete devices such as solenoid valves, pumps, and agitators.

A *loop* is a combination of elements and control functions which is arranged so that signals pass between the elements to measure and control a process variable. A PID control algorithm is a common control loop function.

An example of an *equipment module* is the sequential control of dehydrogenator bed control valves which put one bed online while the other bed is being regenerated according to a time schedule.

Process interlocking and advanced control, in the form of feedforward, predictive, or model-based control, are ad-

ditional control functions which provide a higher level of automation for additional benefits.

Compared to continuous processing, additional control algorithms and control methodology are normally used in batch processing. Functions such as time-based PID (heat-soaked ramp), sequencers, and timers are required. Batch processing commonly uses techniques such as enabling and disabling control functions based on a phase state, enabling and disabling alarms on devices and loops, and employing antireset windup protection on PI or PID loops. Batch processes are device-oriented, while continuous processes are loop-oriented.

### SAFETY INTERLOCKING

Safety interlocks ensure the safety of operating personnel, protect plant equipment, and protect the environment. These interlocks are initiated by equipment malfunctions and usually cause shutdowns. Often, a separate system implements safety interlocks. This system includes the necessary redundancy and fault tolerance and is independent from the other control functions. An example of a safety interlock is the stopping of a centrifugal compressor when its oil gear pump has failed, thus preventing mechanical damage.

Safety interlocking serves a different purpose than process interlocking and permissive interlocking. Process

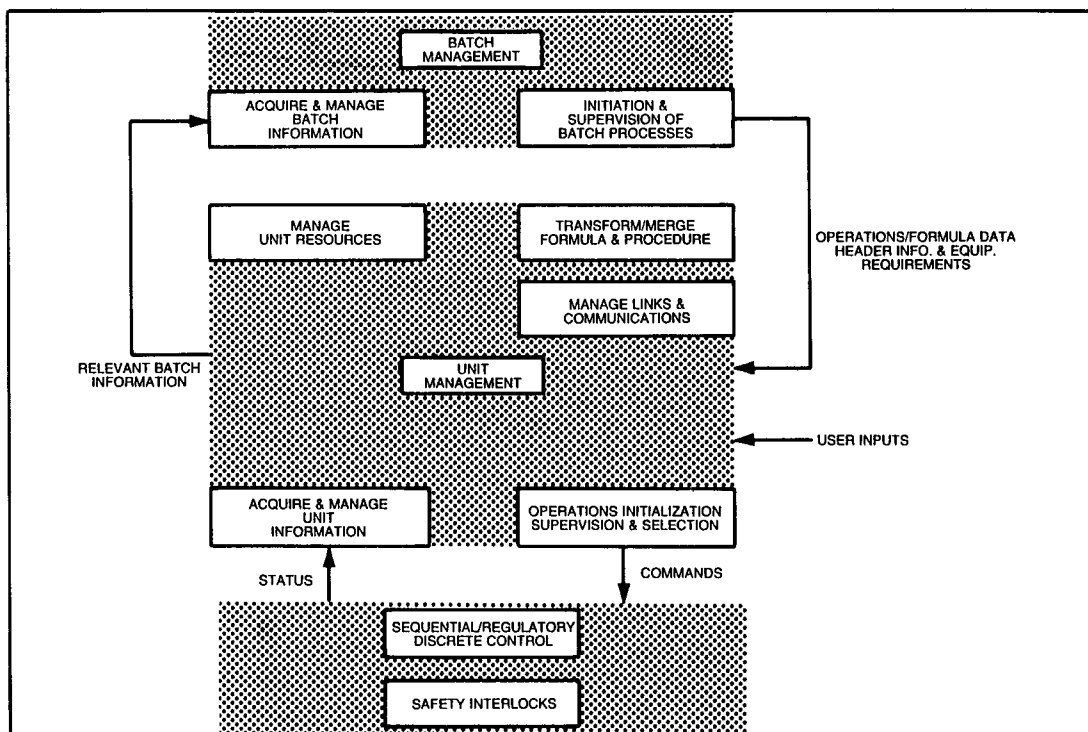

FIG. 3.13.10 Unit management model.

interlocking can be safety-related, but it is primarily associated with the process. An example of a process interlock is to stop charging a material if the agitator is not running. A permissive interlock establishes an orderly progression of sequences. An example of a permissive interlock is to not allow the feeding of an extruder before the barrel temperature has reached a minimum value.

## Continuous Process Automation

Continuous processes require a control system that can minimize cost and optimize grade changes. Multiple products and grades are often made from the same feedstock in a continuous plant. However, since a plant cannot be shutdown between grades, a change-over period occurs during which the product is not on-spec. Thus, shortening the change-over period can minimize the amount of off-spec material being made during grade changes.

Integrated DCSs are essential to control complex manufacturing situations. A single control loop can be handled with traditional instruments alone. However, controlling complex situations requires a broader span of information than is available through discrete instrumentation.

Continuous processes rely heavily on regulatory controls and inferred variables. The DCS must also interface with highly sophisticated instruments and analyzers that have some control capabilities of their own and offer significant inference capabilities. For example, the Btu value of fuel cannot be measured unless it is burned in a calorimeter, but then it is not a useful process control variable.

However, the heating value of the fuel can be inferred from the thermal conductivity, temperature, and pressure of the incoming nature gas.

DCSs achieve high degrees of process accuracy because they incorporate process data archives which allow a better understanding of the process. These data archives allow people other than the operator to view and understand what happens in the process and be able to work on improving it. Optimum operation no longer depends on the operator monitoring the process every minute. Instead, the control system watches the process every second.

Many projects can be identified as being beneficial to the business. These projects frequently require the timely, accurate, and comprehensive information provided by DCSs as input. Such projects encompass a variety of areas including process optimizers, expert systems, quality lab interfaces, statistical process control, and plantwide maintenance programs.

Process optimization is a natural progression of the DCS. A company can use the information available through the DCS archives to optimize process conditions to conserve energy or save raw materials. They can also use the information to modify product mixes and product specifications to optimize costs on a global, rather than individual unit, basis (Funk and McAllister 1989)

Process optimizers provide advanced supervisory control. They monitor the current operating conditions, run advanced algorithms, and return recommended set-point changes to the control systems. However, process opti-

mizers control on such a large scale that separate computer hardware is needed for processing.

Expert systems are another progression of the DCS. They draw process database information from the DCS. Often, these systems are small to midsize and serve one of the two functions. One function is diagnostic, such as determining the cause of an equipment malfunction or maintenance troubleshooting. This analysis begins with embedding an operator's experience in the system's rule database and using it to work through all complicated variations and combinations of conditions related to faults or alarms (Funk and McAllister 1989).

The other function of an expert system is to work through situations that have a high degree of uncertainty and develop a knowledge base from the results of decisions. For example, knowledge about the best way to cut costs given the nature of raw materials and process conditions can be put into a rule database. Then, the system monitors the results using that knowledge and improves

the knowledge base (Funk and McAllister 1989).

Other applications include processes where process dynamics change over time, such as models or controllers that require frequent updating. A fixed-bed reactor which shows how the catalyst's aging affects process dynamics is another example.

—David H.F. Liu

## 3.14 PUBLIC SECTOR ACTIVITIES

---

---

### EPA Pollution Prevention Strategy

Pollution prevention, while not new to the EPA, has emerged as a priority in the 1990s. This prioritization represents a fundamental change from the historical interpretation of the agency's mission as protecting human and environmental health through pollution control. The EPA's pollution control emphasis was to eliminate the options of releasing and transferring industrial pollution in the environment and to increase the cost of the remaining options of treatment and disposal. The net effect has been to encourage industry to limit their pollution through source reduction.

The formal shift in policies and priorities for the EPA is reflected in the 1990 passage of the CAAA and the Pollution Prevention Act. The EPA issued a pollution prevention strategy in 1991 to articulate its position and objectives. This policy serves the following two purposes:

- To guide and direct incorporating pollution prevention into the EPA's existing regulatory and nonregulatory program
- To specify a program with stated goals and a time for their accomplishment

The EPA's goal is to incorporate pollution prevention into every facet of its operations including enforcement actions, regulations, permits, and research.

This strategy confronts the institutional barriers that exist within the EPA which is divided along single environmental medium lines. The agency has accomplished the following:

- Established an Office of Pollution Prevention and Toxics which coordinates the agencywide pollution prevention policy
- Created a Waste Minimization Branch in the Office of Solid Waste to coordinate waste minimization and pollution prevention under the RCRA
- Charged the EPA Risk Reduction Engineering Laboratory with conducting research on industrial pollution prevention and waste minimization technologies
- Developed a Pollution Prevention Advisory Committee to ensure that pollution prevention is incorporated throughout the EPA's programs

All areas of the EPA are developing initiatives to promote a pollution prevention ethic across the agency. These initiatives are characterized by the use of a range of tools including market incentives, public education and information, technical assistance, research and technology applications, and the traditional regulatory and enforcement actions. Examples include:

- Establishing cash rewards for EPA facilities and individuals who devise policies and actions to promote pollution prevention

Public commending and publicizing of industrial facility pollution prevention success stories  
Coordinating the development and implementation of regulatory programs to promote pollution prevention  
Clustering rules to evaluate the cumulative impact of standards in industry, which encourage early investment in prevention technologies and approaches

The EPA is further implementing the 33/50 program which calls for the involuntary cooperation of industry in developing pollution prevention strategies to reduce environmental releases of seventeen selected chemicals by the year 1995 (see Section 3.1).

The EPA's pollution prevention program is multifaceted and expansive. The Pollution Prevention Clearing-House (PPIC) provides current news and information on recent developments in this rapidly changing arena. The PPIC Technical Support Hotline is (703) 821-4800.

Three programs of interest are the Green Lights Program, the Golden Carrot Program, and the Energy Star Computers Program. These programs are described next.

### **GREEN LIGHTS PROGRAM**

The Green Lights Program, launched by the EPA in January 1991, is designed to prevent pollution by encouraging the use of energy-efficient lighting in offices, stores, factories, and other facilities across the country. Lighting consumes about 25% of the nation's electricity, and more than half of the electricity used for lighting is wasted by inefficient technology and design practices. Under the Green Lights Program, the EPA has asked businesses, governments, and other institutions to install energy-efficient lighting over a five-year period, but only where it is profitable and lighting quality is maintained or improved.

Over 600 companies have made voluntary commitments to participate in this program, representing 2.5 billion sq ft of business space. Given the commitments of current participants, over the next five years, they will reduce their electric bills by an estimated \$760 million. In addition, the program will prevent the generation of 7.4 million tn of CO, 59,500 tn of SO, and 25,300 tn of NO emissions.

### **GOLDEN CARROT PROGRAM**

The Golden Carrot Program, promoted by the EPA's Office of Air and Radiation, encourages manufacturers to design superefficient refrigerators that use no CFCs for cooling or insulation. Refrigerators and freezers use about 20% of the nation's electricity and vary in efficiency. To stimulate manufacturers to develop more efficient CFC-free units, twenty-three electric utilities have pooled their resources to offer a \$30 million incentive (the golden carrot) to the winner of a product design competition in super-efficient refrigeration.

The EPA estimates that the Golden Carrot Program is capable of reducing electric power consumption by 3 to 6 billion kWh, saving \$240 to 480 million annually in consumer electric bills.

### **ENERGY STAR COMPUTERS PROGRAM**

The EPA's Energy Star Computers Program is a voluntary, market-based partnership with computer manufacturers to promote energy-efficient personal computers in an effort to reduce the air pollution caused by the generation of electricity. Office equipment is the fastest growing electrical load in the commercial sector. Computer systems alone account for approximately 5% of the commercial electricity consumption—a figure which could reach 10% by the year 2000. Dramatic, cost-effective, efficiency improvements are available for both hardware power consumption and the control of operation hours, offering up to 90% energy savings for many computer applications.

To date eight computer manufacturers—Apple, IBM, Hewlett-Packard, Digital, Compaq, NCR, Smith Corona, and Zenith Data Systems—have signed partnership agreements with the EPA to participate in the program. By the year 2000, the EPA's Energy Star Computers Program and other campaigns to promote energy-efficient computer equipment will probably save 25 billion kWh of electricity annually—down from an estimated consumption of 70 billion kWh per year. These savings will reduce CO emissions by 20 million metric tn, SO emissions by 140,000 metric tn, and NO emissions by 75,000 metric tn.

### **CROSS-CUTTING RESEARCH**

Three major research areas are targeted in the cross-cutting research component of pollution prevention research. Cross-cutting issues have been selected because of their importance in furthering the science of pollution prevention and the agency's ability to promote and implement pollution prevention as the preferred approach to environmental protection. Cross-cutting issues include (1) tool development, (2) application of tools, and (3) measurement of progress.

A balanced cross-cutting research program addresses the development of innovative tools for pollution prevention including technological, informational, and evaluative tools. The cross-cutting research strategy for tools development focuses on performing industry-specific pollution prevention assessments, incorporating pollution prevention factors into process simulation models, developing and testing LCA methodology, and improving the agency's understanding of how individuals and corporations make decisions and the factors that affect their behavior.

Demonstrating the effectiveness of pollution prevention approaches is critical to increasing reliance on this preferred approach to environmental management. The application of the tool research area focuses on incorporat-

ing pollution prevention considerations into the EPA's rule-making process, developing and demonstrating innovative pollution prevention technologies, transferring timely information on pollution prevention approaches, and determining the most effective ways to use incentives and education to promote prevention.

Continued environmental progress depends upon knowing what has worked and how well and what has been less successful and why. Environmental engineers can then use this information to identify areas for additional research, improve approaches, and develop new approaches. The development of techniques to measure and evaluate the effectiveness of pollution prevention approaches is critical to determine which approaches effectively prevent pollution and which approaches fail. These techniques are useful for measuring progress and establishing priorities for research and other activities.

## **Industrial Programs and Activities**

Industries, working harder to be good neighbors and responsible stewards of their products and processes, are aggressively engaged in pollution prevention activities both as trade associations and as individual companies (U.S. EPA 1991). An extended description of successful trade association and company programs is available from the EPA's Office of Pollution Prevention.

### **TRADE ASSOCIATION PROGRAMS**

The CMA, American Petroleum Institute (API), and National Paints and Coating Association (NPCA) are examples of trade associations committed to pollution prevention. Their programs are described next.

#### **CMA**

The CMA started its Responsible Care Program in 1988 to improve the chemical industry's management of chemicals. All CMA members are required to participate and adhere to the ten guiding principles of the program. The principles speak of protecting health, safety, and the environment but do not address pollution prevention specifically. The program outlines the framework for the reduction of waste and releases to the environment (see Section 3.2). To evaluate progress, the CMA requires its companies to submit an annual report that identifies progress in implementation and quantifies facility-specific releases and wastes (CMA 1990).

The program is being implemented in all parts by CMA's 175 member companies. These companies have about 2000 facilities and produce about 90% of the U.S. chemicals. In May 1993, the Synthetic Organic Manufacturing Association (COMA) voted to become a Responsible Care partner association.

#### **American Petroleum Institute (API)**

The API also has a prescribed set of guiding environmental principles its members are encouraged to follow. The API's eleven principles generically promote action to protect health, safety, and the environment. One of the API's principles addresses pollution prevention by requiring its members to reduce overall emissions and waste generation (Chevron Corporation 1990). The API articulates the eleven principles as goals to which members should aspire.

#### **National Paints and Coating Association (NPCA)**

The NPCA has their Paint Pollution Prevention Program (April 1990). The goal of the program is "the promotion of pollution prevention in our environment through effective material utilization, toxics use, and emissions reduction and product stewardship in the paint industry" (NPCA 1990). The statement recommends that each NPCA member company establishes a waste reduction program that includes setting priorities, goals, and plans for waste reduction with preference first to source reduction, second to recycling and reuse, and third to treatment.

### **COMPANY PROGRAMS**

The scope of company programs varies considerably. Some are limited to one environmental medium, while others are multimedia. Some focus on certain types of pollutants, such as toxic release inventory (TRI) chemicals; others are more wide ranging. All include some forms of pollution prevention but vary in their emphasis. Most adopt the EPA's environmental management hierarchy: source reduction first, followed by recycling, treatment, and disposal.

A review of company pollution prevention activities reveals that some companies have programs they are willing to share with the public and other companies consider their efforts internal and proprietary. The more accessible programs are usually with large multifacility companies. Some programs such as Dow Chemical's Waste Reduction Always Pays (WRAP) and 3M's Pollution Prevention Pays (3P program) are well known programs.

Public interest groups have questioned the accountability and reliability of the accomplishments claimed. Legitimate questions remain on whether the cited reductions are real and result from pollution prevention methods or whether they are artifacts of changes in reporting requirements or analytical methods or from waste transfer between sites or between media (U.S. Printing Office 1990).

The concerns notwithstanding, a major change in the industrial perspective on the way business is done has occurred. The programs initiated by industry on pollution prevention are important because they raise the expecta-

tion for future progress. If the successes are real and include financial gains, other firms will likely follow the leaders into this new era of environmental protection.

## State and Local Programs

By 1991, close to fifty state laws were in place (U.S. EPA 1991). More than half the states have passed pollution prevention laws, some states passing more than one. Other states have legislation pending or on their agenda.

The state pollution prevention laws vary in their provisions. Some have detailed requirements. They target specific source reduction goals and provide measures to meet them. Other states have general statutes, dealing with pollution prevention as state policy to be the preferred method of handling hazardous waste. Some states have no formal laws but have operationally included pollution prevention into their programs.

## FACILITY PLANNING REQUIREMENTS

A new trend in state pollution prevention requirements is facility planning. These statutes require industrial facilities to submit pollution prevention plans and update them periodically. Most plans cover facilities obliged to report federal TRI data.

Many of the facility planning laws require industry to consider only pollution prevention options. Others are broader in scope but consider pollution prevention as the preferred approach when technically and economically practical. Facilities that are required to prepare plans must either prepare and submit progress reports or annual reports. Facilities failing to complete adequate plans or submit progress reports may be subject to enforcement actions or negative local publicity.

## STATE POLLUTION PREVENTION PROGRAMS

State programs are at best a barometer of activity in pollution prevention. Programs vary along with their enabling statutes. Some programs are mature, well-established, and independent. Others consist of little more than a coordinator, who pulls together the pollution prevention aspects from other state environmental programs. Some states delegate their pollution prevention to third-party groups at universities and research centers and provide state funding for their operation.

Program elements of state programs include raising the general awareness of benefits from pollution prevention, reducing information and technological barriers, and creating economic and regulatory incentives for pollution prevention. Some also attempt to foster changes in the use of toxic materials and the generation and release of toxic by-products.

## LOCAL PROGRAMS

The effects of hazardous waste production are felt first at the local level. Rather than relying on state and federal efforts, local governments are often in a better position to identify the needs and limitations of local facilities.

Local governments can also be flexible in dealing with specific problems. One example is the potential offered by publicly owned treatment works (POTWs). POTWs receive and process domestic, commercial, and industrial sewage. Under delegated federal authority, they can restrict industrial and commercial pollution from the wastewater they receive. Pollution prevention is becoming a recurrent theme in the operation of POTWs.

## Nongovernmental Incentives

Colleges and universities play a vital role in developing pollution prevention ethics among scientists, business people, and consumers. The efforts of academia assure environmental awareness among students who will design and manage society's institutions and develop ties between industry and the campus (U.S. EPA 1991).

## ACADEMIA

University professors have identified a range of research topics in pollution prevention. Under cooperative programs with state agencies, the EPA has sponsored research on product substitutes and innovative waste stream reduction processes. An increasing number of industries are also beginning to support university research. The evolution of the pollution prevention perspective is reflected in academic environmental programs.

The progression starts with an industry's initial control efforts of good housekeeping, inventory control, and minor operating changes. In the waste minimization stage, an industry uses technologies to modify processes and reduce effluents. The 1990s have introduced highly selective separation and reaction technologies predicated on the precepts of design for technology and toxic use reduction.

The American Institute of Chemical Engineers (AIChE) founded the American Institute of Pollution Prevention (AIPP) to assist the EPA in developing and implementing pollution prevention. The AIChE aggressively encourages industry sponsorship of university research. Targeted research areas include identification and prioritization of waste streams, source reduction and material substitution, process synthesis and control, and separation and recovery technology (through its Center for Waste Reduction Technologies).

The American Chemical Society's effort has been more modest. Clearly contributions are needed from synthetic and organic and inorganic chemists to build more environmentally friendly molecules, molecules designed for the environment, while still fulfilling their intended function

and use. The Center for Process Analytical Chemistry provides an important role in pollution prevention.

## COMMUNITY ACTION

The public, as consumers and disposers of toxic-chemical-containing products, is a major source of toxic pollution. It must and has become involved in toxic pollution prevention.

Public involvement has resulted from state-wide initiatives, the action of interest groups, and individual initiatives. Environmentalists concerned with pollution control advocate source reduction over waste treatment as the preferred environmental option. However, the lack of public information about industrial releases to the environment has effectively blocked community action groups from addressing the toxic issue. The TRI and the right-to-know laws have changed that barrier irreversibly.

#### **Introduction**

Today's air quality standards have emerged from sections 109 and 112 of the 1970 Clean Air Act (CAA) Amendments and Title III of the 1990 CAA Amendments.

#### **SECTION 109, 1970 CAA AMENDMENTS**

The 1970 CAA Amendments define two primary types of air pollutants for regulation: criteria air pollutants and hazardous air pollutants. Under section 108, criteria pollutants are defined as those that "cause or contribute to air pollution that may reasonably be anticipated to endanger public health or welfare . . . the presence of which in the ambient air results from numerous or diverse mobile or stationary sources." Under section 109, the EPA identifies pollutants that meet this definition and prescribes national primary air quality standards, "the attainment and maintenance of which . . . allowing an adequate margin of safety, are requisite to protect the public health."

National secondary air quality standards are also prescribed, "the attainment and maintenance of which . . . is requisite to protect the public welfare from any known or anticipated effects associated with the presence of the air pollutant." Welfare effects include injury to agricultural crops and livestock, damage to and the deterioration of property, and hazards to air and ground transportation. The National Ambient Air Quality Standards (NAAQS) are to be attained and maintained by regulating stationary and mobile sources of the pollutants or their precursors.

#### **SECTION 112, HAZARDOUS AIR POLLUTANTS**

Under section 112, the 1970 amendments also require regulation of hazardous air pollutants. A hazardous air pollutant is defined as one "to which no ambient air standard is applicable and that . . . causes, or contributes to, air pollution which may reasonably be anticipated to result in an increase in serious irreversible, or incapacitating reversible,

illness." The EPA must list substances that meet the definition of hazardous air pollutants and publish national emission standards for these pollutants providing "an ample margin of safety to protect the public health from such hazardous air pollutant[s]." Congress has provided little additional guidance, but identified mercury, beryllium, and asbestos as pollutants of concern.

#### **TITLE III, 1990 CAA AMENDMENTS**

Although the control of criteria air pollutants is generally considered a success, the program for hazardous air pollutants was not. By 1990, the EPA regulated only seven of the hundreds of compounds believed to meet the definition of hazardous air pollutants.

Title III of the 1990 CAA Amendments completely restructured section 112 to establish an aggressive new program to regulate hazardous air pollution. Specific programs have been established to control major-source and area-source emissions. Title III establishes a statutory list of 189 substances that are designated as hazardous air pollutants. The EPA must list all categories of major sources and area sources for each listed pollutant, promulgate standards requiring installation of the maximum achievable control technology (MACT) at all new and existing major sources in accordance with a statutory schedule, and establish standards to protect the public health with an ample margin of safety from any residual risks remaining after MACT technology is applied.

#### **Ambient Concentration Limits**

Air pollution control strategies for toxic air pollutants are frequently based on ambient concentration limits (ACLs). ACLs are also referred to as acceptable ambient limits (AALs) and acceptable ambient concentrations (AACs). A regulatory agency sets an ACL as the maximum allowable ambient air concentration to which people can be exposed. ACLs generally are derived from criteria developed from human and animal studies and usually are presented as weight-based concentrations in air, possibly associated with an averaging time.

The EPA uses this approach for criteria air pollutants but not for toxic air pollutants. The CAA Amendments of 1970 require the EPA to regulate toxic air pollutants through the use of national emission standards. The 1990 amendments continue and strengthen this requirement. However, state and local agencies make extensive use of ACLs for regulatory purposes. This extensive use is because, for most air pollutants, ACLs can be derived easily and economically from readily available health effects information. Also, the maximum emission rate for a source that corresponds to the selected ACL can be determined easily through mathematical modeling. Thus, the regulator can determine compliance or noncompliance. Lastly, the use of ACLs relieves regulators from identifying and specifying acceptable process or control technologies.

ACLs are frequently derived from occupational health criteria. However, ACLs are susceptible to challenge because no technique is widely accepted for translating standards for healthy workers exposed for forty hours a week to apply to the general population exposed for twenty-four hours a day. Another disadvantage of ACLs is that both animal and occupational exposures, from which health criteria are developed, are typically at concentrations greater than normal community exposures. This difference requires extrapolation from higher to lower dosages and often from animals to humans.

## **DERIVATION OF AMBIENT CONCENTRATION LIMITS**

ACLs are typically derived from health criteria for the substance in question. They are usually expressed as concentrations such as micrograms per cubic meter ( $\mu\text{g}/\text{cu m}$ ). Health criteria are generally expressed in terms of dose—the weight of the pollutant taken into the body divided by the weight of the body. To convert a dose into a concentration, assumptions must be made about average breathing rates, average consumption of food and water, and the amount of each that is available to the body (adsorption factors). The EPA has a generally accepted procedure for this process (U.S. EPA 1988, 1989).

Other methods of deriving ACLs are based upon an absolute threshold (CMA 1988). These methods set ACLs at some fraction of an observed threshold or established guideline. A margin of safety is generally added depending on the type and severity of the effect on the body, the quality of the data, and other factors. Still other methods depend upon extrapolation from higher limits established for other similar purposes.

The health criteria felt most appropriate for deriving ACLs is the risk reference dose (RfD) established by the EPA (Patrick 1994). The EPA has developed RfDs for both inhalation and ingestion pathways (U.S. EPA 1986). They require much effort to establish and are generally designed for long-term health effects.

## **USE OF THE RfD**

RfDs are developed for ingestion and inhalation exposure routes. If a relevant inhalation RfD is available, regulatory agencies should use it as the basis for deriving an ACL for an air pollutant. The EPA is currently deriving reference values for inhalation health effects in terms of micrograms per cubic meter. These risk reference concentrations (RfCs) provide a direct link with ACLs. Without more specific information on inhalation rates for the target population, regulators frequently assume the volume of air breathed by an average member of a typical population to be 20 cubic meters per day, which is considered a conservative value.

When an inhalation RfD is not available, regulators must derive an ACL from another source. One approach is to use an ingestion RfD to estimate an RfC. However, this technique can be inaccurate because absorption through the digestive system is different from absorption through the respiratory system.

RfDs and RfCs are available through the EPA's Integrated Risk Information System (IRIS). Many state and local regulatory agencies use the EPA-derived RfDs and RfCs to establish ACLs. These reference values are available through the EPA's National Air Toxics Information Clearing House (NATICH). Because of the large number of state and local agencies, NATICH does not always have the latest information. Therefore, the practicing engineer should get the latest information directly from the local agency.

## **USE OF OCCUPATIONAL EXPOSURE LIMITS**

In some cases, neither RfDs nor RfCs are available, and regulators must use another source of information to derive ACLs. Occupational limits, usually in the form of threshold limit values (TLVs) and permissible exposure limits (PELs), are often used to establish ACLs. Both establish allowable concentrations and times that a worker can be exposed to a pollutant in the work place. TLVs and PELs are particularly useful in establishing acute exposure ACLs.

The American Conference of Governmental Industrial Hygienists (ACGIH) develops TLVs. Three types of TLVs are the time-weighted average (TLV-TWA), the short-term exposure limit (TLV-STEL), and the ceiling limit (TLV-C). The TLV-TWA is the time-weighted average concentration for a normal eight-hour work day and forty-hour work week to which almost all workers can be repeatedly exposed without adverse effects. TLV-STELs are fifteen-minute time-weighted average concentrations that should not be exceeded during the normal eight-hour work day, even if the TLV-TWA is met. TLV-Cs are concentrations that should never be exceeded.

PELs are established by the U.S. Occupational Safety and Health Administration (OSHA) and are defined in

much the same way as the TLVs. OSHA adopted the ACGIH's TLVs when federal occupational standards were originally published in 1974. Since that time, many of the values have been revised and published as PELs.

These occupational levels were developed for relatively healthy workers exposed only eight hours a day, forty hours a week. They do not apply to the general population, which includes the young, the old, and the sick and which is exposed twenty-four hours a day, seven days a week. However, using safety factors, regulators can use occupational levels as a basis for extrapolation to community levels. Different regulatory agencies use different safety factors.

## USE OF OTHER APPROACHES

When no RfD has been derived, regulators can use the level at which no observed adverse effects have been found (NOAEL) or the lowest level at which adverse effects have been observed (LOAEL), with appropriate safety factors. These levels are similar in nature and use to the RfDs. Related levels are the no observed effect level (NOEL) and the lowest observed effect level (LOEL), respectively. Other sources of information are the minimal risk level (MRL), the level that is immediately dangerous to life and health (IDLH), emergency response planning guidelines (ERPG), and emergency exposure guideline levels (EEGL) for specific pollutants. These last four levels are for special situations; for these levels to be useful in assessing danger to the general public, regulators must severely attenuate them by safety factors. However, in the absence of other data, these levels can be useful in establishing an ACL or standard.

A pollutant's NOAEL is the highest tested experimental exposure level at which no adverse effects are observed. The NOEL is the highest exposure level at which no ef-

fects, adverse or other, are observed. The NOEL is generally less useful since factors other than toxicity can produce effects.

A pollutant's LOAEL is the lowest tested experimental exposure level at which an adverse health effect is observed. Since the LOAEL does not convey information on the no-effect level, it is less useful than the NOAEL, but it can still be useful. The LOEL is the lowest level at which any effect is observed, adverse or not. As a result, it is generally less useful than the NOEL.

MRLs are derived by the Agency for the Toxic Substances and Disease Registry (ATSDR), which was formed under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) of 1980. The CERCLA requires ATSDR to prepare and update toxicological profiles for the hazardous substances commonly found at superfund sites (those sites on the National Priority List) that pose the greatest potential risk to human health. As part of the profiles, ATSDR derives MRLs for both inhalation and ingestion exposures.

The National Institute for Occupational Safety and Health (NIOSH) developed IDLHs primarily to select the most effective respirators to use in the work place. IDLHs are the maximum pollutant concentration in the air from which healthy male workers can escape without loss of life or suffering irreversible health effects during a maximum thirty-minute exposure. Another way of thinking of IDLHs is that if levels are above these standards, respirators must be used to escape the area of contamination.

The American Industrial Hygiene Association (AIHA) has derived ERPGs at three levels for several substances. Level 1 is the lowest level; it represents the maximum pollutant concentration in the air at which exposure for one hour results in mild, transient, adverse health effects. Level 2 is the concentration below which one hour of exposure does not result in irreversible or serious health effects or

**TABLE 4.1.1 SUMMARY OF NAAQSs**

Pollutant	Averaging Time	Standard (@ 25°C and 760 mm Hg)	
		Primary	Secondary
Particulate matter, 10 micrometers (PM <sub>10</sub> )	Annual arithmetic mean	50 µg/m <sup>3</sup>	Same as primary
	24-hour	150 µg/m <sup>3</sup>	Same as primary
Sulfur dioxide (SO <sub>2</sub> )	Annual arithmetic mean	0.03 ppm (80 µg/m <sup>3</sup> )	Same as primary
	24-hour	0.14 ppm (365 µg/m <sup>3</sup> )	Same as primary
	3-hour	None	0.5 ppm (1300 µg/m <sup>3</sup> )
Carbon monoxide (CO)	8-hour	9 ppm (10 mg/m <sup>3</sup> )	Same as primary
	1-hour	35 ppm (40 mg/m <sup>3</sup> )	Same as primary
Ozone (O <sub>3</sub> )	1-hour per day	0.12 ppm (235 µg/m <sup>3</sup> )	Same as primary
Nitrogen dioxide (NO <sub>2</sub> )	Annual arithmetic mean	0.053 ppm (100 µg/m <sup>3</sup> )	Same as primary
Lead (Pb)	Quarterly arithmetic mean	1.5 µg/m <sup>3</sup>	Same as primary

Source: David R. Patrick, ed, 1994, *Toxic air pollution handbook* (New York: Van Nostrand Reinhold).

in symptoms that could impair the ability to take protective action. Level 3 is the concentration below which most individuals could be exposed for one hour without experiencing or developing life-threatening health effects.

The National Research Council for the Department of Defense has developed EEGLs. These levels may be unhealthy, but the effects are not serious enough to prevent proper response to emergency conditions to prevent greater risks, such as fire or explosion. These peak levels of exposure are considered acceptable in rare situations, but they are not acceptable for constant exposure.

## Compliance with ACLs

ACLs are useful tools for reducing pollution levels. They also establish a framework to prioritize actions in reducing pollution. Generally, ACLs require sources to reduce

their pollutant emissions to a level that assures that the ACL is not exceeded at the property boundary or other nearby public point. If a monitoring method is established for a pollutant, a regulator can demonstrate compliance using mathematical dispersion modeling techniques of measured emissions or ambient monitoring.

## SOURCE AND AMBIENT SAMPLING

Regulators can sample emissions at the source by withdrawing a sample of gases being released into the atmosphere. The sample can be analyzed by direct measurement or by extraction and analysis in the field or in a laboratory. Flow rate measurements also are needed to establish the rate of a pollutant's release by the source. In a similar manner, the ambient air can be sampled and analyzed by extraction and analysis or by direct measurement.

## AIR DISPERSION MODELING

The regulating agency can estimate the concentrations of pollutants from a source to which a community is exposed by performing mathematical dispersion modeling if they know the rate at which the pollutants are being released. They can also model the ACL backwards to establish the maximum allowable rate of release at the pollutant source.

The EPA has guidelines for using the most popular models (U.S. EPA 1986). Models are available for various meteorological conditions, terrains, and sources. Meteorological data are often difficult to obtain but crucial for accurate results from mathematical models.

## CURRENT USE OF ACLs

The NAAQSs in Table 4.1.1 are ACLs derived from the best available data. State and local regulators have also

used an array of ACLs for regulating toxic air pollutants. Examples are shown in Table 4.1.2.

# 4.2 TECHNOLOGY STANDARDS

---

---

Technology standards, used to control point and area sources of air pollutants, are based upon knowledge of the processes generating the pollutants, the equipment available to control pollutant emissions, and the costs of applying the control techniques. Technology standards are not related to ACLs but rather to the technology that is available to reduce pollution emissions. In the extreme, a technology standard could be to ban a process, product, or raw material.

## Standards Development Process

In response to the requirements of the 1970 CAA Amendments, the EPA established a model process to develop technology standards. Because of their strong technological basis, technology standards are based on rigorous engineering and economic investigations. The EPA process consisted of three phases:

- Screening and evaluating information availability
- Gathering and analyzing data
- Making decisions

In the first phase, the regulating agency reviews the affected source category or subcategory, gathers available information, and plans the next phase. In the second phase, the processes, pollutants, and emission control systems used by facilities in this category are evaluated. This phase

includes measuring the performance of emission control systems; developing costs of the control systems; and evaluating the environmental, energy, and economic effects associated with the control systems. Several regulatory alternatives are also selected and evaluated. In the third phase, regulators select one of the regulatory alternatives as the basis for the standard and initiate the procedures for rule making.

## Elements of an Emission Standard

Emission standards must clearly define what sources are subject to it and what it requires. Standards should contain four main elements: applicability; emission limits; compliance procedures and requirements; and monitoring, reporting, and record-keeping requirements.

### APPLICABILITY

The applicability provision defines who and what are subject to the emission standard requirements. This provision includes a definition of the affected source category or subcategory, the process or equipment included, and any size limitations or exemptions. Any distinction among classes, types, and sizes of equipment within the affected source category is part of the applicability.

## EMISSION LIMITS

Emission limits specify the pollutant being regulated and the maximum permissible emission of that pollutant. In developing emission limits, regulators evaluate the performance, cost, energy, and environmental effects of alternate control systems. As a result of this evaluation, a control system is selected as the basis for the standard.

## COMPLIANCE REQUIREMENTS

This part of the standard specifies the conditions under which the facility is operated for the duration of the compliance test. Generally, a facility is required to operate under normal conditions. Operation under conditions greater than or much less than design levels is avoided unless it represents normal operation.

This part of the standard also specifies the test methods to be used and the averaging time for the test. The test method is usually either reference, equivalent, or alternative. The reference method is widely known and is usually published as part of the regulations. An equivalent method is one that has been demonstrated to have a known, consistent relationship with a reference method. An alternative method is needed when the characteristics of individual sources do not lend themselves to the use of a reference or equivalent method. An alternative method must be demonstrated to produce consistent and useable results. Averaging time for an emission standard is important if the source is variable in its emissions. A short averaging time is more variable and more likely to exceed a standard than a long averaging time.

## MONITORING, REPORTING, AND RECORD KEEPING

Monitoring, reporting, and record-keeping requirements ensure that the facility is operating within normal limits and that control equipment is being properly operated and maintained. Data are generally kept at the facility for review at any time, but regular reporting of critical data to the regulatory agency may be required.

## Ambient Air Quality Standards

In accordance with the CAA, as amended, the EPA has established the NAAQS for criteria pollutants. The NAAQS is based on background studies, including information on health effects, control technology, costs, energy requirements, emission benefits, and environmental impacts.

The pollutants selected as criteria pollutants are sulfur dioxide, particulate matter (now PM<sub>10</sub> and previously TSP or total suspended particulates), nitrogen oxides, carbon monoxide, photochemical oxidants (ozone), volatile organic compounds, and lead. The NAAQS represents the maximum allowable concentration of pollutants allowed

in the ambient air at reference conditions of 25°C and 760 mm Hg. Table 4.1.1 shows the pollutant levels of the national primary and secondary ambient air quality standards.

States are responsible for ensuring that the NAAQS is met. They can establish statewide or regional ambient air quality standards that are more stringent than the national standards. To achieve and maintain the NAAQS, states develop state implementation plans (SIPs) containing emission standards for specific sources. When an area fails to meet an NAAQS, it is considered a nonattainment area. More stringent control requirements, designed to achieve attainment, must be applied to nonattainment areas.

The 1990 amendments to the CAA (1) require states to submit revised SIPs for nonattainment areas, (2) accelerate attainment timetables, and (3) require federally imposed controls if state nonattainment plans fail to achieve attainment. In addition, the amendments expand the number and types of facilities that are regulated under SIPs.

## Hazardous Air Pollution Standards

The 1990 amendments to the CAA totally revise section 112 with regard to hazardous air pollutants, including national emission standards for hazardous air pollutants (NESHAP). They also direct the EPA administrator to establish standards that require the installation of MACT.

### NESHAP

Although section 112 of the 1970 CAA granted the EPA broad authority to adopt stringent emission standards for hazardous air pollutants, as of this writing only seven pollutants are listed as hazardous air pollutants. These pollutants are beryllium, mercury, vinyl chloride, asbestos, benzene, radionuclides, and arsenic. Table 4.2.1 shows the NESHAP. Almost all these standards are technology standards.

### MACT/GACT

A hazardous air pollutant is now defined as “any air pollutant listed pursuant to” section 112(b). In section 112(b), Congress established an initial list of 189 hazardous air pollutants. These listed chemicals are initial candidates for regulation under section 112, and the EPA can add other chemicals to the list.

The control of these substances is to be achieved through the initial promulgation of technology-based emission standards. These standards require major sources to install MACT and area sources to install generally available control technologies (GACT). Major sources are defined as those emitting more than 10 tons per year of any one hazardous air pollutant or more than 25 tons per year of all hazardous air pollutants. MACT/GACT standards

**TABLE 4.2.1 NATIONAL EMISSION STANDARDS FOR HAZARDOUS AIR POLLUTANTS**

<i>Affected Facility</i>	<i>Emission Level</i>	<i>Monitoring</i>
<b>Asbestos</b>		
Asbestos mills	No visible emissions or meet equipment standards	No requirement
Roadway surfacing	Contain no asbestos, except temporary use	No requirement
Manufacturing	No visible emissions or meet equipment standards	No requirement
Demolition/renovation	Wet friable asbestos or equipment standards and no visible emissions	No requirement
Spraying friable asbestos		
Equipment and machinery	No visible emissions or meet equipment standards	No requirement
Buildings, structures, etc.	<1 percent asbestos dry weight	No requirement
Fabricating products	No visible emissions or meet equipment standards	No requirement
Friable insulation	No asbestos	No requirement
Waste disposal	No visible emissions or meet equipment and work practice requirements	No requirement
Waste disposal sites	No visible emissions; design and work practice requirements	No requirement
<b>Beryllium</b>		
Extraction plants	1. 10 g/hour, or	1. Source test
Ceramic plants	2. 0.01 $\mu\text{m}^3$ (thirty-day)	2. Three years CEM <sup>a</sup>

Copper converter	Secondary hooding system Particle limit 11.6 mg/dscm <sup>d</sup>  Approved operating plan	Methods 5 and 108A Continuous opacity for control Airflow monitor for secondary hood
Arsenic trioxide and metallic arsenic plants using roasting/condensation process	Approved plan for control of emissions	Opacity monitor for control Ambient air monitoring
<b>Benzene</b> Equipment leaks (Serving liquid or gas 10 percent by weight benzene; facilities handling 1000 Mg/year and coke oven by-product exempt) Pumps Compressors Pressure relief valves Sampling connection systems Open-end valves/lines	Leak is 10,000 ppm using Method 21; no detectable emissions (NDE) is 500 ppm using Method 21  Monthly LDAR, <sup>e</sup> dual seals, 95 percent control or NDE <sup>f</sup> Seal with barrier fluid, 95 percent control or NDE <sup>f</sup> NDE <sup>f</sup> or 95 percent control Closed purge or closed vent Cap, plug, or second valve	Test of NDE <sup>f</sup>  Test for NDE <sup>f</sup> Test for NDE <sup>f</sup>

*Continued on next page*

**TABLE 4.2.1** *Continued*

<i>Affected Facility</i>	<i>Emission Level</i>	<i>Monitoring</i>
Valves	Monthly LDAR <sup>e</sup> (quarterly if not leaking for two consecutive months) or NDE <sup>f</sup>	Test for NDE <sup>g</sup>
Pressure relief equipment	LDAR <sup>e</sup>	Monitor annually
Product accumulators	95 percent control	
Closed-vent systems and control devices	NDE or 95 percent control	
Coke by-product plants	Enclose source, recover, or destroy. Carbon adsorber or incinerator alternate	Semiannual LDAR, <sup>e</sup> annual maintenance
Equipment and tanks		
Light-oil sumps	Cover, no venting to sump	Semiannual LDAR <sup>e</sup>
Napthalene equipment	Zero emissions	
Equipment leaks (serving 10 percent by weight)	See 40 <i>CFR</i> 61, subpart J.	
Exhauster (1 percent by weight)	Quarterly LDAR <sup>e</sup> or 95 percent control or NDE <sup>f</sup>	Test for NDE <sup>f</sup>
Benzene storage vessels	Equipped with: 1. Fixed roof with internal floating roof-seals, or 2. External floating roof with seals, or 3. Closed vent and 95 percent control	Periodic inspection
Vessels with capacity >10,000 gallon		Periodic inspection
		Maintenance plant and monitoring
Benzene transfer	Vapor collection and 95 percent control	Annual recertification
Producers and terminals (loading >1 300 000/year)		
Loading racks (marine rail, truck)	Load vapor-tight vessels only	Yes
Exemptions:		
Facilities loading <70 percent benzene		
Facilities loading less than required of >70 percent benzene		
Both of above subject to record-keeping		
Waste Operations	1. Facilities $\geq 10$ Mg/year in aqueous wastes must control streams $\geq 10$ ppm. Control to 99 percent or <10 ppm 2. If >10 ppm in wastewater treatment system: Wastes in <10 ppm Total in <1 Mg/year 3. >1 Mg/year to <10 Mg/year 4. <1 Mg facilities	Monitor control and treatment. Also, periodically monitor certain equipment for emissions >500 ppm and inspect equipment
Chemical manufacturing plants		
Petroleum refineries		
Coke by-product plants		
TSDF <sup>g</sup> treating wastes from the three preceding		Report annually One-time report
Radionuclides		
DOE facilities (radon not included)	10 mrem/year <sup>h</sup> radionuclides (any member of the public)	Approved EPA computer model and Method 114 or direct monitoring (ANSIN13.1-1969)

*Continued on next page*

**TABLE 4.2.1** *Continued*

<i>Affected Facility</i>	<i>Emission Level</i>	<i>Monitoring</i>
NRC licensed facilities and facilities not covered by subpart H	10 mrem/year <sup>h</sup> radionuclides (any member of the public)  3 mrem/year iodine (any member of the public)	Approved EPA computer model or Appendix E  Emissions determined by Method 114 or direct monitoring (ANSIN13.1-1969)
Calciners and nodulizing kilns at elemental phosphorus plants	2 curies per year (polonium-210)	Method 111
Storage and disposal facilities for radium-containing material, owned/operated by DOE	20 pCi/m <sup>2</sup> per second <sup>i</sup> (radon-222)	None specified
Phosphogypsum stacks (waste from phosphorus fertilizer production)	20 pCi/m <sup>2</sup> per second <sup>i</sup> (radon-222)	Method 115
Disposal of uranium mill tailings (operational)	20 pCi/m <sup>2</sup> per second <sup>i</sup> (radon-222)	Method 115

<sup>a</sup>CEM = continuous emission monitor.

<sup>b</sup>Before opening equipment, VC must be reduced to 2.0 percent (volume) or 25 gallons, whichever is larger.

<sup>c</sup>Mg/year = megagrams per year.

<sup>d</sup>mg/dscm = milligrams per dry standard cubic meter.

<sup>e</sup>LDAR = leak detection and repair.

<sup>f</sup>NDE = no detectable emissions.

<sup>g</sup>TSDF = treatment, storage, and disposal facilities.

<sup>h</sup>mrem/year = millirems per year (the rem is the unit of effective dose equivalent for radiation exposure).

<sup>i</sup>pCi/m<sup>2</sup> per second = picocuries per square meter per second.

are developed to control hazardous air pollutant emissions from both new and existing sources.

The 1990 amendments establish priorities for promulgating standards. The EPA, in prioritizing its efforts, is to consider the following:

- The known or anticipated adverse effects of pollutants on public health and the environment
- The quality and location of emissions or anticipated emissions of hazardous air pollutants that each category or subcategory emits
- The efficiency of grouping categories or subcategories according to the pollutants emitted or the processes or technologies used

The EPA is to promulgate standards as expeditiously as practicable, but the 1990 amendments also established a minimum number of sources that must be regulated pursuant to a schedule. At this writing, standards for forty categories and subcategories are to be promulgated. The following standards are among those that have been promulgated:

On September 22, 1993, the EPA issued national emission standards for perchloroethylene (PCE) dry cleaning facilities

On October 27, 1993, coke oven battery standards were promulgated

On April 22, 1994, the EPA announced its final decisions on the hazardous organic NESHAP rule (HON), which requires sources to achieve emission limits reflecting the application of the MACT

By November 15, 1994, emission standards for 25 percent of the listed categories and subcategories were promulgated. Another 25 percent must be promulgated by November 15, 1997. All emission standards must be promulgated by November 15, 2000. Generally, existing sources must meet promulgated standards as expeditiously as practicable, but no later than three years after promulgation.

## Other Technology Standards

Other technology standards include new source performance standards, best available control technology (BACT) and lowest achievable emission rate (LAER) standards, best available control technology for toxics (T-BACT) standards, and reasonably available control technology (RACT) standards. These standards are discussed next.

**TABLE 4.2.2 NEW SOURCE PERFORMANCE STANDARDS FOR SOME SOURCES POTENTIALLY EMITTING TOXIC AIR POLLUTANTS**

<i>Source Category</i>	<i>Citation<sup>a</sup></i>	<i>Pollutants Regulated<sup>b</sup></i>
Incinerators (>50 tons/day)	Subpart E	PM
Municipal waste combusters (>250 tons/day)	Subpart Ea	PM, organics, NO <sub>x</sub> , acid gases
Portland cement	Subpart F	PM
Asphalt plants	Subpart I	PM
Petroleum refineries	Subpart J	PM, CO, SO <sub>2</sub> , VOC
Petroleum storage vessels (>40,000 gallon)	Subpart K, Ka	VOC

<sup>b</sup>PM = particulate matter; CO = carbon monoxide; SO<sub>2</sub> = sulfur dioxide; NO<sub>x</sub> = nitrogen oxides; VOC = volatile organic compounds; TRS = total reduced sulfur.

## NEW SOURCE PERFORMANCE STANDARDS

Section 111 of the 1990 CAA Amendments authorizes the EPA to establish new source performance standards for any new stationary air pollution source category that causes, or significantly contributes to, air pollution that may endanger public health or welfare. The new source performance standards should reflect the degree of emission limitation achieved by applying the best demonstrated system of emission reduction. In considering the best, the EPA must balance the level of reduction against cost, other environmental and health impacts, and energy requirements. [Table 4.2.2](#) presents a list of new source performance standards.

### BACT/LAER

The CAA, as amended, provides for the prevention of significant deterioration (PSD) program. This program ensures that sources of air pollutants in relatively unpolluted areas do not cause an unacceptable decline in air quality. Under this program, no major source can be constructed or modified without meeting specific requirements, including demonstrating that the proposed facility is subject to the BACT for each regulated pollutant. A major source is one that emits more than 100 tons per year of regulated pollutants.

In nonattainment areas, proposed sources undergo a new source review. This review includes permits for the construction and operation of new or modified major sources that require the LAER. In nonattainment areas for ozone, a major source is one that emits as little as 10 tons of pollutant per year. The precise definition of a major source varies with the severity of ozone exceedances in the area.

Because BACT and LAER standards are determined on a case-by-case basis, no standards are published. The EPA has established the BACT/LAER Clearinghouse to assist in the consistent selection of BACT and LAER standards. This clearinghouse is designed to assist local and state regulatory agencies rather than industries.

### T-BACT

Before enactment of the 1990 amendments to the CAA, many states developed programs for toxic air pollutants. Some states developed regulations that required new and modified sources of toxic air pollutants to minimize emissions by using T-BACT. These programs can be modified with EPA guidance from the 1990 amendments.

### RACT/CTG

States with NAAQS exceedances have adopted and submitted SIPs to the EPA detailing how they plan to meet the NAAQS within a reasonable time. These SIPs require the installation of RACT for selected stationary sources. Regulating agencies determine RACT on a case-by-case basis within each industry, considering the technological and economic circumstances of the individual source. The EPA has issued a control techniques guideline (CTG) document to provide guidance on RACT for the control of volatile organic compound (VOC) emissions in nonattainment areas. The 1990 amendments require the EPA to issue CTGs within three years for eleven categories of stationary sources for which CTGs have not been issued.

## 4.3 OTHER AIR STANDARDS

---

---

This section discusses other air standards including state and local air toxic programs and air toxics control in Japan and some European countries.

### State and Local Air Toxics Programs

In 1989, the State and Territorial Air Pollution Program Administrators (STAPPA) and the Association of Local Air Pollution Control Officials (ALAPCO) conducted a comprehensive survey of state and local agency toxic air pol-

lution activities. This survey showed that every state had an air toxics program. The approaches used by states varied but generally fell into three categories:

- Formal regulatory programs
- Comprehensive policies
- Informal programs

The approaches used by local agencies are as diverse as the state programs, but they can be categorized similarly.

**TABLE 4.3.1 HARMFUL SUBSTANCES IN JAPAN (JUNE 22, 1971)**

<i>Substance</i>	<i>Facility</i>	<i>Standard Value (mg/Nm<sup>3</sup>)</i>
Cadmium and its compounds	Baking furnace and smelting furnace for manufacturing glass using cadmium sulfide or cadmium carbonate as raw materials.	1.0
	Calcination furnace, sintering furnace, smelting furnace, converter and drying furnace for refining copper, lead, or cadmium.	
	Drying facility for manufacturing cadmium pigment or cadmium carbonate.	
Chlorine and hydrogen chloride	Chlorine quick cooling facility for manufacturing chlorinated ethylene.	30 (chlorine)
	Dissolving tank for manufacturing ferric chloride.	80 (HCl)
	Reaction furnace for manufacturing activated carbon using zinc chloride.	
	Reaction facility and absorbing facility for manufacturing chemical products.	
Fluorine, hydrogen fluoride and silicon fluoride	Waste incinerator (HCl)	700
	Electrolytic furnace for smelting aluminium (harmful substances are emitted from discharge outlet).	3.0
	Electrolytic furnace for smelting aluminum (harmful substances are emitted from top).	1.0
	Baking furnace and smelting furnace for manufacturing glass using fluorite or sodium silicofluoride as raw material.	10
	Reaction facility, concentrating facility, and smelting furnace for manufacturing phosphoric acid.	
	Condensing facility, absorbing facility, and distilling facility for manufacturing phosphoric acid.	
	Reaction facility, drying facility, and baking furnace for manufacturing sodium triple-phosphate.	
	Reaction furnace for manufacturing superphosphate of lime.	15
Baking furnace and open-hearth furnace for manufacturing phosphoric acid fertilizer.	20	

Source: David L. Patrick, ed, 1994, *Toxic air pollution handbook* (New York: Van Nostrand Reinhold).

State and local programs are growing as the federal air toxics program, under Title III of the 1990 amendments, and the new federal and state operating permit program, established under Title V of the 1990 amendments, are fully implemented.

### **Air Toxics Control in Japan**

Japan has taken strong steps to control what are known in the United States as criteria pollutants from both stationary and mobile sources, with the exception of lead. Lead is included in a group of special particulate pollutants. These special particulates include lead and its compounds; cadmium and its compounds; chlorine and hydrogen chloride; fluorine, hydrogen fluoride, and silicon fluoride. The emission standards for these four classes of pollutants are associated with categories of sources and are shown in [Table 4.3.1](#).

Investigations of emission rates and the environmental effects of potentially toxic air pollutants are ongoing. Some substances have been found to have a long-term impact

on the environment, although present levels are not considered toxic. Japan has established regulations to control releases of asbestos and is examining other toxic materials for possible regulation, including various chlorinated volatile organics and formaldehyde.

### **Air Toxics Control in Some European Countries**

Most western countries have some control program for U.S. criteria pollutants. Inter-country transport of air pollutants is a subject of study and concern. However, in most European countries, control of toxic air pollutants is not yet the subject of a regulatory program. Sweden has an action program to reduce or ban the use of harmful chemicals. The Swedes have identified thirteen compounds or categories of compounds for this program, including methylene chloride, trichloroethylene, tetrachloroethylene, lead and lead compounds, organotin compounds, chloroparaffins, phthalates, arsenic and its compounds, creosote, cad-

## 4.4 NOISE STANDARDS

---

---

Sound is transmitted through the air as a series of compression waves. The energy of the noise source causes air molecules to oscillate radially away from the source. This oscillation results in a train of high-pressure regions following one another, travelling at a speed of approximately 760 miles per hour in sea-level air.

Noise can be described in terms of its loudness and its pitch, or frequency. Loudness is measured in decibels (dB). The dB scale, shown in [Table 4.4.1](#), is a logarithmic scale—a 20 dB sound is ten times louder than a 10 dB sound. Pitch is a measure of how high or low a sound is. Pitch is measured in cycles per second (cps), or hertz (Hz). This measurement is the number of compression waves passing a point each second. The human ear is sensitive to sounds in the range of 20 to 20,000 Hz, but the ear is not as sensitive to low- and high-frequency sounds as it is to medium-frequency sounds ([Figure 4.4.1](#)).

### Human Response to Noise

The ability of humans to hear decreases with age and exposure to noise. As we age, the organ that translates sound into nerve impulses slowly degenerates. Continuous exposure to loud noises can result in a permanent loss of hearing. Generally, the louder the noise, the less time it takes to induce a permanent hearing loss. Lower-frequency noise does less damage than higher-frequency sounds at the same level of loudness. However, even a partial hearing loss can severely impact an individual's ability to comprehend speech, negatively impacting that person's comfort level at social gatherings or when interacting with strangers. In children, hearing is important for learning language, and hearing loss can limit development.

Noise also affects sleep and stress levels, albeit more subtly than it affects hearing loss. Sleep disturbance can take the form of preventing sleep, making it difficult to fall asleep, causing a person to wake after falling asleep, or altering the quality of sleep. A high level of background noise, particularly if it is of variable levels, can change the stress and comfort levels of entire neighborhoods.

### Wildlife Response to Noise

The effects of noise on wildlife are similar to its effects on humans. Additionally, noise can affect a creature's ability to obtain food or to breed. Some species that depend on detecting sounds and subtle differences in sound to locate food, to avoid becoming food, or to locate a mate may experience difficulties in high-noise environments. Short, loud noises that do not permanently affect a creature's hearing seem to have much less impact than steady background noise.

### Occupational Noise Standards

The 1970 Occupational Safety and Health Act sets permissible limits on noise exposure for most commercial and industrial settings. [Table 4.4.2](#) presents these limits. Exposure to impulsive or impact noise should not exceed a peak sound pressure of 140 dB. When a worker is exposed daily to more than one period of noise at different levels, these noise exposures can be compared to the standards in [Table 4.4.2](#) by adding the ratio of the time allowed at the noise level to the time of exposure at that level for each period. If that sum is greater than one, then the mixed exposure exceeds the standards.

### Land Use and Average Noise Level Compatibility

Noise conditions are characterized in terms of A-weighted decibels (dBA), using the following common descriptors: (1) equivalent sound level for twenty-four-hour periods,  $L_{eq}(24)$ , and (2) day-night sound level,  $L_{dn}$ . The former is a time-weighted average; the latter is weighted more heavily for noise during the night (for more detail, refer to [Chapter 6](#)).

In general, local ordinances regulate noise outside the workplace, usually as a nuisance, and normally do not have applicable standards. Similarly in most situations, no federal or state noise standards apply. Regulatory agencies have developed guidelines to assist in land use planning and in siting major facilities that generate significant

**TABLE 4.4.1 A DECIBEL SCALE**

Sound Intensity Factor	Sound Level (dB)	Sound Sources	Perceived Loudness	Effects Damage to Hearing	Community Reaction to Outdoor Noise
1,000,000,000,000,000,000	180—	• Rocket engine	↑	↑	
100,000,000,000,000,000	170—				
10,000,000,000,000,000	160—				
1,000,000,000,000,000	150—	• Jet plane at takeoff	Painful	Traumatic injury	
100,000,000,000,000	140—			Injurious range; irreversible damage	
10,000,000,000,000	130—	• Maximum recorded rock music	↓

Duration <sup>a</sup> Daily Exposure	Level (dB re 0.0002 dynes/cm <sup>2</sup> )		
	White Noise (dBA)	1 Octave Bandwidth (dBA)	Pure Tone (dBA)
8 hr	90	85	80
4 hr	90	85	80
2 hr	92	87	82
1 hr	95	90	85
30 min	98	93	88
15 min	102	97	92
7 min	108	103	98
3 min	115	110	105
1As min	125	120	115

Source: B.G. Liptak, ed, 1974, *Environmental engineers' handbook*, Vol. 3 (Radnor, Penna.: Chilton Book Company).

<sup>a</sup>If ear protectors are not worn, even the shortest exposure is considered hazardous at levels above 135 dBA. If ear protectors are worn, no exposure to levels above 150 dB, however short, is considered safe. These criteria assume that hearing loss will be within acceptable limits if, after 10 years, it is no greater than 10 dB below 1000 Hz, 15 dB up to 2000 Hz, or 20 dB up to 3000 Hz.

**TABLE 4.4.3** SUMMARY OF NOISE LEVELS IDENTIFIED AS REQUISITE TO PROTECT PUBLIC HEALTH AND WELFARE WITH AN ADEQUATE MARGIN OF SAFETY

Effect	Level	Area
Hearing loss	$L_{eq}(24) = 70$ dBA*	All areas.
Outdoor activity interference and annoyance	$L_{dn} = 55$ dBA	Outdoors in residential areas where people spend widely varying amounts of time and other places in which quiet is a basis for use.
	$L_{eq}(24) = 55$ dBA	Outdoor areas where people spend limited amounts of time, such as school yards and playgrounds.
Indoor activity interference and annoyance	$L_{dn} = 45$ dBA	Indoor residential areas.
	$L_{eq}(24) = 45$ dBA	Other indoor areas with human activities such as schools, etc.

Source: U.S. Environmental Protection Agency, 1974, *Information on levels of environmental noise requisite to protect public health and welfare with an adequate margin of safety*, EPA/550-9-74-004 (U.S. Environmental Protection Agency).

\*Based on annual averages of the daily level over a period of 40 years.

levels of noise. The EPA guidelines were developed to protect public health and welfare (U.S. EPA 1974). These guidelines are summarized in Table 4.4.3.

The Department of Housing and Urban Development (HUD) has established guidelines for noise levels in residential areas. They define categories of acceptability as follows: acceptable if the  $L_{dn}$  is less than 65 dBA, normally unacceptable if the  $L_{dn}$  is greater than 65 dBA but less than 75 dBA, and unacceptable if the  $L_{dn}$  is greater than 75 dBA (HUD 1979). According to EPA studies, the majority of complaints occur when the  $L_{dn}$  exceeds 65 dBA (U.S. EPA 1973).

When land uses are noise sensitive, as with hospitals, parks, outdoor recreation areas, music shells, nursing homes, concert halls, schools, libraries, and churches, more restrictive guidelines are used. Conversely, less restrictive guidelines are used for commercial and agricultural land uses. For example, Table 4.4.4 shows a set of U.S. Navy noise guidelines for various land uses.

## Traffic Noise Abatement

In America, a common source of community noise is automobile and truck traffic; yet by their nature, roads must be continuous and connected. Therefore, noise abatement strategies must be applied when the actual or projected noise from a highway exceeds its guidelines. This strategy can be considered a technology standard in that barriers, traffic management, alignment modifications, and landscaping have limited ability to reduce noise levels.

## Community Exposure to Airport Noise

Aircraft can directly affect the noise levels of wide areas since no natural or manmade barriers are present. Usually, aircraft noise is infrequent and, when averaged over a twenty-four-hour period, is below guideline levels. However, near airports some areas have high noise levels, measured as  $L_{eq}(24)$  or  $L_{dn}$ . In these areas, regulators can

**TABLE 4.4.4 LAND USE AND AVERAGE NOISE LEVEL COMPATIBILITY**

Land Use	Average Noise Level (CNEL or $L_{dn}$ dBs)						
	50-55	55-60	60-65	65-70	70-75	75-80	80-85

Key:

1 = *Clearly Compatible*—The average noise level is such that indoor and outdoor activities associated with the land use can be carried out with essentially no interference from noise.

2 = *Normally Compatible*—The average noise level is great enough to be of some concern, but common building construction should make the indoor environment compatible with the usual indoor activities, including sleeping.

3 = *Normally Incompatible*—The average noise level is significantly severe so that unusual and costly building construction may be necessary to ensure an adequate environment for indoor activities. Barriers must be erected between the site and prominent noise sources to make the outdoor environment tolerable.

4 = *Clearly Incompatible*—The average noise level is so severe that construction costs to make the indoor environment acceptable for activities would probably be prohibitive. The outdoor environment would be intolerable for outdoor activities associated with the land use.

apply a type of technology standard by changing flight patterns and flight times to reduce noise impacts. New jet aircraft are required to use low-noise engines. The abatement strategy of insulating impacted structures against the intrusion of noise can also reduce the influence of aircraft noise.

### Railroad Noise Abatement

Railroad traffic has noise characteristics that create special abatement problems. Safety horns and whistles are loud and designed to be heard; further, they must be sounded at specific locations. Trains can be long and can maintain a noise level for ten to twenty minutes. Because trains move twenty-four hours a day, night noise events are possible. The tracks are well established and cannot be easily moved.

All of these factors reduce abatement standards to the use of barriers, possibly with landscaping, and traffic management.

—William C. Zegel

## 4.5 WATER QUALITY STANDARDS

---

---

This section discusses the legislative activity, ACLs, technology standards, water quality goals, and toxic pollutants related to water quality standards.

### Legislative Activity

The first substantive water pollution legislation in the United States, the Water Pollution Control Act, was passed in 1948. In 1956, the Federal Water Pollution Control Act, commonly called the Clean Water Act (CWA), provided the first long-term control of water pollution. The act has been amended several times. A key amendment in 1972 establishes a national goal of *zero discharge* by 1985. This concept refers to the complete elimination of all water pollutants from navigable waters of the United States. This amendment also called upon the EPA to establish effluent limitations for industries and make money available to construct sewage treatment plants. The amendments in 1977 direct the EPA to examine less common water pollutants, notably toxic organic compounds.

This legislation has resulted in the development of a complex series of water quality standards. These standards define the levels of specific pollutants in water that protect the public health and welfare and define the levels of treatment that must be achieved before contaminated water is released. The most notable of these standards are the water quality criteria set by the EPA. These criteria describe the levels of specific pollutants that ambient water can contain and still be acceptable for one of the following categories:

- Class A—water contact recreation, including swimming
- Class B—able to support fish and wildlife
- Class C—public water supply
- Class D—agricultural and industrial use

Water quality standards are set by the states and are subject to approval by the EPA. These standards define the conditions necessary to maintain the quality of water for its intended use. Per a provision of the CWA, existing uses of a body of water must be maintained (i.e., uses that downgrade water quality resulting in a downgraded use category are not allowed).

The primary enforcement mechanism established by the CWA, as amended in 1977, is the National Pollution Discharge Elimination System (NPDES). The NPDES is administered by the states with EPA oversight. Facilities that discharge directly into waters of the United States must obtain NPDES permits.

Under NPDES, permits for constructing and operating new sources and existing sources are subject to different standards. Discharge permits are issued with limits on the quantity and quality of effluents. These limits are based on a case-by-case evaluation of potential environmental impacts. Discharge permits are designed as an enforcement tool, with the ultimate goal of meeting ambient water quality standards.

Most states have assumed primary authority for the enforcement and permit activities regulated under the CWA. In those states that have not assumed primacy, discharges to surface waters require two permits, one from the EPA under CWA and one from the state under its regulations. In addition, such discharges are frequently regulated by local governments.

The EPA does not have permit responsibility under section 404 of the CWA, nor does it have responsibility for discharges associated with marine interests. Consequently, other federal water programs affect water quality. [Table 4.5.1](#) summarizes selected regulations promulgated by the U.S. Army Corps of Engineers, the Coast Guard, and the EPA.

[Figure 4.5.1](#) shows the relationship of water quality criteria, water quality standards, effluent guidelines, effluent limitations and permit conditions.

### ACLs

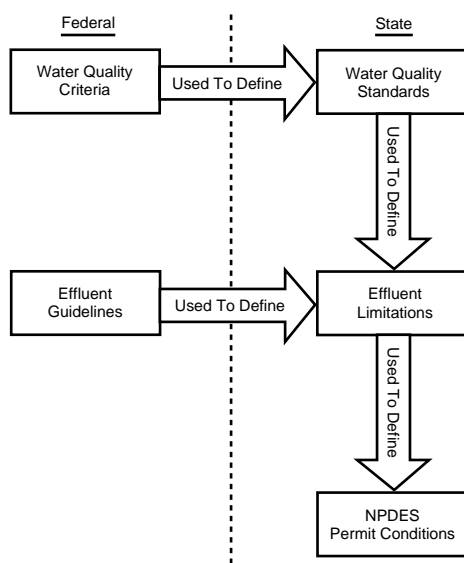

Water quality standards are frequently expressed in terms of ambient concentration. The regulatory agency determines ACLs, which are the maximum concentration of a contaminant in water to which people are exposed. The degree of human exposure depends upon the use of the water body. Thus, different ACLs apply to different water bodies. Generally, regulators derive ACLs from health effects information. Using ACLs, regulators can mathematically determine the maximum contribution that an ef-

fluent source makes to a water body without violating relevant ACL(s).

### Technology Standards

Permits for discharges of pollutants into the waters of the United States are subject to the NPDES effluent limits and permit requirements. Such source standards are generally based upon the best available technology (BAT). These technology standards can be effluent guidelines, effluent limits, and the definition of BAT.

Effluent guidelines define uniform national guidelines for specific pollutant discharges for each type of industry regulated. These are not, in fact, guidelines but are regulatory requirements. Federal effluents guidelines and standards cover more than fifty industrial categories, as shown in [Table 4.5.2](#).

Effluent limits are specific control requirements that apply to a specific point-source discharge. They are based

on both national effluent guidelines and state water quality standards, as shown in Figure 4.5.1.

In some cases, a standard consists of a treatment technology that the regulatory agency accepts as the BAT for that type of source or a unique combination of source and receiving water body.

## Water Quality Goals

The discharge standards under the NPDES refer to specific potential contaminants. A series of water quality goals are associated with each potential contaminant. Goals for a specific situation depend on the established use of the water body. The regulated contaminants vary from state to state. Schultz has classified more than fifty water quality parameters into four groups based on the frequency of their use in state ACLs and associated NPDES water quality standards (Schultz 1972).

All state water quality standards classify the following nine parameters: dissolved oxygen (D), pH, coliform, temperature, floating solids (oil-grease), settleable solids, turbidity-color, taste-odors, and toxic substances. In 50 to 99 percent of the state standards, three groups of parameters are categorized. In most regions, these frequently sampled parameter groups (radioactivity, total dissolved solids, and U.S. Public Health Service Drinking Water Standards) are sampled less frequently than the first nine. Sixteen parameters, eleven of which are heavy metals and other toxic substances, are found in the 20 to 49 percent of the state standards. Eighteen parameters appear in less than 20 percent of the state standards.

Table 4.5.3 shows the optimum and maximum values of water quality characteristics related to type of use published by California as an example of water quality goals.

## Effluent Standards

NPDES permits are issued to municipal and industrial discharge sources to ensure that they do not violate water quality standards. In addition, state and federal monitoring, inspection, and enforcement ensures compliance with standards and permits.

## MUNICIPAL EFFLUENT LIMITS

Municipal effluent limits are less complex than industrial limits. All publicly owned treatment works must meet a secondary treatment level (Table 4.5.4). This treatment level implies the following technologies: mechanical removal of solids by screening and settling, removal of additional organic wastes and solids by treating the waste with air or oxygen and allowing bacteria to consume the organic chemicals, and chlorination. Table 4.5.5 summarizes the requirements of this program.

**TABLE 4.5.4 NATIONAL PRETREATMENT STANDARDS**

1. General Prohibitions: A user may not introduce into a publicly owned treatment works, POTW, any pollutant(s) which cause "pass through" without a change in nature or "interference" with treatment processes, including sludge use or disposal.
2. Specific Prohibitions: The following pollutants shall not be introduced into a POTW:
  - a. Pollutants which create a fire or explosion hazard in the POTW;
  - b. Pollutants which will cause corrosive structural damage to the POTW, but in no case discharges with pH lower than 5.0, unless the works is specifically designed to accommodate such discharges;
  - c. Solid or viscous pollutants in amounts which will cause obstruction to the flow in the POTW resulting in interference;
  - d. Any pollutant, including oxygen, demanding pollutants (BOD, etc.) released in a discharge at a flow rate and/or pollutant concentration which will cause interference with the POTW;
  - e. Heat in amounts which will inhibit biological activity in the POTW resulting in interference, but in no case heat in such quantities that the temperature at the POTW exceeds 40° C (104° F) unless the approval authority, upon request of the POTW, approves alternate temperature limits.
3. Categorical Requirements: Standards specifying quantities or concentrations of pollutants or pollutant properties which may be discharged to a POTW by existing or new industrial users in specific industrial subcategories will be established as separate regulations under the appropriate subpart of 40 CFR Chapter 1, Subchapter N. These standards, unless specifically noted otherwise, shall be in addition to the general prohibitions established above (40 CFR 403.5).

Source: U.S. Environmental Protection Agency, 1973–1985, Secondary treatment regulation, *Code of Federal Regulations*, Title 40, part 133 (Washington, D.C.: U.S. Government Printing Office).

**INDUSTRIAL EFFLUENTS**

Industrial effluents are subject to state and federal requirements (see Table 4.5.2). States must tailor effluents discharge programs to water quality goals. Regulating agencies must monitor each segment of a water body at specified intervals and evaluate the impact of each discharger. Based on the evaluation, each water body is put into one of two groups:

Effluent limited—Water bodies for which the standards are met or will be met if the nationwide limits are implemented

Water quality limited—Water bodies that cannot meet the quality standards even when nationwide limits are ap-

plied. Effluent requirements must be tailor-made for each discharger along this group of water.

The NPDES requires all dischargers to file a standardized report with the EPA and their state agency. This report indicates the quality and quantity of their discharges. Where appropriate, the state and the EPA can respond to the report with a set of effluent limits, an abatement schedule to meet the effluent limits, and a monitoring schedule. A permit is issued upon agreement by the discharger, interested citizens, the state regulatory agency, and the EPA.

**STORM WATER DISCHARGE**

Storm water is defined as storm water runoff, surface runoff, and drainage. The regulations apply only to point-source discharges. A permit is required for both direct discharges into U.S. waters and for indirect discharges into a facility’s drainage system or a separate city storm water system. However, an industry that separates its nonindustrial storm water, such as drainage from office buildings and parking lots, from the plant’s industrial storm water does not have to include the nonindustrial areas in their permit.

These industrial discharges must meet effluent standards under sections 301 and 402 of the CWA, including the use of BAT and best practicable control technology (PCT). Industrial discharges must apply best management practices (BMPs) to control and reduce storm water discharges. These standards are technological and are measures and controls designed to eliminate or minimize pollutant loadings in storm water discharges.

General BMPs include good housekeeping, preventative maintenance, visual inspection, spill prevention and response, sediment erosion prevention, management of runoff, employee training, and record keeping and re-

(A) An average per working day, calculated over any calendar month.

(B) Monthly average daily loading per quantity of pollutant produced.

(C) A sample(s) representing any working day.

porting. These BMPs can be applied to a variety of industrial facilities and are considered to be *source reduction* practices. These BMPs eliminate or reduce the pollutant generation at the source.

The next best BMP options include reuse or recycling of storm water in the industrial processes, followed by runoff management controls, such as vegetative swales and infiltration devices. Finally, if none of these applications control the storm water pollutants, regulators should explore treatment options. Treatment options include engineered systems, such as oil-water separators, sedimentation tanks, and metal precipitation systems, depending on the pollutants to be removed.

## Toxic Pollutants

The CWA regulates many toxic pollutants through NPDES permits. Table 4.5.6 lists priority pollutants that the EPA has designated as toxic. Effluent standards have been promulgated for some of these pollutants, listed in Table 4.5.7.

The water environment can be monitored for toxic pollutants in the following three ways:

By biological and chemical analyses of the water

By a bioassay in which organisms are placed in water samples and their reaction is compared with control. This method is receiving attention for monitoring toxic discharges.

By plants and animals that are reactive to types and degrees of pollution. The absence of organisms known to be intolerant of pollution also serves as an indication of pollution; the presence and expansion of pollution-tolerant organisms is a related index of pollution.

—William C. Zegel

## 4.6 DRINKING WATER STANDARDS

---

---

The Safe Drinking Water Act (SDWA) is designed to achieve uniform safety and quality of drinking water in the United States. To achieve this goal, the SDWA identifies contaminants and establishes maximum acceptable levels for those contaminants. The major provisions of the act with respect to establishing drinking water quality standards are (1) the establishment of primary regulations to protect public health and (2) the establishment of secondary regulations that are related to the taste, odor, and appearance of drinking water.

### Drinking Water Regulation

The EPA's philosophy in setting drinking water regulation is to initially assess the potential for harm and determine the feasibility of attainment (57 *FR* pt. 219 [13 November 1985] 46936). Regulatory actions must be scientifically, legally, defensibly, technically, and economically feasible. This feasibility requires careful study and analysis and extensive communication with those affected by the regulations (i.e., state agencies, public water supplies, and the scientific community), as well as other interested parties in the public sector.

Terms such as *regulations, standards, goals, guidelines, criteria, advisories, limits, levels, and objectives* describe numerical or narrative qualities of drinking water that protect public health. Distinctions between these terms generally fall into either (1) legally enforceable concentrations (regulations or standards) or (2) concentrations that represent desirable water quality but are not enforceable (goals or criteria). In addition, both regulations and goals usually represent either (1) a health-related NOAEL or (2) a level representing a balance between health risks and the feasibility of achieving these levels.

### MAXIMUM CONTAMINANT LEVEL GOALS

Maximum contaminant level goals (MCLGs) must be set at a level at which "no known or anticipated adverse effects on the health of persons occur and which (sic) allows an adequate margin of safety" (Cotruvo 1987, 1988). First, the highest NOAEL is based upon an assessment of human or animal data (usually from animal experiments). To determine the RfD for regulatory purposes, the NOAEL is divided by an uncertainty factor (UF). This process corrects for the extrapolation of animal data to human data, the existence of weak or insufficient data,

and individual differences in human sensitivity to toxic agents, among other factors.

For MCLG purposes, the NOAEL must be measurable in terms of concentration in drinking water (e.g., milligrams per liter). An adjustment of the RfD, which is reported in milligrams per kilograms (body weight) per day to milligrams per liter, is necessary. This adjustment is made by factoring in a reference amount of drinking water consumed per day and a reference weight for the consumer. The NOAEL, in milligrams per liter, is called the drinking water equivalent level (DWEL).

DWELs are calculated as follows:

$$DWEL = \frac{[NOAEL \text{ in mg/kg}\cdot\text{day}](70 \text{ kg})}{(UF)(2 \text{ L/day})} \quad 4.6(1)$$

where:

- NOAEL = no observed adverse effect level
- 70 kg = assumed weight of an adult
- 2 L/day = assumed amount of water consumed by an adult per day
- UF = uncertainty factor (usually 10, 100, or 1000)

(Note: An uncertainty factor of 10 is used when good acute or chronic human exposure data are available and supported by acute and chronic data in other species; an uncertainty factor of 1000 is used when acute or chronic data in all species are limited or incomplete [National Academy of Science, 1977]).

To determine the MCLG, regulators account for the contribution from other sources of exposure, including air and food. Comprehensive data are usually not available on exposures from air and food. In this case, the MCLG is determined by

$$MCLG = DWEL \times (\text{percentage of the drinking water contribution}) \quad 4.6(2)$$

When specific data are not available, regulators often use a 20 percent drinking water contribution.

Maximum contaminant levels (MCLs) are set "as close to" the MCLGs "as is feasible." The term *feasible* means feasible with the use of the BAT, which is a technology standard rather than an ACL, taking costs into consideration (Cotruvo 1987, 1988). The general approach to setting MCLs is to determine the feasibility of controlling contaminants. This approach requires (1) evaluating the availability and cost of analytical methods, (2) evaluating the availability and performance of technologies and other factors related to feasibility and identifying those that are best, and (3) assessing the costs of applying the technologies to achieve various concentrations.

## EPA PROCESS FOR SETTING STANDARDS

EPA regulation development involves interpreting the mandates and directives of the SDWA, performing technical and scientific assessments to meet SDWA requirements, preparing regulations that blend technical and scientific aspects with policy considerations, reviewing draft regulations within the agency, and facilitating public review of the draft and proposed regulations.

Figure 4.6.1 shows the development of draft EPA regulations. The EPA presents analytical methods and monitoring techniques in the methods and monitoring support document. The following factors are among those they consider in specifying which analytical methods should be approved:

- Reliability (precision and accuracy) of the analytical results
- Specificity in the presence of interferences
- Availability and performance of laboratories
- Rapidity of analysis to permit routine use
- Costs of analysis

Guidance to implement the monitoring requirements is also in the document. States have an active role in determining appropriate monitoring requirements. The EPA generally specifies a minimum frequency and provides guidance on factors to consider when assessing a system's vulnerability to contamination.

The treatment technologies and costs document summarizes the availability and performance of the treatment technologies that can reduce contaminants in drinking water. Costs of treatment are determined for each technology for many sizes of water systems. The EPA determines the BAT based upon a number of factors, some of which include technologies that

- Have the highest efficiency of removal
- Are compatible with other types of water treatment processes
- Are available as manufactured items or components
- Are not limited to application in a particular geographic region
- Have integrity for a reasonable service life as a public work
- Are reasonably affordable by large metropolitan or regional systems
- Can be mass-produced and put into operation in time for implementation of the regulations

## PUBLIC PARTICIPATION

Figure 4.6.2 shows the public participation part of the process. Public workshops, meetings, and hearings are conducted from early in the process until completion. These meetings allow informal and formal discussions of issues

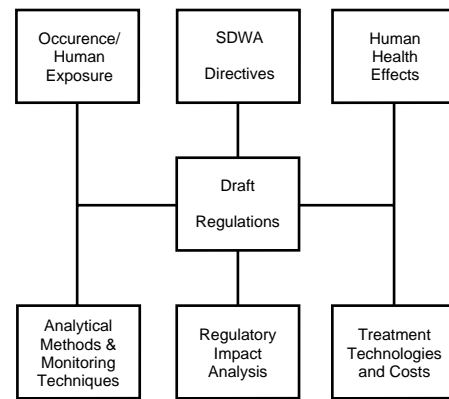

FIG. 4.6.1 Development of draft U.S. EPA regulations (Adapted from the *Federal Register*).

and the opportunity for the public to provide data and information to the EPA. The advance notice of proposed rule making (ANPRM) is an optional step that provides an extra opportunity for public comment. Public comment periods generally last from 30 to 45 days and up to 120 days. The EPA reviews each submitted comment and uses it to prepare the proposed and final regulations. They also prepare a detailed document that presents each comment and the EPA's responses.

## EPA Drinking Water and Raw Water Standards

Table 4.6.1 presents the national primary drinking water standards. These standards are enforceable MCLs until they are revised. Associated with these concentration standards are the surface water treatment standards (filtration

FIG. 4.6.2 Public participation in regulation development (Adapted from the *Federal Register*).

<i>Contaminants</i>	<i>MCLG (mg/L)</i>	<i>MCL (mg/L)</i>	<i>Potential Health Effects from Ingestion of Water</i>	<i>Sources of Contaminant in Drinking Water</i>
Fluoride	4.0	4.0	Skeletal and dental fluorosis	Natural deposits; fertilizer, aluminum industries; water additive
<b>Volatile Organics</b>				
Benzene	zero	0.005	Cancer	Some foods; gas, drugs, pesticide, paint, plastic industries
Carbon Tetrachloride	zero	0.005	Cancer	Solvents and their degradation products
p-Dichlorobenzene	0.075	0.075	Cancer	Room and water deodorants, and mothballs
1,2-Dichloroethane	zero	0.005	Cancer	Leaded gas, fumigants, paints
1,1-Dichloroethylene	0.007	0.007	Cancer, liver and kidney effects	Plastics, dyes, perfumes, paints
Trichloroethylene	zero	0.005	Cancer	Textiles, adhesives and metal degreasers
1,1,1-Trichloroethane	0.2	0.2	Liver, nervous system effects	Adhesives, aerosols, textiles, paints, inks, metal degreasers
Vinyl Chloride	zero	0.002	Cancer	May leach from PVC pipe; formed by solvent breakdown
<b>Coliform and Surface Water Treatment</b>				
<i>Giardia lamblia</i>	zero	TT	Gastroenteric disease	Human and animal fecal waste
<i>Legionella</i>	zero	TT	Legionnaire's disease	Indigenous to natural waters; can grow in water heating systems
Standard Plate Count	N/A	TT	Indicates water quality, effectiveness of treatment	
Total Coliform*	zero	<5%+	Indicates gastroenteric pathogens	Human and animal fecal waste
Turbidity*	N/A	TT	Interferes with disinfection, filtration	Soil runoff
Viruses	zero	TT	Gastroenteric disease	Human and animal fecal waste
<b>Phase II: Inorganics</b>				
Asbestos (>10 μm)	7MFL	7MFL	Cancer	Natural deposits; asbestos cement in water systems
Barium*	2	2	Circulatory system effects	Natural deposits; pigments, epoxy sealants, spent coal
Cadmium*	0.005	0.005	Kidney effects	Galvanized pipe corrosion; natural deposits; batteries, paints
Chromium* (total)	0.1	0.1	Liver, kidney, circulatory disorders	Natural deposits; mining, electroplating, pigments
Mercury* (inorganic)	0.002	0.002	Kidney, nervous system disorders	Crop runoff; natural deposits; batteries, electrical switches
Nitrate*	10	10	Methemoglobinemia	Animal waste, fertilizer, natural deposits, septic tanks, sewage
Nitrite	1	1	Methemoglobinemia	Same as nitrate; rapidly converted to nitrate
Selenium*	0.05	0.05	Liver damage	Natural deposits; mining, smelting, coal/oil combustion
<b>Phase II: Organics</b>				
Acrylamide	zero	TT	Cancer, nervous system effects	Polymers used in sewage/wastewater treatment
Alachlor	zero	0.002	Cancer	Runoff from herbicide on corn, soybeans, other crops
Aldicarb*	0.001	0.003	Nervous system effects	Insecticide on cotton, potatoes, others; widely restricted
Aldicarb sulfone*	0.001	0.002	Nervous system effects	Biodegradation of aldicarb
Aldicarb sulfoxide*	0.001	0.004	Nervous system effects	Biodegradation of aldicarb
Atrazine	0.003	0.003	Mammary gland tumors	Runoff from use as herbicide on corn and noncropland
Carbofuran	0.04	0.04	Nervous, reproductive system effects	Soil fumigant on corn and cotton; restricted in some areas
Chlordane*	zero	0.002	Cancer	Leaching from soil treatment for termites

TABLE 4.6.1 *Continued*

<i>Contaminants</i>	<i>MCLG (mg/L)</i>	<i>MCL (mg/L)</i>	<i>Potential Health Effects from Ingestion of Water</i>	<i>Sources of Contaminant in Drinking Water</i>
Chlorobenzene	0.1	0.1	Nervous system and liver effects	Waste solvent from metal degreasing processes
2,4-D*	0.07	0.07	Liver and kidney damage	Runoff from herbicide on wheat, corn, rangelands, lawns
o-Dichlorobenzene	0.6	0.6	Liver, kidney, blood cell damage	Paints, engine cleaning compounds, dyes, chemical wastes
cis-1,2-Dichloroethylene	0.07	0.07	Liver, kidney, nervous, circulatory	Waste industrial extraction solvents
trans-1,2-Dichloroethylene	0.1	0.1	Liver, kidney, nervous, circulatory	Waste industrial extraction solvents
Dibromochloropropane	zero	0.0002	Cancer	Soil fumigant on soybeans, cotton, pineapple, orchards
1,2-Dichloropropane	zero	0.005	Liver, kidney effects; cancer	Soil fumigant; waste industrial solvents
Epichlorohydrin	zero	TT	Cancer	Water treatment chemicals; waste epoxy resins, coatings
Ethylbenzene	0.7	0.7	Liver, kidney, nervous system	Gasoline; insecticides; chemical manufacturing wastes
Ethylene dibromide	zero	0.00005	Cancer	Leaded gas additives; leaching of soil fumigant
Heptachlor	zero	0.0004	Cancer	Leaching of insecticide for termites, very few crops
Heptachlor epoxide	zero	0.0002	Cancer	Biodegradation of heptachlor
Lindane	0.0002	0.0002	Liver, kidney, nerve, immune, circulatory	Insecticide on cattle, lumber, gardens; restricted 1983
Methoxychlor	0.04	0.04	Growth, liver, kidney, nerve effects	Insecticide for fruits, vegetables, alfalfa, livestock, pets
Pentachlorophenol	zero	0.001	Cancer; liver and kidney effects	Wood preservatives, herbicide, cooling tower wastes
PCBs	zero	0.0005	Cancer	Coolant oils from electrical transformers; plasticizers
Styrene	0.1	0.1	Liver, nervous system damage	Plastics, rubber, resin, drug industries; leachate from city landfills
Tetrachloroethylene	zero	0.005	Cancer	Improper disposal of dry cleaning and other solvents
Toluene	1	1	Liver, kidney, nervous, circulatory	Gasoline additive; manufacturing and solvent operations
Toxaphene	zero	0.003	Cancer	Insecticide on cattle, cotton, soybeans; cancelled 1982
2,4,5-TP	0.05	0.05	Liver and kidney damage	Herbicide on crops, right-of-way, golf courses; cancelled 1983
Xylenes (total)	10	10	Liver, kidney; nervous system	By-product of gasoline refining; paints, inks, detergents
<b>Lead and Copper</b>				
Lead*	zero	TT†	Kidney, nervous system damage	Natural/industrial deposits; plumbing, solder, brass alloy faucets
Copper	1.3	TT‡	Gastrointestinal irritation	Natural/industrial deposits; wood preservatives, plumbing
<b>Phase V: Inorganics</b>				
Antimony	0.006	0.006	Cancer	Fire retardants, ceramics, electronics, fireworks, solder
Beryllium	0.004	0.004	Bone, lung damage	Electrical, aerospace, defense industries
Cyanide	0.2	0.2	Thyroid, nervous system damage	Electroplating, steel, plastics, mining, fertilizer
Nickel	0.1	0.1	Heart, liver damage	Metal alloys, electroplating, batteries, chemical production
Thallium	0.0005	0.002	Kidney, liver, brain, intestinal	Electronics, drugs, alloys, glass
<b>Phase V: Organics</b>				
Adipate, (di(2-ethylhexyl))	0.4	0.4	Decreased body weight; liver and testes damage	Synthetic rubber, food packaging, cosmetics
Dalapon	0.2	0.2	Liver, kidney	Herbicide on orchards, beans, coffee, lawns, road/railways
Dichloromethane	zero	0.005	Cancer	Paint stripper, metal degreaser, propellant, extraction

Dinoseb	0.007	0.007	Thyroid, reproductive organ damage	Runoff of herbicide from crop and noncrop applications
Diquat	0.02	0.02	Liver, kidney, eye effects	Runoff of herbicide onland & aquatic weeds
Dioxin	zero	0.00000003	Cancer	Chemical production by-product; impurity in herbicides
Endothall	0.1	0.1	Liver, kidney, gastrointestinal	Herbicide on crops, land/aquatic weeds; rapidly degraded
Endrin	0.002	0.002	Liver, kidney, heart damage	Pesticide on insects, rodents, birds; restricted since 1980
Glyphosate	0.7	0.7	Liver, kidney damage	Herbicide on grasses, weeds, brush
Hexachlorobenzene	zero	0.001	Cancer	Pesticide production waste by-product
Hexachlorocyclopentadiene	0.05	0.05	Kidney, stomach damage	Pesticide production intermediate
Oxamyl (Vydate)	0.2	0.2	Kidney damage	Insecticide on apples, potatoes, tomatoes
PAHs (benzo(a)pyrene)	zero	0.0002	Cancer	Coal tar coatings; burning organic matter; volcanoes, fossil fuels
Phthalate, (di(2-ethylhexyl))	zero	0.006	Cancer	PVC and other plastics
Picloram	0.5	0.5	Kidney, liver damage	Herbicide on broadleaf and woody plants
Simazine	0.004	0.004	Cancer	Herbicide on grass sod, some crops, aquatic algae
1,2,4-Trichlorobenzene	0.07	0.07	Liver, kidney damage	Herbicide production; dye carrier
1,1,2-Trichloroethane	0.003	0.005	Kidney, liver, nervous system	Solvent in rubber, other organic products; chemical production wastes
<b>Other Proposed (P) and Interim (I) Standards</b>				
Beta/photon emitters (I) and (P)	zero	4 mrem/yr	Cancer	Decay of radionuclides in natural and manmade deposits
Alpha emitters (I) and (P)	zero	15 pCi/L	Cancer	Decay of radionuclides in natural deposits
Combined Radium 226/228 (I)	zero	5 pCi/L	Bone cancer	Natural deposits
Radium 226* (P)	zero	20 pCi/L	Bone cancer	Natural deposits
Radium 228* (P)	zero	20 pCi/L	Bone cancer	Natural deposits
Radon (P)	zero	300 pCi/L	Cancer	Decay of radionuclides in natural deposits
Uranium (P)	zero	0.02	Cancer	Natural deposits
Sulfate (P)	400/500	400/500	Diarrhea	Natural deposits
Arsenic* (I)	0.05	0.05	Skin, nervous system toxicity	Natural deposits; smelters, glass, electronics wastes; orchards
Total Trihalomethanes (I)	zero	0.10	Cancer	Drinking water chlorination by-products

and disinfection) and total coliform standards promulgated on June 29, 1989. (54 *FR* pt. 124 [29 June 1989]: 27486, 27544; U.S. EPA 1989)

Table 4.6.2 provides the EPA's secondary standards that set levels of drinking water contaminants that affect the aesthetic value of drinking water, such as taste, odor, color, and appearance. These standards are not enforceable by the federal government, but states are encouraged to adopt them. States can establish higher or lower levels based on local conditions, such as availability of alternative source waters, provided that public health and welfare are not adversely affected.

In some areas of the country, raw surface water is used directly as a domestic water supply. California has issued standards for such water used as a source of drinking water. Table 4.6.3 presents these California standards as an example.

### Canadian Drinking Water Guidelines

In Canada, drinking water is a shared federal–provincial responsibility. In general, provincial governments are responsible for an adequate, safe supply, whereas the Federal Department of National Health and Welfare develops

**TABLE 4.6.3 STANDARDS FOR RAW WATER USED AS SOURCES OF DOMESTIC WATER SUPPLY**

Source: Health and Welfare Canada, 1987, *Guidelines for Canadian drinking water quality*.

<sup>a</sup>I—Inorganic constituent; O—Organic constituent; P—Pesticide; R—Radionuclide.

<sup>b</sup>Unless otherwise specified, units are mg/L; limits apply to the sum of all forms of each substance present. MAC = maximum acceptable concentration; IMAC = interim maximum acceptable concentration; AO = aesthetic objectives.

<sup>c</sup>An objective concentration only was set in 1978, based on health considerations.

<sup>d</sup>Assessment of data indicates no need to set numerical guideline.

<sup>e</sup>No sample should contain more than 10 total coliform organisms per 100 mL; not more than 10 percent of the samples taken in a 30-day period should show the presence of coliform organisms; not more than two consecutive samples from the same site should show the presence of coliform organisms; and none of the coliform organisms detected should be fecal coliform.

<sup>f</sup>It is recommended, however, that the concentration of fluoride be adjusted to 1.0 mg/L, which is the optimum level for the control of dental caries. Where the annual mean daily temperature is less than 10°C, a concentration of 1.2 mg/L should be maintained.

<sup>g</sup>Assessment of data indicates no need to set a numerical guideline.

<sup>h</sup>Public acceptance of hardness varies considerably. Generally hardness levels between 80 and 100 mg/L (as CaCO<sub>2</sub>) are considered acceptable; levels greater than 200 mg/L are considered poor but can be tolerated; those in excess of 500 mg/L are normally considered unacceptable. Where water is softened by sodium-ion exchange, it is recommended that a separate unsoftened supply be retained for culinary and drinking purposes.

<sup>i</sup>2-Methyl-4-chlorophenoxyacetic acid.

<sup>j</sup>As nitrate- or nitrite-nitrogen concentration.

<sup>k</sup>Dimensionless.

<sup>l</sup>It is recommended that sodium be included in routine monitoring programs since levels may be of interest to authorities who wish to prescribe sodium-restricted diets for their patients.

<sup>m</sup>Trichloroacetic acid.

<sup>n</sup>For water entering a distribution system. A maximum of 5 NTU may be permitted if it can be demonstrated that disinfection is not compromised by the use of this less stringent value.

<sup>o</sup>At the point of consumption.

Notes:

1. Under review for possible revision, deletion from, or addition to the guidelines.

2. It is proposed that a guideline be added for this parameter for the first time (A); a change be made to the previous guideline (R); or the guideline be deleted (D). If after 1 year, no evidence comes to light that questions the appropriateness of the proposal, it will be adopted as the guideline.

3. Reassessment of data indicates no need to change 1978 recommendation.

4. Adapted from *Guidelines for Canadian Drinking Water Quality: 1978*; reassessment considered unnecessary at this time.

5. Previously listed in *Guidelines for Canadian Drinking Water Quality: 1978* as a maximum acceptable concentration based on aesthetic considerations.

quality guidelines and conducts research. Guidelines for Canadian drinking water quality are developed through a joint federal–provincial mechanism and are not legally enforceable unless promulgated as regulations by the appropriate provincial agency. Table 4.6.4 lists the current guidelines for Canadian drinking water quality.

### European Economic Community Drinking Water Directives

The European Economic Community (EEC), established by a treaty of the Council of the European Communities, issued a council directive relating to the quality of water

**TABLE 4.6.6 RECOMMENDED WATER TESTS FOR EXISTING HOME WELLS (NONPUBLIC WATER SYSTEMS)**

Test Name	MCL or SMCL
<i>Recommended:</i>	
Bacteria (Total Coliform) <sup>1</sup>	None detected
Nitrate <sup>1</sup>	10 mg/l NO <sub>3</sub> <sup>-</sup>
Lead <sup>1</sup>	0.05 mg/l
<i>Consider:</i>	
Volatile organic <sup>1</sup> chemical scan	If positive retest for specific chemicals
Hardness (Total)	150 mg/l
Iron	0.3 mg/l
Manganese	0.05 mg/l
Sodium	50 mg/l
pH	6.5–8.5
Corrosivity	Langelier Index +–1.0
Radioactivity (Gross Alpha) <sup>2</sup>	5 pico curies/l
Mercury <sup>2</sup>	.002 mg/l

Source: S.D. Faust, 1974, *Water from home wells—Problems and treatment, Circular 594-B* (Cook College, Rutgers University: New Jersey Experiment Station).

<sup>1</sup>Denotes an MCL-based on health standard. If these levels are exceeded consult with the local health department for interpretation and guidance.

<sup>2</sup>In wells between 50–150 feet deep in South Jersey, the Department of Environmental Protection also recommends that the homeowner consider these tests. Consult with your local health officer for the applicability of these tests to your municipality.

for human consumption. Specifically, the EEC standards provide for both setting standards for toxic chemicals and bacteria that present a health hazard and defining the physical, chemical, and biological parameters for different water uses, specifically for human consumption. The member states are directed to bring laws, regulations, and administrative provisions into force to comply with the directive on water standards (Table 4.6.5).

## Home Wells

State health agencies generally regulate the water quality from home wells. As an example, Table 4.6.6 presents a list of recommended water tests for home wells in New Jersey. The list of tests is designed to ensure maximum water supply safety while keeping the cost of testing at a minimum.

As an absolute minimum, testing should include the coliform test for bacteriological safety. Additional chemical testing is warranted:

1. if the home is located in a heavily industrialized area; near service stations, machine shops, or dry cleaners
2. if the home is near a hazardous waste source or a land-fill
3. if the home is near houses that have reported problems
4. if the water has an unusual chemical taste, odor, or color

Testing for specific organic chemicals is usually expensive. For accurate and reliable results, tests should be performed in a state-certified laboratory.

## Bottled Water

The United States Food and Drug Administration (FDA) regulates bottled water on a national level. Some states have promulgated their own standards for bottled water (Shelton 1994). The FDA has quality standards for bottled drinking water and Good Manufacturing Practice Regulations for processing and bottling all bottled water. These standards and regulations outline in detail the sanitary conditions under which the water is to be obtained, processed, bottled, and tested. They require that water be obtained from sources free from pollution and be of good sanitary quality when judged by the results of bacteriological and chemical analysis. Water bottlers must list the addition of salt and carbon dioxide on their labels.

## 4.7

# GROUNDWATER STANDARDS

---

---

Vast reserves of water are in the ground in many areas of the world. Little is known about the quality of this groundwater, except in areas where aquifers are being exploited. In Europe and the United States, where groundwater represents a significant source of fresh water, between 5 and 10 percent of all investigated wells have nitrate levels higher than the maximum recommended value of 45 mg/L<sup>(A)</sup>. Many organic pollutants find their way into groundwater as seepage from dumps, leakage from sewers and fuel tanks, and runoff from agricultural land or paved surfaces.

Because groundwater is cut off from the atmosphere's oxygen supply, its capacity for self-purification is low. The microbes that perform this function in surface waters need oxygen to function. Microbes that do not use oxygen are in groundwater, but their destruction of pollutants is slow. Thus, although the pollution of rivers and lakes can be rapidly reversed, pollution of groundwater is not easily reversed. Generally, the only practical control for groundwater pollution is to eliminate sources of contamination, particularly in areas of rapid aquifer recharge from the surface.

For regulatory purposes, groundwaters are classified according to use, generally potable and nonpotable. In some areas, such as Florida, almost all drinking water comes from groundwater. They have four classes of groundwater, with the additional discrimination based on levels of dissolved solids. Because of Florida's strong dependence on groundwater, it has developed some of the most sophisticated regulations and standards to manage the resource. For this reason, this section focuses on the current regulation of groundwater in Florida as a model that may become more common in the next century.

### Groundwater Classifications

Florida's groundwaters are classified as follows:

Class G-I: Potable groundwaters in single source aquifers that have a total dissolved solids content less than 3,000 mg/L

Class G-II: Potable groundwaters in single source aquifers that have a total dissolved solids content less than 10,000 mg/L

Class G-III: Nonpotable groundwaters in unconfined aquifers that have a total dissolved solids content of 10,000 mg/L or greater, or with a content of 3,000–10,000 mg/L that have been reclassified as having no

potential as a future drinking water source, or have been designated as an exempt aquifer

Class G-IV: Nonpotable groundwaters in confined aquifers that have a total dissolved solids content of 10,000 mg/L or greater

Other areas usually classify potable and nonpotable groundwaters in some manner.

### Groundwater Standards

In Florida, any discharge into Class G-I and G-II groundwaters must comply with the water quality criteria of each classification and with minimum criteria. Discharges into Class G-III groundwaters must comply only with minimum criteria, and discharges into Class G-IV groundwaters must comply with minimum criteria only when the state regulatory agency determines a danger to public health, safety, or welfare.

Minimum criteria include all substances in concentrations that are harmful to plants, animals, or organisms native to the soil and responsible for treatment or stabilization of the discharge. The minimum criteria also include substances in concentrations that:

- Are carcinogenic, mutagenic, teratogenic, or toxic to humans
- Are acutely toxic to indigenous species of significance to the aquatic community
- Pose a serious danger to public health, safety, or welfare
- Create or constitute a nuisance
- Impair the reasonable and beneficial use of adjacent waters
- Waters classified as Classes G-I and G-II must also meet the primary and secondary drinking water standards

### Wellhead Protection

A developing area of regulation is the control of land use in the vicinity of drinking water wells or in the recharge area(s) for wells. This control restricts uses that could release contaminants and adversely affect the quality of groundwaters. It imposes standards upon the contemplated use of land in such an area, called the wellhead protection (WHP) area. The WHP area is the surface and subsurface area surrounding a public water well or wellfield

through which contaminants could pass and eventually reach the groundwater supply.

Implementation of a WHP plan can cover a range of actions. The minimum action is to develop plans for alternate sources of drinking water in the event of well contamination, to inventory potential sources of contamina-

tion in the area, and to educate the population of the area as to the potential danger. Stronger actions include control of nonpoint sources of pollution, banning certain land uses and facilities, and a strong enforcement agency.

—William C. Zegel

## *International Standards*

### **4.8 ISO 14000 Environmental Standards**

---

---

ISO 14000 is a different kind of environmental standard than others discussed in this chapter. It is a series of process standards developed by the International Organization for Standardization (ISO). They consist of a family of voluntary environmental management standards and guidelines. The purpose of the standards is to establish an organizational environmental ethic and enhance an organization's ability to measure and attain standards of environmental performance. As such, it has the potential to help companies act as responsible environmental citizens by providing a commonly accepted basis for corporate commitment to the environment and to provide a platform from which environmental professionals may take their companies in new directions.

ISO 14000 is also an international system for the certification of users. This extends the standards into the domains of international policy and trade, which is consistent with the mission of ISO to facilitate the international exchange of goods and services. The system consists of:

1. Environmental Management System Standard
2. Environmental Auditing Standard
3. Environmental Labeling Standard
4. Environmental Performance Evaluation Standard
5. Life Cycle Analysis Standard
6. Product Standards
7. Terms & Definitions

The standards deal with management systems, *not* with performance; they are voluntary and require no public reporting; and they are designed for organizations in the developed world. As such, they will provide a company with internal benefits, but will not fully address a company's concerns about international trade requirements, regulatory compliance, or public image as environmentally re-

sponsible corporate citizens. It is up to the company implementing the environmental management system at the heart of ISO 14000 to integrate it into the business in a manner that will realize financial and environmental performance improvements.

The Environmental Management System Standard is the centerpiece of ISO 14000. The essential elements of this standard are summarized below. Please refer to the final standards and their associated documents for further guidance and clarification.

1. Top management defines the organization's environmental policy.
2. The organization establishes and maintains:
  - a. a procedure or process to identify the environmental issues pertaining to its activities, products, and services that it can control and over which it has an influence, in order to determine those aspects of operations that have or can have a significant impact upon the environment;
  - b. a procedure or process to identify and have access to legal and other requirements that are directly applicable to the environmental aspects of its activities, products, and services;
  - c. documented environmental objectives and targets for each relevant function and at each level within the organization;
  - d. a program for setting and achieving its objectives and targets.
3. The plan is implemented by:
  - a. management defining a structure and providing resources to effectively manage environmental issues;
  - b. identifying the training, education, and skills needed for all personnel whose work may significantly affect the environment;

- c. establishing and maintaining internal and external communication procedures regarding environmental aspects of the organization's activities and its environmental management system;
  - d. identifying and maintaining information on operations, plans, and procedures related to the environmental management system;
  - e. establishing and maintaining procedures for controlling all the documents required for effective implementation of the environmental management system;
  - f. developing and maintaining documented procedures to facilitate implementation of the organization's environmental policies, objectives, targets, and programs;
  - g. establishing and maintaining procedures for prevention of—and response to—accidents and emergency situations, and for prevention or mitigation of the environmental impacts that may be associated with them.
4. The plan is monitored and corrective actions taken by establishing and maintaining:
- a. documented procedures to monitor and measure the key characteristics of those processes that can have a significant impact on the environment;
  - b. documented procedures both for handling and investigating non-conformance with the environmental management system and for initiating corrective and preventive action;
  - c. procedures for the identification, maintenance, and disposition of the environmental records needed to implement and operate the environmental management system;
  - d. a program and procedures for periodically conducting environmental management system audits.
5. To ensure the continuing suitability and effectiveness of the environmental management system, a process must be established and maintained—and implemented at defined intervals—for management to review and evaluate the efficacy of the environmental management system.

—William C. Zegel

## **5.1**

### **SOURCES, EFFECTS, AND FATE OF POLLUTANTS**

---

---

Air pollution is defined as the presence in the outdoor atmosphere of one or more contaminants (pollutants) in quantities and duration that can injure human, plant, or animal life or property (materials) or which unreasonably interferes with the enjoyment of life or the conduct of business. Examples of traditional contaminants include sulfur dioxide, nitrogen oxides, carbon monoxide, hydrocarbons, volatile organic compounds (VOCs), hydrogen sulfide, particulate matter, smoke, and haze. This list of air pollutants can be subdivided into pollutants that are gases or particulates. Gases, such as sulfur dioxide and nitrogen oxides exhibit diffusion properties and are normally formless fluids that change to the liquid or solid state only by a combined effect of increased pressure and decreased temperature. Particulates represent any dispersed matter, solid or liquid, in which the individual aggregates are larger than single small molecules (about  $0.0002\ \mu\text{m}$  in diameter) but smaller than about 500 micrometers ( $\mu\text{m}$ ). Of recent attention is particulate matter equal to or less than  $10\ \mu\text{m}$  in size, with this size range of concern relative to potential human health effects. (One  $\mu\text{m}$  is  $10^{-4}$  cm).

Currently the focus is on air toxics (or hazardous air pollutants [HAPs]). Air toxics refer to compounds that are present in the atmosphere and exhibit potentially toxic effects not only to humans but also to the overall ecosystem. In the 1990 Clean Air Act Amendments (CAAAAs), the air toxics category includes 189 specific chemicals. These chemicals represent typical compounds of concern in the industrial air environment adjusted from workplace standards and associated quality standards to outdoor atmospheric conditions.

The preceding definition includes the quantity or concentration of the contaminant in the atmosphere and its associated duration or time period of occurrence. This concept is important in that pollutants that are present at low concentrations for short time periods can be insignificant in terms of ambient air quality concerns.

Additional air pollutants or atmospheric effects that have become of concern include photochemical smog, acid

rain, and global warming. Photochemical smog refers to the formation of oxidizing constituents such as ozone in the atmosphere as a result of the photo-induced reaction of hydrocarbons (or VOCs) and nitrogen oxides. This phenomenon was first recognized in Los Angeles, California, following World War II, and ozone has become a major air pollutant of concern throughout the United States.

Acid rain refers to atmospheric reactions that lead to precipitation which exhibits a pH value less than the normal pH of rainfall (the normal pH is approximately 5.7 when the carbon dioxide equilibrium is considered). Recently, researchers in central Europe, several Scandinavian countries, Canada, and the northeastern United States, have directed their attention to the potential environmental consequences of acid precipitation. Causative agents in acid rain formation are typically associated with sulfur dioxide emissions and nitrogen oxide emissions, along with gaseous hydrogen chloride. From a worldwide perspective, sulfur dioxide emissions are the dominant precursor of acid rain formation.

Another global issue is the influence of air pollution on atmospheric heat balances and associated absorption or reflection of incoming solar radiation. As a result of increasing levels of carbon dioxide and other carbon-containing compounds in the atmosphere, concern is growing that the earth's surface is exhibiting increased temperature levels, and this increase has major implications in shifting climatic conditions throughout the world.

### **Sources of Air Pollution**

Air pollutant sources can be categorized according to the type of source, their number and spatial distribution, and the type of emissions. Categorization by type includes natural and manmade sources. Natural air pollutant sources include plant pollens, wind-blown dust, volcanic eruptions, and lightning-generated forest fires. Manmade sources include transportation vehicles, industrial processes, power plants, municipal incinerators, and others.

## POINT, AREA, AND LINE SOURCES

Source categorization according to number and spatial distribution includes single or point sources (stationary), area or multiple sources (stationary or mobile), and line sources. Point sources characterize pollutant emissions from industrial process stacks and fuel combustion facility stacks. Area sources include vehicular traffic in a geographical area as well as fugitive dust emissions from open-air stock piles of resource materials at industrial plants. Figure 5.1.1 shows point and area sources of air pollution. Included in these categories are transportation sources, fuel combustion in stationary sources, industrial process losses, solid waste disposal, and miscellaneous items. This organization of source categories is basic to the development of emission inventories. Line sources include heavily travelled highway facilities and the leading edges of uncontrolled forest fires.

## GASEOUS AND PARTICULATE EMISSIONS

As stated earlier, air pollution sources can also be categorized according to whether the emissions are gaseous or particulates. Examples of gaseous pollutant emissions include carbon monoxide, hydrocarbons, sulfur dioxide, and nitrogen oxides. Examples of particulate emissions include smoke and dust emissions from a variety of sources. Often, an air pollution source emits both gases and particulates into the ambient air.

## PRIMARY AND SECONDARY AIR POLLUTANTS

An additional source concept is that of primary and secondary air pollutants. This terminology does not refer to the National Ambient Air Quality Standards (NAAQSs), nor is it related to primary and secondary impacts on air quality that result from project construction and opera-

tion. Primary air pollutants are pollutants in the atmosphere that exist in the same form as in source emissions. Examples of primary air pollutants include carbon monoxide, sulfur dioxide, and total suspended particulates. Secondary air pollutants are pollutants formed in the atmosphere as a result of reactions such as hydrolysis, oxidation, and photochemical oxidation. Secondary air pollutants include acidic mists and photochemical oxidants. In terms of air quality management, the main strategies are directed toward source control of primary air pollutants. The most effective means of controlling secondary air pollutants is to achieve source control of the primary air pollutant; primary pollutants react in the atmosphere to form secondary pollutants.

## EMISSION FACTORS

In evaluating air quality levels in a geographical area, an environmental engineer must have accurate information on the quantity and characteristics of the emissions from numerous sources contributing pollutant emissions into the ambient air. One approach for identifying the types and estimating the quantities of emissions is to use emission factors. An emission factor is the average rate at which a pollutant is released into the atmosphere as a result of an activity, such as combustion or industrial production, divided by the level of that activity. Emission factors relate the types and quantities of pollutants emitted to an indicator such as production capacity, quantity of fuel burned, or miles traveled by an automobile.

## EMISSION INVENTORIES

An emission inventory is a compilation of all air pollution quantities entering the atmosphere from all sources in a geographical area for a time period. The emission inventory is an important planning tool in air quality management. A properly developed inventory provides information concerning source emissions and defines the location,

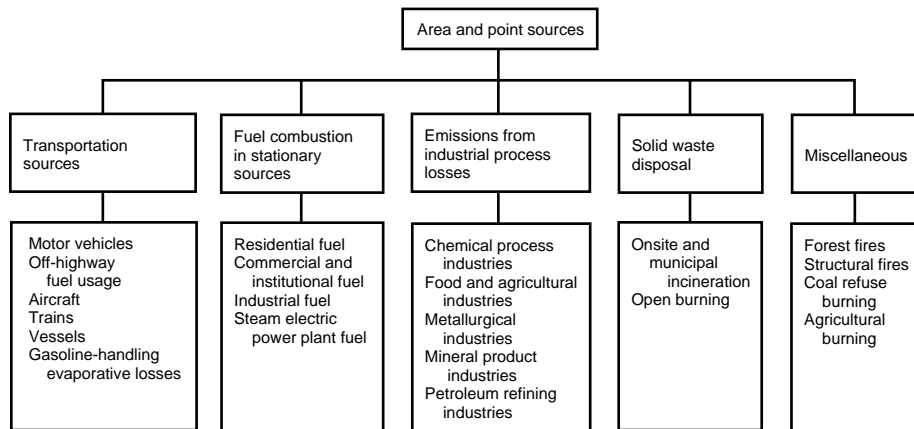

FIG. 5.1.1 Source categories for emission inventories.

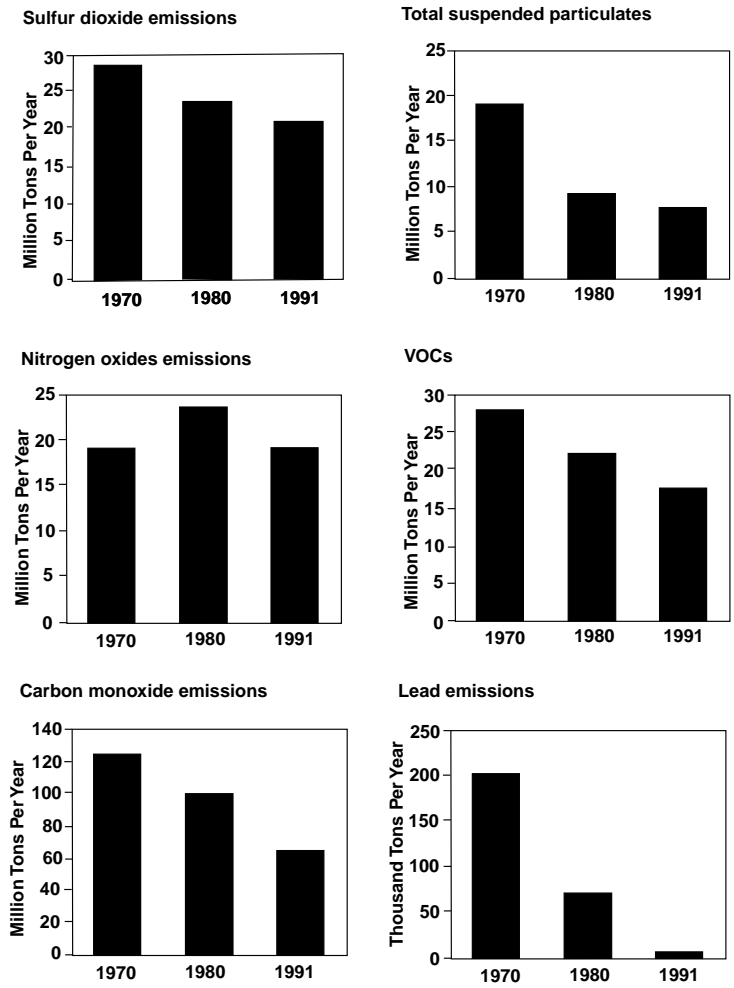

FIG. 5.1.2 Air pollution emission trends in the United States, 1970–1991. (Reprinted from Council on Environmental Quality, 1993, *Environmental quality*, 23rd Annual Report, Washington, D.C.: U.S. Government Printing Office [January].)

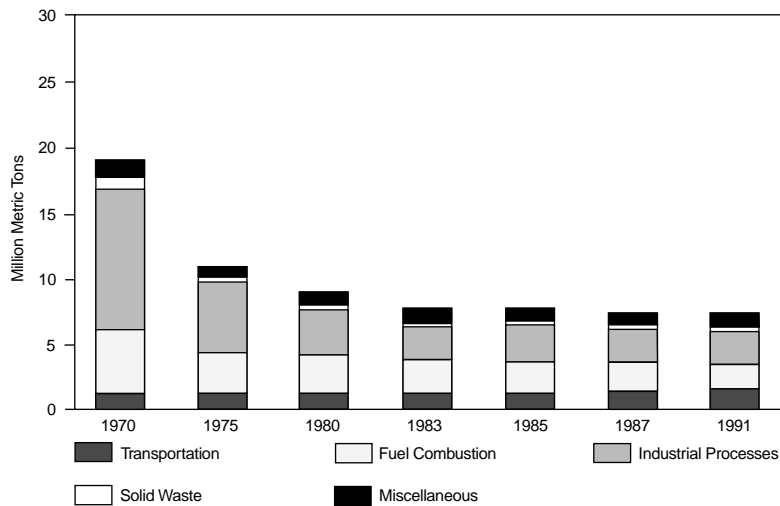

FIG. 5.1.3 People residing in counties that fail to meet NAAQS. Numbers are for 1991 based on 1990 U.S. county population data. Sensitivity to air pollutants can vary from individual to individual. (Reprinted from Council on Environmental Quality 1993.)

magnitude, frequency, duration, and relative contribution of these emissions. It can be used to measure past successes and anticipate future problems. The emission inventory is also a useful tool in designing air sampling networks. In many cases, the inventory is the basis for identifying air quality management strategies such as transportation control plans, and it is useful for examining the long-term effectiveness of selected strategies.

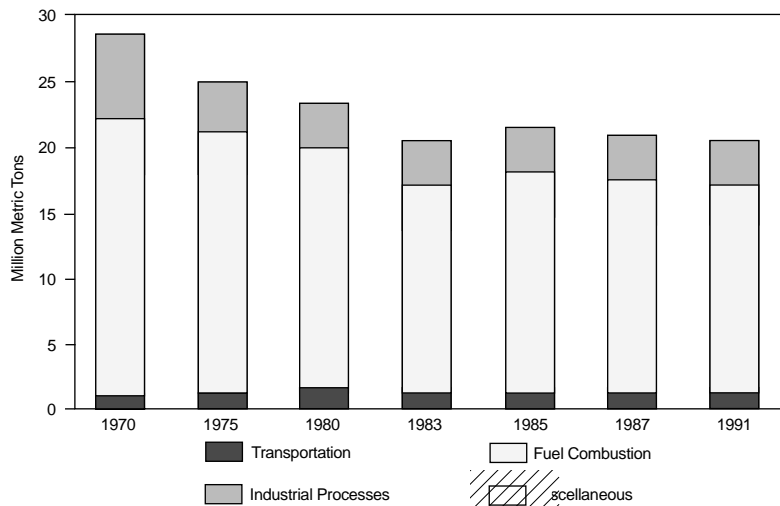

### NATIONWIDE AIR POLLUTION TRENDS

Based on source emission factors and geographically based emission inventories, nationwide information can be developed. Figure 5.1.2 summarizes nationwide air pollution emission trends from 1970 to 1991 for six key pollutants. The figure shows significant emission reductions for total suspended particulates, VOCs, carbon monoxide, and lead. The greatest reduction from 1982–1991 was an 89% reduction in lead levels in the air resulting primarily from

**FIG. 5.1.4** U.S. emissions of particulates by source, 1970–1991. (Reprinted from Council on Environmental Quality 1993.)

**FIG. 5.1.5** U.S. emissions of sulfur oxides by source, 1970–1991. (Reprinted from Council on Environmental Quality 1993.)

the removal of lead from most gasoline. In addition, the gradual phase in of cleaner automobiles and powerplants reduced atmospheric levels of carbon monoxide by 30%, nitrogen oxides by 6%, ozone by 8%, and sulfur dioxide by 20%. Levels of fine particulate matter (PM-10, otherwise known as dust and soot) dropped 10% since the PM-10 standard was set in 1987 (Council on Environmental Quality 1993).

Despite this progress, 86 million people live in U.S. counties where the pollution levels in 1991 exceeded at least one national air quality standard, based on data for a single year. Figure 5.1.3 shows this data. Urban smog continues to be the most prevalent problem; 70 million people live in U.S. counties where the 1991 pollution levels exceeded the standard for ozone.

Many areas release toxic pollutants into the air. The

latest EPA toxics release inventory shows a total of 2.2 billion lb of air toxics released nationwide in 1990 (Council on Environmental Quality 1993).

The primary sources of major air pollutants in the United States are transportation, fuel combustion, industrial processes, and solid waste disposal. Figures 5.1.4 through 5.1.9 show the relative contribution of these sources on a nationwide basis for particulates, sulfur oxides, nitrogen oxides, VOCs, carbon monoxide, and lead. Table 5.1.1 contains statistics on the emissions from key sources of these six major pollutants.

Figure 5.1.10 shows anthropogenic sources of carbon dioxide emissions, mainly fuel combustion, from 1950–1990. Table 5.1.2 contains information on the source contributions. Solid and liquid fuel combustion have been the major contributors.

FIG. 5.1.9 U.S. emissions of lead by source, 1970–1991. (Reprinted from Council on Environmental Quality 1993.)

## Effects of Air Pollution

Manifold potential effects result from air pollution in an area. These effects are manifested in humans, animals, plants, materials, or climatological variations.

The potential effects of air pollution can be categorized in many ways. One approach is to consider the type of effect and identify the potential air pollutants causing that effect. Another approach is to select an air pollutant such as sulfur dioxide and list all potential effects caused by sulfur dioxide. The types of potential air pollutant effects include aesthetic losses, economic losses, safety hazards, personal discomfort, and health effects. Aesthetic effects include loss of clarity of the atmosphere as well as the presence of objectionable odors. Atmospheric clarity loss can be caused by particulates and smog as well as by visibility reductions due to nitrate and sulfate particles. Objectionable odors encompass a range of potential air pollutants; the majority are associated with the gaseous form. Examples of odorous air pollutants include hydrogen sulfide, ammonia, and mercaptans. Mercaptans are thio alcohols which are characterized by strong odors often associated with sulfur.

## ECONOMIC LOSSES

Economic losses resulting from air pollutants include soiling, damage to vegetation, damage to livestock, and deterioration of exposed materials. Soiling represents the general dirtiness of the environment that necessitates more frequent cleaning. Examples include more frequent cleaning of clothes, washing of automobiles, and repainting of structures. Soiling is typically due to particulate matter being deposited, with the key component being settleable particulates or dustfall.

Examples of damage to vegetation are numerous and include both commercial crops and vegetation in scenic ar-

reas. Most vegetation damage is due to excessive exposure to gaseous air pollutants, including sulfur dioxide and nitrogen oxides. Oxidants formed in the atmosphere due to photochemically induced reactions also cause damage to vegetation. Some studies indicate that settleable particulates also disrupt normal functional processes within vegetation and thus undesirable effects take place. An example is the deposit of settleable particulates around a cement plant.

## VISIBLE AND QUANTIFIABLE EFFECTS

The visible and quantifiable effects of air pollution include tree injury and crop damage, with examples occurring nationwide (Mackenzie and El-Ashry 1989). Many influences shape the overall health and growth of trees and crops. Some of these influences are natural: competition among species, changes in precipitation, temperature fluctuations, insects, and disease. Others result from air pollution, use of pesticides and herbicides, logging, land-use practices, and other human activities. With so many possible stresses, determining which are responsible when trees or crops are damaged is difficult. Crop failures are usually easier to diagnose than widespread tree declines. By nature, agricultural systems are highly managed and ecologically simpler than forests. Also, larger resources have been devoted to developing and understanding agricultural systems than natural forests. Figure 5.1.11 shows the states in the contiguous United States where air pollution can affect trees or crops (Mackenzie and El-Ashry 1989).

The air pollutants of greatest national concern to agriculture are ozone ( $O_3$ ), sulfur dioxide ( $SO_2$ ), nitrogen dioxide ( $NO_2$ ), sulfates, and nitrates. Of these, ozone is of greatest concern; the potential role of acid deposition at ambient levels has not been determined. At present deposition rates, most studies indicate that acid deposition does no identifiable harm to foliage. However, at lower-than-ambient

Notes: Estimates of emissions from transportation sources have been recalculated using a revised model. These estimates supersede those reported in 1992's report and are not directly comparable to historical estimates calculated using different models. PM-10 refers to particulates with an aerodynamic diameter smaller than 10  $\mu\text{m}$ . These smaller particles are likely responsible for most adverse health effects of particulates because of their ability to reach the thoracic or lower regions of the respiratory tract. Detail may not agree with totals because of independent rounding.

pH levels, various impacts include leaf spotting, acceleration of epicuticular wax weathering, and changes in foliar leaching rates. When applied simultaneously with ozone, acid deposition also reduces a plant's dry weight (Mackenzie and El-Ashry 1989).

**BIODIVERSITY**

Air pollution can effect biodiversity. For example, prolonged exposure of the vegetation in the San Bernardino

Mountains in southern California to photochemical oxidants has shifted the vegetation dominance from ozone-sensitive pines to ozone-tolerant oaks and deciduous shrubs (Barker and Tingey 1992). The fundamental influencing factors include the pollutant's environmental partitioning, exposure pattern, and toxicity and the sensitivity of the affected species. Biodiversity impacts occur on local, regional, and global scales. Local plume effects reduce vegetation cover, diversity, and ecosystem stability. Regional impacts occur via exposure to photochemical ox-

**FIG. 5.1.11** Areas where air pollution affects forest trees and agricultural crops. (Reprinted, with permission, from J.J. Mackenzie and M.T. El-Ashry, 1989, *Tree and crop injury: A summary of the evidence*, chap. 1 in *Air pollution's toll on forests and crops*, edited by J.J. Mackenzie and M.T. El-Ashry, New Haven, Conn.: Yale University Press.)

idants, wet or dry acid or metal deposition, and the long-range transport of toxic chemicals.

Air pollution effects on biodiversity are difficult to document. Unlike habitat destruction, which results in a pronounced and rapid environmental change, the effects of air pollution on biota are usually subtle and elusive because of their interactions with natural stressors. Years can be required before the ecological changes or damage within ecosystems become evident due to continuous or episodic exposure to toxic airborne contaminants or global climate changes (Barker and Tingey 1992).

A number of domestic animals are subject to air pollutant effects. The most frequently cited example is the effects of fluoride on cattle. Other air pollutants also affect animals, including ammonia, carbon monoxide, dust, hydrogen sulfide, sulfur dioxide, and nitrogen oxides.

### DETERIORATION OF EXPOSED MATERIALS

The deterioration of exposed materials includes the corrosion of metals, weathering of stone, darkening of lead-based white paint, accelerated cracking of rubber, and deterioration of various manmade fabrics. Sulfur dioxide accelerates the corrosion of metals, necessitating more frequent repainting of metal structures and bridges. The weathering of stone is attributed to the effects of acidic mists formed in the atmosphere as a result of oxidative processes combined with water vapor. Some types of acidic mists include sulfuric acid, carbonic acid, and nitric acid.

### HEALTH EFFECTS

The category of health effects ranges from personal discomfort to actual health hazards. Personal discomfort is

characterized by eye irritation and irritation to individuals with respiratory difficulties. Eye irritation is associated with oxidants and the components within the oxidant pool such as ozone, peroxyacetyl nitrate, and others. The burning sensation experienced routinely in many large urban areas is due to high oxidant concentrations. Individuals with respiratory difficulties associated with asthma, bronchitis, and sinusitis experience increased discomfort as a result of oxidants, nitrogen oxides, and particulates.

Health effects result from either acute or chronic exposures. Acute exposures result from accidental releases of pollutants or air pollution episodes. Episodes with documented illness or death are typically caused by persistent (three to six days) thermal inversions with poor atmospheric dispersion and high air pollutant concentrations (Godish 1991). Exposures to lower concentrations for extended periods of time have resulted in chronic respiratory and cardiovascular disease; alterations of body functions such as lung ventilation and oxygen transport; impairment of performance of work and athletic activities; sensory irritation of the eyes, nose, and throat; and aggravation of existing respiratory conditions such as asthma (Godish 1991).

An overview of ambient air quality indicates the potential health effects. Table 5.1.3 shows ambient air quality trends in major urban areas in the United States. The table uses the pollutants standard index (PSI) to depict trends for fifteen of the largest urban areas.

Table 5.1.4 summarizes the effects attributed to specific air pollutants. Many of these effects are described in previous examples, thus this table is a composite of the range of effects of these air pollutants. Table 5.1.5 contains information on the effects of sulfur dioxide. The effects are arranged in terms of health, visibility, materials, and veg-

Notes: PMSA = Primary Metropolitan Statistical Area. PSI = Pollutant Standards Index. na = not applicable. The PSI index integrates information from many pollutants across an entire monitoring network into a single number which represents the worst daily air quality experienced in the urban area. Only carbon monoxide and ozone monitoring sites with adequate historical data are included in the PSI trend analysis above, except for Pittsburgh, where sulfur dioxide contributes a significant number of days in the PSI high range. PSI index ranges and health effect descriptor words are as follows: 0 to 50 (good); 51 to 100 (moderate); 101 to 199 (unhealthy); 200 to 299 (very unhealthy); and 300 and above (hazardous). The table shows the number of days when the PSI was greater than 100 (= unhealthy or worse days).

**TABLE 5.1.4 QUALITATIVE SUMMARY OF THE EFFECTS ATTRIBUTED TO SPECIFIC POLLUTANTS**

Air Pollutant	Effects
Particulates	Speeds chemical reactions; obscures vision; corrodes metals; causes grime on belongings and buildings; aggravates lung illness
Sulfur oxides	Causes acute and chronic leaf injury; attacks a wide variety of trees; irritates upper respiratory tract; destroys paint pigments; erodes statuary; corrodes metals; ruins hosiery; harms textiles; disintegrates book pages and leather
Hydrocarbons (in solid and gaseous states)	May be cancer-producing (carcinogenic); retards plant growth; causes abnormal leaf and bud development
Carbon monoxide	Causes headaches, dizziness, and nausea; absorbs into blood; reduces oxygen content; impairs mental processes
Nitrogen oxides	Causes visible leaf damage; irritates eyes and nose; stunts plant growth even when not causing visible damage; creates brown haze; corrodes metals
Oxidants:	
Ozone	Discolors the upper surface of leaves of many crops, trees, and shrubs; damages and fades textiles; reduces athletic performance; hastens cracking of rubber; disturbs lung function; irritates eyes, nose, and throat; induces coughing
Peroxyacetyl nitrate (PAN)	Discolors the lower leaf surface; irritates eyes; disturbs lung function

etation. Many health effects and visibility are related to the combination of sulfur dioxide and particulates in the atmosphere.

Numerous acute air pollution episodes have caused dramatic health effects to the human population. One of the first occurred in the Meuse Valley in Belgium in 1930 and was characterized by sixty deaths and thousands of ill peo-

ple. In Donoro, Pennsylvania in 1948, seventeen people died, and 6000 of the population of 14,000 were reported ill. In Poza Rica, Mexico in 1950, twenty-two people died, and 320 people were hospitalized as a result of an episode. Several episodes with excess deaths have been recorded in London, England, with the most famous being in 1952 when 3500 to 4000 excess deaths occurred over a one-

**TABLE 5.1.5 EFFECTS ATTRIBUTED TO SULFUR DIOXIDE**

<i>Category of Effect</i>	<i>Comments</i>
Health	<ul style="list-style-type: none"> <li>a. At concentrations of about 1500 <math>\mu\text{g}/\text{m}^3</math> (0.52 ppm) of sulfur dioxide (24-hr average) and suspended particulate matter measured as a soiling index of 6 cohs or greater, mortality can increase.</li> <li>b. At concentrations of about 715 <math>\mu\text{g}/\text{m}^3</math> (0.25 ppm) of sulfur dioxide and higher (24-hr mean), accompanied by smoke at a concentration of 750 <math>\mu\text{g}/\text{m}^3</math>, the daily death rate can increase.</li> <li>c. At concentrations of about 500 <math>\mu\text{g}/\text{m}^3</math> (0.19 ppm) of sulfur dioxide (24-hr mean), with low particulate levels, mortality rates can increase.</li> <li>d. At concentrations ranging from 300 to 500 <math>\mu\text{g}/\text{m}^3</math> (0.11 to 0.19 ppm) of sulfur dioxide (24-hr mean) with low particulate levels, increase hospital admissions of older people for respiratory disease can increase; absenteeism from work, particularly with older people, can also occur.</li> <li>e. At concentrations of about 715 <math>\mu\text{g}/\text{m}^3</math> (0.25 ppm) of sulfur dioxide (24-hr mean) accompanied by particulate matter, illness rates for patients over age 54 with severe bronchitis can rise sharply.</li> <li>f. At concentrations of about 600 <math>\mu\text{g}/\text{m}^3</math> (about 0.21 ppm) of sulfur dioxide (24-hr mean) with smoke concentrations of about 300 <math>\mu\text{g}/\text{m}^3</math>, patients with chronic lung disease can experience accentuation of symptoms.</li> <li>g. At concentrations ranging from 105 to 265 <math>\mu\text{g}/\text{m}^3</math> (0.037 to 0.092 ppm) of sulfur dioxide (annual mean) accompanied by smoke concentrations of about 185 <math>\mu\text{g}/\text{m}^3</math>, the frequency of respiratory symptoms and lung disease can increase.</li> <li>h. At concentrations of about 120 <math>\mu\text{g}/\text{m}^3</math> (0.046 ppm) of sulfur dioxide (annual mean) accompanied by smoke concentrations of about 100 <math>\mu\text{g}/\text{m}^3</math>, the frequency and severity of respiratory diseases in school children can increase.</li> <li>i. At concentrations of about 115 <math>\mu\text{g}/\text{m}^3</math> (0.040 ppm) of sulfur dioxide (annual mean) accompanied by smoke concentrations of about 160 <math>\mu\text{g}/\text{m}^3</math>, mortality from bronchitis and lung cancer can increase.</li> </ul>
Visibility	At a concentration of 285 $\mu\text{g}/\text{m}^3$ (0.10 ppm) of sulfur dioxide with a comparable concentration of particulate matter and relative humidity of 50%, visibility can be reduced to about 5 mi.
Materials	At a mean sulfur dioxide level of 345 $\mu\text{g}/\text{m}^3$ (0.12 ppm) accompanied by high particulate levels, the corrosion rate for steel panels can increase by 50%.
Vegetation	<ul style="list-style-type: none"> <li>a. At a concentration of about 85 <math>\mu\text{g}/\text{m}^3</math> (0.03 ppm) of sulfur dioxide (annual mean), chronic plant injury and excessive leaf drop can occur.</li> <li>b. After exposure to about 860 <math>\mu\text{g}/\text{m}^3</math> (0.3 ppm) of sulfur dioxide for 8 hr, some species of trees and shrubs show injury.</li> <li>c. At concentrations of about 145 to 715 <math>\mu\text{g}/\text{m}^3</math> (0.05 to 0.25 ppm), sulfur dioxide can react synergistically with either ozone or nitrogen dioxide in short-term exposures (e.g., 4 hr) to produce moderate to severe injury to sensitive plants.</li> </ul>

week time period. Other episodes occurred recently in locations throughout the United States, and others are anticipated in subsequent years. Generally, the individuals most affected by these episodes are older people already experiencing difficulties with their respiratory systems. Common characteristics of these episodes include pollutant releases from many sources, including industry, and limiting atmospheric dispersion conditions.

### ATMOSPHERIC EFFECTS

Air pollution causes atmospheric effects including reductions in visibility, changes in urban climatological characteristics, increased frequency of rainfall and attendant meteorological phenomena, changes in the chemical characteristics of precipitation, reductions in stratospheric

ozone levels, and global warming (Godish 1991). The latter three effects can be considered from a macro (large-scale) perspective and are addressed in Section 5.5.

Particulate matter can reduce visibility and increase atmospheric turbidity. Visibility is defined as the greatest distance in any direction at which a person can see and identify with the unaided eye (1) a prominent dark object against the sky at the horizon in the daytime, and (2) a known, preferably unfocused, moderately intense light source at night. In general, visibility decreases as the concentration of particulate matter in the atmosphere increases. Particle size is important in terms of visibility reduction, with sizes in the micron and submicron range of greatest importance. Turbidity in ambient air describes the phenomena of back scattering of direct sunlight by particles in the air, thus reducing the amount of direct sunlight

**TABLE 5.1.6 QUALITY FACTORS OF URBAN AIR IN RATIO TO THOSE OF RURAL AIR EXPRESSED AS 1**

<i>Urban</i>	<i>Quality Factor</i>
10	Dust particles
5	Sulfur dioxide
10	Carbon dioxide
25	Carbon monoxide
0.8	Total sunshine
0.7	Ultraviolet, winter
0.95	Ultraviolet, summer
1.1	Cloudiness
2	Fog, winter
1.3	Fog, summer

reaching the earth. As an illustration of the effect of turbidity increases in the atmosphere, the total sunshine in urban areas is approximately 80% of that in nearby rural areas. The ultraviolet (UV) component of sunlight in the winter in urban areas is only 70% of that in nearby rural areas; in the summer the UV component in urban areas is 95% of the rural areas' value.

Table 5.1.6 summarizes the quality factors of urban air in ratio to those of rural air when rural air is a factor of 1. The quantity of urban air pollutants and some of the results of the effects of cloudiness and fog are evident in urban areas more than rural areas. Urban areas and the associated air pollutants also influence certain climatological features such as temperature, relative humidity, cloudiness, windspeed and precipitation.

### RAINFALL QUALITY

One issue related to the general effects of air pollution is the physical and chemical quality of rainfall. Air pollution can cause the pH of rainfall to decrease, while the suspended dissolved solids and total solids in rainfall increase. Nitrogen and phosphorus concentrations in rainfall can also increase as a result of the atmospheric releases of pollutants containing these nutrients. Finally, increases in lead and cadmium in rainfall are also a result of air pollutant emissions.

An important issue related to air pollution effects is acid rainfall and the resultant effects on aquatic ecosystems. Acid rainfall is any rainfall with a pH less than 5.7. The natural pH of rainfall is 5.7 and reflects the presence of weak carbonic acid (H<sub>2</sub>CO<sub>3</sub>) resulting from the reaction of water and carbon dioxide from green plants. Rainfall becomes more acid as a result of acidic mists such as H<sub>2</sub>SO<sub>4</sub> and HNO<sub>3</sub>. Atmospheric emissions of carbon monoxide also add to the carbonic acid mist in the atmosphere and cause the pH of rainfall to be less than 5.7. Numerous locations in the United States have rainfall with the pH values around 4.0. Some of the lowest recorded pH values of rainfall are 2.0 to 3.0.

The chief concerns related to acid rainfall are the potential adverse effects. For example, the pH of the soil can be changed and this change can have unfavorable implications. Changes in the pH in soil can cause changes in adsorption and desorption patterns and lead to differences in nonpoint source water pollution as well as changes in nutrients in both surface runoff as well as from infiltration to groundwater. Acid rain can decrease plant growth, crop growth, and growth in forested areas. Acid rainfall can accelerate the weathering and erosion of metals, stone buildings, and monuments. One concern is related to changes in the quality of surface water and the resultant potential toxicity to aquatic species.

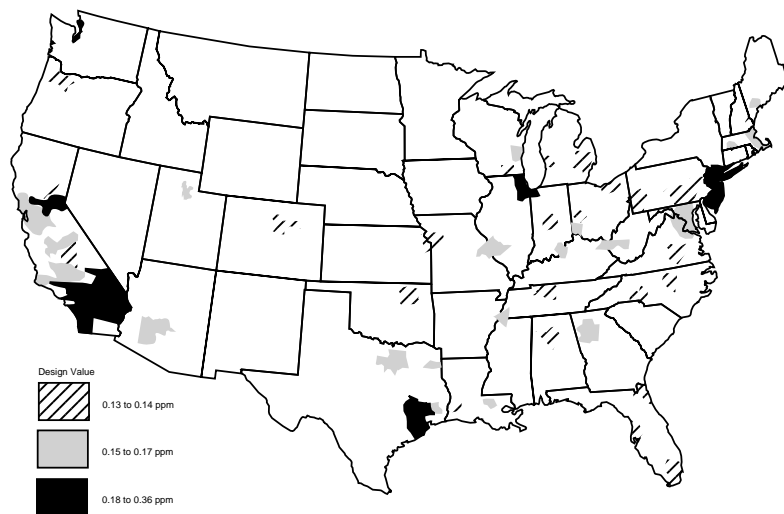

### Tropospheric Ozone—A Special Problem

The most widespread air quality problem in the United States is exceedances of the ozone standard (0.12 ppm for 1 hr per year) in urban areas. The ozone standard is based on protecting public health. Ozone is produced when its precursors, VOCs and nitrogen oxides (NO<sub>x</sub>), combine in the presence of sunlight (Office of Technology Assessment 1989). VOCs, a broad class of pollutants encompassing hundreds of specific compounds, come from manmade sources including automobile and truck exhaust, evaporation of solvents and gasoline, chemical manufacturing, and petroleum refining. In most urban areas, such manmade sources account for the majority of VOC emissions, but in the summer in some regions, natural vegetation produces an almost equal quantity. NO<sub>x</sub> arises primarily from fossil fuel combustion. Major sources include highway vehicles and utility and industrial boilers.

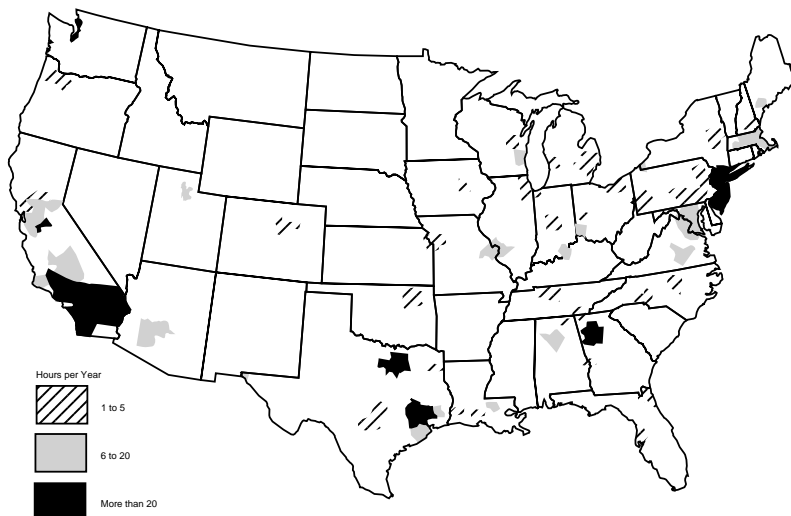

About 100 nonattainment areas dot the country from coast to coast, with *design values* (a measure of peak ozone concentrations) ranging from 0.13 ppm to as high as 0.36 ppm. Figure 5.1.12 summarizes the data for the 3-year period 1983–85 (Office of Technology Assessment 1989). Generally, the higher the design value, the stricter the emission controls needed to meet the standard.

From one-third to one-half of all Americans live in areas that exceed the standard at least once a year. As shown in Figure 5.1.13, 130 of the 317 urban and rural areas exceeded 0.12 ppm for at least 1 hr between 1983 and 1985 (Office of Technology Assessment 1989). Sixty had concentrations that high for at least 6 hr per year. A number of areas topped the standard for 20 or more hr, with the worst, Los Angeles, averaging 275 hr per year.

Ozone's most perceptible short-term effects on human health are respiratory symptoms such as coughing and painful deep breathing (Office of Technology Assessment 1989). It also reduces people's ability to inhale and exhale normally, affecting the most commonly used measures of lung function (e.g., the maximum amount of air a person can exhale in 1 sec or the maximum a person can exhale

**FIG. 5.1.12** Areas classified as nonattainment for ozone based on 1983–85 data. The shading indicates the fourth highest daily maximum one-hour average ozone concentration, or design value, for each area. (Reprinted from Office of Technology Assessment, 1989, *Catching our breath—Next steps for reducing urban ozone*, OTA-0-412, Washington, D.C.: U.S. Congress [July].)

**FIG. 5.1.13** Areas where ozone concentrations exceeded 0.12 ppm at least one hour per year on average, from 1983–85. Data from all monitors located in each area were averaged in the map construction. The shading indicates the number of hours that a concentration of 0.12 ppm was exceeded. The areas shown have 130 million residents. (Reprinted from Office of Technology Assessment, 1989.)

after taking a deep breath). As the intensity of exercise rises so does the amount of air drawn into the lungs and thus the dose of ozone. The more heavily a person exercises at a level of ozone concentration and the longer the exercise lasts, the larger the potential effect on lung function.

The U.S. Environmental Protection Agency (EPA) has identified two subgroups of people who may be at special risk for adverse effects: athletes and workers who exercise heavily outdoors and people with preexisting respiratory

problems (Office of Technology Assessment 1989). Also problematic are children, who appear to be less susceptible to (or at least less aware of) acute symptoms and thus spend more time outdoors in high ozone concentrations. Most laboratory studies show no special effects in asthmatics, but epidemiologic evidence suggests that they suffer more frequent attacks, respiratory symptoms, and hospital admissions during periods of high ozone. In addition, about 5 to 20% of the healthy adult population appear to

be *responders*, who for no apparent reason are more sensitive than average to a dose of ozone.

At the summertime ozone levels in many cities, some people who engage in moderate exercise for extended periods can experience adverse effects. For example, as shown in Figure 5.1.14, on a summer day when ozone concentrations average 0.14 ppm, a construction worker on an 8-hr shift can experience a temporary decrease in lung function that most scientists consider harmful (Office of Technology Assessment 1989). On those same summer days, children playing outdoors for half the day also risk the effects on lung function that some scientists consider adverse. And some heavy exercisers, such as runners and bicyclists, notice adverse effects in about 2 hr. Even higher levels of ozone, which prevail in a number of areas, have swifter and more severe impacts on health.

## Brief Synopsis of Fate of Air Pollutants

Atmospheric dispersion of air pollutants from point or area sources is influenced by wind speed and direction, atmospheric turbulence, and atmospheric stability (Godish 1991).

### EFFECTS OF WIND SPEED AND DIRECTION

Horizontal winds play a significant role in the transport and dilution of pollutants. As wind speed increases, the volume of air moving by a source in a period of time also increases. If the emission rate is relatively constant, a doubling of the wind speed halves the pollutant concentration, as the concentration is an inverse function of the wind speed.

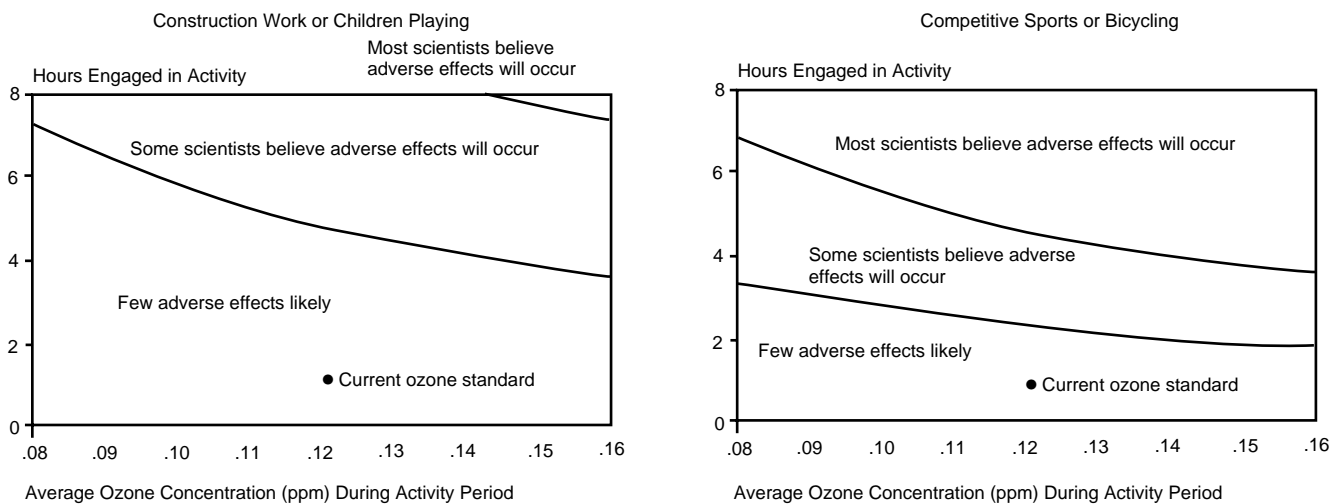

Pollutant dispersion is also affected by the variability in wind direction (Godish 1991). If the wind direction is relatively constant, the same area is continuously exposed to high pollutant levels. If the wind direction is constantly shifting, pollutants are dispersed over a larger area, and concentrations over any exposed area are lower. Large changes in wind direction can occur over short periods of time.

### EFFECTS OF ATMOSPHERIC TURBULENCE

Air does not flow smoothly near the earth's surface; rather, it follows patterns of three-dimensional movement which are called turbulence. Turbulent eddies are produced by two specific processes: (1) thermal turbulence, resulting from atmospheric heating, and (2) mechanical turbulence caused by the movement of air past an obstruction in a windstream. Usually both types of turbulence occur in any atmospheric situation, although sometimes one prevails. Thermal turbulence is dominant on clear, sunny days with light winds. Although mechanical turbulence occurs under a variety of atmospheric conditions, it is dominant on windy nights with neutral atmospheric stability. Turbulence enhances the dispersion process although in mechanical turbulence, downwash from the pollution source can result in high pollution levels immediately downstream (Godish 1991).

### EFFECTS OF ATMOSPHERIC STABILITY

In the troposphere, temperature decreases with height to an elevation of approximately 10 km. This decrease is due to reduced heating processes with height and radiative

**FIG. 5.1.14** Likelihood of adverse effects from ozone while exercising. The likelihood of experiencing adverse effects depends on 1) the ozone concentration, 2) the vigorousness of the activity, and 3) the number of hours engaged in that activity. The figure on the left shows the number of hours to reach an adverse effect under moderate exercise conditions (e.g., construction work or children playing). The figure on the right shows that fewer hours are needed under heavy exercise (e.g., competitive sports or bicycling). The current 1-hr ozone standard is shown for comparison. (Reprinted from Office of Technology Assessment 1989.)

cooling of air and reaches its maximum in the upper levels of the troposphere. Temperature decrease with height is described by the lapse rate. On the average, temperature decreases  $-0.65^{\circ}\text{C}/100\text{ m}$  or  $-6.5^{\circ}\text{C}/\text{km}$ . This decrease is the normal lapse rate. If warm dry air is lifted in a dry environment, it undergoes adiabatic expansion and cooling. This adiabatic cooling results in a lapse rate of  $-1^{\circ}\text{C}/100\text{ m}$  or  $-10^{\circ}\text{C}/\text{km}$ , the dry adiabatic lapse rate.

Individual vertical temperature measurements vary from either the normal or dry adiabatic lapse rate. This change of temperature with height for measurement is the *environmental lapse rate*. Values for the environmental lapse rates characterize the stability of the atmosphere and profoundly affect vertical air motion and the dispersion of pollutants (Godish 1991).

If the environmental lapse rate is greater than the dry adiabatic lapse rate, dispersion characteristics are good to excellent. The greater the difference, the more unstable the atmosphere and the more enhanced the dispersion. If the environmental lapse rate is less than the dry adiabatic lapse rate, the atmosphere becomes stable, and dispersion becomes more limited. The greater the difference from the adiabatic lapse rate, the more stable the atmosphere and the poorer the dispersion potential (Godish 1991).

## EFFECTS OF TOPOGRAPHY ON AIR MOTION

Topography can affect micro- and mesoscale air motion near point and area sources. Most large urban centers in this country are located along sea (New York City and Los Angeles) and lake (Chicago and Detroit) coastal areas, and heavy industry is often located in river valleys, e.g., the Ohio River Valley. Local air flow patterns in these regions have a significant impact on pollution dispersion processes. For example, land-water mesoscale air circulation patterns develop from the differential heating and cooling of land and water surfaces. During the summer when skies are clear and prevailing winds are light, land surfaces heat more rapidly than water. The warm air rises and moves toward water. Because of the differences of temperature and pressure, air flows in from the water, and a sea or lake breeze forms. Over water, the warm air from the land cools and subsides to produce a weak circulation cell. At night, the more rapid radiational cooling of land surfaces results in a horizontal flow toward water, and a land breeze forms (Godish 1991).

Air flows downhill into valley floors, and the winds produced are called *slope winds*. As the air reaches the valley floor, it flows with the path of the river. This air movement is called the *valley wind*. The formation of valley wind lags several hours after slope winds. Because of a smaller vertical gradient, downriver valley winds are lighter

and because of the large volume, cool dense air accumulates, flooding the valley floor and intensifying the surface inversion that is normally produced by radiative cooling (Godish 1991). The inversion deepens over the course of the night and reaches its maximum depth just before sunrise. The height of the inversion layer depends on the depth of the valley and the intensity of the radiative cooling process.

Mountains affect local air flow by increasing surface roughness and thereby decreasing wind speed. In addition, mountains and hills form physical barriers to air movement.

In summary, the atmospheric dispersion of air pollution emissions depends on the interplay of a number of factors which include (1) the physical and chemical nature of the pollutants, (2) meteorological parameters, (3) the location of the source relative to obstructions, and (4) downwind topography (Godish 1991).

## OTHER FACTORS

In addition to dispersion, wet and dry removal processes as well as atmospheric reactions affect the concentrations of air pollutants in the atmosphere. Atmospheric reactions include ozone or acid rain formation. In dry removal, particles are removed by gravity or impaction, and gases diffuse to surfaces where they are absorbed or adsorbed. Wet removal is the major removal process for most particles and can be a factor in the removal of gaseous contaminants as well. Wet removal can involve the in-cloud capture of gases or particles (rainout) or the below-cloud capture (washout). In washout, raindrops or snowflakes strike particles and carry them to the surface; gases are removed by absorption (Godish 1991).

## 5.2

# VOCs AND HAPs EMISSION FROM CHEMICAL PLANTS

---

---

### Emission Points

Emission sources (or points) of volatile organic chemicals (VOCs) and hazardous air pollutants (HAPs) in a chemical plant can be classified into three groups: (1) process point sources, (2) process fugitive sources, and (3) area fugitive sources (U.S. EPA 1991). VOCs refer to compounds which produce vapors at room temperature and pressure; whereas, HAPs include VOCs as well as non-volatile organics and inorganics present as vapors or particulates.

#### PROCESS POINT SOURCES

Process point sources of VOCs and HAPs can be individually defined for a chemical plant. Chemical reactors, distillation columns, catalytic cracking units, condensers, strippers, furnaces, and boilers are examples of point sources that discharge both air toxics and criteria pollutants through vent pipes or stacks. Emission reductions or control are achieved through process changes focused on pollution prevention and the use of add-on control devices such as adsorbers, absorbers, thermal or catalytic incinerators, fabric filters, or electrostatic precipitators (ESPs).

#### PROCESS FUGITIVE SOURCES

Although typically more numerous than process point sources, process fugitive sources can also be individually defined for a chemical plant. Inadvertent emissions from or through pumps, valves, compressors, access ports, storage tank vents, and feed or discharge openings to a process classify such units or equipment as process fugitive sources. Vent fans from rooms or enclosures containing an emissions source can also be classified this way (U.S. EPA 1991). Once process fugitive emissions are captured by hooding, enclosures, or closed-vent systems, they can often be controlled by add-on devices used for process point sources.

#### AREA FUGITIVE SOURCES

Large surface areas characterize area fugitive sources. Examples of such sources include waste storage ponds and raw material storage piles at many chemical plants. VOC and HAP control measures for area fugitive sources typically focus on release prevention measures such as the use of covers or chemical adjustments in terms of the pH and oxidation state for liquid wastes.

### Classification of VOCs and HAPs

The HAPs described in this manual are not limited to the specific compounds listed in current laws such as the CAAAs of 1990, the Resource Conservation and Recovery Act (RCRA), or the Toxic Substances Control Act. HAPs can be classified relative to the type of compounds (i.e., organic or inorganic) and the form in which they are emitted from process point, process fugitive, or area fugitive sources (i.e., vapor or particulate).

This section discusses two examples of VOC and HAP emissions from chemical plant classes. [Table 5.2.1](#) summarizes emissions from the inorganic chemical manufacturing industry. This industry produces basic inorganic chemicals for either direct use or use in manufacturing other chemical products. Although the potential for emissions is high, in many cases they are recovered due to economic reasons. As shown in [Table 5.2.1](#), the chemical types of inorganic emissions depend on the source category, while the emission sources vary with the processes used to produce the inorganic chemical.

The second example is from petroleum-related industries, including the oil and gas production industry, the petroleum refining industry, and the basic petrochemicals industry. [Table 5.2.2](#) summarizes the emission sources within these three categories. Sources of emissions from the oil and gas production industry include blowouts during drilling operations; storage tank breathing and filling losses; wastewater treatment processes; and fugitive leaks in valves, pumps, pipes, and vessels. In the petroleum refining industry, emission sources include distillation and fractionating columns, catalytic cracking units, sulfur recovery processes, storage tanks, fugitives, and combustion units (e.g., process heaters). Fugitive emissions are a major source in this industry. Emission sources in the basic petrochemicals industry are similar to those from the petroleum refining segments (U.S. EPA 1991).

[Table 5.2.3](#) summarizes the potential HAP emissions from the petroleum refining segment of the petroleum industries. A large proportion of the emissions occur as organic vapors; for example, benzene, toluene, and xylenes are the principal organic vapor emissions. These organic vapors are due to the chemical composition of the two starting materials used in these industries: crude oil and natural gas. Crude oil is composed chiefly of hydrocarbons (paraffins, naphthalenes, and aromatics) with small amounts of trace elements and organic compounds containing sulfur, nitrogen, and oxygen. Natural gas is largely saturated hydrocarbons (mainly methane). The remainder

## 5.3 HAPs FROM SYNTHETIC ORGANIC CHEMICAL MANUFACTURING INDUSTRIES

The Synthetic Organic Chemical Manufacturing Industry (SOCMI), as a source category, emits a larger volume of a variety of HAPs compared to other source categories (see [Table 5.3.1](#)). In addition, individual SOCMI sources tend to be located close to the population. As such, components of SOCMI sources have been subject to various federal, state, and local air pollution control rules. However, the existing rules do not comprehensively regulate emissions for all organic HAPs emitted from all emissions points at both new and existing plants.

By describing hazardous organic national emission standards for air pollutants (NESHAP), or the HON, this section describes the emission points common to all SOCMI manufacturing processes and the maximum achievable control technology (MACT) required for reducing these emissions.

### Hazardous Organic NESHAP

The HON is one of the most comprehensive rules issued by the EPA. It covers more processes and pollutants than

**TABLE 5.3.1 EMISSION POTENTIAL ACCORDING TO BASIC MANUFACTURING CATEGORY**

<i>Emission Potential<sup>a</sup></i>	<i>Category</i>	<i>% Total Industry Emissions (U.S.)</i>
1	Chemical synthesis	64
2	Fermentation	19
3	Extraction <sup>b</sup>	7
4	Formulation	5
5	Other <sup>c</sup>	5

*Notes:*

<sup>a</sup>Decreasing order.

<sup>b</sup>Listed as botanicals.

<sup>c</sup>Includes research and development, animal sources, and biological products.

previous EPA air toxic programs (40 CFR Part 63). For example, one major portion of the rule applies to sources that produce any of the 396 SOCMI products (see [Table 5.3.2](#)) that use any of the 112 organic HAPs (see [Table 5.3.3](#)) either in a product or as an intermediate or reactant. An additional 37 HAPs are regulated under another part of the HON (40 CFR Part 63). The HON lists 189 HAPs regulated under the air toxic program.

The focus of this rule is the SOCMI. For purposes of the MACT standard, a SOCMI manufacturing plant is viewed as an assortment of equipment—process vents, storage tanks, transfer racks, and wastewater streams—all of which emit HAPs. The HON requires such plants to monitor and repair leaks to eliminate fugitive emissions and requires controls to reduce toxics coming from discrete emission points to minuscule concentrations. [Table 5.3.4](#) summarizes the impacts of these emission sources.

### PROCESS VENTS

A process vent is a gas stream that is continuously discharged during the unit operation from an air oxidation unit, reactor process unit, or distillation operation within a SOCMI chemical process. Process vents include gas streams discharged directly to the atmosphere after diversion through a product recovery device. The rule applies only to the process vents associated with continuous (non-batch) processes and emitting vent streams containing more than 0.005 wt % HAP. The process vent provisions do not apply to vents from control devices installed to comply with wastewater provisions. Process vents exclude relief valve discharges and other fugitive leaks but include vents from product accumulation vessels.

Halogenated streams that use a combustion device to comply with 98% or 20 parts per million by volume (ppmv) HAP emissions must vent the emissions from the combustion device to an acid gas scrubber before venting to the atmosphere.

TABLE 5.3.2 SOCML

<i>Chemical Name<sup>a</sup></i>		
Acenaphthene	Chloroacetophenone (2-)	Dihydroxybenzoic acid (Resorcylic acid)
Acetal	Chloroaniline (p-)	Dilsodecyl phthalate
Acetaldehyde	Chlorobenzene	Dilsooctyl phthalate
Acetaldol	Chlorodifluoroethane	Dimethylbenzidine (3,3'-)
Acetamide	Chlorodifluoromethane	Dimethyl ether
Acetanilide	Chloroform	Dimethylformamide (N,N-)
Acetic acid	Chloronaphthalene	Dimethylhydrazine (1,1-)
Acetic anhydride	Chloronitrobenzene (1,3-)	Dimethyl phthalate
Acetoacetanilide	Chloronitrobenzene (o-)	Dimethyl sulfate
Acetone	Chloronitrobenzene (p-)	Dimethyl terephthalate
Acetone cyanohydrin	Chlorophenol (m-)	Dimethylamine
Acetonitrile	Chlorophenol (o-)	Dimethylaminoethanol (2-)
Acetophenone	Chlorophenol (p-)	Dimethylaniline (N,N)
Acrolein	Chloroprene	Dinitrobenzenes (NOS)
Acrylamide	Chlorotoluene (m-)	Dinitrophenol (2,4-)
Acrylic acid	Chlorotoluene (o-)	Dinitrotoluene (2,4-)
Acrylonitrile	Chlorotoluene (p-)	Dioxane
Adiponitrile	Chlorotrifluoroethane	Dioxolane (1,3-)
Alizarin	Chrysene	Diphenyl methane
Alkyl anthraquinones	Cresol and cresylic acid (m-)	Diphenyl oxide
Allyl alcohol	Cresol and cresylic acid (o-)	Diphenyl thiourea
Allyl chloride	Cresol and cresylic acid (p-)	Diphenylamine
Allyl cyanide	Cresols and cresylic acids (mixed)	Dipropylene glycol
Aminophenol sulfonic acid	Crotonaldehyde	Di(2-methoxyethyl)phthalate
Aminophenol (p-)	Cumene	Di-o-tolylguanidine
Aniline	Cumene hydroperoxide	Dodecyl benzene (branched)
Aniline hydrochloride	Cyanoacetic acid	Dodecyl phenol (branched)
Anisidine (o-)	Cyanoguanamide	Dodecylaniline
Anthracene	Cyclohexane	Dodecylbenzene (n-)
Anthraquinone	Cyclohexanol	Dodecylphenol
Azobenzene	Cyclohexanone	Epichlorohydrin
Benzaldehyde	Cyclohexylamine	Ethane
Benzene	Cyclooctadienes	Ethanolamine
Benzenedisulfonic acid	Decahydronaphthalene	Ethyl acrylate
Benzenesulfonic acid	Diacetoxy-2-Butene (1,4-)	Ethylbenzene
Benzil	Dialyl phthalate	Ethyl chloride
Benzilic acid	Diaminophenol hydrochloride	Ethyl chloroacetate
Benzoic acid	Dibromomethane	Ethylamine
Benzoin	Dibutoxyethyl phthalate	Ethylaniline (n-)
Benzonitrile	Dichloroaniline (inbred isomers)	Ethylaniline (o-)
Benzophenone	Dichlorobenzene (p-)	Ethylcellulose
Benzotrithloride	Dichlorobenzene (m-)	Ethylcyanoacetate
Benzoyl chloride	Dichlorobenzene (o-)	Ethylene carbonate
Benzyl acetate	Dichlorobenzidine (3,5-)	Ethylene dibromide
Benzyl alcohol	Dichlorodifluoromethane	Ethylene glycol
Benzyl benzoate	Dichloroethane (1,2-) (Ethylene dichloride) (EDC)	Ethylene glycol diacetate
Benzyl chloride	Dichloroethyl ether	Ethylene glycol dibutyl ether
Benzyl dichloride	Dichloroethylene (1,2-)	Ethylene glycol diethyl ether (1,2-diethoxyethane)
Biphenyl	Dichlorophenol (2,4-)	Ethylene glycol dimethyl ether
Bisphenol A	Dichloropropene (1,3-)	Ethylene glycol monoacetate
Bis(Chloromethyl)Ether	Dichlorotetrafluoroethane	Ethylene glycol monobutyl ether acetate
Bromobenzene	Dichloro-1-butene (3,4-)	Ethylene glycol monobutyl ether
Bromoform	Dichloro-2-butene (1,4-)	Ethylene glycol monoethyl ether acetate
Bromonaphthalene	Diethanolamine	Ethylene glycol monoethyl ether
Butadiene (1,3-)	Diethyl phthalate	Ethylene glycol monohexyl ether
Butanediol (1,4-)	Diethyl sulfate	Ethylene glycol monomethyl ether acetate
Butyl acrylate (n-)	Diethylamine	Ethylene glycol monomethyl ether
Butylbenzyl phthalate	Diethylaniline (2,6-)	Ethylene glycol monooctyl ether
Butylene glycol (1,3-)	Diethylene glycol	Ethylene glycol monophenyl ether
Butyrolactone	Diethylene glycol dibutyl ether	Ethylene glycol monopropyl ether
Caprolactam	Diethylene glycol diethyl ether	Ethylene oxide
Carbaryl	Diethylene glycol dimethyl ether	Ethylenediamine
Carbazole	Diethylene glycol monobutyl ether acetate	Ethylenediamine tetracetic acid
Carbon disulfide	Diethylene glycol monobutyl ether	Ethylenimine (Aziridine)
Carbon tetrabromide	Diethylene glycol monoethyl ether acetate	Ethylhexyl acrylate (2-isomer)
Carbon tetrachloride	Diethylene glycol monoethyl ether	Fluoranthene
Carbon tetrafluoride	Diethylene glycol monohexyl ether	Formaldehyde
Chloral	Diethylene glycol monomethyl ether acetate	Formamide
Chloroacetic acid	Diethylene glycol monomethyl ether	Formic acid

TABLE 5.3.2 Continued

Chemical Name <sup>a</sup>		
Fumaric acid	Naphthylamine sulfonic acid (2,1-)	Styrene
Glutaraldehyde	Naphthylamine (1-)	Succinic acid
Glyceraldehyde	Naphthylamine (2-)	Succinonitrile
Glycerol	Nitroaniline (m-)	Sulfanilic acid
Glycerol tri(polyoxypropylene)ether	Nitroaniline (o-)	Sulfolane
Glycine	Nitroanisole (o-)	Tartaric acid
Glyoxal	Nitroanisole (p-)	Terephthalic acid
Hexachlorobenzene	Nitrobenzene	Tetrabromophthalic anhydride
Hexachlorobutadiene	Nitronaphthalene (1-)	Tetrachlorobenzene (1,2,4,5-)
Hexachloroethane	Nitrophenol (p-)	Tetrachloroethane (1,1,2,2-)
Hexadiene (1,4-)	Nitrophenol (o-)	Tetrachlorophthalic anhydride
Hexamethylenetetramine	Nitropropane (2-)	Tetraethyl lead
Hexane	Nitrotoluene (all isomers)	Tetraethylene glycol
Hexanetriol (1,2,6-)	Nitrotoluene (o-)	Tetraethylenepentamine
Hydroquinone	Nitrotoluene (m-)	Tetrahydrofuran
Hydroxyadipaldehyde	Nitrotoluene (p-)	Tetrahydronaphthalene
Iminodiethanol (2,2-)	Nitroxylene	Tetrahydrophthalic anhydride
Isobutyl acrylate	Nonylbenzene (branched)	Tetramethylenediamine
Isobutylene	Nonylphenol	Tetramethylethylenediamine
Isophorone	N-Vinyl-2-Pyrrolidone	Tetramethyllead
Isophorone nitrile	Octene-1	Thiocarbamide
Isophthalic acid	Octylphenol	Toluene
Isopropylphenol	Paraformaldehyde	Toluene 2,4 diamine
Lead phthalate	Paraldehyde	Toluene 2,4 diisocyanate
Linear alkylbenzene	Pentachlorophenol	Toluene diisocyanates (mixture)
Maleic anhydride	Pentaerythritol	Toluene sulfonic acids
Maleic hydrazide	Peracetic acid	Toluenesulfonyl chloride
Malic acid	Perchloroethylene	Toluidine (o-)
Metanilic acid	Perchloromethyl mercaptan	Trichloroaniline (2,4,6-)
Methacrylic acid	Phenanthrene	Trichlorobenzene (1,2,3-)
Methanol	Phenetidine (p-)	Trichlorobenzene (1,2,4-)
Methionine	Phenol	Trichloroethane (TCA) (1,1,1-)
Methyl acetate	Phenolphthalein	TCA (1,1,2-)
Methyl acrylate	Phenolsulfonic acids (all isomers)	Trichloroethylene (TCE)
Methyl bromide	Phenyl anthranilic acid (all isomers)	Trichlorofluoromethane
Methyl chloride	Phenylenediamine (p-)	Trichlorophenol (2,4,5-)
Methyl ethyl ketone	Phloroglucinol	Trichlorotrifluoroethane (1,2,2-1,1,2)
Methyl formate	Phosgene	Triethanolamine
Methyl hydrazine	Phthalic acid	Triethylamine
Methyl isobutyl carbinol	Phthalic anhydride	Triethylene glycol
Methyl isocyanate	Phthalimide	Triethylene glycol dimethyl ether
Methyl mercaptan	Phthalonitrile	Triethylene glycol monoethyl ether
Methyl methacrylate	Picoline (b-)	Triethylene glycol monomethyl ether
Methyl phenyl carbinol	Piperazine	Trimethylamine
Methyl tert-butyl ether	Polyethylene glycol	Trimethylcyclohexanol
Methylamine	Polypropylene glycol	Trimethylcyclohexanone
Methylaniline (n-)	Propiolactone (beta-)	Trimethylcyclohexylamine
Methylcyclohexane	Propionaldehyde	Trimethylolpropane
Methylcyclohexanol	Propionic acid	Trimethylpentane (2,2,4-)
Methylcyclohexanone	Propylene carbonate	Tripropylene glycol
Methylene chloride	Propylene dichloride	Vinyl acetate
Methylene dianiline (4,4'-isomer)	Propylene glycol	Vinyl chloride
Methylene diphenyl diisocyanate (4,4'-) (MDI)	Propylene glycol monomethyl ether	Vinyl toluene
Methylionones (a-)	Propylene oxide	Vinylcyclohexane (4-)
Methylpentynol	Pyrene	Vinylidene chloride
Methylstyrene (a-)	Pyridine	Vinyl(N)-pyrrolidone (2-)
Naphthalene	p-tert-Butyl toluene	Xanthates
Naphthalene sulfonic acid (a-)	Quinone	Xylene sulfonic acid
Naphthalene sulfonic acid (b-)	Resorcinol	Xylenes (NOS)
Naphthol (a-)	Salicylic acid	Xylene (m-)
Naphthol (b-)	Sodium methoxide	Xylene (o-)
Naphtholsulfonic acid (1-)	Sodium phenate	Xylene (p-)
Naphthylamine sulfonic acid (1,4-)	Stilbene	Xylenol

<sup>a</sup>Isomer means all structural arrangements for the same number of atoms of each element and does not mean salts, esters, or derivatives.

**TABLE 5.3.3 ORGANIC HAPs**

<i>Chemical Name<sup>a,b</sup></i>		
Acetaldehyde	Dimethylformamide	Methylene chloride (Dichloromethane)
Acetamide	1,1-Dimethylhydrazine	Methylene diphenyl diisocyanate (MDI)
Acetonitrile	Dimethyl phthalate	4,4'-Methylenedianiline
Acetophenone	Dimethyl sulfate	Naphthalene
Acrolein	2,4-Dinitrophenol	Nitrobenzene
Acrylamide	2,4-Dinitrotoluene	4-Nitrophenol
Acrylic acid	1,4-Dioxane (1,4-Diethyleneoxide)	2-Nitropropane
Acrylonitrile	1,2-Diphenylhydrazine	Phenol
Allyl chloride	Epichlorohydrin (1-Chloro-2,3-epoxypropane)	p-Phenylenediamine
Aniline	Ethyl acrylate	Phosgene
o-Anisidine	Ethyl benzene	Phthalic anhydride
Benzene	Ethyl chloride (Chloroethane)	Polycyclic organic matter <sup>d</sup>
Benzotrichloride	Ethylene dibromide (Dibromoethane)	Propiolactone (beta-isomer)
Benzyl chloride	Ethylene dichloride (1,2-Dichloroethane)	Propionaldehyde
Biphenyl	Ethylene glycol	Propylene dichloride (1,2-Dichloropropane)
Bis(chloromethyl)ether	Ethylene oxide	Propylene oxide
Bromoform	Ethylidene dichloride (1,1-Dichloroethane)	Quinone
1,3-Butadiene	Formaldehyde	Styrene
Caprolactam	Glycol ethers <sup>c</sup>	1,1,2,2-Tetrachloroethane
Carbon disulfide	Hexachlorobenzene	Tetrachloroethylene (Perchloroethylene)
Carbon tetrachloride	Hexachlorobutadiene	Toluene
Chloroacetic acid	Hexachloroethane	2,4-Toluene diamine
2-Chloroacetophenone	Hexane	2,4-Toluene diisocyanate
Chlorobenzene	Hydroquinone	o-Toluidine
Chloroform	Isophorone	1,2,4-Trichlorobenzene
Chloroprene	Maleic anhydride	1,1,2-TCA
Cresols and cresylic acids (mixed)	Methanol	TCB
o-Cresol and o-cresylic acid	Methyl bromide (Bromomethane)	2,4,5-Trichlorophenol
m-Cresol and m-cresylic acid	Methyl chloride (Chloromethane)	Triethylamine
p-Cresol and p-cresylic acid	Methyl chloroform (1,1,1-Trichloroethane)	2,2,4-Trimethylpentane
Cumene	Methyl ethyl ketone (2-Butanone)	Vinyl acetate
1,4-Dichlorobenzene(p-)	Methyl hydrazine	Vinyl chloride
3,3'-Dichlorobenzidine	Methyl isobutyl ketone (Hexone)	Vinylidene chloride (1,1-Dichloroethylene)
Dichloroethyl ether (Bis(2-chloroethyl)ether)	Methyl isocyanate	Xylenes (isomers and mixtures)
1,3-Dichloropropene	Methyl methacrylate	o-Xylene
Diethanolamine	Methyl tert-butyl ether	m-Xylene
N,N-Dimethylaniline		p-Xylene
Diethyl sulfate		
3,3'-Dimethylbenzidine

Notes: <sup>a</sup>For all listings containing the word "Compounds" and for glycol ethers, the following applies: Unless otherwise specified, these listings include any unique chemical substance that contains the named chemical (i.e., antimony, arsenic) as part of that chemical's infrastructure.

<sup>b</sup>Isomer means all structural arrangements for the same number of atoms of each pigment and does not mean salts, esters, or derivatives.

<sup>c</sup>Includes mono- and di-ethers of ethylene glycol, diethylene glycol, and triethylene glycol R-(OCH<sub>2</sub>CH<sub>2</sub>)<sub>n</sub>-OR where n = 1, 2, or 3; R = alkyl or aryl groups; and R' = R, H, or groups which, when removed, yield glycol ethers with the structure: R-(OCH<sub>2</sub>CH<sub>2</sub>)<sub>n</sub>-OH Polymers are excluded from the glycol category.

<sup>d</sup>Includes organic compounds with more than one benzene ring, and which have a boiling point greater than or equal to 100°C.

## STORAGE VESSELS

A storage vessel is a tank or vessel storing the feed or product of a SOCM chemical manufacturing process when the liquid is on the list of HAPs (see Table 5.3.3). The storage vessel provisions require that one of the following control systems is applied to storage vessels:

- An internal floating roof with proper seals and fittings
- An external floating roof with proper seals and fittings
- An external floating roof converted to an internal floating roof with proper seals and fittings
- A closed-vent system with 95% efficient control

**TABLE 5.3.4 NATIONAL PRIMARY AIR POLLUTION IMPACTS IN THE FIFTH YEAR<sup>a</sup>**

<i>Emission Points</i>	<i>Baseline Emissions (Mg/yr)</i>		<i>Emission Reductions</i>			
	<i>HAP</i>	<i>VOC<sup>c</sup></i>	<i>(Mg/yr)</i>		<i>(Percent)</i>	
			<i>HAP</i>	<i>VOC<sup>b</sup></i>	<i>HAP</i>	<i>VOC<sup>b</sup></i>
Equipment leaks	66,000	84,000	53,000	68,000	80	81
Process vents	317,000	551,000	292,000	460,000	92	83
Storage vessels	15,200	15,200	5,560	5,560	37	37
Wastewater collection and treatment operations	198,000	728,000	124,000	452,000	63	62
Transfer loading operations	900	900	500	500	56	56
<b>Total</b>	<b>597,000</b>	<b>1,380,000</b>	<b>475,000</b>	<b>986,000</b>	<b>80</b>	<b>71</b>

*Source: Code of Federal Regulations, Title 40, part 63; Clean Air Act Amendments, amended 1990, Section 112.*

<sup>a</sup>These numbers represent estimated values for the fifth year. Existing emission points contribute 84% of the total. Emission points associated with chemical manufacturing process equipment built in the first 5 yr of the standard contribute 16% of the total.

<sup>b</sup>The VOC estimates consist of the sum of the HAP estimates and the nonHAP VOC estimates.

### TRANSFER OPERATIONS

Transfer operations are the loading of liquid products on the list of HAPs from a transfer rack within the SOCMII chemical manufacturing process into a tank truck or railcar. The transfer rack includes the total loading arms, pumps, meters, shutoff valves, relief valves, and other piping and valves necessary to load trucks or railcars.

The proposed transfer provisions control transfer racks to achieve a 98% organic HAP reduction or an outlet concentration of 20 ppmv. Combustion devices or product recovery devices can be used. Again, halogenated streams that use combustion devices to comply with the 98% or 20 ppmv emission reduction must vent the emissions from the combustion device to an acid scrubber before venting to the atmosphere.

### WASTEWATER

The wastewater to which the proposed standard applies is any organic HAP-containing water or process fluid discharged into an individual drain system. This wastewater includes process wastewater, maintenance-turnaround wastewater, and routine and routine-maintenance wastewater. Examples of process wastewater streams include those from process equipment, product or feed tank drawdown, cooling water blowdown, steam trap condensate, reflux, and fluid drained into and material recovered from waste management units. Examples of maintenance-turnaround wastewater streams are those generated by the descaling of heat exchanger tubing bundles, cleaning of distillation column traps, and draining of pumps into individual drain system. A HAP-containing

wastewater stream is a wastewater stream that has a HAP concentration of 5 parts per million by weight (ppmw) or greater and a flow rate of 0.02 liters per minute (lpm) or greater.

The proposed process water provisions include equipment and work practice provisions for the transport and handling of wastewater streams between the point of generation and the wastewater treatment processes. These provisions include the use of covers, enclosures, and closed-vent systems to route organic HAP vapors from the transport and handling equipment. The provisions also require the reduction of volatile organic HAP (VOHAP) concentrations in wastewater streams.

### SOLID PROCESSING

The product of synthetic organic processes can be in solid, liquid, or gas form. Emissions of solid particulates are also of concern. One reason is that particulate emissions occur with drying, packaging, and formulation operations. Additionally, these emissions can be in the respirable size range. Within this range, a significant fraction of the particulates can be inhaled directly into the lungs, thereby enhancing the likelihood of being absorbed into the body and damaging lung tissues.

### Toxic Pollutants

Table 5.3.3 shows that halogenated aliphatics are the largest class of priority toxics. These chemicals can cause damage to the central nervous system and liver. Phenols are carcinogenic in mice; their toxicity increases with the

**TABLE 5.3.5 HEALTH EFFECTS OF SELECTED HAPS**

<i>Pollutant</i>	<i>Major Health Effects</i>
Acrylonitrile (CH <sub>2</sub> =CH•C≡N)	Dermatitis; haematological changes; headaches; irritation of eyes, nose, and throat; lung cancer
Benzene (C <sub>6</sub> H <sub>6</sub> )	Leukemia; neurotoxic symptoms; bone marrow injury including anaemia, and chromosome aberrations
Carbon disulfide (CS <sub>2</sub> )	Neurologic and psychiatric symptoms, including irritability and anger; gastrointestinal troubles; sexual interferences
1,2 Dichloroethane (C <sub>2</sub> H <sub>2</sub> Cl <sub>2</sub> )	Damage to lungs, liver, and kidneys; heart rhythm disturbances; effects on central nervous systems, including dizziness; animal mutagen and carcinogen
Formaldehyde (HC HO)	Chromosome aberrations; irritation of eyes, nose, and throat; dermatitis; respiratory tract infections in children
Methylene chloride (CH <sub>2</sub> Cl <sub>2</sub> )	Nervous system disturbances
Polychlorinated bi-phenyls (PCB) (coplanar)	Spontaneous abortions; congenital birth defects; bioaccumulation in food chains
Polychlorinated dibenzo-dioxins and furans	Birth defects; skin disorders; liver damage; suppression of the immune system
Polycyclic organic matter (POM) [including benzo(a)pyrene (BaP)]	Respiratory tract and lung cancers; skin cancers
Styrene (C <sub>6</sub> H <sub>5</sub> •CH=CH <sub>2</sub> )	Central nervous system depression; respiratory tract irritations; chromosome aberrations; cancers in the lymphatic and haematopoietic tissues
Tetrachloroethylene (C <sub>2</sub> Cl <sub>4</sub> )	Kidney and genital cancers; lymphosarcoma; lung, cervical, and skin cancers; liver dysfunction; effects on central nervous system
Toluene (C <sub>6</sub> H <sub>5</sub> •CH <sub>3</sub> )	Dysfunction of the central nervous system; eye irritation
TCE (C <sub>2</sub> HCl <sub>3</sub> )	Impairment of psychomotoric functions; skin and eye irritation; injury to liver and kidneys; urinary tract tumors and lymphomas
Vinyl chloride (CH <sub>2</sub> =CHCl)	Painful vasospastic disorders of the hands; dizziness and loss of consciousness; increased risk of malformations, particularly of the central nervous systems; severe liver disease; liver cancer; cancers of the brain and central nervous system; malignancies of the lymphatic and haematopoietic system

Source: OECD.

degree of chlorination of phenolic molecules. Maleic anhydride and phthalic anhydride are irritants to the skin, eyes, and mucous membranes. Methanol vapor is irritating to the eyes, nose, and throat; this vapor explodes if ignited in an enclosed area.

Table 5.3.5 lists the health effects of selected HAPs. Because of the large number of HAPs, enumerating the potential health effects of the category as a whole is not possible. However, material safety data sheets (MSDS) for the HAPs are available from chemical suppliers on request,

and handbooks such as the *Hazardous chemical data book* (Weiss 1980) provide additional information.

## 5.4 ATMOSPHERIC CHEMISTRY

Pollutants enter the atmosphere primarily from natural sources and human activity. This pollution is called *primary pollution*, in contrast to *secondary pollution*, which is caused by chemical changes in substances in the atmosphere. Sulfur dioxides, nitric oxides, and hydrocarbons are major primary gaseous pollutants, while ozone is a secondary pollutant, the result of atmospheric photochemistry between nitric oxide and hydrocarbons.

Pollutants do not remain unchanged in the atmosphere after release from a source. Physical changes occur, especially through dynamic phenomena, such as movement and scattering in space, turbulent diffusion, and changes in the concentration by dilution.

Changes also result from the chemistry of the atmosphere. These changes are often simple, rapid chemical reactions, such as oxidation and changes in temperature to condense some gases and vapors to yield mist and droplets. After a long residence of some gaseous pollutants in the atmosphere, these gases convert into solid, finely dispersed substances. Solar conditions cause chemical reactions in the atmosphere among various pollutants and their supporting media. Figure 5.4.1 shows simplified schemes of the main chemical changes of pollutants in the atmosphere.

### Basic Chemical Processes

A basic chemical process in the atmosphere is the oxidation of substances by atmospheric oxygen. Thus, sulfur dioxide ( $\text{SO}_2$ ) is oxidized to sulfur trioxide ( $\text{SO}_3$ ), and nitric oxide to nitrogen dioxide. Similarly, many organic substances are oxidized, for example, aldehydes to organic acids and unsaturated hydrocarbons. While pollutant clouds are transported and dispersed to varying degrees, they also age. Pollutant cloud aging is a complex combination of homogeneous and heterogeneous reactions and physical processes (such as nucleation, coagulation, and the Brownian motion). Chemically unlike species can make contact and further branch the complex pattern (see Figure 5.4.1). Table 5.4.1 summarizes the major removal reactions and sinks. Most of these reactions are not understood in detail.

Sulfur oxides, in particular  $\text{SO}_2$ , have been studied with respect to atmospheric chemistry. However, an understanding of the chemistry of  $\text{SO}_2$  in the atmosphere is still far from complete. Most evidence suggests that the eventual fate of atmospheric  $\text{SO}_2$  is oxidation to sulfate. One problem that complicates understanding atmospheric  $\text{SO}_2$  processes is that reaction paths can be homogeneous and

heterogeneous. Two processes convert  $\text{SO}_2$  to sulfate: catalytic and photochemical.

### CATALYTIC OXIDATION OF $\text{SO}_2$

In clear air,  $\text{SO}_2$  is slowly oxidized to  $\text{SO}_3$  by homogeneous reactions. However, studies show that the rate of  $\text{SO}_2$  oxidation in a power plant plume can be 10 to 100 times the clear-air photooxidation rate (Gartrell, Thomas, and Carpenter 1963). Such a rapid rate of reaction is similar to that of oxidation in solution in the presence of a catalyst.

$\text{SO}_2$  dissolves readily in water droplets and can be oxidized by dissolved oxygen in the presence of metal salts, such as iron and manganese. The overall reaction can be expressed as:

Catalysts for the reaction include sulfates and chlorides of manganese and iron which usually exists in air as sus-

FIG. 5.4.1 Examples of chemical reactions in the atmosphere.

**TABLE 5.4.1 SUMMARY OF SOURCES, CONCENTRATIONS, AND SCAVENGING PROCESSES OF ATMOSPHERIC TRACE GASES**

<i>Contaminant</i>	<i>Major Pollutant Sources</i>	<i>Natural Sources</i>	<i>Estimated Annual Emissions Tg/yr*</i>		<i>Atmospheric Background Concentrations</i>	<i>Estimated Atmospheric Residence Time</i>	<i>Removal Reactions and Sinks</i>	<i>Remarks</i>
			<i>Pollutants</i>	<i>Natural</i>				
SO <sub>2</sub>	Fossil fuel combustion	Volcanoes, reactions of biogenic S emissions	212 <sup>1</sup>	20 <sup>2</sup>	About 0.1 ppb <sup>3</sup>	1–4 days	Oxidation to sulfate by photochemical reactions or in liquid droplets	High reaction rates in summer due to photochemical processes

<sup>23</sup>Based on estimated reaction of NaCl to form Cl<sub>2</sub>.

pended particles. At high humidities, these particles act as condensation nuclei or undergo hydration to become solution droplets. The oxidation then proceeds by absorption of both SO<sub>2</sub> and O<sub>2</sub> by the liquid aerosols with subsequent chemical reactions in the liquid phase. The oxidation slows considerably when the droplets become highly acidic because of the decreased solubility of SO<sub>2</sub>. However if sufficient ammonia is present, the oxidation process is not impeded by the accumulation of H<sub>2</sub>SO<sub>4</sub>. Measurements of particulate composition in urban air often show large concentrations of ammonium sulfate.

## PHOTOCHEMICAL REACTIONS

In the presence of air, SO<sub>2</sub> is slowly oxidized to SO<sub>3</sub> when exposed to solar radiation. If water is present, the SO<sub>2</sub> rapidly converts to sulfuric acid. Since no radiation wavelengths shorter than 2900 Å reach the earth's surface and the dissociation of SO<sub>2</sub> to SO and O is possible only for wavelengths below 2180 Å, the primary photochemical processes in the lower atmosphere following absorption by SO<sub>2</sub> involve activated SO<sub>2</sub> molecules and not direct dissociation. Thus, the conversion of SO<sub>2</sub> to SO<sub>3</sub> in clear air is a result of a several-step reaction sequence involving excited SO<sub>2</sub> molecules, oxygen, and oxides of sulfur other than SO<sub>2</sub>. In the presence of reactive hydrocarbons and nitrogen oxides, the conversion rate of SO<sub>2</sub> to SO<sub>3</sub> increases markedly. In addition, oxidation of SO<sub>2</sub> in systems of this type is frequently accompanied by aerosol formation.

A survey of possible reactions by Bufalini (1971) and Sidebottom et al. (1972) concludes that the most important oxidation step for the triplet state <sup>3</sup>SO<sub>2</sub> from among those involving radiation only is:

Other primary substances absorbing UV radiation include sulfur and nitrogen oxides and aldehydes. UV radiation excites the molecules of these substances, which then react with atmospheric molecular oxygen to yield atomic oxygen. Analogous to SO<sub>2</sub> oxidation, aldehydes react as follows:

Atomic oxygen can also be formed by the following reactions:

SO<sub>2</sub> and aldehydes react irreversibly, whereby the amount of atomic oxygen formed by these processes is relatively small and corresponds to the amount of SO<sub>2</sub> and aldehydes

in the atmosphere. In the reaction of nitrogen dioxide, however, the absorption of UV radiation leads to the destruction of one bond between the nitrogen and oxygen atoms and to the formation of atomic oxygen and nitrogen oxide. Further reactions lead to the formation of atomic oxygen and nitrogen oxide as follows:

The regenerated nitrogen dioxide can reenter the reaction, and this process can repeat until the nitrogen dioxide converts into nitric acid or reacts with organic substances to form nitrocompounds. Therefore, a low concentration of nitrogen dioxide in the atmosphere can lead to the formation of a considerable amount of atomic oxygen and ozone. This nitrogen dioxide is significant in the formation of oxidation smog.

Olefins with a large number of double bonds also react photochemically to form free radicals. Inorganic substances in atomic form in the atmosphere also contribute to the formation of free radicals. On reacting with oxygen, some free radicals form peroxy compounds from which new peroxides or free radicals are produced that can cause polymerization of olefins or be a source of ozone. The photochemistry is described by the thirty-six reactions for the twenty-seven species in Table 5.4.2 which includes four reactive hydrocarbon groups: olefins, paraffins, aldehydes, and aromatics.

## Particulates

Atmospheric reactions are strongly affected by the number of suspended solid particles and their properties. The particles supply the surfaces on which reactions can occur thus acting as catalysts. They can also affect the absorption spectrum through the adsorption of gases (i.e., in the wavelength range of adsorbed radiation) and thus affect the intensities of radiation absorption and photochemical reactions. Moreover, solid particles can react with industrially emitted gases in common chemical reactions.

Combustion, volcanic eruptions, dust storms, and sea spray are a few processes that emit particles. Many particulates in the air are metal compounds that can catalyze secondary reactions in the air or gas phase to produce aerosols as secondary products. Physical processes such as nucleation, condensation, absorption, adsorption, and coagulation are responsible for determining the physical properties (i.e., the number concentration, size distribution, optical properties, and settling properties) of the formed aerosols. Particles below 0.1 μ, (known as Aitken nuclei), although not significant by gravity, are capable of serving as condensation nuclei for clouds and fog. Secondary effects are the results of gas-phase chemistry and photochemistry that form aerosols.

Note: M stands for any available atom or molecule which by collision with the reaction product carries off the excess energy of the reaction and prevents the reaction product from flying apart as soon as it is formed.

The removal of particles (aerosols and dust) from the atmosphere involves dry deposition by sedimentation, washout by rainfalls and snowfalls, and dry deposition by impact on vegetation and rough surfaces.

A volcanic eruption is a point source which has local effects (settling of particles and fumes) and global effects since the emissions can circulate in the upper atmosphere (i.e., the stratosphere) and increase the atmospheric aerosol content.

From the point of view of atmospheric protection, some of these reactions are favorable as they quickly yield products that are less harmful to humans and the biosphere. However, the products of some reactions are even more toxic than the reactants, an example being peroxyacetyl nitrate.

The atmospheric chemical reactions of solid and gaseous substances in industrial emissions are complex. A deeper analysis and description is beyond the scope of this section.

## Long-Range Planning

Other long-range problems caused by atmospheric chemical reactions occur in addition to those of sulfur and nitrogen compounds. States and provinces must formulate strategies to achieve oxidant air quality standards. They must assess both the transport of oxidants from outside local areas and the estimated influx of precursors that create additional oxidants. Lamb and Novak (1984) give the principal features of a four-layer regional oxidant model (see Figure 5.4.2) designed to simulate photochemical processes over time scales of several days and space scales

of 1000 km. Temporal resolution yields hourly concentrations from time steps of 30 min and spatial resolution of about 18 km. The model includes the following processes:

- Horizontal transport
- Photochemistry using thirty-five reactions of twenty-three species
- Nighttime chemistry
- Nighttime wind shear, thermal stratification, and turbulent episodes associated with nocturnal jet
- Cumulus cloud effects, including venting from the mixed layer and photochemical reactions caused by their shadows
- Mesoscale vertical motion induced by terrain and horizontal divergence
- Mesoscale eddy effects on trajectories and growth rates of urban plumes
- Terrain effects on flow and diffusion
- Subgrid-scale chemical processes due to subgrid-scale emissions
- Natural sources of hydrocarbons and nitrogen oxides
- Wet and dry removal processes

The model was initially applied to the northeastern quarter of the United States. A 1980 emissions inventory gathered data on nitrogen oxides, VOCs, carbon dioxide, sulfur oxides, and total suspended particulate matter. In the model, volatile organics are considered as four reactive classes: olefins, paraffins, aldehydes, and aromatics. Applying the model requires acquiring and preparing emission and meteorological information for an area and a

## 5.5

# MACRO AIR POLLUTION EFFECTS

---

---

Macro air pollution effects refer to those consequences of air pollution exhibited on a large geographical scale, with the scale ranging from regional to global. Examples of such effects include acid rain, losses in the stratospheric ozone layer, and global warming.

### Acid Rain Effects

Acid precipitation causes multiple effects on both terrestrial and aquatic ecosystems. Also, acid precipitation and dry deposition can affect materials and even human health. Demonstrated effects on terrestrial ecosystems include necrotic lesions on foliage, nutrient loss from foliar organs, reduced resistance to pathogens, accelerated erosion of the waxes on leaf surfaces, reduced rates of decomposition of leaf litter, inhibited formation of terminal buds, increased seedling mortality, and heavy metal accumulation (Cowling and Davey 1981). Soil and vegetation and crop-related effects include soil acidification, calcium removal, aluminum and manganese solubilization, tree growth reduction, reduction of crop quality and quantity, elimination of useful soil microorganisms, and selective exchange of heavy metal elements for more beneficial mono- and divalent cations (Glass, Glass, and Rennie 1979). Soil microbiological processes such as nitrogen fixation, mineralization of forest litter, and nitrification of ammonium compounds can be inhibited, the degree depending on the amount of cultivation and soil buffering capacity (Cowling and Davey 1981).

### EFFECTS ON FORESTS

Field studies of the effects of acid precipitation on forests have been conducted in the United States and Europe. Reports of decreased growth and increased mortality of forest trees in areas receiving high rates of atmospheric pollutants emphasize the need to understand and quantify both the mechanisms and kinetics of changes in forest productivity. The complex chemical nature of combined pollutant exposures and the fact that these changes can involve both direct effects to vegetation and indirect and possibly beneficial effects mediated by a variety of soil processes make quantification of such effects challenging. However, evidence is growing on the severity of forest problems in central Europe due to acid precipitation. For example, in West Germany, fully 560,000 hectares of forests have been damaged (Wetstone and Foster 1983).

### EFFECTS ON SOIL

Acid precipitation can affect soil chemistry, leaching, and microbiological processes. In addition, various types of soils exhibit a range of sensitivities to the effects of acid rain; for example, some soils are more sensitive than others. Factors influencing soil sensitivity to acidification include the lime capacity, soil profile buffer capacity, and water-soil reactions (Bache 1980). Wiklander (1980) reviews the sensitivity of various soils, and Peterson (1980) identifies soil orders and classifications according to their response to acid precipitation.

Two important effects of acid precipitation on soil are associated with changes in the leaching patterns of soil constituents and with the potential removal and subsequent leaching of chemical constituents in the precipitation. For example, Cronan (1981) describes the results of an investigation of the effects of regional acid precipitation on forest soils and watershed biogeochemistry in New England. Key findings include the following:

1. Acid precipitation can cause increased aluminum mobilization and leaching from soils to sensitive aquatic systems
2. Acid deposition can shift the historic carbonic acid/organic acid leaching regime in forest soils to one dominated by atmospheric  $H_2SO_4$
3. Acid precipitation can accelerate nutrient cation leaching from forest soils and can pose a threat to the potassium resources of northeastern forested ecosystems
4. Progressive acid dissolution of soils in the laboratory is an important tool for predicting the patterns of aluminum leaching from soils exposed to acid deposition.

Soil microorganisms and microbiological processes can be altered by acid precipitation. The effects of acid precipitation include changes in bacterial numbers and activity, alterations in nutrient and mineral cycling, and changes in the decomposition of organic matter.

### EFFECTS ON GROUNDWATER

As groundwater quality is becoming increasingly important, a concern is growing related to the effects of acid precipitation on quality constituents. Direct precipitation in recharge areas is of particular concern. The most pronounced effects are associated with increased acidity causing accelerated weathering and chemical reactions as the precipitation passes through soil and rock in the process

of recharging an aquifer. The net effect on groundwater is reduced water quality because of increased mineralization.

## EFFECTS ON SURFACE WATER

Acid precipitation causes many observable, as well as nonobservable, effects on aquatic ecosystems. Included are changes in water chemistry and aquatic faunal and floral species. One reason for changes in surface water chemistry is the release of metals from stream or lake sediments. For example, Wright and Gjessing (1976) note that concentrations of aluminum, manganese, and other heavy metals are higher in acid lakes due to enhanced mobilization of these elements in acidified areas.

Due to the extant water chemistry and sediment characteristics, some surface water is more susceptible to changes in water chemistry than others. Several surface water sensitivity studies leading to classification schemes have been conducted. For example, Hendrey et al. (1980) analyzed bedrock geology maps of the eastern United States to determine the relationship between geological material and surface water pH and alkalinity. They verified map accuracy by examining the current alkalinity and pH of water in several test states, including Maine, New Hampshire, New York, Virginia, and North Carolina. In regions predicted to be highly sensitive, the alkalinity in upstream sites was generally low, less than 200 microequivalents per liter. They pinpoint many areas of the eastern United States in which some of the surface water, especially upstream reaches, are sensitive to acidification.

Acid precipitation affects microdecomposers, algae, aquatic macrophytes, zooplankton, benthos, and fish (Hendrey et al. 1976). For example, many of the 2000 lakes in the Adirondack Region of New York are experiencing acidification and declines or loss of fish populations. Baker (1981) found that, on the average, aluminum complexed with organic ligands was the dominant aluminum form in the dilute acidified Adirondack surface water studied. In laboratory bioassays, speciation of aluminum had a substantial effect on aluminum and hydrogen ions, and these ions appeared to be important factors for fish survival in Adirondack surface water affected by acidification.

## EFFECTS ON MATERIALS

Acid precipitation can damage manmade materials such as buildings, metals, paints, and statuary (Glass, Glass, and Rennie 1980). For example, Kucera (1976) has reported data on the corrosion rates of unprotected carbon steel, zinc and galvanized steel, nickel and nickel-plated steel, copper, aluminum, and antirust painted steel due to sulfur dioxide and acid precipitation in Sweden. Corrosion rates are higher in polluted urban atmospheres than in rural atmospheres because of the high concentrations of airborne sulfur pollutants in urbanized areas. Economic damage is significant in galvanized, nickel-plated, and painted steel and painted wood.

## EFFECTS ON HEALTH

Acid precipitation affects water supplies which in turn affects their users. Taylor and Symons (1984) report the results of the first study concerning the impact of acid precipitation on drinking water; the results report health effects in humans as measured by U.S. EPA maximum contaminant levels. The study sampled surface water and groundwater supplies in the New England states, but it also included other sites in the northeast and the Appalachians. No adverse effects on human health were demonstrated, although the highly corrosive nature of New England water may be at least partly attributable to acidic deposition in poorly buffered watersheds and aquifers.

## Losses in Stratospheric Ozone Layer

The stratospheric ozone layer occurs from 12 to 50 km above the earth; the actual ozone concentration in the layer is in the order of ppmv (Francis 1994). Ozone can be both formed and destroyed by reactions with  $\text{NO}_x$ ; of recent concern is the enhanced destruction of stratospheric ozone by chlorofluorocarbons (CFCs) and other manmade oxidizing air pollutants. The natural ozone layer fulfills several functions related to absorbing a significant fraction of the ultraviolet (uv) component of sunlight and terrestrial infrared radiation, and it also emits infrared radiation.

Several potential deleterious effects result from decreasing the stratospheric ozone concentration. Of major concern is increased skin cancer in humans resulting from greater UV radiation reaching the earth's surface. Additional potential concerns include the effects on some marine or aquatic organisms, damage to some crops, and alterations in the climate (Francis 1994). While environmental engineers are uncertain about all seasonal and geographic characteristics of the natural ozone layer and quantifying these effects, the effects are recognized via precursor pollutant control measures included in the 1990 CAAAs.

Precursor pollutants that reduce stratospheric ozone concentrations via atmospheric reactions include CFCs and nitrous oxide. Principal CFCs include methylchloroform and carbon tetrachloride; these CFCs are emitted to the atmosphere as a result of their use as aerosol propellants, refrigerants, foam-blowing agents, and solvents. Example reactions for one CFC (CFC-12) and ozone follow (Francis 1994):

$\text{Cl}\cdot$  denotes atomic chlorine.  $\text{ClO}$  is also chemically reactive and combines with atomic oxygen as follows:

Because of the preceding cycling of  $\text{Cl}\cdot$ , environmental engineers estimate that a single Cl atom can destroy an average of 100,000 ozone molecules (Francis 1994).

## Global Warming

The potential effects of global climate change can be considered in terms of ecological systems, sea-level rise, water resources, agriculture, electric demand, air quality, and health effects (Smith and Tirpak 1988). Since climate influences the location and composition of plants and animals in the natural environment, changes in climate have numerous consequences on ecological systems. One consequence includes shifts in forests in geographic range and composition; for example, the current southern boundary of hemlock and sugar maple in the eastern United States could move northward by about 400 mi (Smith and Tirpak 1988). An example of compositional change is that the mixed boreal and northern hardwood forest in northern Minnesota could become all northern hardwood.

### ECOLOGICAL IMPACT

Biodiversity is also impacted by climate change, with *diversity* defined as the variety of species in ecosystems and the variability within each species. Examples of impact include an increased extinction of many species; growth or losses in freshwater fish populations depending on geographic location; and mixed effects on migratory birds, with some arctic-nesting herbivores benefiting and continental nesters and shorebirds suffering (Smith and Tirpak 1988).

Sea-level rises can cause increased losses of coastal wetlands, inundation of coastal lowlands, increased erosion of beaches, and increased salinity in estuaries. Coastal wetlands currently total 13,145 sq mi; with a 1-m rise in sea level, 26 to 66% of these wetlands can be lost, with the majority occurring in states bordering the Gulf of Mexico (Smith and Tirpak 1988).

### IMPACT ON WATER RESOURCES

The main consequences of climatic changes to inland waters include the following (da Cunha 1988): (a) changes in the global amount of water resources and in the spatial and temporal distribution of these resources; (b) changes in soil moisture; (c) changes in extreme phenomena related to water resources, i.e., floods and droughts; (d) changes in water quality; (e) changes in sedimentation processes; and (f) changes in water demand.

The consequences of climatic change on water quality include possible changes in the precipitation regime and the occurrence of acid rain. Direct consequences of climatic changes on water quality occur. For example, temperature increases can decrease levels of dissolved oxygen in the water. Second, the biochemical oxygen demand (BOD) also increases with temperature. These two effects can decrease the dissolved oxygen concentration in a surface water system. Also, climatic changes can have indirect consequences on water quality since a decrease of river discharges, particularly during the dry season, can increase the concentration of pollutants in water bodies.

Climatic changes influence not only water availability but also water demand. For example, water demand for irrigation is largely affected by climatic change which conditions evapotranspiration. Water demands for domestic or industrial use are also affected by climatic change, for example, as a result of temperature increases that influence water consumption for cooling systems, bathing, washing, and gardening.

The simplest way to view the implications of global climate change on water resources is to consider the relationship between increasing atmospheric CO<sub>2</sub> and the hydrologic cycle; this relationship is shown in Figure 5.5.1. The following comments relate to the implications of Figure 5.5.1 (Waggoner and Revelle 1990):

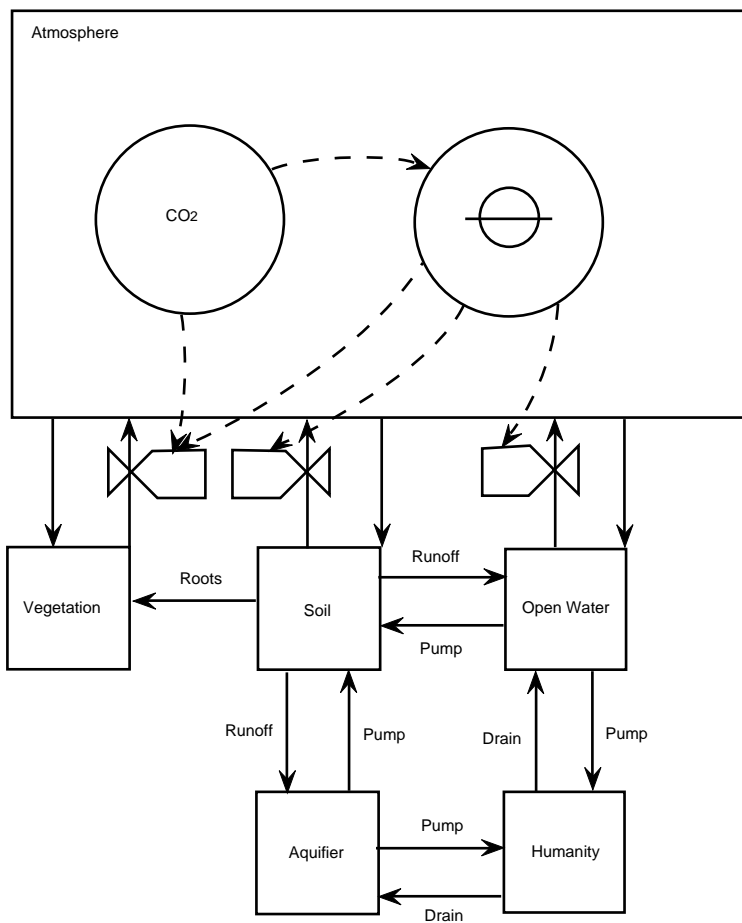

1. When the atmosphere reaches a new and warmer equilibrium, more precipitation balances faster evaporation. This faster hydrologic cycle is predicted to raise the global averages of the up-and-down arrows of precipitation and evaporation in Figure 5.5.1 by 7 to 15%. However, the predicted change in precipitation is not a uniform increase. The net of precipitation and evaporation, that is, soil moisture, is predicted to fall in some places. Also, precipitation is predicted to increase in some seasons and decrease in others. Although global climatic models disagree on where precipitation will decrease and although they do not simulate the present seasonal change in precipitation correctly, disregarding the warning of a drier climate is unwise.
2. To be most usable for water resource considerations, frequency distributions of precipitation (and flood and drought projections) are needed. Models to develop such information are in their infancy.
3. A dimensionless elasticity for runoff and precipitation is:

$$\left[ \frac{\text{Percentage change in runoff}}{\text{percentage change in precipitation}} \right] \quad 5.5(4)$$

If the elasticity for runoff and precipitation is greater than 1, the percentage change in runoff is greater than the percentage change in precipitation that causes it. Therefore, a general conclusion about the transformation of climate change into runoff change can be stated. Over diverse climates, the elasticities of percentage change in runoff to percentage change in precipitation and evaporation are 1 to 4. The percentage change in runoff is greater than the percentage change in the forcing factor.

Based on this brief review of water resource issues related to global climate change, the following summary comments can be made:

1. Global climate change caused by the greenhouse effect appears to be a reality although scientific opinion differs as to the rate of change.
2. Numerous inland and coastal water resource management issues are impacted when temperature and precipitation patterns change.

**FIG. 5.5.1** The hydrologic cycle. The large rectangle at the top represents the water in the atmosphere. The rectangles beneath represent the water in vegetation, in the soil reached by roots, in the aquifers below, and in open bodies of water. The rectangle for humanity represents the water in people and pipes. Arrows represent fluxes. Valves are placed on three fluxes to show their control by  $\text{CO}_2$ .  $\text{CO}_2$  directly affects transpiration from foliage by enlarging it through faster photosynthesis and by narrowing leaf pores. Indirectly,  $\text{CO}_2$  warms the air temperature, speeding the evaporation from vegetation, soil, and open water. Faster evaporation decreases the water that runs off to bodies of water or into aquifers, increases pumping to irrigate soil, and even raises humanity's demands. The arrows from air down to vegetation, soil, and open water are the flux and addition to them by precipitation. Water resources are the pools signified by the rectangles for open water and aquifers. (Reprinted, with permission, from P.E. Waggoner and R.R. Revelle, 1990, Summary, Chap. 19 in *Climate change and U.S. water resources*, edited by P.E. Waggoner, New York: John Wiley and Sons.)

3. The global perspective presented in most studies is not specific enough to address the water resource implications in regional and local areas.
4. Global climate change might be controlled by effective programs to reduce the atmospheric emissions of greenhouse gases.
5. Global climate change must rise higher on national and international political agendas before effective societal measures can be implemented to control or manage the water resources implications.

### IMPACT ON AGRICULTURE

Agricultural productivity in the United States is based on the temperate climate and rich soils. Global warming exhibits direct and indirect geographical effects on agricultural productivity. Direct effects occur through changes in the length of the growing season, the frequency of heat waves, and altered patterns of rainfall; while indirect effects result from changes in topsoil management practices. Dryland yields of corn, wheat, and soybeans could decrease in many regions as a result of higher temperatures

**FIG. 5.5.2** Changes in electric generation by state induced by climate change to 2055. (Reprinted from J.B. Smith and D.A. Tirpak, 1988, *The potential effects of global climate change on the United States*, Washington, D.C.: U.S. EPA [October].)

which shorten a crop's life cycle (Smith and Tirpak 1988). In contrast, in northern areas such as Minnesota, dryland yields of corn and soybeans could double as warmer temperatures extend the frost-free growing season. Crop acreage could decrease by 5 to 25% in Appalachia, the southeast, and the southern Great Plains areas; conversely, acreage could increase by 5 to 17% in the northern Great Lakes states, the northern Great Plains, and the Pacific northwest areas (Smith and Tirpak 1988). Irrigation would probably increase in many areas because irrigated yields are more stable than dry-land yields under conditions of increased heat stress and reduced precipitation.

Climate-sensitive electric end uses include space heating and cooling and, to a lesser degree, water heating and refrigeration. Summer cooling electric demands would increase, while winter heating demands would decrease. As a result of climate change, annual electric demands are expected to increase by 4 to 6% by the year 2055. Figure 5.5.2 summarizes regional demand changes. Additional power plants will be required to meet peak demands.

### IMPACT ON AIR QUALITY

Global climate change also has implications for ambient air quality. Increased emissions of SO<sub>x</sub>, NO<sub>x</sub>, and CO are associated with power plants meeting increased electric demands. Plume rises from stacks would decrease due to higher ambient air temperatures and reduced buoyancy effects; these decreases would be manifested in higher

ground-level concentrations of air pollutants located closer to their stacks. Air pollutant dispersion is also affected by weather variables such as windspeed and direction, temperature, precipitation patterns, cloud cover, atmospheric water vapor, and global circulation patterns (Smith and Tirpak 1988). Ozone pollution problems in many urban areas would worsen due to higher reaction rates at higher temperatures and lengthened summer seasons.

### IMPACT ON HUMAN HEALTH

Human health effects are manifested by changes in morbidity and increases in mortality, particularly for the elderly during hotter and extended summer periods. Geographical patterns in relation to health effects are also expected.

## 5.6 METEOROLOGY

Clinging to the surface of the earth is a thin mantle of air known as the atmosphere (Figure 5.6.1). Calling the atmosphere thin may be confusing; however, 99% of the atmosphere mass lies within just 30 km (19 mi) of the earth's surface, and 90% of the atmosphere's mass lies within just 15 km (9 mi) of the surface.

FIG. 5.6.1 Classification of atmosphere based on temperature. (This figure is not drawn to scale.)

The atmosphere is often classified in terms of temperature. Starting at the earth's surface and moving upward, temperature generally decreases with increasing altitude. This region, termed the *troposphere*, is of most interest to meteorologists because it is where weather and air pollution problems occur.

The *tropopause* is the boundary between the troposphere and the *stratosphere*. Below the tropopause, atmospheric processes are governed by turbulent mixing of air; but above it, they are not. In the stratosphere, temperature increases with height because of the high ozone concentration. Ozone absorbs radiation from the sun, resulting in an increase in stratospheric temperature.

The meteorological elements that have the most direct and significant effects on the distribution of air pollutants in the atmosphere are wind speed, wind direction, solar radiation, atmospheric stability, and precipitation.

### Wind

The effects of wind on the distribution of air pollutants in the atmosphere involve understanding the scales of air motion, wind rose, and turbulence.

### SCALES OF AIR MOTION

*Wind* is the motion of air relative to earth's surface. On the macroscale, the movement originates in the unequal distribution of atmospheric temperature and pressure over

the earth's surface and is influenced by the earth's rotation. The direction of wind flow is characteristically from high pressure to low, but the Coriolis force deflects the air current out of these expected patterns (see Figure 5.6.2). These phenomena occur on scales of thousands of kilometers and are exemplified by the semipermanent high- and low-pressure areas over oceans and continents.

On the mesoscale and microscale, topographical features critically influence wind flow. Surface variations have an obvious effect on wind velocity and the direction of air flow. Monsoons, sea and land breezes, mountain-valley winds, coastal fogs, windward precipitation systems, and urban heat islands are all examples of the influence of regional and local topography on atmospheric conditions. Mesoscale phenomena occur over hundreds of kilometers; microscale phenomena, over areas less than 10 kilometers.

For an area, the total effect of these circulations establishes the hourly, daily, and seasonal variation in wind speed and direction. The frequency distribution of wind direction indicates the areas toward which pollutants are most frequently transported.

## WIND ROSE

Wind speed determines the travel time of a pollutant from its source to a receptor and accounts for the amount of pollutant diffusion in the windward direction. Therefore, the concentration of pollutant at any receptor is inversely proportional to the wind speed. Wind direction determines in what direction a pollutant travels and what receptor is affected at a given time. Wind direction is normally defined by a *wind rose*, a graphic display of the distribution of wind direction at a location during a defined period. The characteristic patterns can be presented in either tabular or graphic forms.

Wind speed is usually measured by an anemometer, which consists of three or four hemispherical cups arranged around a vertical axis. The faster the rotation of the cups, the higher the speed of the wind. A wind vane indicates wind direction. Although wind is three-dimensional in its movement, generally only the horizontal component is denoted because the vertical component is much smaller.

A. If the earth did not turn, air would circulate in a fixed pattern.

B. The earth turns, creating variable wind patterns.

**FIG. 5.6.2** Global wind patterns. (Reprinted, with permission, from the American Lung Association.)

A wind rose is a set of wind statistics that describes the frequency, direction, force, and speed (see Figure 5.6.3). In this plot, the average wind direction is shown as one of the sixteen compass points, each separated by 22.5° measured from true north. The length of the bar for a direction indicates the percent of time the wind came from that direction. Since the direction is constantly changing, the time percentage for a compass point includes those times for wind direction at 11.25° on either side of the point. The percentage of time for a velocity is shown by the thickness of the direction bar. Figure 5.6.3 shows that the average wind direction from the southwest direction is 19% of the time and 7% of the time the southwesterly wind velocity is 16–30 mph.

Figure 5.6.4 shows the particulate fallout around an emission source and a wind rose based on the same time period.

The wind rose is imprecise in describing a point in a study region because the data are collected at one location in the region and not at each location. The data are often a seasonal or yearly average and therefore not accurate in describing any point in time in an ideal representation of atmospheric diffusion. A final limitation of wind rose is that the wind is only measured in the horizontal plane and is assumed identical at any height above the earth's surface. (Note: wind speed generally increases with height in lower levels due to the decrease of the frictional drag effect of the underlying ground surface features.)

### TURBULENCE

In general, atmospheric pollutants are dispersed by two mechanisms: wind speed and atmospheric turbulence.

FIG. 5.6.3 Wind rose showing direction and velocity frequencies.

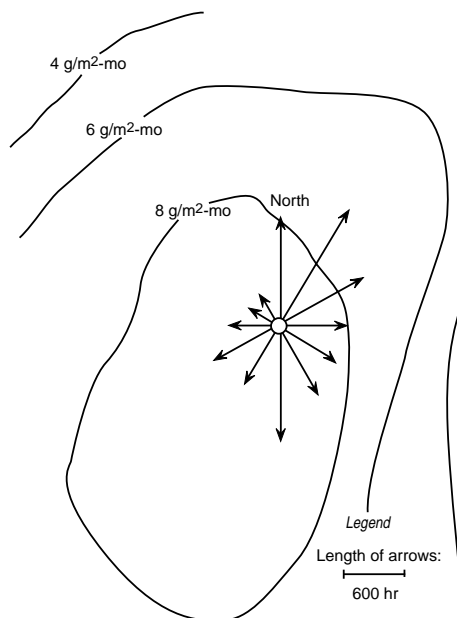

FIG. 5.6.4 Wind rose and corresponding particulate fallout pattern.

FIG. 5.6.5 Effect of wind direction variability or pollutant concentration from constant source. (Continuous emission of 4 units per sec.)

Atmospheric turbulence usually includes those wind flow fluctuations that have a frequency of more than 2 cycles/hr. The more important fluctuations have frequencies in the 1-to-0.01-cycles/sec range. Turbulent fluctuations occur randomly in both vertical and horizontal directions. This air motion provides the most effective mechanism to disperse or dilute a cloud or plume of pollutants. Figure 5.6.5 shows the dispersive effect of fluctuations in horizontal wind direction.

Turbulence is induced in air flow in two ways: by thermal current from heating below (*thermal turbulence*) and by disturbances or eddies from the passage of air over irregular, rough ground surfaces (*mechanical turbulence*). These small eddies feed large ones.

Generally turbulent motion and, in turn, the dispersive ability of the atmosphere, are enhanced during solar heating over rough terrain. Conversely, turbulence is suppressed during clear nights over smooth terrain.

## Lapse Rates and Stability

Lapse rates, stability, and inversions also affect the dispersion of pollutants in the atmosphere.

### LAPSE RATES

In the stratosphere, the temperature of the ambient air usually decreases with an increase in altitude. This rate of temperature change is called the *lapse rate*. Environmental engineers can determine this rate for a place and time by sending up a balloon equipped with a thermometer. The balloon moves through the air, not with it, and measures the temperature gradient of ambient air, called the *ambient lapse rate*, the *environmental lapse rate*, or the *prevailing lapse rate*.

Using the ideal-gas law and the law of conservation of energy, environmental engineers have established a mathematical ratio for expressing temperature change against altitude under adiabatic conditions (Petterssen 1968). This rate of decrease is termed the *adiabatic lapse rate*, which is independent of the prevailing atmospheric temperature.

Dry air, expanding adiabatically, cools at  $9.8^{\circ}\text{C}$  per km (or  $5.4^{\circ}\text{F}$  per 1000 ft), which is the dry adiabatic lapse rate (Smith 1973). In a wet as in a dry adiabatic process, a parcel of air rises and cools adiabatically, but a second factor affects its temperature. Latent heat is released as water vapor condenses within the saturated parcel of rising air. Temperature changes in the air are then due to the liberation of latent heat as well as the expansion of air. The wet adiabatic lapse rate ( $6^{\circ}\text{C}/\text{km}$ ) is thus less than the dry adiabatic lapse rate. Since a rising parcel of effluent gases is seldom completely saturated or completely dry, the adiabatic lapse rate generally falls somewhere between these two extremes.

### STABILITY

Ambient and adiabatic lapse rates are a measure of atmospheric stability. Figure 5.6.6 shows these stability conditions. The atmosphere is *unstable* as long as a parcel of air moving upward cools at a slower rate than the surrounding air and is accelerated upward by buoyancy force. Moving downward, the parcel cools slower and is accelerated downward. Under these conditions, vertical air motions and turbulence are enhanced.

Conversely, when a rising parcel of air is cooler than the surrounding air, the parcel settles back to its original elevation. Downward movement produces a warmer parcel, which rises to its original elevation. Under these conditions, vertical movement is dampened out by adiabatic cooling or warming, and the atmosphere is *stable*.

Figure 5.6.7 shows that the boundary line between stability and instability is the dry adiabatic lapse line. When

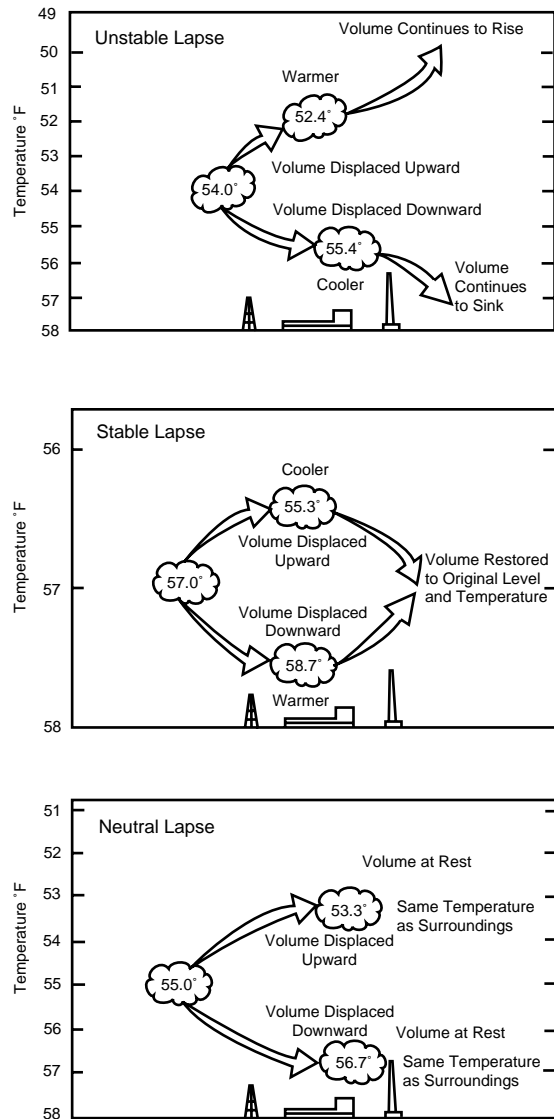

FIG. 5.6.6 The effect of lapse rate on vertical stability.

the ambient lapse rate exceeds the adiabatic lapse rate, the ambient lapse rate is termed *superadiabatic*, and the atmosphere is highly unstable. When the two lapse rates are equal, the atmosphere is *neutral*. When the ambient lapse rate is less than the dry adiabatic lapse rate, the ambient lapse rate is termed *subadiabatic*, and the atmosphere is stable (Figure 5.6.8). If the air temperature is constant throughout a layer of atmosphere, the ambient lapse rate is zero, the atmosphere is described as *isothermal*, and the atmosphere is stable (Battan 1979).

When the temperature of ambient air increases (rather than decreases) with altitude, the lapse rate is negative, or inverted, from the normal state. A negative lapse rate occurs under conditions referred to as an *inversion*, a state in which warmer air blankets colder air. Thermal or temperature inversions represent a high degree of atmospheric

FIG. 5.6.7 Relationship of the ambient lapse rates to the dry adiabatic rate.

FIG. 5.6.8 Typical ambient lapse rates during a sunny day and clear night.

stability (Battan 1979). An inversion is an extreme subadiabatic condition, thus almost no vertical air movement occurs.

## INVERSIONS

Three types of inversions develop in the atmosphere: radiational (surface), subsidence (aloft), and frontal (aloft).

### Radiational Inversions

A radiational inversion occurs at low levels, seldom above a few hundred feet, and dissipates quickly. This type of inversion occurs during periods of clear weather and light to calm winds and is caused by rapid cooling of the ground by radiation. The inversion develops at dusk and continues until the surface warms again the following day. Initially, only the air close to the surface cools, but after several hours, the top of the inversion can extend to 500 ft (see Figure 5.6.9). Pollution emitted during the night is caught under this “inversion lid.”

FIG. 5.6.9 Formation of subsidence inversion.

### Subsidence Inversions

A subsidence inversion is important in pollution control because it can affect large areas for several days. A subsidence inversion is associated with either a stagnant high-pressure cell or a flow aloft of cold air from an ocean over land surrounded by mountains (Cooper and Alley 1986). Figure 5.6.9 shows the inversion mechanism.

A significant condition is the subsidence inversion that develops with a stagnating high-pressure system (generally associated with fair weather). Under these conditions, the pressure gradient becomes progressively weaker so that winds become light. These light winds greatly reduce the horizontal transport and dispersion of pollutants. At the same time, the subsidence inversion aloft continuously descends, acting as a barrier to the vertical dispersion of the pollutants. These conditions can persist for several days, and the resulting accumulation of pollutants can cause serious health hazards.

Fog almost always accompanies serious air pollution episodes. These tiny droplets of water are detrimental in two ways: (1) fogs makes the conversion of  $\text{SO}_3$  to  $\text{H}_2\text{SO}_4$  possible, and (2) fogs sits in valleys and prevents the sun from warming the valley floor to break inversions, thus prolonging air pollution episodes.

Figure 5.6.10 shows the frequency of stagnation periods of high-pressure cells over the eastern United States.

### Frontal Inversions

A frontal inversion usually occurs at high altitudes and results when a warm air mass overruns a cold air mass below. This type of inversion is not important from a pollution control standpoint.

## Precipitation

Precipitation serves an effective cleansing process of pollutants in the atmosphere as follows:

**FIG. 5.6.10** Frequency of stagnating high-pressure cells over the eastern United States. The contours give the number of periods of four or more successive days between 1936–1965.

The washing out or scavenging of large particles by falling raindrops or snowflakes (washout)

The accumulation of small particles in the formation of raindrops or snowflakes in clouds (rainout)

The removal of gaseous pollutants by dissolution or absorption

The efficiencies of these processes depend on complex relationships between the properties of the pollutants and the characteristics of precipitation. The most effective and prevalent process is the washout of large particles in the lower layer of the atmosphere where most pollutants are released.

## Topography

The topographic features of a region include both natural (hills, bridges, roads, canals, oceans, rivers, lakes, and foliage) and manmade (cities, bridges, roads, and canals) elements in a region. The prime significance of topography is its effects on meteorological elements, particularly the local or small-scale circulations that develop. These circulations contribute either favorably or unfavorably to the transport and dispersion of the pollutants.

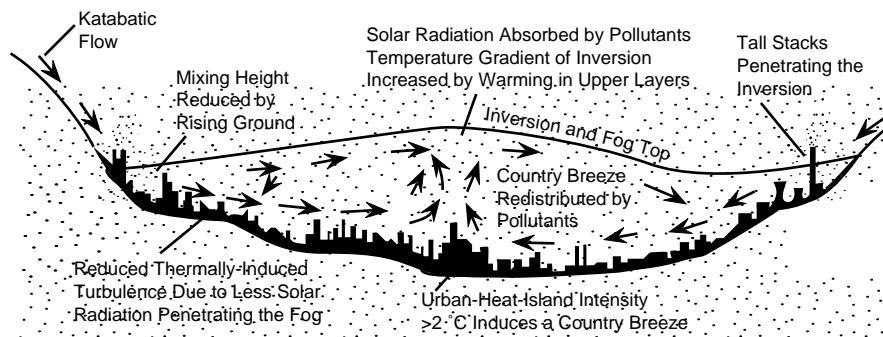

## LAND-SEA BREEZE

In the daytime, land heats rapidly, which heats the air above it. The water temperature remains relatively constant. The air over the heated land surface rises producing low pressure compared with the pressure over water. The resulting pressure gradient produces a surface flow off the water toward land. This circulation can extend to a considerable distance inland. Initially, the flow is onto the land, but as the breeze develops, the Coriolis force gradually shifts the direction so that the flow is more parallel to the land mass. After sunset and several hours of cooling by radiation, the land mass is cooler than the water temperature. Then, the reverse flow pattern develops, resulting in a wind off the land. During a stagnating high-pressure system when the transport and dispersion of pollutants are reduced, this short-period, afternoon increase in airflow can prevent the critical accumulation of pollutants.

## MOUNTAIN-VALLEY WINDS

In the valley region, particularly in winter, intensive surface inversions develop from air cooled by the radiation-

**FIG. 5.6.11.** Meteorology-pollution relationships during a smog in a valley location. (Reprinted, with permission, from D.M. Elsom, 1992, *Atmospheric pollution*, 2d ed., Oxford, U.K.: Blackwell Publishers.)

ally cooled valley wall surfaces. Populated and industrialized bottom valley areas are subject to a critical accumulation of pollutants during this period.

Areas on the windward side of mountain ranges expect added precipitation because of the forced rising, expansion, and cooling of the moving air mass with the resultant release of moisture. The precipitation increases the removal of pollutants.

#### URBAN-HEAT-ISLAND EFFECT

The increased surface roughness created by buildings throughout a city enhances the turbulence of airflow over the city, thus improving the dispersion of the pollutants emitted. However, at the same time, the city's buildings and asphalt streets act as a heat reservoir for the radiation received during the day. This heat plus the added heat from nighttime heating during cool months creates a tempera-

ture and pressure differential between the city and surrounding rural area so that a local circulation inward to the city develops. This circulation concentrates the pollutants in the city.

Figure 5.6.11 shows the combined effects of the urban-heat-island effect and katabatic winds.

## 5.7 METEOROLOGIC APPLICATIONS IN AIR POLLUTION CONTROL

This section gives examples of meteorologic applications in air pollution control problems.

#### Air Pollution Surveys

Air pollution surveys are unique in their development and conduct. A common goal is to obtain a representative sample from an unconfined volume of air in the vicinity of one or more emission sources.

Depending on the objectives of an air pollution survey, a mobile or fixed sampler can be used. Other than the obvious considerations such as accessibility and the relation-

ship to interfering pollutant sources, the principal factors in site selection are meteorology and topography. The controlling factor for site selection is wind movement. With some knowledge of the predominant wind direction, the environmental engineer can predict the path of pollution from the emission source to the point of ground-level impact and determine the most suitable location for an air monitoring site. The most convenient method for performing this analysis is to use the wind rose described in Section 5.5.

Besides wind direction and wind speed, other meteorological data necessary for sample correlations are temper-

ature, cloud cover, and lapse rate where possible. The environmental engineer uses local temperatures to estimate the contribution of home heating to the total pollutant emission rates.

The simplest case is one where one wind direction predominates over a uniform topography for an isolated plant emitting a single pollutant that remains unchanged in the atmosphere. Two monitors are used: one monitors the effects of the source and the other is placed upwind to provide background concentrations. Where wind directions vary and other emission sources are operating nearby, the environmental engineer requires additional samples to identify the concentrations attributable to the source.

Environmental engineers often use a variation of the wind rose, called a *pollution rose*, to determine the source of a pollutant. Instead of plotting all winds on a radial graph, they use only those days when the concentration of a pollutant is above a minimum. Figure 5.7.1 is a plot of pollution roses. Only winds carrying SO<sub>3</sub> levels greater than 250 μg/m are plotted. The fingers of the roses point to plant three. Pollution roses can be plotted for other pollutants and are useful for pinpointing sources of atmospheric contamination.

### Selection of Plant Site

In selecting a plant site, planners should consider the air pollution climatology of the area. They should prepare seasonal wind roses to estimate pollution dispersion patterns. Wind roses based on average winds excluding frontal weather systems are especially helpful. Planners must con-

sider the frequency of stagnant weather periods and the effects of topography and local wind systems, such as land-sea breezes and mountain-valley winds, with respect to dispersion patterns and nearby residential and industrial areas.

The location of the plant within an area can depend on local wind speed and directions data. For example, residential areas may lie downwind of a proposed plant, in line with the prevailing wind direction. Considering a more suitable site would reduce the air pollution impact of the plant. Figure 5.7.2 illustrates this point.

Data on temperature, humidity, wind speed and direction, and precipitation are generally available through official weather agencies. Other potential sources of information are local airports, military installations, public utilities, and colleges and universities. The National Climatological Data Center, Asheville, North Carolina, is a major source of information. The center also contracts to prepare specific weather summaries and frequency.

### Allowable Emission Rates

In plant planning, planners should consider local, state, and federal air pollution authorities, which can shutdown or curtail plant emission activities during times of air pollution emergency. Plants must have standby plans ready for reducing the emission of air contaminants into the atmosphere.

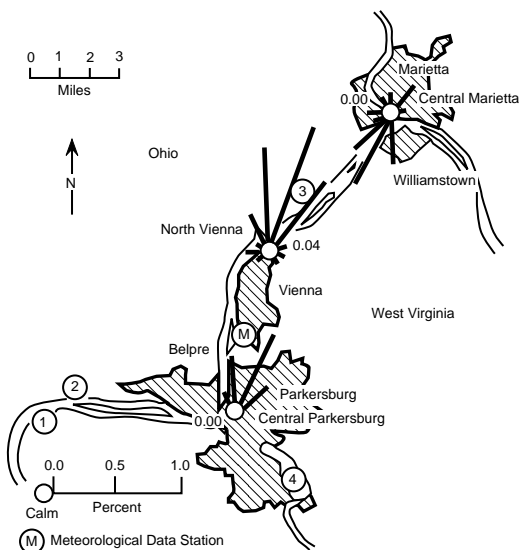

FIG. 5.7.1 Pollution roses, with SO<sub>2</sub> concentrations greater than 250 μg/m. The major suspected sources are the four chemical plants, but the data indicates that Plant Three is the primary culprit. (Reprinted, with permission, from P.A. Vesilind, 1983, *Environmental pollution and control*, Ann Arbor Science Publishers.)

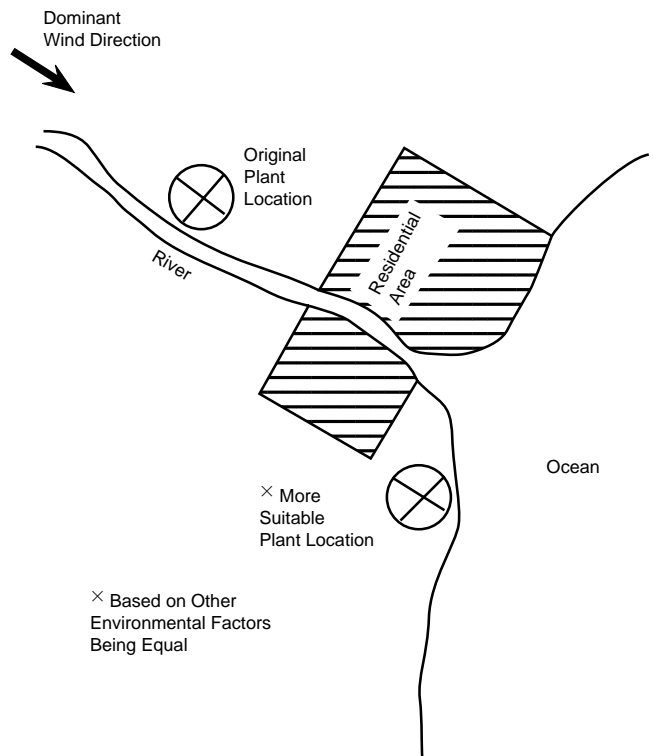

FIG. 5.7.2 Plant site selection within a localized region influenced by meteorological conditions.

A plant must control emission rates to ensure that problems do not occur even during poor dispersion conditions. This control requires full knowledge of the frequency of poor dispersion weather. In addition, weather conditions should be considered when plant start ups are scheduled or major repairs that may produce more emissions are undertaken.

## Stack Design

Section 5.4 presents stack design procedures and lists the weather parameters required. The stack height design must

consider the average height at stack elevation, average temperature, average mixing conditions (stability), and average lapse rate. The stack height design must also consider the average height and frequencies of inversions. For emission sources such as generating stations, the ideal stack height should exceed the most frequent inversion height. Also, planners should consider not only the averages of temperature, wind speed, and stability, but also the frequency with which worst-case combinations of these parameters occur.

—David H.F. Liu

# 5.8 ATMOSPHERIC DISPERSION MODELING

## The Gaussian Model

The goal of air quality dispersion modeling is to estimate a pollutant's concentration at a point downwind of one or more emission sources. Since the early 1970s, the U.S. EPA has developed several computer models based on the Gaussian (or normal) distribution function curve. The models were developed from the research of Turner (1964; 1970); Pasquill (1974; 1967), Gifford (1968; 1975), and others. The Gaussian-based model is effective for representing the plume diffusion for a range of atmospheric conditions. The technique applies the standard deviations of the Gaussian distribution in two directions to represent the characteristics of the plume downwind of its origin. The plume's shape, and hence the standard deviations, varies according to different meteorological conditions. The following equation gives the ordinate value of the Gaussian distribution:

$$y = [1/(2\pi\sigma^2)]\{\exp[-(1/2)(x - \bar{x})^2/\sigma^2]\} \quad 5.8(1)$$

which is depicted as a bell-shaped curve as shown in Figure 5.8.1.

The coordinate system used in models dealing with the Gaussian equation defines the x axis as downwind of the source, the y axis as horizontal (lateral) to the x axis, and the z axis as the vertical direction. The Gaussian lateral distribution can be restated as follows:

$$\chi(y) = [1/(2\pi\sigma_y^2)]\{\exp[-(1/2)(y/\sigma_y)^2]\} \quad 5.8(2)$$

Shown in Figure 5.8.2.

A second, similar Gaussian distribution describes the distribution of the plume in the vertical, or z, direction. The distribution of the plume around the centerline in both

the y and z directions can be represented when the two single distributions in each of the two coordinate directions are multiplied to give a double Gaussian distribution. Projecting this distribution downwind through x gives the volume of space that contains the plume as shown in Figure 5.8.3.

Shifting the centerline upward a distance H corrects the equation for emissions at the effective stack height (stack height plus plume rise above stack) as follows:

$$\chi(x,y,z;H) = [Q/(2\pi\sigma_y\sigma_zu)]\{\exp[-(1/2)(y/\sigma_y)^2]\} \{\exp[-(1/2)(z - H/\sigma_z)^2]\} \quad 5.8(3)$$

where:

$\chi(x,y,z; H)$  = the downwind concentration at a point  
x,y,z,  $\mu\text{g}/\text{m}^3$

Q = the emission rate of pollutants, g/s

- |                      |   |
|----------------------|---|
| $\sigma_y, \sigma_z$ | = the plume standard deviations, m                          |
| $u$                  | = the mean vertical wind speed across the plume height, m/s |
| $y$                  | = the lateral distance, m                                   |
| $z$                  | = the vertical distance, m                                  |
| $H$                  | = the effective stack height, m                             |

As the plume propagates downwind, at some point the lowest edge of the plume strikes the ground. At that point, the portion of the plume impacting the ground is reflected upward since no absorption or deposition is assumed to occur on the ground (conservation of matter). This reflection

causes the concentration of the plume to be greater in that area downwind and near the ground from the impact site. Functionally this effect can be mimicked, within the model with a virtual point source created identical to the original, emitting from a mirror image below the stack base as shown in Figure 5.8.4. Adding another term to the equation can account for this reflection of the pollutants as follows:

$$\chi(x,y,z; H) = [Q/(2\pi\sigma_y\sigma_z u)] \{ \exp[-(1/2)(y/\sigma_y)^2] \exp[-(1/2)(z - H/\sigma_z)^2] + \exp[-(1/2)(z + H/\sigma_z)^2] \} \quad 5.8(4)$$

When the plume reaches equilibrium (total mixing) in the layer, several more iterations of the last two terms can be added to the equation to represent the reflection of the plume at the mixing layer and the ground. Generally, no more than four additional terms are needed to approximate total mixing in the layer.

For the concentrations at ground level,  $z$  can be set equal to zero, and Equation 5.8(4) reduces as follows:

$$\chi(x,y,H) = [Q/(\pi\sigma_y\sigma_z u)] \{ \exp[-(1/2)(y/\sigma_y)^2] \exp[-(1/2)(H/\sigma_z)^2] \} \quad 5.8(5)$$

In addition, the plume centerline gives the maximum values. Therefore, setting  $y$  equal to zero gives the following equation:

$$\chi(x,H) = [Q/(\pi\sigma_y\sigma_z u)] \{ \exp[-(1/2)(H/\sigma_z)^2] \} \quad 5.8(6)$$

which can estimate the concentration of pollutants for a distance  $x$ .

Finally, if the emission source is located at ground level with no effective plume rise, the equation can be reduced to its minimum as follows:

$$\chi(x) = Q/(\pi\sigma_y\sigma_z u) \quad 5.8(7)$$

A number of assumptions are typically used for Gaussian modeling. First, the analysis assumes a steady-state system (i.e., a source continuously emits at a constant strength; the wind speed, direction, and diffusion characteristics of the plume remain steady; and no chemical transformations take place in the plume). Second, diffusion in the  $x$  direction is ignored although transport in this direction is accounted for by wind speed. Third, the plume is reflected up at the ground rather than being deposited, according to the rules of conservation of matter (i.e., none of the pollutant is removed from the plume as it moves downwind). Fourth, the model applies to an ideal aerosol or an inert gas. Particles greater than 20  $\mu\text{m}$  in diameter tend to settle out of the atmosphere at an appreciable rate. More sophisticated EPA models consider this deposition, as well as the decay or scavenging of gases. Finally, the calculations are only valid for wind speeds greater than or equal to 1 m per sec.

Application of the Gaussian models is limited to no more than 50 km due to extrapolation of the dispersion coefficients. Other factors that influence the Gaussian dis-

**FIG. 5.8.4** Multiple plume images used to simulate plume reflections. (Reprinted from U.S. Environmental Protection Agency (EPA), 1987, *Industrial source complex (ISC) dispersion model user's guide—Second edition (revised)*, Vol. 1, EPA-450/4-88-002a, Research Triangle Park, N.C.: Office of Air Quality Planning and Standards, [December].)

persion equations are ground roughness, thermal characteristics, and meteorological conditions. Plume dispersion tends to increase as each of these factors increases, with the models most sensitive to atmospheric stability.

## PLUME CHARACTERISTICS

Boilers or industrial furnaces that have a well-defined stack and emissions resulting from products of combustion are the most common sources of pollutants modeled. The hot plume emitted from the stack rises until it has expanded and cooled sufficiently to be in volumetric and thermal equilibrium with the surrounding atmosphere. The height at which the plume stabilizes is referred to as the effective plume height ( $H$ ) and is defined as:

$$H = h_s + \Delta H \quad 5.8(8)$$

where ( $h_s$ ) is the physical stack height portion and ( $\Delta H$ ) is the plume rise portion as shown in Figure 5.8.5. The plume rise is the increase in height induced by both the momen-

tum and buoyancy effects of the plume. The momentum component of the rise is the physical speed at which the effluent is ejected from the stack, while the buoyancy component is due to the thermal characteristics of the plume in relation to ambient air. In the modeling, pollutants are assumed either to emit from a point directly above the stack at the effective plume height or to gradually rise over some distance downwind of the emission point until the effective plume height is reached.

The standard plume rise formula used in most EPA air dispersion models is based on a review of empirical data performed by Briggs (1969). (The next section includes a more detailed description.) The Briggs formula takes into account both momentum and buoyancy factors as well as meteorological conditions.

## DISPERSION COEFFICIENTS

Sigma y ( $\sigma_y$ ) and sigma z ( $\sigma_z$ ) are the standard deviations of the Gaussian distribution functions. Since they are used

**FIG. 5.8.5** Effective stack height ( $H$ ), with dispersion beginning at a theoretical point above the stack. (Adapted with permission from American Society for Mechanical Engineers [ASME] Air Pollution Control Div., 1973, *Recommended guide for the prediction of the dispersion of airborne effluents*, 2d ed., New York: ASME.)

in describing a plume as it disperses, they increase with time and distance traveled. The rates of growth for  $\sigma_y$  and  $\sigma_z$  depend upon meteorological conditions. Sigma  $y$  is generally larger than  $\sigma_z$ , since no stratification obstacles are in the  $y$  (horizontal) direction. Sigma  $y$  and  $\sigma_z$  are strongly influenced by heat convection and mechanical turbulence, and, as these forces become more pronounced, the sigmas increase more quickly.

As a standard deviation,  $\sigma_y$  and  $\sigma_z$  characterize the broadness or sharpness of the normal distribution of pollutants within the plume. As both sigmas increase, the concentration value of a pollutant at the plume centerline decreases. However, the total amount of the pollutant in the plume remains the same; it is merely spread out over a wider range and thus, the concentration changes. Approximately two thirds of the plume is found between plus or minus one sigma, while 95% of the plume is found between plus or minus 2 sigma as shown in Figure 5.8.2. The plume edge is considered to be that concentration that is one-tenth the concentration of the centerline.

Sigma  $y$  and  $\sigma_z$  are generally determined from equations derived using empirical data obtained by Briggs (1969) and McElroy and Pooler (1968) and research performed by Bowne (1974). Figures 5.8.6 and 5.8.7 show plots of these curves. These plots were developed from the observed dispersion of a tracer gas over open, level terrain.

## STABILITY CLASSES

In the late 1960s, Pasquill developed a method for classifying atmospheric conditions which was later modified by Gifford (1975), resulting in six stability classes, labeled A through F. The method was based on the amount of incoming solar radiation, cloud cover, and surface wind speed as shown in Table 5.8.1.

Stability greatly affects plume behavior as demonstrated by the dispersion curves discussed above. Classes E and F indicate stable air in which stratification strongly dampens mechanical turbulence, typically with strong winds in a constant wind direction. These conditions can produce a fanning plume that does not rise much and retains a narrow shape in the vertical dimension for a long distance downwind as shown in part (a) of Figure 5.8.8.

A situation where a plume in a stable layer is brought quickly to the surface by turbulence in a less stable layer is termed *fumigation* and is shown in part (b) of Figure 5.8.8. This can occur as the result of heat convection in the morning.

Class D stability is neutral, with moderate winds and even mixing properties. These conditions produce a coning plume as shown in part (c) of Figure 5.8.8. Classes A, B, and C represent unstable conditions which indicate various levels of extensive mixing. These conditions can produce a looping plume as shown in part (d). If the effective stack height exceeds the mixing height, the plume is assumed to remain above it, and no ground-level concentrations are calculated. This effect is known as lofting and is shown in part (e).

Rough terrain or heat islands from cities increase the amount of turbulence and change the classification of ambient conditions, usually upward one stability class.

In general, a plume under stability class A conditions affects areas immediately near the emission source with high concentrations. Class F stability causes the plume to reach ground level further away, with a lower concentration (unless terrain is a factor).

## WIND SPEED

The wind speed is the mean wind speed over the vertical distribution of a plume. However, usually the only wind

**FIG. 5.8.6** Horizontal dispersion coefficient as a function of downwind distance from the source. (Reprinted from D.B. Turner, 1970, *Workbook of atmospheric dispersion estimates (Revised)*, Office of Air Programs Pub. No. AP-26, Research Triangle Park, N.C.: U.S. EPA.)

speed available is that monitored at ground-level meteorological stations. These stations record ambient atmospheric characteristics, usually at the 10-m level, and typically with lower wind speeds than those affecting the plume. These lower speeds are due to the friction caused by the surface as shown in Figure 5.8.9. Therefore, the wind speed power law must be used to convert near-surface wind speed data into a wind speed representative of the conditions at the effective plume height. The wind speed power law equation is as follows:

$$u_2 = u_1 * (z_2/z_1)^p \quad 5.8(9)$$

where  $u_1$  and  $z_1$  correspond to the wind speed and vertical height of the wind station, while  $u_2$  and  $z_2$  pertain to the characteristics at the upper elevation. This formula is empirical, with the exponent derived from observed data. The exponent ( $p$ ) varies with the type of ambient weather conditions, generally increasing with stability and surface roughness (Irwin 1979). It can range from 0.1 for calm conditions to 0.4 for turbulent weather conditions. Table 5.8.2 shows exponents for various types of surface characteristics. Table 5.8.3 shows selected values for both ur-

ban and rural modes as used for the six stability categories in the industrial source complex (ISC3) models.

## Plume Rise and Stack Height Considerations

In dispersion modeling, the plume height is critical to the basic equation for determining downwind concentrations at receptors. Several factors affect the initial dispersion of the plume emitted from a stack, including the plume rise, the presence of buildings or other features disturbing the wind stream flow, and the physical stack height. This section discusses these factors.

### PLUME RISE

Various attempts have been made to estimate the plume rise from stationary sources. Two types of equations have resulted: theoretical and empirical. Theoretical models are generally derived from the laws of buoyancy and momentum. They are often adjusted for empirical data. Empirical models are developed from large amounts of ob-

**FIG. 5.8.7** Vertical dispersion coefficient as a function of downwind distance from the source. (Reprinted from Turner, 1970.)

served data such as tracer studies, wind tunnel experiments, and photographic evidence. Most plume rise equations apply to uniform or smoothly varying atmospheric conditions. An important consideration is that while they often predict the plume rise reasonably well under similar conditions, they can give wrong answers for other conditions.

### Momentum and Buoyancy Factors

The plume rises mainly due to two factors: 1) the velocity of the exhaust gas, which imparts momentum to the plume, and 2) the temperature of the exhaust gas, which gives the plume buoyancy in ambient air. The momentum flux comes from mechanical fans in duct systems and the

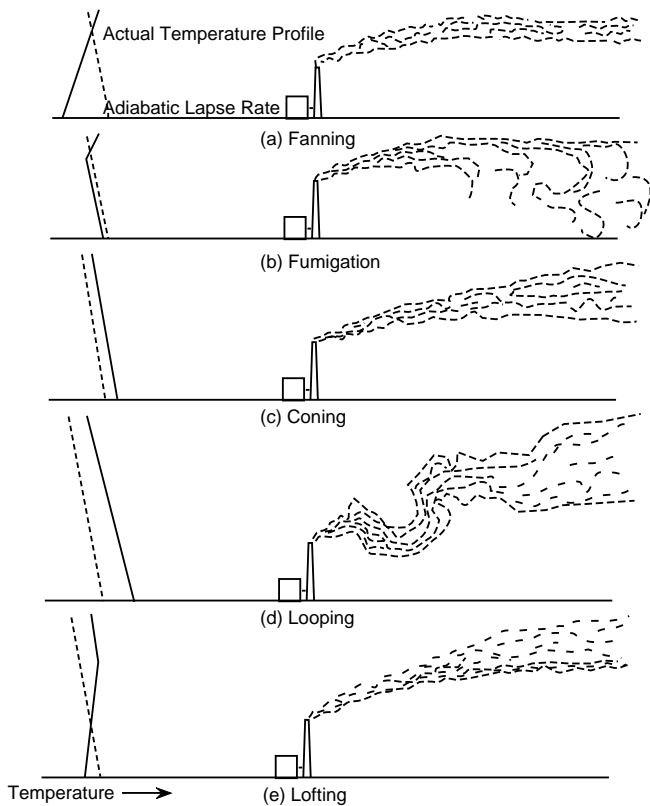

**TABLE 5.8.1 KEY TO PASQUILL STABILITY CATEGORIES**

Surface Wind Speed (at 10 m) (m/sec)	Day			Night	
	Incoming Solar Radiation			Thinly Overcast or $\geq \frac{1}{8}$ Low Cloud	Clear or $\leq \frac{1}{8}$
	Strong	Moderate	Slight		
<2	A	A-B	B		
2-3	A-B	B	C	E	F
3-5	B	B-C	C	D	E
5-6	C	C-D	D	D	D
>6	C	D	D	D	D

Note: The neutral class D should be assumed for overcast conditions during day or night.

**FIG. 5.8.8** Effect of temperature profile on plume rise and diffusion. (Reprinted from G.A. Briggs, 1969, *Plume rise*, U.S. Atomic Energy Commission Critical Review Series T10-25075. Clearinghouse for Federal Scientific and Technical Information.)

natural draft that occurs in the stack. If the gas in the plume is less dense than the surrounding atmosphere, this condition also causes the plume to rise and adds to its upward momentum. The plume rise also depends upon the growth of the plume, which is caused by turbulence, whether pre-existing in the atmosphere or induced by interaction with the plume. One method of increasing the upward momentum of the plume is to constrict the exit diameter of the stack.

The buoyancy flux is an effect of the plume's increased temperature. For most large combustion sources (such as power plants), the buoyancy flux dominates the momentum flux. Buoyant plumes contribute to both the vertical and horizontal velocity of the plume, in addition to that caused by ambient turbulent levels. This condition is caused by entrainment of the surrounding air into the expanding plume in relation to its surroundings. Buoyancy can also affect both  $\sigma_y$  and  $\sigma_z$  because of buoyancy-induced atmospheric turbulence.

### Meteorological Factors

Some meteorological factors affecting plume rise include wind speed, air temperature, atmospheric stability, turbulence, and wind shear at the stack height. As these conditions vary, the rise of the plume is enhanced or reduced. The final effective plume height is reached only at some point downwind of the stack; this condition is known as gradual plume rise. Many dispersion models (especially where terrain is an important consideration) incorporate special algorithms to analyze ambient concentrations in

**FIG. 5.8.9** Variation of wind with height for different roughness elements (figures are percentages of gradient wind). (Reprinted from D.B. the region before the final rise is attained. However, models usually apply the final effective stack height at the point above the source to simplify calculations.

An early equation to predict plume rise was developed by Holland (1953) for the Atomic Energy Commission. This equation accounted for momentum and buoyancy by having a separate term for each. A major problem with the equation was that it did not account for meteorological effects. At the time of his work, Holland recognized that the formula was appropriate only for class D stability conditions.

**BRIGGS PLUME RISE**

Briggs (1969) developed a plume rise formula that is applicable to all stability cases. The Briggs plume rise formula is now the standard used by the EPA in its disper-

sion models, but it is not as straightforward as Holland's approach. For the Briggs equation, determining the buoyancy flux,  $F_b$ , is usually necessary using the following equation:

$$F_b = g v_s d_s^2 [(\Delta T)/4T_s] \tag{5.8(10)}$$

where:

- $g$  = the gravitational constant (9.8 m/s<sup>2</sup>)
- $v_s$  = the stack gas exit velocity, m/s
- $d_s$  = the diameter of the stack, m
- $T_s$  = the stack gas temperature, deg. K
- $\Delta T$  = the difference between  $T_s$  and  $T_a$  (the ambient temperature), deg. K

When the ambient temperature is less than the exhaust gas temperature, it must be determined whether momentum or buoyancy dominates. Briggs determines a crossover temperature difference  $(\Delta T)_c$  for  $F_b \geq 55$ , and one for  $F_b < 55$ . If  $\Delta T$  exceeds  $(\Delta T)_c$ , then a buoyant plume rise algorithm is used; if less, then a momentum plume rise equation is employed. The actual algorithms developed by Briggs to calculate the plume rise further depend upon other factors, such as the atmospheric stability, whether the plume has reached the distance to its final rise (i.e., gradual rise), and building downwash effects (U.S. EPA 1992d).

**DOWNWASH**

All large structures distort the atmosphere and interfere with wind flow to some extent. These atmospheric distortions usually take the form of a wake, which consists of a pocket of slower, more turbulent air. If a plume is

Source: U.S. Environmental Protection Agency (EPA), 1987, *Industrial source complex (ISC) dispersion model user's guide—Second edition (Revised)*, Vol. 1, EPA-450/4-88-002a (Research Triangle Park, N.C.: Office of Air Quality Planning and Standards [December]).

emitted near a wake, it is usually pulled down because of the lower pressure in the wake region. This effect is termed *downwash*. When downwash occurs, the plume is brought down to the ground near the emission source more quickly.

A wake that causes downwash usually occurs as the result of one of three physical conditions: 1) the stack, referred to as stack-tip downwash, 2) local topography, or 3) nearby large structures or building downwash. Figure 5.8.10 shows examples of each of these conditions.

### Stack-Tip Downwash

Stack-tip downwash occurs when the ambient wind speed is high enough relative to the exit velocity of the plume so that some or all of the plume is pulled into the wake directly downwind of the stack, as shown in Figure 5.8.11. This downwash has two effects on plume rise. First, the pollutants drawn into the stack wake leave the stack region at a lower height than that of the stack and with a lower upward velocity. Second, the downwash increases the plume cross section, which decreases the concentration.

To avoid stack-tip downwash, environmental engineers should consider the ratio of emission velocity ( $v_s$ ) to wind speed velocity at the stack height ( $u_s$ ) in the stack design. If  $v_s < 1.5 u_s$ , then the physical stack height should be adjusted by the following equation:

$$h_{std} = 2d_s[(v_s/u_s) - 1.5] \quad 5.8(11)$$

If  $v_s/u_s > 1.5$ , then stack-tip downwash is avoided since the exhaust gas is emitted from the stack at sufficient velocity to clear the downwash area on the downwind side of the stack. If  $v_s/u_s < 1.0$ , downwash will probably occur, possibly seriously. For intermediate values of  $v_s/u_s$ ,

FIG. 5.8.10 Physical conditions that cause downwash. Reprinted from G.A. Briggs, 1969. *Plume rise*, U.S. Atomic Energy Commission Critical Review Series TID-25075, Clearinghouse for Federal Scientific and Technical Information.

downwash may occur depending on the ambient conditions at the time.

### Downwash Caused by Topography

Downwash can also be caused by local topography. Large hills or mountains can change the normal wind patterns of an area. If the stack is located closely downwind of a hill above stack height, the air flowing off the hill can cause the plume to impact closer to the stack than normal as shown in part (c) of Figure 5.8.10. Modeling of these situations often employs physical models in wind tunnels. A recently developed model, the complex terrain dispersion model plus algorithms for unstable situations (CTDM-PLUS), employs a critical hill height calculation that determines if the plume impacts the hill or follows the uninterrupted laminar flow around it (U.S. EPA 1989).

### Building Downwash

Large structures surrounding the stack also affect ambient wind conditions. The boundaries of the wake region resulting from surrounding structures are not sharply defined. They depend on the three-dimensional characteristics of the structure and are time dependent. The extent of distortion depends extensively upon building structure geometry and wind direction. Generally, a single cylindrical structure (e.g., a free-standing silo) has little influence on the wind flow compared to a rectangular structure.

**FIG. 5.8.12** Building structure downwash with cavity zone and wake effect. (Reprinted, with permission, from American Society of Mechanical Engineers [ASME].)

Part (b) in Figure 5.8.10 shows the building downwash that occurs when the plume is drawn into a wake from a nearby structure. Two zones exist within the downwash area of a structure. The first zone, which extends approximately three building heights downwind, is the cavity region where plume entrainment can occur. The second zone, which extends from the cavity region to about ten times the lesser dimension of the height or projected width, is the wake region where turbulent eddies exist as a result of structure disturbance to the wind flow. Figure 5.8.12 shows an example of these zones. Generally, the cavity region concentration is higher than the wake region concentration due to plume entrainment. Bittle and Borowsky

(1985) examined the impact of pollutants in cavity zones and found several calculations apply depending on the building and stack geometry. Beyond these zones, wind flow is unaffected by the structure.

The first downwash calculations were developed as the result of studies in a wind tunnel by Snyder and Lawson (1976) and Huber (1977). However, these studies were limited to a specific stability, structure shape, and orientation to the wind. Additional work by Hosker (1984), Schulman and Hanna (1986), and Schulman and Scire (1980) refined these calculations. Figure 5.8.13 shows the areas where the Huber-Snyder and Schulman-Scire downwash calculations apply. The following equation determines whether the Huber-Snyder or Schulman-Scire downwash calculations apply:

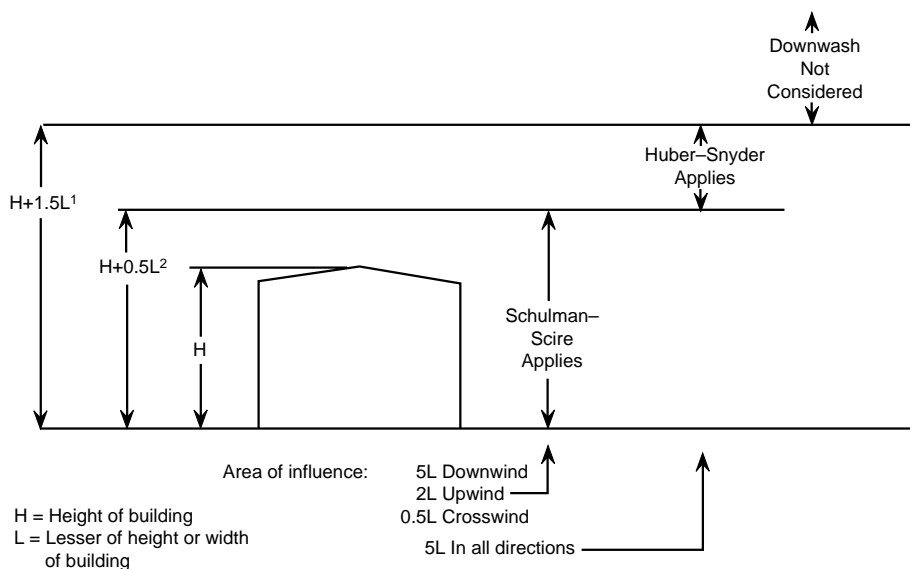

$$h_s = H + 0.5L \quad 5.8(12)$$

where:

- $h_s$  = the physical stack height
- $H$  = the structure height
- $L$  = the lesser dimension of the height or projected width

The adjustments are made to the dispersion parameters.

To avoid building downwash, the EPA has developed a general method for designing the minimum stack height needed to prevent emissions from being entrained into any wake created by the surrounding buildings. In this way, emissions from a stack do not result in an excessive concentration of the pollutant close to the stack. This ap-

<sup>1</sup>Compare  $H+1.5L$  to plume elevation (stack height above grade + momentum plume rise  $2L$  downwind-stack-tip downwash)

<sup>2</sup>Compare  $H+.5L$  to physical stack height above grade

**FIG. 5.8.13** Selection of downwash algorithms in the ISCST model. (Reprinted, with permission, from Trinity Consultants, Inc., 1989, *Atmospheric diffusion notes*, Issue no. 13, Dallas, Tex. [June].)

proach is called the good engineering practice (GEP) of stack height design (U.S. EPA 1985) and retroactively covers all stacks built since December 31, 1970. The following equation determines the GEP stack height:

$$H_{GEP} = H + 1.5(L) \quad 5.8(13)$$

where:

- $H_{GEP}$  = the GEP stack height
- $H$  = the maximum height of an adjacent or nearby structure
- $L$  = the lesser dimension of the height or projected width of an adjacent or nearby structure

The projected width of a structure is the exposed area perpendicular to the wind as shown in Figure 5.8.14. Environmental engineers should check all structures within  $5L$  of the stack for their possible effect on the plume. The range of influence for a given structure is defined by Tickvart (1988) as  $2L$  upwind of the structure,  $5L$  downwind, and  $0.5L$  on the sides parallel to the wind flow.

### TALL STACKS

If concentration impacts are excessive, constructing a tall stack is one approach to reduce them. A tall stack dilutes ambient ground-level concentrations near the emission source. However, this approach does not reduce emission levels or total pollution loadings in a region; it merely provides greater initial dispersion at the source. The EPA regulates stack height under its tall stacks policy to encourage better control technology application.

*Tall stacks* describes stacks that are greater than the GEP stack height. For stacks which are taller than GEP guidelines, dispersion modeling is conducted as if the emission source has a GEP stack height. When the stack height is at the GEP level, downwash is not likely to occur, and modeling can proceed without further changes. If the proposed or existing stack is less than the GEP stack height, surrounding structures must be investigated as possible downwash sources for modifying dispersion parameters in the air dispersion model. Under GEP guidelines, however, a source that has a GEP stack height less than 65 m can raise it to that level (and still be considered GEP).

A consideration for building a tall stack is the cost of construction; investments for tall stacks usually start at \$1 million, and costs of \$4–5 million are not uncommon (Vatavuk 1990). Stacks of this size typically consist of an outer shell and a liner. The outer shell is usually constructed of concrete, while the liner is usually steel or acid-resistant brick. The choice of liner depends on whether the exhaust gas is above the acid dew point (steel above it, brick below). Given these costs, building a stack taller than GEP is rare; however, constructing a stack below GEP and conducting the additional downwash modeling required may be worthwhile. In some cases, if the environmental engineer is involved early in the design phase of the pro-

FIG. 5.8.14 GEP determination of projected structure width and associated region of adverse influence for a structure in four different wind directions. (Reprinted from U.S. Environmental Protection Agency (EPA), 1985, *Guideline for determination of good engineering practice stack height [Technical support document for the stack height regulations] [Revised]*, EPA-450/4-80-023R, Research Triangle Park, N.C.: U.S. EPA, Office of Air Quality Planning and Standards [June].)

ject, designing the height and shape of buildings and nearby structures to lessen the need for a taller stack is possible.

### Computer Programs for Dispersion Modeling

Air quality dispersion models are useful tools for determining potential concentration impacts from proposed as well as existing sources. The models can be categorized into four general classes: Gaussian, numerical, statistical (empirical), and physical. The first three models are computer based, with numerical and Gaussian models dominating the field. This section focuses on Gaussian-based models since they are the most widely applied. This wide application is almost entirely due to their ease of application and the conservative estimates they provide, despite

any of their shortcomings in precisely describing a plume's diffusion in the atmosphere.

Gaussian-based models generally require three types of input data: source emission data, receptor data, and meteorological data, though the latter two can be assumed in some cases. Source emission data provide the characteristics of the pollutant released to the atmosphere. Receptor data provide the location where a predicted concentration is desired. Meteorological data provide the conditions for the model to determine how the emissions are transported from the source to the receptor.

## GUIDELINE MODELS

To promote consistency in applying models, the U.S. EPA has developed a document entitled *Guideline on Air Quality Models* (1978; 1986; 1987; 1993a; 1996). In this document, the EPA summarizes the performance of models in several comparative analyses and suggests the best applications of the model. As a result of the EPA's evaluations, those that perform well for a general set of conditions are classified as *Appendix A* models, and these models are listed in [Table 5.8.4](#). Of the models listed, only the urban airshed model (UAM) and the emission and dispersion model (EDMS) are not Gaussian-based.

Models not classified as Appendix A but recognized as having potential application for a specific case can be used pending EPA approval. These models are designated as Appendix B models and are listed in [Table 5.8.5](#). However, a performance demonstration may be required for an Appendix B model to demonstrate its suitability over a standard Appendix A model. This section addresses Appendix A models.

All Appendix A and B models and user's documentation are available from the U.S. Department of Commerce's National Technical Information Service (NTIS), in Springfield, Virginia 22161. In addition, model codes and selected abridged user's guides are available from the U.S. EPA's Support Center for Regulatory Air Models Bulletin Board System (SCRAM BBS), which can be accessed on the Internet (at <http://ttnwww.rtpnc.epa.gov>).

## MODEL OPTIONS

Due to the range and combinations of physical conditions, dispersion models are often simplified and designed for specialized applications in limited situations. The EPA has designated Appendix A models for use under such specific applications and may require the selection of predetermined options for regulatory application. Some examples of specialized functions include simple screening versus refined modeling, terrain features, surrounding land use, pollutant averaging period, number and type of sources to be modeled, and additional influences to the release. These functions are discussed next.

## SCREENING AND REFINED MODELS

Dispersion models have two levels of sophistication. The first, referred to as *screening modeling*, is a preliminary approach designed to simplify a source's emissions and provide conservative plume concentration impact estimates. The model user compares the results of screening modeling to the NAAQS, prevention of significant deterioration (PSD) increments, and/or ambient significance levels to determine if a second level of analysis, *refined modeling*, is required for a better estimate of the predicted concentrations. The purpose of screening is to identify if the potential for exceeding applicable air quality threshold levels exists, and thus the need for refined analysis. Screening eliminates the time and expense of refined modeling if the predicted concentrations do not approach the applicable levels.

A refined model provides a more detailed analysis of the parameters and thus gives a more accurate estimate of the pollutant concentration at receptors. However, a refined model demands more specific input data. The specific data can include topography, better receptor grid resolution, downwash or other plume adjustments, and pollutant decay or deposition.

## SIMPLE AND COMPLEX TERRAIN

Air quality dispersion models can also be divided into three categories based on their application to terrain features (Wilson 1993) which address the relationship between receptor elevations and the top of the stack. Early models were developed without any terrain consideration (i.e., they were flat). In simple terrain models, receptors are located below the stack top, while in complex terrain models, receptors are located at or above the stack top.

More recently, model developers have focused attention on elevations which are located between the stack top and the final height of the plume rise. These elevations are classified as intermediate terrain (see [Figure 5.8.15](#)), and calculations within the intermediate region can be evaluated by either simple or complex models. The model predicting the highest concentration for a receptor is conservatively selected for that point. Thus, intermediate terrain is an overlapping region for model predictions.

A model, CTDMPLUS, is included in the EPA's Appendix A to address this concern. The model can predict concentrations at the stack top or above for stability conditions and has been approved for intermediate and complex terrain applications (U.S. EPA 1989).

## URBAN AND RURAL CLASSIFICATION

EPA recommends models for either urban or rural applications, and most models contain an option for selecting urban or rural dispersion coefficients. These coefficients

affect the plume's spread in the y and z directions and are determined by the characteristics of the area surrounding the site. In heavily developed areas such as cities, the urban heat island and structures affect the surrounding atmosphere, increasing turbulence and air temperature. In the country, the foliage and undeveloped land reduce long-wave radiation and generate less turbulence. The amount of turbulence generated by each of these locations affects how the plume is dispersed in the atmosphere.

Irwin (1978) recommends two methods for categorizing the surrounding area as urban or rural. One technique relies on a methodology developed by Auer (1978), which characterizes the land use within a 3-km radial area. The second technique is based on a population density threshold (750 people/sq km) within a 3-km area. The Auer method is typically the preferred approach; it would identify a large industrial plant with storage yards (i.e., a steel mill) as an industrial (urban) site instead of an unpopulated rural site. [Table 5.8.6](#) lists the Auer land use categories.

## AVERAGING PERIODS

While several averaging periods are available for pollutants, the models are divided into two groups. The first group, referred to as short-term models, handles averaging periods from an hour to a year using hourly meteorological conditions. Note that most refined short term models calculate concentrations for block averaging periods rather than for running average periods within a day. Screening models fall into this category and predict concentrations for one averaging period only.

Long-term models use meteorological conditions ranging from a month or season to one or more years. The climatological data used in these models are generated from hourly data into joint frequency–distribution tables of wind speed, wind direction, and Pasquill–Gifford stability categories. These data are referred to as stability array (STAR) data sets.

## SINGLE AND MULTIPLE SOURCES

To simplify calculations, some models predict concentrations for only one source at a time, while others can calculate concentrations for a complex combination of sources. Screening models are usually limited to one source. As a compromise to these two extremes, some models collocate numerous sources at the same point and add individual source concentrations together. This approach is usually applied for conservative screening estimates.

## TYPE OF RELEASE

Four types of releases can be simulated: point, area, line, and volume sources. Some models can be limited to the

types of releases they handle. For most applications, line sources can be treated as area or volume sources, as well as in individual line models (see the subsection on mobile and line source modeling). Point sources are the most common modeling application and are defined by height, temperature, diameter, and velocity parameters.

In some cases, small or insignificant point sources may be grouped into either point or area sources to simplify the calculation. Area sources are only defined by a release height and the length of a side (which represents a square area). Models calculate the emissions from area sources using a virtual point source located some distance upwind so that the plume dispersion is equal to the width of the box at the center of the area source (see [Figure 5.8.16](#)). The models typically ignore concentrations calculated upwind and over the area source.

Volume sources represent continuous releases over a length, such as a conveyor or monitor. They are defined in the models by a release height, length of a side, and initial dispersions in the y and z directions ( $\sigma_y$  and  $\sigma_z$ ). Simulation of these sources is similar to the virtual point source used for area sources.

## ADDITIONAL PLUME INFLUENCES

Some models handle various factors that affect the plume. These options include stack-tip downwash, buoyancy-induced dispersion, gradual plume rise, and building or topography downwash factors as described in previous sections. Other factors include pollutant decay (half-life) and deposition. Pollutant decay considers chemical changes or scavenging of the pollutant in the atmosphere, typically through the use of a half-life duration factor. Deposition accounts for the settling of the pollutant from the plume. This deposition can either occur through dry (gravitational) settling or wet (rainwash) removal. Dry deposition modeling usually requires particle size and settling velocities for the pollutant emitted; wet deposition also requires meteorological data about precipitation frequency and characteristics.

## METEOROLOGY

As previously mentioned, the type of meteorology used in a model depends on the pollutant averaging period as well as the level of modeling and site characteristics. If the modeling is performed for a state implementation plan (SIP) or a PSD permit, five years of meteorological data are typically required.

Most screening models use a preselected set of meteorological conditions that provide the worst-case plume transport and ground-level concentrations. The basic data used by models include wind speed, wind direction, stability, temperature, and mixing height.

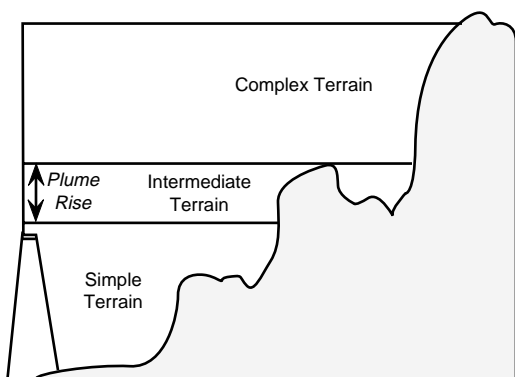

FIG. 5.8.15 Terrain categories. (Reprinted, with permission, from Trinity Consultants, Inc., 1993, *Air issues review*, Issue no. 5, Dallas, Tex. [September].)

A minimum of one year of site-specific data is preferred for refined and complex terrain models. However, these data often either are not available or require a year to collect. In most cases (i.e., noncomplex terrain), the National Weather Service (NWS) observations from a nearby station can be substituted in refined modeling applications. Five years of meteorological data from a representative station provide the best, reasonable representation of climatology at the station.

For refined, simple terrain modeling, representative data from both a NWS surface and upper air station are the required minimum. The model user can modify the data for input using standard EPA meteorological preprocessor programs. For complex terrain modeling, site-specific data are critical to represent the conditions within the local topographic regime. In most cases, site-specific data are incomplete for all the required parameters and must usually be supplemented by NWS preprocessed data. To retain

TABLE 5.8.6 IDENTIFICATION AND CLASSIFICATION OF LAND USE TYPES

Type	Use and Structures	Vegetation
I1	Heavy industrial Major chemical, steel, and fabrication industries generally 3–5 story buildings, flat roofs	Grass and tree growth extremely rare; <5% vegetation
I2	Light–moderate industrial Rail yards, truck depots, warehouse, industrial parks, minor fabrications; generally 1–3 story buildings, flat roofs	Very limited grass, trees almost totally absent; <5% vegetation
C1	Commercial Office and apartment buildings, hotels; >10 story heights, flat roofs	Limited grass and trees; <15% vegetation
R1	Common residential Single-family dwelling with normal easements; generally one story, pitched roof structures; frequent driveways	Abundant grass lawns and light–moderately wooded; >70% vegetation
R2	Compact residential Single-, some multiple-, family dwellings with close spacing; generally <2 story height, pitched roof structures; garages (via alley), no driveways	Limited lawn sizes and shade trees; <30% vegetation
R3	Compact residential Old multifamily dwellings with close (<2m) lateral separation; generally 2 story height, flat roof structures; garages (via alley) and ash pits, no driveways	Limited lawn sizes, old established shade trees; <35% vegetation
R4	Estate residential Expansive family dwelling on multiacre tracts	Abundant grass lawns and light wooded; >80% vegetation
A1	Metropolitan natural Major municipal, state, or federal parks, golf courses, cemeteries, campuses; occasional single-story structures	Nearly total grass and light wooded; >95% vegetation
A2	Agricultural rural	Local crops (e.g., corn, soybean); 95% vegetation
A3	Undeveloped Uncultivated, wasteland	Mostly wild grasses and weeds, lightly wooded; >90% vegetation
A4	Undeveloped rural	Heavy wooded; 95% vegetation
A5	Water surfaces Rivers, lakes

consistency, the EPA has a protocol to follow when data are substituted for missing observations.

Both short- and long-term models also require mixing height data to define the upper limit of the area where effluent mixing occurs (the ground being the lower limit). Holzworth (1972) developed a set of figures and tables for seasonal and annual mixing heights, which are typically used in long-term modeling. For short-term applications, model users can interpolate hourly mixing height values (using the EPA's RAMMET preprocessor) based on twice-a-day upper air data collected by radiosonde measurements at numerous sites throughout the country and available through the National Climatic Center (NCC).

## OTHER MODELS

In addition to the Gaussian-based models in Appendix A, computer programs have also been created for modeling other specific cases or pollutants. These other models include photochemical reactions or Eulerian or LaGrangian equations. Some, such as the chemical mass balance (CMB7) or fugitive dust model (FDM), are available for addressing specific pollutants, while others are implemented on a case-by-case basis for unique source or topographic conditions. The environmental engineer is directed to the appropriate U.S. EPA Region office to consult on selection and approval of the appropriate model for these cases.

The urban airshed model (UAM) is an Appendix A model applicable to most regions of the United States (USEPA 1990). The reactive plume model (RPM-IV) (USEPA 1993) accounts for ozone and other photochemically reactive pollutants over a smaller area than the urban airshed model.

Toxic or hazardous gas releases can be simulated with several models incorporated into Appendix A. These models are the toxic modeling system short-term (TOXST) (U.S. EPA 1992b) and toxic modeling system long-term (TOXLT) (U.S. EPA 1992a) models which are based on the ISC3 algorithms as well as the dense gas dispersion model (DEGADIS2.1) (U.S. EPA 1989a).

## Mobile and Line Source Modeling

Mobile sources are difficult to model because the source is moving and may not be continuously emitting pollutants at a constant emission rate. Nonetheless, environmental engineers often model these sources using line source techniques that assign emissions at fixed points along a line. The U.S. EPA has developed a program called MOBILE5b to calculate emissions from mobile sources based on EPA tests of emissions from a variety of vehicle classes and types. In certain cases, environmental engineers can use the ISC3 models to estimate concentrations at receptors, but the EPA has identified the California line (CALINE3), CAL3QHHC or CAL3QHCR, and the buoyant line and point source (BLP) models as the most appropriate for calculating emission concentrations from line sources.

### CALINE3 MODEL

The CALINE3 model (Benson 1979) was designed to estimate highway traffic concentrations of nonreactive pollutants for the state of California. The model is a steady-state, Gaussian-based model capable of predicting 1-hr to 24-hr average concentrations from urban or rural roadway emission sources located at grade, in cut sections, in fill sections, and over bridges as shown in Figure 5.8.17. The program assumes all roadways have uncomplicated topography (i.e., simple terrain). Any wind direction and roadway orientation can be modeled. Primary pollutants can be modeled, including particulate matter, for which the model uses deposition and settling velocity factors. However, unlike the other models, CALINE3 does not account for any plume rise calculations.

### CAL3QHC MODEL

While the CAL3QHC model (U.S. EPA 1992c) is not officially part of the Appendix A models, it is a recommended model for CO emissions in the *Guidelines on Air Quality Models* (U.S. EPA 1993). The model predicts carbon monoxide concentrations at signalized intersections. In effect, the model determines the increase in emissions and their resultant concentrations during queuing periods at stoplights. A version of the model, referred to as CAL3QHCR,

FIG. 5.8.17 Four roadway cross sections treated by the CALINE3 model.

has recently been created to process up to a year of meteorology, vehicle emissions, traffic volume, and signalization data.

## BLP MODEL

The BLP model (Schulman and Scire 1980) is a Gaussian-based, plume dispersion model that deals with plume rise and downwash effects from stationary line sources. It was originally designed to simulate emissions from an aluminum reduction plant. The model can predict short-term concentrations in rural areas for buoyant, elevated line sources. However, it does not treat deposition or settling of particles.

# Air Quality

## 5.9 EMISSION MEASUREMENTS

---

Data from emission measurements benefit a company in many ways. Companies use these data for permits and compliance audits, for determining the effectiveness of control equipment, for the design of pollution control strategies, and for implementation of waste minimization and pollution prevention programs. The work involves sampling and testing procedures and physical and chemical measurements.

### Planning an Emissions Testing Program

The first step in planning an emissions testing program is to define its objectives. Essentially, the testing objectives dictate the accuracy of the data needed, which dictate the following four conditions of a testing program:

**Stream**—This testing condition specifies whether sampling is performed directly at the point where the pollutant is generated (e.g., valves, pumps, or compressors) or on ambient air.

**Frequency**—This testing condition specifies whether samples are taken periodically or continuously.

**Method**—This testing condition specifies whether standardized reference methods are used to analyze for a particular compound or if a customized method must be developed.

**Location**—This testing condition specifies whether samples are taken from the field to the laboratory or are tested directly in the field. For stack sampling, environmental engineers must refine arrangements to obtain representative samples for analysis. [Figure 5.9.1](#) shows the requirements for stack sampling.

[Table 5.9.1](#) provides recommendations for the four preceding primary testing conditions based on the end uses of the data.

### Analyzing Air Emissions

The technologies for sampling air are many and varied. The choice of the air sampling and analysis method de-

**FIG. 5.9.1** Typical sampling point provisions. (Reprinted from U.S. Environmental Protection Agency [EPA].)

depends on the source. For example, emissions from stacks can be measured directly at release points. If the amounts and concentrations of contaminants are needed for a large area, then area or remote methods are preferable to source testing. To detect fugitive emissions from equipment, such as valves, flanges, pumps, or motors, screening or bagging tests are used, in which the device is enclosed to capture leaks.

## STACK SAMPLING

The U.S. EPA has published standard sampling routines for stack gases. These reference methods give representative concentration data for compounds. These test methods are validated by laboratory and field studies, and the data obtained from them have predictable accuracies and reproducibilities. Table 5.9.2 lists the standard sampling routines for stack gases (see also, *Code of Federal Regulations*, Title 40, Part 60 App. A).

The sampling train described in reference methods 5 and 8 together with operating procedures are discussed in Section 5.14. The following sampling method numbers refer to the methods identified in EPA guidance documents and reports (U.S. EPA 1989; 1990; Harris et al. 1984):

### Semivolatile Organics (Method 0010)

The sampling train in reference method 5 must be modified to include an adsorbent trap (see Figures 5.9.2 and 5.9.3) when organic compounds with a boiling point between 100 and 300°C are present in the gas. The adsorbent module is inserted between the filter and the first impinger. Gas chromatography–mass spectrometry (GC–MS) is typically used to analyze for organic compounds.

### Volatile Organics (Method 0030)

The volatile organics sampling train (VOST) is used for organics that boil below 100°C. The VOST system involves drawing a stack gas sample through two adsorbent tubes in series. The first tube contains Tenax resins, and the second contains Tenax and activated carbon. The pollutants adsorbed on these tubes are then desorbed. GC–MS is a typical method for low-boiling-point organics.

### HCl and Cl<sub>2</sub> (Method 0050)

This method is used to collect HCl and Cl<sub>2</sub> in stack gases. It collects emission samples isokinetically and can be combined with reference method 5 for particulate determination.

FIG. 5.9.3 Condenser and absorbent trap.

### Trace Metals (Method 0012)

The metals sampling train is used to determine the total chromium, cadmium, arsenic, nickel, manganese, beryllium, copper, zinc, lead, selenium, phosphorous, thallium, silver, antimony, barium, and mercury in incinerator stack emissions. The stack gas is withdrawn isokinetically from the source with the particulate emissions collected in a probe and on heated filters and the gaseous emissions collected in a series of chilled impingers. These impingers contain a solution of dilute nitric acid combined with hydrogen peroxide in two impingers and an acidic potassium permanganate solution in two impingers. Analyzing the

metals in particulates involves using either inductive coupled argon plasma (ICAP) spectroscopy or a graphite furnace atomic adsorption (GFAA) spectrometer.

### Formaldehyde (Method 0011)

This method is used to collect formaldehyde in stack emissions.

### Other Sampling Methods

Reference methods are continuously being developed to keep up with the demands of new regulations. Among the

most recent introductions are the aldehydes-ketones sampling train and the hexavalent chromium sampling train (U.S. EPA 1990).

### AIR TOXICS IN AMBIENT AIR

In addition to the reference methods, the EPA has developed methods to detect toxic and radioactive pollutants under NESHAP. Table 5.9.3 lists these test methods as well as methods for the analysis of low concentrations of organics in ambient air.

**TABLE 5.9.4 COMPENDIUM METHODS**

Number	Method
TO-1	Determination of VOCs in ambient air using Tenax adsorption and GC-MS.
TO-2	Determination of VOCs in ambient air by carbon molecular sieve adsorption and GC-MS.
TO-3	Determination of VOCs in ambient air using cryogenic preconcentration techniques and GC with flame ionization and electron capture detection.
TO-4	Determination of organochlorine pesticides and PCBs in ambient air.
TO-5	Determination of aldehydes and ketones in ambient air using high-performance liquid chromatography (HPLC).
TO-6	Determination of phosgene in ambient air using HPLC.
TO-7	Determination of N-nitrosodimethylamine in ambient air using GC.
TO-8	Determination of phenol and methylphenols (cresols) in ambient air using HPLC.
TO-9	Determination of polychlorinated dibenzo-p-dioxins (PCDDs) in ambient air using high-resolution GC-high-resolution mass spectrometry.
TO-10	Determination of organochlorine pesticides in ambient air using low-volume polyurethane foam (PUF) sampling with GC-electron capture detector (GC-ECD).
TO-11	Determination of formaldehyde in ambient air using adsorbent cartridge followed by HPLC.
TO-12	Determination of nonmethane organic compounds (NMOC) in ambient air using cryogenic preconcentration and direct flame ionization detection (PDFID).
TO-13	Determination of PAHs in ambient air using high-volume sampling with GC-MS and HPLC analysis.
TO-14	Determination of VOCs in ambient air using SUMMA polished canister sampling and GC analysis.

The EPA's Atmospheric Research and Exposure Assessment Laboratory (AREAL) has also developed a compendium of methods for quantifying HAPs in ambient air. Table 5.9.4 identifies the methods, and Figure 5.9.4 shows the categories of HAPs in the compendium. Two popular methods are compendium method TO-13 for semivolatiles and TO-12 for VOCs. Method TO-13 describes a sampling and analysis procedure for semivolatiles, such as benzo(a)pyrene and polynuclear aromatic hydrocarbons (PAHs). Compendium method TO-14 involves the collection of VOHAPs in stainless canisters.

A copy of the compendium of methods can be obtained from the following:

U.S. EPA, Atmospheric Research and Exposure Assessment Laboratory (AREAL), MD-77, Research Triangle, NC 27711.

Noyes Publication, Mill Road at Grand Ave., Park Ridge, NJ 07656.

A copy of the statement of work (SOWs) for HAPs from superfund sites can be obtained from the U.S. EPA, Office of Solid Waste and Energy Response, Analytical Operation Branch, 401 M St., S.W., Washington, DC 20460.

Many of the sampling and analytic procedures recommended most likely need additional development and validation to improve accuracy and precision. A method that requires validation is not an inferior method; the method simply requires additional experimentation to define accuracy, precision, and bias. The environmental engineer begins experimental work with analyses of a known concentration of the target pollutant. Then, the engineer determines the potential interferences by repeating the tests

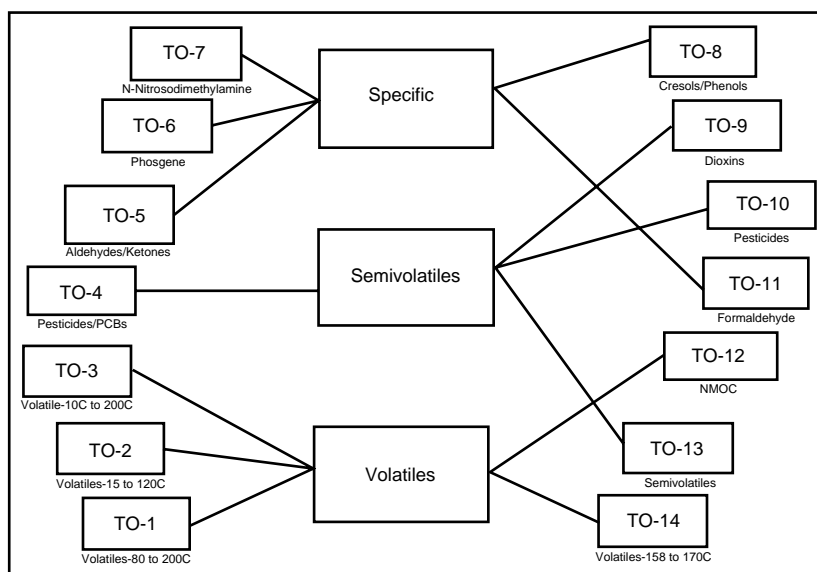

FIG. 5.9.4 Compendium of methods.

FIG. 5.9.5 Bagging test—Blow-through method.

with a gas that models the emission matrix. Validation is completed with field tests on an actual emission stream. The EPA has prepared standard protocols for validation of sampling and analysis methods (U.S. EPA 1991).

## EQUIPMENT EMISSIONS

Equipment emission measurements are made by a portable hydrocarbon analyzer at potential leak points. The analyzer is a flame ionization detector (FID) that measures total hydrocarbons over a range of 1 to 10,000 ppm on a logarithmic scale. Since these measurements are basic for regulatory compliance, procedures are formalized in the EPA's reference method 21.

Environmental engineers can determine emission rates from stand-alone equipment such as valves and pumps by using bagging tests in which the source is enclosed and

leaks are captured in a known value of air or inert gas. Two different methods are commonly used: the vacuum method and the blow-through method. Figure 5.9.5 shows the blow-through method. Multiplying the concentration of the exhaust stream by the flow rate of air through the equipment calculates the emission rates. Samples are usually analyzed with a total-hydrocarbon analyzer. Toxics are detected by gas chromatography (GC).

## Monitoring Area Emissions

Measuring the concentration of air pollutants in a large area presents different problems. The potential sources of these emissions are many. For example, VOCs are emitted from hazardous waste sites; organic and inorganic gases are emitted from landfills, lagoons, storage piles, and spill sites. Area emissions can be measured either directly

**FIG. 5.9.6** Cutaway diagram of the emission isolation flux chamber and support equipment. (Reprinted, with permission, from J.C. Harris, C.E. Rechsteiner, and K.E. Thrun, 1984, *Sampling and analysis methods for hazardous waste combustion*, EPA-600/8-84/002, PB 84-155545, U.S. EPA [February].)

or indirectly. In direct measurements, ambient air is sampled at various points in the area of emission. Indirect methods sample ambient air at points upwind and downwind of the emission.

## DIRECT MEASUREMENTS

Environmental engineers use an emission-flux chamber to make direct measurements of concentrations (see [Figure 5.9.6](#)). The atmospheric emissions in an area enter the chamber where they are mixed with clean dry air or nitrogen that is fed in at a fixed rate. The analyzer measures the pollutant concentration. The emission flux is the exit gas concentration multiplied by the flow rate divided by the surface area covered by the chamber.

When the area is several acres in size, measurements must be taken at various points to develop an overall emission rate. The number of measurements needed depends on the precision required and the size of the source.

Flux chambers are best suited to measure small to medium size areas (as large as a few acres) in which the pollutant concentration is fairly homogeneous. Because the flux chamber is isolated, measurements are independent from environmental influences such as wind; therefore, the measurement data are independent of the meteorological conditions at the site and are comparable from day to day and site to site.

## INDIRECT METHODS

Indirect methods are best suited for the measurement of emission rates from large, heterogeneous sources. The en-

vironmental engineer measures the emission flux indirectly by collecting ambient concentrations upwind and downwind of the emission source.

The main disadvantage of indirect methods is that the analytical results rely on meteorological conditions, which can invalidate the data or preclude the collection altogether. In addition to weather patterns, buildings and hills also influence dispersion characteristics and limit sampling. The sensitivity of the analytical method is also critical since the ambient concentration of the emission can be low.

The downwind measurement determines the average concentration of contaminants in the plume. The upwind measurement monitors background readings. The volume of air passing over the monitors in a time period is recorded, and a computer model calculates an emission rate from the concentration data. The average emission rate is equal to the difference in mass measurements (downwind minus upward concentration) divided by the transit time across the source. Environmental engineers have tried various approaches for making these estimates using conventional ambient air monitoring methods (Schmidt et al. 1990).

In some cases, gaseous tracers are released at the emission source. These tracers mimic the dispersion of the emissions. When a tracer is released at a known rate, the environmental engineer can determine the emission rates of compounds by comparing the measured pollutant concentration to that of the tracer at the same location. Sections 5.12 and 5.13 describe other techniques such as continuous emission monitoring and remote sensing.

This section describes ambient air sampling, air quality monitoring systems, and microprocessor-based portable ambient air analyzers.

### Sampling of Ambient Air

All substances in ambient air exist as either particulate matter, gases, or vapors. In general, the distinction is easily made; gases and vapors consist of substances dispersed as molecules in the atmosphere, while particulate matter consists of aggregates of molecules large enough to behave like particles. Particulate matter, or particulates, are filterable, can be precipitated, and can settle out in still air. By contrast, gases and vapors do not behave in this way and are homogeneously mixed with the air molecules.

### SAMPLING METHOD SELECTION

A substance, such as carbon monoxide, exists only as a gas; an inorganic compound like iron oxide exists only as a particle. Many substances exist as either particles or vapors, however; substances that are gases can be attached by some means to particulate matter in the air.

To conduct sampling, environmental engineers must have prior knowledge of the physical state in which a substance exists or make a judgment. Devices suitable for collecting particulate matter do not usually collect gases or vapors; hence, selection of an incorrect sampling method can lead to erroneous results. Fortunately, considerable knowledge concerning the more common pollutants is available, and in most cases, selecting a suitable sampling method is not difficult.

### GENERAL AIR SAMPLING PROBLEMS

Certain general observations related to sampling ambient air must be recognized. For example, the quantity of a substance contained in a volume of air is often extremely small; therefore, the sample size for the analytical method must be adequate. Even heavily polluted air is not likely to contain more than a few milligrams per cubic meter of most contaminants; and frequently, the amount present is best measured in micrograms, or even nanograms, per cubic meter.

For example, the air quality standard for particulates is  $75 \mu\text{g}/\text{M}^3$ . A cubic meter of air, or 35.3 cu ft, is a large volume for many sampling devices, and a considerable sampling period is required to draw such a quantity of air through the sampler. When atmospheric mercury analyses are made, the environmental engineer must realize that background levels are likely to be as low as several nanograms per cubic meter. In general, most substances are of concern at quite low levels in ambient air.

In addition to the problems from low concentrations of the substances being sampled, the reactivity of some substances causes other problems, resulting in changes after collection and necessitating special measures to minimize such changes.

Whenever a substance is removed from a volume of air by sampling procedures, the substance is altered, and the analysis can be less informative or even misleading. Ideally,

environmental engineers should perform analyses of the unchanged atmosphere using direct-reading devices that give accurate information concerning the chemical and physical state of contaminants as well as concentration information. Such instruments exist for some substances, and many more are being developed. However, conventional air sampling methods are still used in many instances and will continue to be required for some time.

## Gas and Vapor Sampling

The methods for gas and vapor sampling include collection in containers or bags, absorption, adsorption, and freeze-out sampling.

### COLLECTION IN CONTAINERS OR BAGS

The simplest method of collecting a sample of air for analysis is to fill a bottle or other rigid container with it or to use a bag of a suitable material. Although sampling by this method is easy, the sample size is distinctly limited, and collecting a large enough sample for subsequent analysis may not be possible.

Bottles larger than several liters in capacity are awkward to transport; and while bags of any size are conveniently transported when empty, they can be difficult to handle when inflated. Nevertheless, collecting several samples in small bags can prove more convenient than taking more complex sampling apparatus to several sampling sites. If analyzing the contaminant is possible by GC procedures or gas-phase infrared spectroscopy, samples as small as a liter or less can be adequate and can be easily collected with bags.

Several methods exist for filling a rigid container such as a bottle. One method is to evacuate the bottle beforehand, then fill it at the sampling site by drawing air into the bottle and resealing it (see Figure 5.10.1). Alternatively, a bottle can be filled with water, which is then allowed to drain and fill with the air. A third method consists of passing a sufficient amount of air through the bottle using a pumping device until the original air is completely displaced by the air being sampled.

Plastic bags are frequently filled by use of a simple hand-operated squeeze bulb with valves on each end (see Figure 5.10.1) that are connected to a piece of tubing attached to the sampling inlet of the bag. In most cases, this procedure is satisfactory; but the environmental engineer must be careful to avoid contaminating the sampled air with the sampling bulb or losing the constituent on the walls of the sampling bulb. Problems of this kind can be avoided when the bag is placed in a rigid container, such as a box, and air is withdrawn from the box so that a negative pressure is created, resulting in air being drawn into the bag.

Selecting bag materials requires care; some bags permit losses of contaminants by diffusion through the walls, and others contribute contaminants to the air being sampled.

FIG. 5.10.1 Devices for obtaining grab samples.

A number of polymers have been studied, and several are suitable for many air sampling purposes. Materials suitable for use as sampling bags include Mylar, Saran, Scotchpak (a laminate of polyethylene, aluminum foil, and Teflon), and Teflon.

Even when a bag is made of inert materials, gas-phase chemical reactions are always possible, and after a period of time, the contents of the bag are not identical in composition to the air originally sampled. Thus, a reactive gas like sulfur dioxide or nitric oxide gradually oxidizes, depending on the storage temperature. Generally, analyses should be performed as soon as possible after the samples are collected. Losses by adsorption or diffusion are also greater with the passage of time and occur to some extent even when the best available bag materials are used.

The use of small bags permits the collection of samples to be analyzed for a relatively stable gas, such as carbon monoxide, at a number of locations throughout a community, thus permitting routine air quality measurements that might otherwise be inordinately expensive.

### ABSORPTION

Most air sampling for gases and vapors involves absorbing the contaminant in a suitable sampling medium. Ordinarily, this medium is a liquid, but absorption can also take place in solid absorbents or on supporting materials such as filter papers impregnated with suitable absorbents. Carbon dioxide, for example, is absorbed in a

granular bed of alkaline material, and sulfur dioxide is frequently measured by the absorption of reactive chemicals placed on a cloth or ceramic support. Environmental engineers also detect a number of gases by passing them through filter papers or glass tubes containing reactive chemicals. The reaction produces an immediate color change that can be evaluated by eye to measure the concentration of a substance.

Most commonly, however, gases and vapors are absorbed when they are passed through a liquid in which they are soluble or which contains reactive chemicals that combine with the substance being sampled. Many absorption vessels have been designed, ranging from simple bubblers, made with a piece of tubing inserted beneath the surface of a liquid, to complex gas-washing devices, which increase the time the air and liquid are in contact with each other (see Figure 5.10.2).

The impinger is probably the most widely used device. It is available in several sizes and configurations. An impinger consists of an entrance tube terminating in a small orifice that causes the velocity of the air passing through the orifice to increase. When this jet of air strikes a plate or the bottom of the sampling vessel at an optimal distance from the orifice, an intense impingement or bubbling action occurs. This impingement results in more efficient absorption of gases from the airstream than takes place if the air is simply bubbled through at low velocity. The two most frequently used impingement devices are the *standard impinger* and the *midget impinger* (see Figure 5.10.3). They are designed to operate at an airflow of 1 cubic foot per minute (cfm) and 0.1 cfm, or 28.3 and 2.8 lpm, respectively. Using such devices for sampling periods of 10 or 30 min results in a substantial amount of air passing through the devices, thus permitting low concentrations of trace substances to be determined with improved sensitivity and accuracy. Many relatively insoluble gases, such as nitrogen dioxide, are not quantitatively removed by passing through an impinger containing the usual sampling solutions.

The most useful sampling devices for absorbing trace gases from air are those in which a gas dispersion tube made of fritted or sintered glass, ceramic, or other material is immersed in a vessel containing the absorption liq-

FIG. 5.10.2 Gas-absorbing vessels.

uid (see Figure 5.10.2). This device causes the gas stream to be broken into thousands of small bubbles, thus promoting contact between the gas and the liquid with resulting high-collection efficiencies. In general, fritted absorbers are more applicable to sampling gases and vapors than impingers and are not as dependent on flowrates as impingers. Fritted absorbers are available from scientific supply companies and come in various sizes suitable for many sampling tasks. Prefiltering the air prior to sampling with a fritted absorber is advisable to prevent the gradual accumulation of dirt within the pores of the frit.

The use of solid adsorbents is not widely practiced in ambient air sampling because the quantity of absorbed gases is usually determined by gravimetric means. With the exception of carbon dioxide, few atmospheric gases lend themselves to this type of analysis.

## ADSORPTION

Adsorption, by contrast with absorption, consists of the retention of gaseous substances by solid adsorbents which, in most cases, do not chemically combine with the gases. Instead, adsorptive forces hold the gases or vapors which can subsequently be removed unchanged. Any solid substance adsorbs a small amount of most gases; but to be useful as an adsorbent, a substance must have a large surface area and be able to concentrate a substantial amount of gas in a small volume of adsorbent.

FIG. 5.10.3 Standard and midget impingers.

Activated carbon or charcoal and activated silica gel are most widely used for this purpose. A small quantity of either adsorbent placed in a U-tube or other container through which air is passed quantitatively removes many vapors and gases from a large volume of air. These gases can then be taken to the laboratory where desorption removes the collected substances for analysis. Desorption commonly involves heating the adsorbent and collecting the effluent gases or eluting the collected substances with a suitable organic liquid.

For most organic vapors, subsequent analysis by GC, infrared (IR), or UV spectroscopy is most convenient. For some purposes, either silica gel or activated carbon is used; but the use of silica gel is not recommended because it also adsorbs water vapor, and a short sampling period in humid air can saturate the silica gel before sufficient contaminant is adsorbed. Because charcoal does not adsorb water, it can be used in humid environments for days or even weeks if the concentration of the contaminant is low.

The ease of sampling using adsorbents is offset somewhat by the difficulty of quantitatively desorbing samples for analysis. When published data are not available to predict the behavior of a new substance, the environmental engineer should perform tests in the laboratory to determine both the collection efficiency and the success of desorption procedures after sample collection.

## FREEZE-OUT SAMPLING

Vapors or gases that condense at a low temperature can be removed from the sampled airstream by passage through a vessel immersed in a refrigerating liquid. Table 5.10.1 lists liquids commonly used for this purpose. Usually forming a sampling train in which two or three coolant liquids progressively lower the air temperature in its passage through the system is recommended.

All freeze-out systems are hampered somewhat by the accumulation of ice from water vapor and can eventually become plugged with ice. Flow rates through a freeze-out train are also limited because a sufficient residence time in the system is necessary for the air to be cooled to the required degrees. For these reasons and because of the inconvenience of assembling freeze-out sampling trains, they

**TABLE 5.10.1 COOLANT SOLUTIONS FOR FREEZE-OUT SAMPLING**

<i>Coolant</i>	<i>Temperature (°C)</i>
Ice water	0
Ice and salt (NaCl)	-21
Dry ice and isopropyl alcohol	-78.5
Liquid air	-147
Liquid oxygen	-183
Liquid nitrogen	-196

are not used for routine sampling purposes unless no other approach is feasible.

However, freeze-out sampling is an excellent means of collecting substances for research studies inasmuch as the low temperatures tend to arrest further chemical changes and ensure that the material being analyzed remains in the sampling container ready for analysis after warming. Analysis is usually conducted by GC, IR, or UV spectrophotometry or by mass spectrometry.

## Particulate Matter Sampling

Particulate matter sampling methods include filtration, impingement and impaction, electrostatic precipitation, and thermal precipitation.

### FILTRATION

Passing air through a filter is the most convenient method to remove particulate matter (see Figure 5.10.4). Before filtration is used to obtain a sample, however, the purpose of the sample should be considered. Many filters collect particulates efficiently, but thereafter removing the collected matter may be impossible except by chemical treatment.

If samples are collected for the purpose of examining the particles and measuring their size or noting morphological characteristics, many filters are not suitable because the particles are imbedded in the fibrous web of the filter and cannot readily be viewed or removed. If the sample is collected for the purpose of performing a chemical analysis, the filter must not contain significant quantities of the substance. If the purpose of sampling is to collect an amount of particulate matter for weighing, then a filter which can be weighed with the required precision must be selected. Many filtration materials are hygroscopic and change weight appreciably in response to changes in the relative humidity.

Filters can be made of many substances, and almost any solid substance could probably be made into a filter. In practice, however, fibrous substances, such as cellulose or paper, fabrics, and a number of plastics or polymerized materials, are generally used. The most readily available filters are those made of cellulose or paper and used in chemical laboratories for filtering liquids. These filter papers come in a variety of sizes and range in efficiency from loose filters that remove only larger particles to papers that remove fine particles with high efficiency. All filters display similar behavior, and ordinarily a high collection efficiency is accompanied by increased resistance to airflow.

Certain filtration media are more suited to air sampling than most paper or fibrous filters. Of these, membrane filters have the greatest utility, and commercially available membrane filters combine high-collection efficiencies with low resistance to flow. Such filters are not made up of a fibrous mat but are usually composed of gels of cellulose

FIG. 5.10.4 High-volume sampler: (A) assembled sampler and shelter; (B) exploded view of typical high-volume air sampler.

esters or other polymeric substances that form a smooth surface of predictable characteristics.

Such filters contain many small holes, or pores, and can be made to exacting specifications so that their performance characteristics can be predicted. In addition, the filters usually have high chemical purity and are well suited to trace metal analyses. Some membrane filters can also be transparent and thus permit direct observation of collected particles with a microscope. Alternatively, the filters can be dissolved in an organic solvent, and the particles can be isolated and studied. Most membrane filters are not affected by relative humidity changes and can be weighed before and after use to obtain reliable gravimetric data.

Another kind of filter that is widely used in sampling ambient air is the fiberglass filter. These filters are originally made of glass fibers in an organic binder. Subsequently, the organic binder is removed by firing, leaving a web of glass that is efficient in collecting fine particles from the air. The principal advantages of using this type of filter are its low resistance to air flow and its unchanging weight regardless of relative humidity.

However, these filters are not well suited to particle size studies. In addition, they are not chemically pure, and the environmental engineer must ensure that the filter does not contribute the substance being analyzed in unknown quantities. In the United States, most data relating to suspended particulate matter in our cities have been obtained on filters made of fiberglass and used in conjunction with a sampling device referred to as a high-volume sampler (see Figure 5.10.4). Many other kinds of filters are available, but most sampling needs are well met by membrane or fiberglass filters.

## IMPINGEMENT AND IMPACTION

The impingers previously described for sampling gases and vapors (see Figure 5.10.3) can also be used for the collection of particles and, in fact, were originally developed for that purpose. However, in ambient air sampling, they are not used because their collection efficiency is low and unpredictable for the fine particles present in ambient air. The low sampling rates also make them less attractive than filters for general air sampling, but instances do arise when impingers can be satisfactorily used. When impingers are used, the correct sampling rates must be maintained since the collection efficiency of impingers for particles varies when flow rates are not optimal.

Impactors are more widely used in ambient air sampling. In these devices, air is passed through small holes or orifices and made to impinge or impact against a solid surface. When these devices are constructed so that the air passing through one stage is subsequently directed onto another stage containing smaller holes, the resulting device is known as a *cascade impactor* and has the capability of separating particles according to sizes.

Various commercial devices are available. Figure 5.10.5 shows one impactor that is widely used and consists of several layers of perforated plates through which the air must pass. Each plate contains a constant number of holes, but the hole size progressively decreases so that the same air volume passing through each stage impinges at an increased velocity. The result is that coarse particles are deposited on the first stage and successively finer particles are removed at each subsequent stage. Although these instruments do not achieve exact particle size fractions, they

FIG. 5.10.5 Cascade impactor (Andersen sampler).

do perform predictably when the characteristics of the aerosol being sampled are known.

In use, an environmental engineer assembles a cascade impactor after scrupulously cleaning each stage and applying, if necessary, a sticky substance or a removable surface on which the particles are deposited. After a period of sampling during which time the volume of air is metered, the stages can be removed, and the total weight of each fraction is determined, as well as its chemical composition. Such information is sometimes more useful than a single weight or chemical analysis of the total suspended particulate matter without regard to its particle size.

## ELECTROSTATIC PRECIPITATION

Particulate matter can be quantitatively removed from air by ESPs. Devices that operate on the same principal but are much larger are frequently used to remove particulate matter from stack gases prior to discharging into the atmosphere. Several commercially available ESPs can be used for air sampling, and all operate on the same general principle of passing the air between charged surfaces, imparting a charge to particles in the air, and collecting the particles on an oppositely charged surface or plate.

In one of widely used commercial devices (see Figure 5.10.6), a high-voltage discharge occurs along a central wire; the collecting electrode is a metallic cylinder placed around the central wire while the air is passing through the tube. An intense corona discharge takes place on the central wire; the particles entering the tube are charged and are promptly swept to the walls of the tube where they remain firmly attached. With this method, collecting a sample for subsequent weighing or chemical analysis and

examining the particles and studying their size and shape is possible. However, the intense electrical forces can produce aggregates of particles that are different from those in the sampled air.

ESPs are not as widely used as filters for ambient air sampling because they are less convenient and tend to be heavy due to the power pack necessary to generate the high voltage. Nevertheless, they are excellent instruments for obtaining samples for subsequent analysis and sample, at high-flow rates and low resistance.

## THERMAL PRECIPITATORS

Whenever a strong temperature gradient exists between two adjacent surfaces, particles tend to be deposited on the colder of these surfaces. Collecting aerosols by this means is termed *thermal precipitation*, and several commercial devices are available.

Because thermal forces are so weak, a large temperature difference must be maintained in a small area, and the air flow rate between the two surfaces must be low in order not to destroy the temperature gradient and to permit particles to be deposited before moving out of the collection area. As a result of these requirements, most devices use a heated wire as the source of the temperature differential and deposit a narrow ribbon of particles on the cold surface. Airflows are small, on the order of 10 to 25 ml per minute. At such low rates, the amount of material collected is normally insufficient for chemical analysis or weight determinations but is ample for examination by optical or electron microscopy.

Collection for particle size studies is the principal use for thermal precipitation units, and they are well suited to collecting samples for such investigations. Because the collecting forces are gentle, the particles are deposited unchanged. The microscopic examination gives information that can be translated into data concerning the number of particles and their morphological characteristics. The use of a small grid suitable for insertion into an electron microscope is also convenient as the collecting surface; this use eliminates additional manipulation of the sample prior to examination by electron microscopy.

## Air Quality Monitoring Systems

Many options are available for the type of air quality information which can be collected, and the cost of air quality monitoring systems varies greatly. Only with a thorough understanding of the decisions which must be made based on the information received from the air quality monitoring system can an environmental engineer make an appropriate selection.

Regardless of the instruments used to measure air quality, the data are only as good as they are representative of the sampling site selected.

FIG. 5.10.6 Electrostatic precipitator. (Reprinted, with permission, from Mine Safety Appliances Company.)

The simplest air quality monitors are static sensors that are exposed for a given length of time and are later analyzed in the laboratory. In some cases, these devices provide all the required information. More commonly, a system of automatic instruments measuring several different air quality parameters is used. When more than a few instruments are used, the signals from these instruments can be retained on magnetic tape rather than on recorder charts.

The most common errors in the design of air quality monitoring systems are poor site location and the acquisition of more data than necessary for the purpose of the installation.

### PURPOSES OF MONITORING

The principal purpose of air quality monitoring is to acquire data for comparison to regulated standards. In the United States, standards have been promulgated by the federal government and by many states. Where possible,

these standards are based on the physiological effect of the air pollutant on human health. The averaging time over which various concentration standards must be maintained differs for each pollutant. (See Chapter 4 for tabulations of the ambient air quality standards promulgated by the federal government.)

Some air quality monitoring systems determine the impact of a single source or a concentrated group of sources of emissions on the surrounding area. In this case, determining the background level, the maximum ground-level concentration in the area, and the geographical extent of the air pollutant impact is important.

When the source is isolated, e.g., a single industrial plant in a rural area, the system design is straightforward. Utilizing the meteorological records available from nearby airports or government meteorological reporting stations, environmental engineers can prepare a wind rose to estimate the principal drift direction of the air pollutant from the source. Then they can perform dispersion calculations to estimate the location of the expected point of maximum

ground-level concentration. As a general rule with stacks between 50 and 350 ft tall, this point of maximum concentration is approximately 10 stack heights downwind.

The air quality monitoring system should include at least one sensor at the point of expected maximum ground-level concentration. Additional sensors should be placed not less than 100 stack heights upwind (prevailing) to provide a background reading, and at least two sensors should be placed between 100 and 200 stack heights downwind to determine the extent of the travel of the pollutants from the source. If adequate resources are available, sampling at the intersection points of a rectilinear grid with its center at the source is recommended.

With such a system for an isolated source, environmental engineers can obtain adequate data in a one-year period to determine the impact of the source on the air quality of the area. Because of the variability in climatic conditions on an annual basis, few areas require less than one year of data collection to provide adequate information. If a study is performed to determine the effect of process changes on air quality, the study may have to continue for two to five years to develop information that is statistically reliable.

Some air quality monitoring is designed for the purpose of investigating complaints concerning an unidentified source. This situation usually happens in urban areas for odor complaints. In these cases, human observers use a triangulation technique to correlate the location of the observed odor with wind direction over several days. Plotting on a map can pinpoint the offending source in most cases. While this technique is not an air pollution monitoring system in an instrumental sense, it is a useful tool in certain situations.

Air pollution research calls for a completely different approach to air quality monitoring. Here, the purpose is to define some unknown variable or combination of variables. This variable can be either a new atmospheric phenomenon or the evaluation of a new air pollution sensor. In the former case, the most important consideration is the proper operation of the instrument used. In the latter case, the most important factor is the availability of a reference determination to compare the results of the new instrument against.

## MONITORING IN URBAN AREAS

Urban areas are of major interest in air pollution monitoring in the United States since most of the population lives in these areas. The most sophisticated and expensive air quality monitoring systems in the United States are those for large cities (and one or two of the largest states) where data collection and analysis are centralized at a single location through the use of telemetry. Online computer facilities provide data reduction.

The three philosophies that can be used in the design of an urban air quality monitoring system are locating sen-

sors on a uniform area basis (rectilinear grid), locating sensors at locations where pollutant concentrations are high, and locating sensors in proportion to the population distribution. The operation of these systems is nearly identical, but the interpretation of the results can be radically different.

The most easily designed systems are those where sensors are located uniformly on a geographical basis according to a rectilinear grid. Because adequate coverage of an urban area frequently requires at least 100 sensors, this concept is usually applied only with static or manual methods of air quality monitoring.

Locating air quality sensors at points of maximum concentration indicates the highest levels of air pollutants encountered throughout the area. Typically, these points include the central business district and the industrial areas on the periphery of the community. This type of data is useful when interpreted in the context of total system design. One or two sensors are usually placed in clean or background locations, so that the environmental engineer can estimate the average concentration of air pollutants over the entire area. The basis of this philosophy is that if the concentrations in the dirtiest areas are below air quality standards, certainly the cleaner areas will have no problems.

The design of air quality monitoring systems based on population distribution means placing air quality sensors in the most populous areas. While this philosophy may not include all high-pollutant concentration areas in the urban region, it generally encompasses the central business district and is a measure of the air pollution levels to which most of the population are exposed. The average concentrations from this type of sampling network are an adequate description from a public health standpoint. This system design can, however, miss some localized high concentration areas.

Before the system is designed, the system designer and those responsible for interpreting the data must agree on the purpose of air quality monitoring.

## SAMPLING SITE SELECTION

Once the initial layout has been developed for an air quality monitoring system, specific sampling sites must be located as close as practical to the ideal locations. The major considerations are the lack of obstruction from local interferences and the adequacy of the site to represent the air mass, accessibility, and security.

Local interferences cause major disruptions to air quality sensor sites. A sampler inlet placed at a sheltered interior corner of a building is not recommended because of poor air motion. Tall buildings or trees immediately adjacent to the sampling site can also invalidate most readings.

The selection of sampling sites in urban areas is complicated by the canyon effect of streets and the high den-

sity of pollutants, both gaseous and particulate, at street level. In order for the data to represent the air mass sampled, environmental engineers must again review the purpose of the study. If the data are collected to determine areawide pollutant averages, the sampler inlet might best be located in a city park, vacant lot, or other open area. If this location is not possible, the sampler inlet could be at the roof level of a one- or two-story building so that street-level effects are minimized. On the other hand, if the physiological impact of air pollutants is a prime consideration, the samplers should be at or near the breathing level of the people exposed. As a general rule, an elevation of 3 to 6 m above the ground is an optimum elevation.

The sampling site location can be different for the same pollutant depending on the purpose of the sampling. Carbon monoxide sampling is an example. The federally promulgated air quality standards for carbon monoxide include both an 8-hr and a 1-hr concentration limit. Maximum 1-hr concentrations are likely to be found in a high-traffic density, center-city location. People are not ordinarily exposed to these concentrations for 8-hr periods. When sampling for comparison with the 1-hr standard, the environmental engineer should locate the sensor within about 20 ft of a major traffic intersection. When sampling for comparison with the 8-hr standard, the engineer should locate the sensor near a major thoroughfare in either the center-city area or in the suburban area with the sampler less than 50 ft from the intersection. The reason for two different sampling site locations is to be consistent with the physiological effects of carbon monoxide exposure and the living pattern of most of the population. If only one site can be selected, the location described for the 8-hr averaging time is recommended.

When the sampling instruments are located inside a building and an air sample is drawn in from the outside, using a sampling pipe with a small blower is advantageous to bring outside air to the instrument inlets. This technique improves sampler line response time. An air velocity of approximately 700 ft per min in the pipe balances problems of gravitational and inertial deposition of particulate matter when particulates are sampled.

The sampling site should be accessible to operation and maintenance personnel. Since most air pollution monitoring sites are unattended much of the time, sample site security is a real consideration; the risk of vandalism is high in many areas.

## STATIC METHODS OF AIR MONITORING

Static sensors used to monitor air quality require the minimum capital cost. While averaging times are in terms of weeks and sensitivity is low, in many cases, static monitors provide the most information for the amount of investment. Although inexpensive, they should not be rejected but should be considered as useful adjuncts to more sophisticated systems.

## Dustfall Jars

The simplest of all air quality monitoring devices is the dustfall jar (see Figure 5.10.7). This device measures the fallout rate of coarse particulate matter, generally above about 10  $\mu\text{m}$  in size. Dustfall and odor are two major reasons for citizen complaints concerning air pollution. Dustfall is offensive because it builds up on porches and automobiles and is highly visible and gritty to walk upon.

Dustfall seldom carries for distances greater than  $\frac{1}{2}$  mi because these large particles are subject to strong gravitational effects. For this reason, dustfall stations must be spaced more closely than other air pollution sensors for a detailed study of an area.

Dustfall measurements in large cities in the United States in the 1920s and 1930s commonly indicated dustfall rates in hundreds of tn per sq mi per mon. These levels are considered excessive today, as evidenced by the dustfall standards of 25 to 30 tn per sq mi per mon promulgated by many of the states. While the measurement of low or moderate values of dustfall does not indicate freedom from air pollution problems, measured dustfall values in excess of 50 to 100 tn per sq mi per mon are an indication of excessive air pollution.

The large size of the particulate matter found in dustfall jars makes it amenable to chemical or physical analysis by such techniques as microscopy. These analyses are useful to identify specific sources.

## Lead Peroxide Candles

For many years, sulfur dioxide levels have been determined through the use of lead peroxide candles. These devices, known as candles because they are a mixture of lead peroxide paste spread on a porcelain cylinder about the size and shape of a candle, are normally exposed for periods of 1 mon. Sulfur gases in the air react with lead peroxide to form lead sulfate. Environmental engineers analyze the sulfate according to standard laboratory procedures to indicate the atmospheric levels of sulfur gases during the period of exposure.

A modification of this technique that simplifies the laboratory procedure is to use a fiber filter cemented to the inside of a plastic petri dish (a flat-bottom dish with shallow walls used for biological cultures). The filter is satu-

FIG. 5.10.7 Dustfall jar.

rated with an aqueous mixture of lead peroxide and a gel, commonly gum tragacanth, and is allowed to dry. These dishes or plates are exposed in an inverted position for periods of 1 to 4 wk.

The lead peroxide estimation of sulfur dioxide has inherent weaknesses. All sulfur gases, including reduced sulfur, react with lead peroxide to form lead sulfate. More importantly, the reactivity of lead peroxide depends on its particle size distribution. For this reason, the results from different investigators are not directly comparable. Nevertheless, a network of lead peroxide plates over an area provides a good indication of the exposure to sulfur gases during the exposure period. This technique is useful for determining the geographical extent of sulfur pollution.

### Other Static Methods

Environmental engineers have modified the technique of using fiber filter cemented to a petri dish by using sodium carbonate rather than lead peroxide to measure sulfur gases. This method also indicates the concentration of other gases, including nitrogen oxides and chlorides. Engineers have measured relative levels of gaseous fluoride air pollution using larger filters, e.g., 3-in diameter, dipped in sodium carbonate, and placed in shelters to protect them from the rain. With all these static methods, the accuracy is low, and the data cannot be converted directly into ambient air concentrations. They do, however, provide a low-cost indicator of levels of pollution in an area.

Environmental engineers have evaluated the corrosive nature of the atmosphere using standardized steel exposure plates for extended periods to measure the corrosion rate. This method provides a gross indication of the corrosive nature of the atmosphere. As with other static samplers, the results are not directly related to the concentration of air pollutants.

### Manual Analyses

Manual analyses for air quality measurements are those that require the sample first be collected and then analyzed in the laboratory. Manual instruments provide no automatic indication of pollution levels.

The manual air sampling instrument in widest use is the high-volume sampler. With this method, ambient air is drawn through a preweighed filter at a rate of approximately 50 atmospheric cubic feet per minute (acfm) for a period of 24 hr. The filter is then removed from the sampler, returned to the laboratory, and weighed. The weight gain, combined with the measured air volume through the sampler, allows the particulate mass concentration, expressed in micrograms per cubic meter, to be calculated.

Reference methods for nearly all gaseous air pollutants involve the use of a wet sampling train in which air is drawn through a collecting medium for a period of time. The exposed collecting medium is then returned to the laboratory for chemical analysis. Sampling trains have been

developed that allow sampling of five or more gases simultaneously into separate bubblers. Sequential samplers, which automatically divert the airflow from one bubbler to another at preset time intervals, are also available.

These sampling methods can be accomplished with a modest initial investment; however, the manpower required to set out and pick up the samples, combined with the laboratory analysis, raises the total cost to a point where automated systems can be more economical for long-term studies.

### Instrumental Analyses

As the need for accurate data that can be statistically reduced in a convenient manner increases, automated sampling systems become necessary. The elements of an automated system include the air-flow handling system, the sensors, the data transmission storage and display apparatus, and the data processing facility. The overall system is no more valuable than its weakest link.

### SENSORS

The output reliability from an air quality sensor depends on its inherent accuracy, sensitivity, zero drift, and calibration. The inherent accuracy and sensitivity are a function of the instrument's design and its operating principle. Zero drift can be either an electronic phenomenon or an indication of difficulties with the instrument. In instruments that use an optical path, lenses become dirty. In wet chemical analyzers, the flow rates of reagents can vary, changing both the zero and the span (range) of the instrument. Because of these potential problems, every instrument should have routine field calibration at an interval determined in field practice as reasonable for the sensor.

Environmental engineers calibrate an air quality sensor using either a standard gas mixture or a prepared, diluted gas mixture using permeation tubes. In some cases, they can currently sample the airstream entering the sensor by using a reference wet chemical technique.

The operator of air quality sensors should always have a supply of spare parts and tools to minimize downtime. At a minimum, operator training should include instruction to recognize the symptoms of equipment malfunction and vocabulary to describe the symptoms to the person responsible for instrument repair. Ideally, each operator should receive a short training session from the instrument manufacturer or someone trained in the use and maintenance of the instrument so that the operator can make repairs on site. Since this training is seldom possible in practice, recognition of the symptoms of malfunction becomes increasingly important.

### DATA TRANSMISSION

The output signal from a continuous monitor in an air quality monitoring system is typically the input to a strip

**TABLE 5.10.2 COMPOUNDS THAT CAN BE ANALYZED BY THE MICROPROCESSOR-CONTROLLED PORTABLE IR SPECTROMETER**

<i>Compound</i>	<i>Range of Calibration (ppm)</i>	<i>Compound</i>	<i>Range of Calibration (ppm)</i>
Acetaldehyde	0 to 400	Ethylene oxide	0 to 10 and 0 to 100

chart recorder, magnetic tape data storage, or an online data transmission system. The output of most air quality sensors is in analog form. This form is suitable for direct input to a strip chart recorder; but in automated systems, the analog signal is commonly converted to a digital signal. For those sensors that have linear output, the signal can go directly to the recorder or transmission system. For sensors with logarithmic output, it may be advantageous to convert this signal to a linear form.

Many early automated air quality monitoring systems in the United States had difficulty with the data transmission step in the system. In some cases, this difficulty was caused by attempts to overextend the lower range of the sensors so that the signal-to-noise ratio was unfavorable. In other cases, matching the sensor signal output to the data transmission system was poor. With developments and improvements in systems, these early difficulties were overcome.

Online systems, i.e., those that provide an instantaneous readout of the dynamic situation monitored by the system, add an additional step to air quality monitoring systems. Data from continuous monitors can be stored on magnetic tape for later processing and statistical reduction. In an online system, this processing is done instantaneously. The added expense of this sophistication must be evaluated in terms of the purposes of the air quality monitoring system. When decisions with substantial community impact must be made within a short time, this real-time capability may be necessary.

## DATA PROCESSING

The concentration of many air pollutants follows a log normal rather than a normal distribution. In a log normal distribution, a plot of the logarithm of the measured values more closely approximates the bell-shaped Gaussian distribution curve than does a plot of the numerical data. Suspended particulate concentrations are a prime example of this type of distribution. In this case, the geometric mean is the statistical parameter that best describes the population of data. The arithmetic mean is of limited value because it is dominated by a few occurrences of high values. The geometric mean, combined with the geometric standard deviation, completely describes a frequency distribution for a log normally distributed pollutant.

Environmental engineers should consider the averaging time over which sample results are reported in processing and interpreting air quality data. For sulfur dioxide, various agencies have promulgated air quality standards based on annual arithmetic average, monthly arithmetic average, weekly arithmetic average, 24-hr arithmetic average, 3-hr arithmetic average, and 1-hr arithmetic average concentrations. The output of a continuous analyzer can be averaged over nearly any discrete time interval. To reduce the computation time, an environmental engineer must consider the time interval over which continuous analyzer output is averaged to obtain a discrete input for the calculations. If a 1-hr average concentration is the shortest

time interval of value in interpreting the study results, using a 1- or 2-min averaging time for input to the computation program is not economic.

Environmental engineers must exercise caution in using strip chart recorders to acquire air quality data. The experience of many organizations, both governmental and industrial, is that the reduction of data from strip charts is tedious. Many organizations decide that they do not really need all that data once they find a large backlog of unreduced strip charts. Two cautions are suggested by this experience. First, only data that is to be used should be collected. Second, magnetic tape data storage followed by computer processing has advantages.

The visual display of air quality data has considerable appeal to many nontechnical personnel. Long columns of numbers can be deceptive if only one or two important trends are shown. The use of bar charts or graphs is frequently advantageous even though they do not show the complete history of air quality over a time span.

## Portable and Automatic Analyzers

Microprocessor-controlled spectrometers are available to measure concentrations of a variety of gases and vapors in ambient air. These units can be portable or permanently installed and can comply with environmental and occupational safety regulations. In the IR spectrometer design, an integral air pump draws ambient air into the test cell, operating at a flow rate of 0.88 acfm (25 l/min). The microprocessor selects the wavelengths for the components and the filter wheel in the analyzer allows the selected wavelengths to pass through the ambient air sample in the cell. The microprocessor automatically adjusts the path length through the cell to give the required sensitivity. Because of the folded-path-length design, the path length can be increased to 20 m (60 ft), and the resulting measurement sensitivity is better than 1 ppm in many cases.

As shown in [Table 5.10.2](#), practically all organic and some inorganic vapors and gases can be monitored by these IR spectrometers. The advantage of the microprocessor-based operation is that the monitor is precalibrated for the analysis of over 100 Occupational Safety and Health Administration (OSHA)-cited compounds. The memory capacity of the microprocessor is sufficient to accommodate another ten user-selected and user-calibrated gases. Analysis time is minimized because the microprocessor automatically sets the measurement wavelengths and parameters for any compound in its memory. A general scan for a contaminant in the atmosphere takes about 5 min, while the analysis of a specific compound can be completed in just a few minutes. The portable units are battery-operated for 4 hr of continuous operation and are approved for use in hazardous areas.

# 5.11 STACK SAMPLING

**Type of Sample**

Gas containing particulates

**Standard Design Pressure**

Generally atmospheric or near-atmospheric

**Standard Design Temperature**

-25 to 1500°F (-32 to 815°C)

**Sample Velocity**

400 to 10,000 ft (120 to 3000 m) per minute

**Materials of Construction**

316 or 304 stainless steel for pitot tubes; 304 or 316 stainless, quartz, or Incoloy for sample probes

**Partial List of Suppliers**

Andersen Samplers, Inc.; Applied Automation/Hartmann & Braun Process Control Systems Div.; Bacharach, Inc.; Columbia Scientific Industries Corp.; Cosa Instruments; Gastech, Inc.; Mine Safety

Appliance Co., Instrument Division; Sensidyne, Inc. Gas & Particulate Detection Systems; Scientific Glass & Instruments Inc.; Sierra Monitor Corp.; Teledyne Analytical Instrument, Teledyne Inc.

A complete EPA particulate sampling system (reference method 5) is comprised of the following four subsystems (U.S. EPA 1971; 1974; 1977; 1987; 1989; 1991; Morrow, Brief, and Bertrand 1972):

1. A pitot tube probe or pitot assembly for temperature and velocity measurements and for sampling
2. A two-module sampling unit that consists of a separate heated compartment with provisions for a filter assembly and a separate ice-bath compartment for the impinger train and bubblers

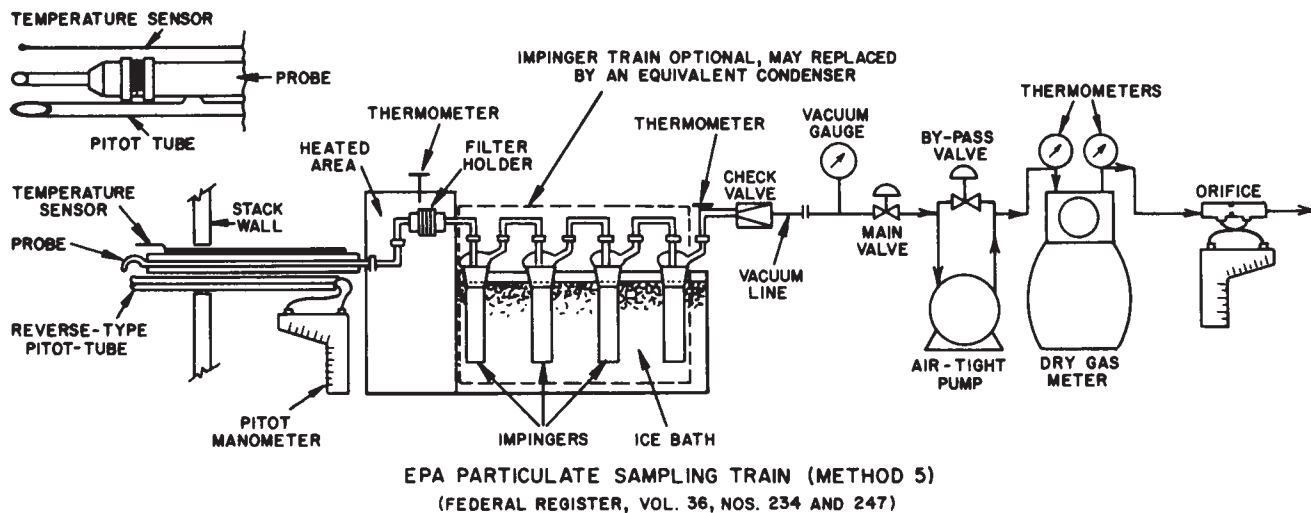

FIG. 5.11.1 (Top) EPA particulate sampling train (reference method 5); (Bottom) Sampling case for SO<sub>2</sub>, SO<sub>3</sub>, and H<sub>2</sub>SO<sub>4</sub> mist (reference method 8). (Reprinted from *Federal Register* 36, nos. 234 and 247.)

3. An operating or control unit with a vacuum pump and a standard dry gas meter
4. An integrated, modular umbilical cord that connects the sample unit and pitot tube to the control unit.

Figure 5.11.1 is a schematic of a U.S. EPA particulate sampling train (reference method 5). As shown in the figure, the system can be readily adapted for sampling sulfur dioxide ( $\text{SO}_2$ ), sulfur trioxide ( $\text{SO}_3$ ), and sulfuric acid ( $\text{H}_2\text{SO}_4$ ) mist (reference method 8) (U.S. EPA 1971; 1977).

This section gives a detailed description of each of the four subsystems.

## Pitot Tube Assembly

Procuring representative samples of particulates suspended in gas streams demands that the velocity at the entrance to the sampling probe be equal to the stream velocity at that point. The environmental engineer can equalize the velocities by regulating the rate of sample withdrawal so that the static pressure within the probe is equal to the static pressure in the fluid stream at the point of sampling. A specially designed pitot tube with means for measuring the pertinent pressures is used for such purposes. The engineer can maintain the pressure difference at zero by automatically controlling the sample drawoff rate.

Figure 5.11.2 shows the pitot tube manometer assembly for measuring stack gas velocity. The type S (Stauscheibe or reverse) pitot tube consists of two opposing openings, one facing upstream and the other downstream during the measurement. The difference between the impact pressure (measured against the gas flow) and the static pressure gives the velocity head.

FIG. 5.11.2 Type S pitot tube manometer assembly.

Figure 5.11.3 illustrates the construction of the type S pitot tube. The external tubing diameter is normally between  $\frac{1}{8}$  in and  $\frac{3}{8}$  in (4.8 and 9.5 mm). As shown in the figure, the distance is equal from the base of each leg of the tube to its respective face-opening planes. This distance ( $P_A$  and  $P_B$ ) is between 1.05 and 1.50 times the external tube diameter. The face openings of the pitot tube should be aligned as shown.

Figure 5.11.4 shows the pitot tube combined with the sampling probe. The relative placement of these components eliminates the major aerodynamic interference effects. The probe nozzle has a bottom-hook or elbow design. It is made of seamless 316 stainless steel or glass with a sharp, tapered leading edge. The angle of taper should be less than  $30^\circ$ , and the taper should be on the outside to preserve a constant internal diameter. For the probe lining, either borosilicate or quartz glass probe liners are used for stack temperatures to approximately  $900^\circ\text{F}$  ( $482^\circ\text{C}$ ); quartz liners are used for temperatures between  $900$  and  $1650^\circ\text{F}$  ( $482$  and  $899^\circ\text{C}$ ). Although borosilicate or quartz glass probe linings are generally recommended, 316 stainless steel, Incoloy, or other corrosion-resistant metal can also be used.

## INSTALLATION

The environmental engineer selects the specific points of the stack for sampling to ensure that the samples represent the material being discharged or controlled. The en-

FIG. 5.11.3 Properly constructed type S pitot tube. (a) End view: face-opening planes perpendicular to transverse axis, (b) Top view: face-opening planes parallel to longitudinal axis, (c) Side view: both legs of equal length and center lines coincident; when viewed from both sides, baseline coefficient values of 0.84 can be assigned to pitot tubes constructed this way.

FIG. 5.11.4 Proper pitot tube with sampling probe nozzle configuration to prevent aerodynamic interference. (a) Bottom view: minimum pitot nozzle separation. (b) Side view: the impact pressure opening plane of the pitot tube located even with or above the nozzle entry plane so that the pitot tube does not interfere with gas flow streamlines approaching the nozzle.

gineer determines these points after examining the process or sources of emissions and their variation with time.

In general, the sampling point should be located at a distance equal to at least eight stack or duct diameters downstream and two diameters upstream from any source of flow disturbance, such as expansion, bend, contraction, valve, fitting, or visible flame. (Note: This eight-and-two-diameter criterion ensures the presence of stable, fully developed flow patterns at the test section.) For rectangular stacks, the equivalent diameter is calculated from the following equation:

$$\text{Equivalent diameter} = 2 (\text{length} \times \text{width}) / (\text{length} + \text{width}) \quad 5.11(1)$$

Next, provisions must be made to traverse the stack. The number of traverse points is 12. If the eight-and-two-diameter criterion is not met, the required number of traverse points depends on the sampling point distance from the nearest upstream and downstream disturbances. Figure 5.11.5 shows how to determine this number.

The cross-sectional layout and location of traverse points are as follows:

1. For circular stacks, the traverse points should be located on two perpendicular diameters as shown in Figure 5.11.6 and Table 5.11.1.
2. For rectangular stacks, the cross section is divided into as many equal rectangular areas as traverse points so that the length-to-width ratio of the elemental area is between one and two. The traverse points are located at the centroid of each equal area as shown in Figure 5.11.6.

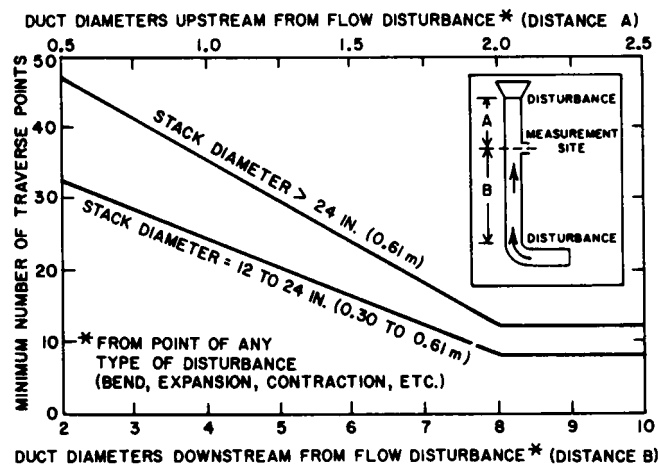

FIG. 5.11.5 Minimum number of traverse points for particulate traverses.

FIG. 5.11.6 Traverse point locations for velocity measurement or for multipoint sampling.

## OPERATION

The environmental engineer measures the velocity head at various traverse points using the pitot tube assembly shown in Figure 5.11.2. The engineer collects the gas samples at a rate proportional to the stack gas velocity and analyzes them for carbon monoxide (CO), carbon dioxide (CO<sub>2</sub>), and oxygen (O<sub>2</sub>). Measuring the velocity head at a point in the flowing gas stream with both the type S pitot tube and a standard pitot tube with a known coefficient calibrates the pitot tube. Other data needed to calculate the volumetric flow are the stack temperature, stack and barometric pressures, and wet-bulb and dry-bulb temperatures of the gas sample at each traverse.

Table 5.11.2 gives the equations for converting pitot tube readings into velocity and mass flow and shows a typical data sheet for stack flow measurements (Morrow, Brief, and Bertrand 1972).

Based on the range of velocity heads, the environmental engineer selects a probe with a properly sized nozzle to maintain isokinetic sampling of particulate matter. As shown in Figure 5.11.7, a converging stream develops at the nozzle face if the sampling velocity is too high. Under this subisokinetic sampling condition, an excessive amount of lighter particles enters the probe. Because of the inertia effect, the heavier particles, especially those in the range of  $3\mu$  or greater, travel around the edge of the nozzle and are not collected. The result is a sample indicating an excessively high concentration of lighter particles, and the weight of the solid sample is in error on the low side.

Conversely, portions of the gas stream approaching at a higher velocity are deflected if the sampling velocity is below that of the flowing gas stream. Under this superisokinetic sampling condition, the lighter particles follow the deflected stream and are not collected, while the heavier particles, because of their inertia, continue into the probe. The result is a sample indicating a high concentration of heavier particles, and the weight of the solid sample is in error on the high side.

Isokinetic sampling requires precisely adjusting the sampling rate with the aid of the pitot tube manometer readings and nomographs such as APTD-0576 (Rom). If the pressure drop across the filter in the sampling unit becomes

too high, making isokinetic sampling difficult to maintain, the filter can be replaced in the midst of a sample run.

Measuring the concentration of particulate matter requires a sampling time for each run of at least 60 min and

a minimum volume of 30 dry acfm (51 m<sup>3</sup>/hr) (U.S. EPA 1974).

## Two-Module Sampling Unit

The two-module sampling unit has a separate heated compartment and ice-bath compartment.

### HEATED COMPARTMENT

As shown in Figure 5.11.1, the probe is connected to the heated compartment that contains the filter holder and other particulate-collecting devices, such as the cyclone and flask. The filter holder is made of borosilicate glass, with a frit filter support and a silicone rubber gasket. The compartment is insulated and equipped with a heating system capable of maintaining the temperature around the filter holder during sampling at  $248 \pm 25^\circ\text{F}$  ( $120 \pm 14^\circ\text{C}$ ), or at another temperature as specified by the EPA. The thermometer should measure temperature to within  $5.4^\circ\text{F}$  ( $3^\circ\text{C}$ ). The compartment should have a circulating fan to minimize thermal gradients.

### ICE-BATH COMPARTMENT

The ice-bath compartment contains the system's impingers and bubblers. The system for determining the stack gas moisture content consists of four impingers connected in series as shown in Figure 5.11.1. The first, third, and fourth impingers have the Greenburg–Smith design. The pressure drop is reduced when the tips are removed and replaced with a 1/2-in (12.5 mm) ID glass tube extending to 1/2in (12.5 mm) from the bottom of the flask. The second impinger has the Greenburg–Smith design with a standard tip. During sampling for particulates, the first and second impingers are filled with 100 ml (3.4 oz) of distilled and deionized water. The third impinger is left dry to separate entrained water. The last impinger is filled with 200 to 300 g (7 to 10.5 oz) of precisely weighed silica gel (6 to 16 mesh) that has been dried at  $350^\circ\text{F}$  ( $177^\circ\text{C}$ ) for 2 hr to completely remove any remaining water. A thermometer, capable of measuring temperature to within  $2^\circ\text{F}$  ( $1.1^\circ\text{C}$ ), is placed at the outlet of the last impinger for monitoring purposes. Adding crushed ice during the run maintains the temperature of the gas leaving the last impinger at  $60^\circ\text{F}$  ( $16^\circ\text{C}$ ) or less.

## Operating or Control Unit

As shown in Figure 5.11.1, the control unit consists of the system's vacuum pump, valves, switches, thermometers, and the totalizing dry gas meter and is connected by a vacuum line with the last Greenburg–Smith impinger. The pump intake vacuum is monitored with a vacuum gauge just after the quick disconnect. A bypass valve parallel with

the vacuum pump provides fine control and permits recirculation of gases at a low-sampling rate so that the pump motor is not overloaded.

Downstream from the pump and bypass valve are thermometers, a dry gas meter, and calibrated orifice and inclined or vertical manometers. The calibrated orifice and inclined manometer indicate the instantaneous sampling rate. The totalizing dry gas meter gives an integrated gas volume. The average of the two temperatures on each side of the dry gas meter gives the temperature at which the sample is collected. The addition of atmospheric pressure to orifice pressure gives meter pressure.

Precise measurements require that the thermometers are capable of measuring the temperature to within  $5.4^\circ\text{F}$  ( $3^\circ\text{C}$ ); the dry gas meter is inaccurate to within 2% of the volume; the barometer is inaccurate within 0.25 mmHg (torr) (0.035 kPa); and the manometer is inaccurate to within 0.25 mmHg (torr) (0.035 kPa).

The umbilical cord is an integrated multiconductor assembly containing both pneumatic and electrical conductors. It connects the two-module sampling unit to the control unit, as well as connecting the pitot tube stack velocity signals to the manometers or differential pressure gauges.

FIG. 5.11.8 Components of common sampling systems.

## Sampling for Gases and Vapors

Some commonly used components in stack sampling systems are shown in Figure 5.11.8. If ball-and-socket joints and compression fittings are used, any arrangement of components is readily set up for field use. Environmental engineers select the stack sampling components on the basis of the source to be sampled, the substances involved, and the data needed.

Industrial hygienists developed a summary of sampling procedure outlines for specific substances (Vander Kolk 1980). After considering the complications that might arise from the presence of interfering substances in the gas samples, an environmental engineer should use the procedural outlines as a starting point in assembling a stack sampling system. The American Society for Testing and Materials (1971) provides other recommended sampling procedures for gases and vapors.

### Requirements

More stringent clean air standards require more stringent monitoring of the release of pollutants into the atmosphere. The need is growing for reliable continuous emission monitoring (CEM) capabilities and for documenting the release amount from process plants. Therefore, a CEM system is an integral part of utility and industrial operations. For operators, collecting real-time emission data is the first step to attaining the nationally mandated reduction in SO<sub>x</sub> and NO<sub>x</sub> emissions. A company uses CEM to ensure compliance with the Acid Rain Program requirements of the CAAA.

A CEM system is defined by the U.S. EPA in Title 40, Part 60, Appendix B, Performance Specification 2 of the *Code of Federation Regulations*, as all equipment required to determine a gas concentration or emission rate. The regulation also defines a CEM system as consisting of subsystems that acquire, transport, and condition the sample, determine the concentration of the pollutant, and acquire and record the results. For the measurement of opacity, the specifics of the major subsystems are slightly different but basically the same.

The EPA has codified the standards of performance, equipment specifications, and installation and location specifications for the measurement of opacity, total reduced sulfur (TRS), sulfur dioxide, carbon dioxide, and hydrogen sulfide. These standards include requirements for the data recorder range, relative accuracy, calibration drift and frequency of calibration, test methods, and quarterly and yearly audits. The regulations also require opacity to be measured every 10 sec, the average to be recorded every 6 min, and pollutants to be measured a minimum of one cycle of sampling, analyzing, and data recording every 15 min. The readings from the gas analyzer must agree with a stack sampler to within 20% relative accuracy.

This section provides an overview of the CEM technology, the components of a proper analysis system, and some details in the reliable and accurate operation of CEM.

## System Options

Figure 5.12.1 shows the various CEM options. All systems fall into one of two categories: in situ or extractive. Extractive units can be further classified into full-extractive (wet or dry basis) or dilution-extractive systems.

### IN SITU SYSTEMS

An in situ system measures a gas as it passes by the analyzer in a stack. Figure 5.12.2 shows an in situ probe-type analyzer. The measurement cavity is placed directly into the sample flow system to measure the gas received on a wet basis.

The most commonly accepted in situ analyzer is the zirconium oxide ( $ZrO_2$ ) oxygen analyzer. It is the most reliable method for measuring and controlling a combustion process. Since the introduction of  $ZrO_2$  analyzers, many other gases have been measured in situ with light absorption instrumentation, such as UV and IR spectrometers. The gases that can be measured with such spectrometers include  $CO$ ,  $CO_2$ ,  $SO_2$  and  $NO$ .

Most of the first analyzers designed to measure these gases have disappeared. Most noticeably, across-the-stack technology units are no longer used in this country due primarily to the promulgation of Title 40, Part 60,

Appendix F of the *Code of Federal Regulations* by the EPA in 1986. Appendix F requires that an analyzer be able to complete gas calibrations and that it be certified quarterly. An across-the-stack unit works like an opacity instrument in that it lacks the capability of using protocol gases for cylinder gas audits (CGA) as allowed by the EPA under Appendix F.

### EXTRACTIVE SYSTEMS

Extractive CEM systems can be configured for either dry- or wet-basis measurements. Both configurations can achieve the CAAA-required 10% relative accuracy.

#### Dry-Extractive Systems

A standard extractive system (see Figure 5.12.3) extracts a gas sample from the stack and delivers it to an analyzer cabinet through heated sample lines. Filtration removes particulates at the sample probe. (However, uncontrolled condensation can block the sample line because it cannot trap and hold fines that pass through the stack filter.) The dry-extractive CEM system removes moisture through a combination of refrigeration, condensation, and permeation tube dryers that pass the sample through water-excluding membranes. This system helps keep the gas analyzer dry and removes any interferences caused by water.

To convert the volumetric concentration into a mass emission rate when using velocity-measuring flow moni-

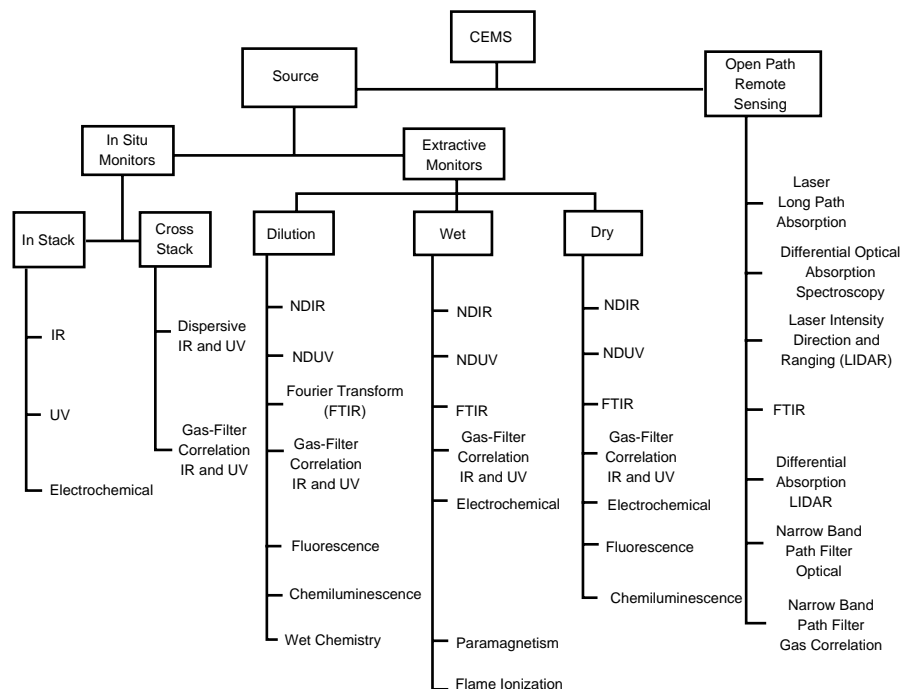

FIG. 5.12.1 CEM options. (Reprinted, with permission, from J. Schwartz, S. Sample, and R. McIlvaine, 1994, Continuous emission monitors—Issues and predictions, *Air & Waste*, Vol. 44 [January].)

FIG. 5.12.2 Probe-type stack gas analyzer. (Reprinted, with permission, from Lear Siegler Inc.)

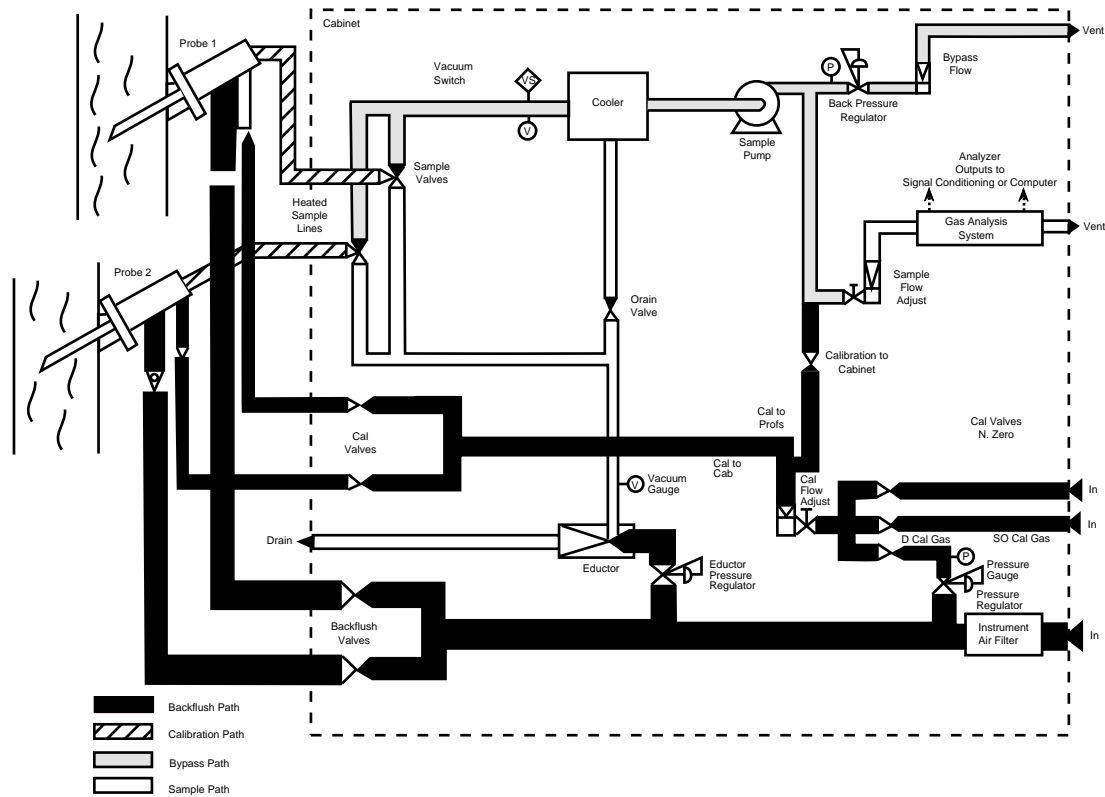

FIG. 5.12.3 Standard extractive system.

tors, the environmental engineer must measure or calculate the flue-gas moisture to account for the moisture removed before dry-extractive analysis. This additional measurement or calculation adds complexity to the system, which lowers the reliability and accuracy of dry-extractive CEM systems.

Operating an extractive system is complicated by the daily calibration, zero and span checks of the analyzers, and the need to backpurge the sample handling system to clear the probe and filters. These tasks are accomplished with additional lines and connections to the stack probe

and control valves. A controller system sequences the operation of all valves and controls gas flows.

The major advantages of extractive systems is their ability to share analyzers and spread the analyzer cost over several measurement points. An extractive system can be used to monitor two or eight points.

### Wet-Extraction Systems

Wet-extraction CEM systems are similar to dry-extraction ones except that the sample is maintained hot, and mois-

ture in the flue gas is retained throughout. Heat tracing is the critical component of a wet-extractive system. Sample temperatures must be maintained between 360° and 480°F to prevent acid gases from condensing within the sampling lines and analyzer.

Since nothing is done to the sample before analysis, wet-extractive CEM has the potential of being the most accurate measurement technique available. However, only a limited number of vendors supply wet-extractive CEM systems. In addition, increased flexibility and accuracy makes the wet-extractive CEM systems more costly than dry-extractive ones.

### Dilution-Extractive Systems

The newest, accepted measurement system is dilution-extractive CEM. By precisely diluting the sample at stack temperature with clean, dry (lower than -40°F dewpoint) instrument air, dilution-extractive systems eliminate the need for heat tracing and conditioning of extracted samples. Particulates are filtered out at the sample point. Thus, a dilution system measures all of the sample along with the water extracted with the sample on a wet basis. Figure 5.12.4 shows a schematic of a dilution-extractive system.

The dilution-extraction CEM system uses a stack dilution probe (see Figure 5.12.5) designed in Europe. A precisely metered quantity of flue gas is extracted through a critical orifice (or sonic orifice) mounted inside the probe. Dilution systems deliver the sample under pressure from the dilution air to the gas analyzers. Thus, the system pro-

tecs the sample from any uncontrolled dilution from a leak in the sample line or system.

The environmental engineer selects the dilution ratios based on the expected water concentration in the flue gas and the lower limit of the ambient air temperature to avoid freezing. This kind of sample line is still considerably less expensive than the heated sample line for wet-extractive CEM.

When choosing the dilution ratio, the engineer must also consider the lowest pollutant concentration that can be detected by the monitoring device. These systems use a dilution ratio ranging from 12:1 to more than 700:1. Irrespective of the dilution ratio, the diluted sample must match the analyzer range.

### SYSTEM SELECTION

The majority of the systems purchased for existing utility boilers are the dilution-extractive type. Beyond the utility industry, the dry-extractive, wet-extractive, and dilution-extractive systems are all viable choices. The accuracy, reliability, and cost differences must be considered in the selection of a system for a specific application. The CEM system selection process can also be limited by local regulatory agencies. These restrictions can include preapproval procedures that limit the type of system an agency accepts. For example, with some types of emission monitors, some states require that only dedicated, continuous measurement are used; that is no time-sharing. They can also define such terms as "continuous." This factor directly defines the requirements for a data acquisition system.

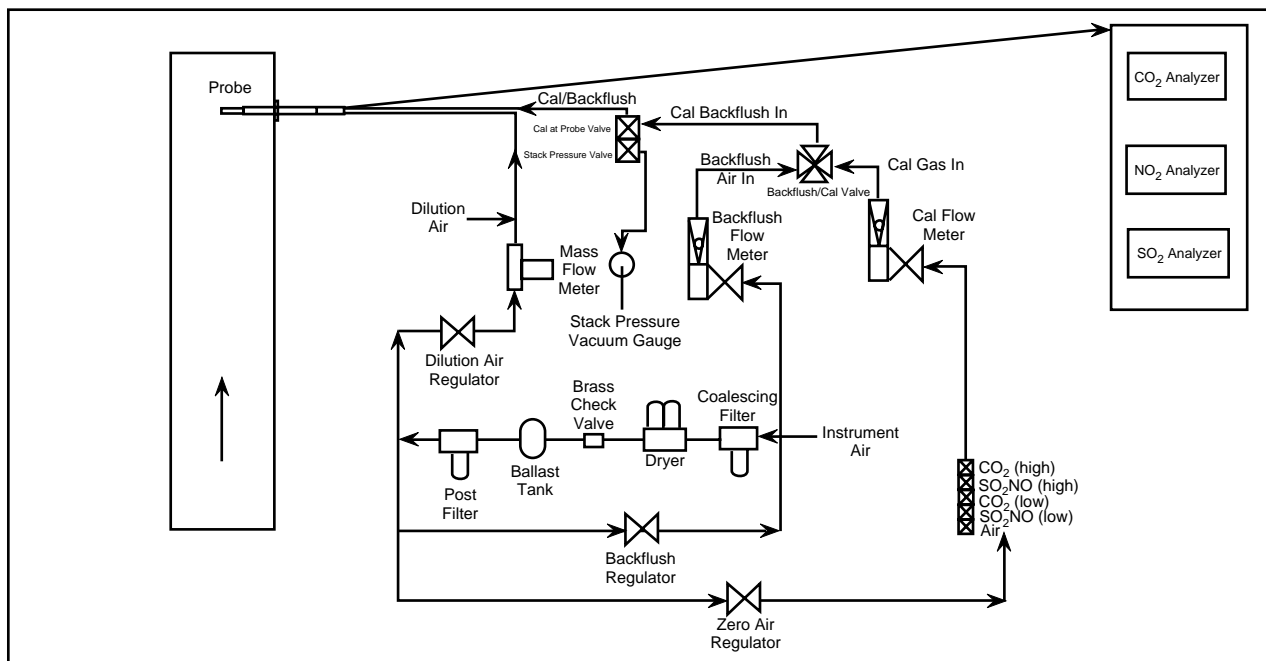

FIG. 5.12.4 Dilution-extractive system schematic. (Reprinted, with permission, from Lear Siegler.)

FIG. 5.12.5 Dilution probe.

## Continuous Emission Monitors

A complex combination of regulatory bodies determines which pollutants must be measured and in what manner the measurement must be made for a specific plant. Figure 5.12.6 shows the complexity of laws that affect the CEM design for a plant. For example, if the plant falls under the incentive program in Title IV of the 1990 CAA, this plant has an emission allowance in tons of  $\text{SO}_2$  per year. It must continually monitor its mass flow and accurately record its total mass emissions in tons per year for the entire period. This requirement means that a data acquisition and reporting system must be incorporated into the CEM sys-

tem (see Figure 5.12.7). A plant in a nonattainment area or region can be required to reduce  $\text{NO}_x$  to a greater degree than that required in Title IV. This requirement could mean installing control equipment and measuring ammonia and other pollutants.

Table 5.12.1 shows the pollutants measured for various applications.

Table 5.12.2 summarizes the type of monitors and the concentration measurement range available for several CEM systems. Performance specifications for CO and  $\text{O}_2$  are given in Table 5.12.3. Dilution-extractive systems prefer a pulse of chopped fluorescence for  $\text{SO}_2$  analysis.

$\text{NO}$  is generally measured using chemiluminescence (see

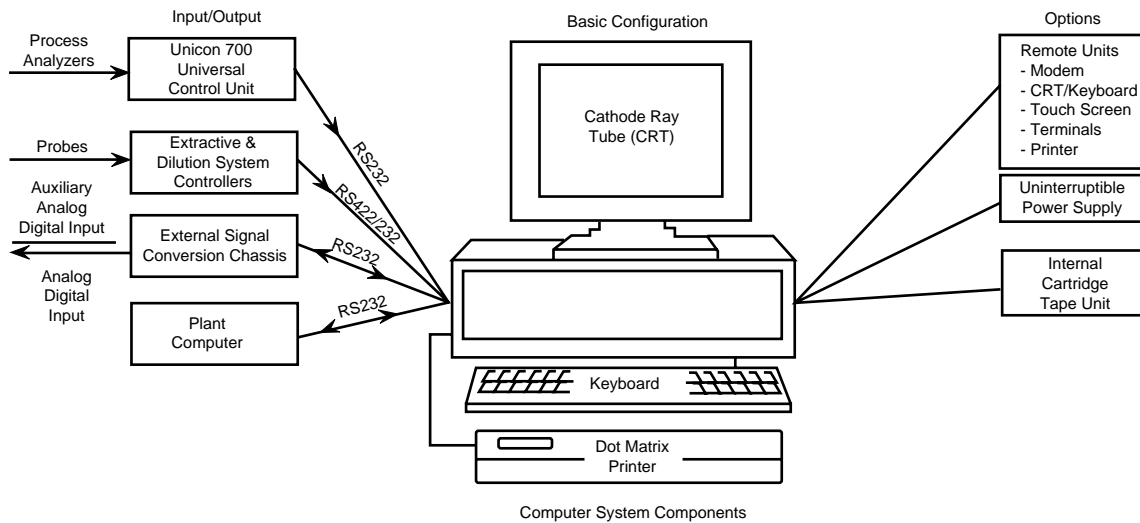

FIG. 5.12.7 Data acquisition and reporting computer system.

†Can be substituted for O<sub>2</sub>.

Figure 5.12.8). The term NO<sub>x</sub> refers to all nitrogen oxides; however, in air pollution work, NO<sub>x</sub> refers only to NO (about 95–98%) and NO<sub>2</sub>. Because NO is essentially transparent in the visible and UV light region, it must be converted to NO<sub>2</sub> before it can be measured. NO can then react with ozone to form NO<sub>2</sub> with chemiluminescence. The light emitted can be measured photometrically as an indication of the reaction's extent. With excess ozone, the emission is in proportion to the amount of NO. Including NO<sub>2</sub> (which reacts slowly with ozone) involves bringing the sample gas in contact with a hot molybdenum catalyst. This technique converts all NO<sub>2</sub> to NO before it reacts with ozone.

## LOCATION OF SYSTEMS

Title 40, Part 60 of the *Code of Federal Regulations* includes guidelines for instrument location within specific performance specifications. GEP dictates a location sepa-

rate from bends, exits, and entrances to prevent measurements in areas of high gas or material stratification. Environmental engineers can determine the degree of stratification of either the flowrate or pollution concentration by taking a series of preliminary measurements at a range of operating conditions. For gas measurements, certification testing confirms the proper location. Under the certification, readings from the gas analyzer must agree with the stack sampler measurements to within 20% relative accuracy (RA).

To convert the volumetric pollution concentration (ppmv) measured by the CEM system to the mass emission rate (lb/hr) required by the CAAA, an environmental engineer must measure the flowrate. Proper placement of the sensor in the flue-gas stream is a key requirement. The goal is to measure flow that represents the entire operation at various boiler loads. Measurement must compare favorably with the standard EPA reference methods to demonstrate the RA of the unit.

**TABLE 5.12.2 SUMMARY OF CONTINUOUS EMISSION MONITORS**

## MAINTENANCE OF SYSTEMS

Because downtime can result in a fine, designing and engineering CEM systems to maximize reliability is essential. Certification follows start up and commissioning. Once a CEM system is running, users must devote appropriate resources to the ongoing maintenance and calibration requirements.

Proper maintenance procedures require periodically inspecting the probe and replacing the filter material. A good

blowback system increases the time interval between these maintenance inspections.

Cochran, Ferguson, and Harris (1993) outline ways of enhancing the accuracy and reliability of CEM systems.

## 5.13 REMOTE SENSING TECHNIQUES

### PARTIAL LIST OF SUPPLIERS

Altech Systems Corp.; Ametek, Process and Analytical Instruments Div.; Extrel Corp.; The Foxboro., Environmental Monitoring Operations; KVB Analect, Inc.; MDA Scientific, Inc.; Nicolet Instrument Corp.; Radian Corp.; Rosemount Analytical, Inc.

The open-path, optical remote sensing techniques make new areas of monitoring possible. These techniques measure the interaction of light with pollutants in real time (see Figure 5.13.1). In an open-path configuration, path lengths—the distance between a light source and a re-

flecting device—can range to kilometers. Thus, these techniques are ideal for characterizing emission clouds wafting over process areas, storage tanks, and waste disposal sites. Open-path optical sensing systems can monitor gas concentrations at the fence lines of petrochemical plants and hazardous waste sites.

Wide-area systems are also being used indoors for emergency response and to demonstrate compliance with OSHA regulations. When used indoors, these systems can quickly detect routine or accidental releases of many chemical species. They are frequently fitted to control systems

**FIG. 5.13.1** Open-path monitoring system. A beam of light is transmitted from a transmitter through an area of contamination to a receiver. (Reprinted, with permission, from L. Nudo, 1992, *Emerging technologies—Air, Pollution Engineering* [15 April].)

and alarms to evacuate personnel when toxins are detected above a threshold limit.

## Open-Path Optical Remote Sensing Systems

Table 5.13.1 describes several sensing techniques. Of the techniques listed, the FTIR and UV differential optical absorption spectroscopy (UV-DOAS) are the most widely publicized. They both measure multiple compounds in open areas in near real time.

These systems use a high-pressure xenon lamp in the UV-DOAS or a grey-body source in the FTIR to produce a broadband light that is collimated by a telescope into a narrow beam. This beam is then transmitted through the area of contamination to a receiver. The transmission path can range from several feet, in stacks, to 1 to 3 km, in ambient air over large areas (see Figure 5.13.1).

In route to the receiver, a portion of the light energy is absorbed by the pollutants. The light that reaches the receiver is sent to a spectrometer or interferometer, which generates a spectrum. The computer analyzes the spectrum by comparing it with a precalibrated reference spectrum for both the measured and the interfering components. Because each pollutant absorbs a unique pattern of wavelengths, missing light reveals the presence of a pollutant. The amount of missing light determines its concentration. Measurements are taken as often as every minute and averaged at any interval.

UV-DOAS systems are best suited to monitor criteria pollutants such as SO<sub>2</sub>, NO, NO<sub>2</sub>, O<sub>3</sub> and benzene, toluene, and xylene (BTX). FTIR systems are better suited to measure VOCs. FTIR systems also detect criteria pollutants but not with the same degree of sensitivity as UV-DOAS. These limitations stem from interferences of water vapor, which absorbs strongly in the IR region but does not absorb in the UV region. However, powerful software algorithms are becoming available to filter out the interference signals from water.

In general, more chemicals absorb light in the IR spectrum than in the UV spectrum. Thus, FTIR systems measure a broader range of compounds (more than fifty) than UV-DOAS systems, which detect about twenty-five (Nudo 1992). With the aid of a contractor, the EPA has developed reference IR spectra for approximately 100 of the 189 HAPs listed under Title III. The maximum number of HAPs to which FTIR might ultimately be applicable is about 130 (Schwartz, Sample, and McIlvaine 1994). The EPA plans to initiate its own investigation into this area. Additional investigation into the potential of FTIR in continuous applications is underway at Argonne National Labs.

**TABLE 5.13.1 REMOTE SENSING TECHNIQUES FOR AIR ANALYSIS**

Method	Operating Principle
FTIR	A broadband source allows collection and analysis of a full IR spectrum. This method compares standard spectra with field readings to determine constituents and concentrations
UV spectroscopy	UV spectra are collected over a limited absorption spectral region. This method uses the differential absorptions of the compounds in the air to determine the identity and concentrations of contaminants
Gas-filter correlation	A sample of the gas to be detected is used as a reference. This method compares the correlation between the spectrum of the sample gas to the gas in the measurement path to determine concentration
Filtered band-pass absorption	This method measures absorption of the gas in certain bands to detect composition and concentration
Laser absorption	This method uses one or more lasers to measure absorption at different wavelengths
Photoacoustic spectroscopy	The pressure change from the deactivation of excited molecules is measured in a closed acoustic chamber
LIDAR	This method measures molecular or aerosol backscatter by either differential absorption or Raman scattering to identify gases and determine their concentrations. Unlike the other methods listed, this method provides ranging information on measurements
Diode-laser spectroscopy	A developing technology for open-air use. This method scans a line feature of the gas spectrally to identify and quantify the compound

**FIG. 5.13.2** Bistatic and unistatic systems. Bistatic systems (top), which place the IR source and receiver in different positions, require two power sources and precise alignment to record properly. Unistatic systems (bottom) are simpler to operate. Most installations use four separate bi- or unistatic source-receiver pairs—one for each side of a property. The next step may be to use one centrally located IR source on a tower, with retroreflectors around it.

UV-DOAS systems are more selective. They have a lower limit of detection and fewer problems with interferences from water vapor and carbon dioxide. For the best features of both systems, these complimentary systems can be integrated.

## Instrumentation

The instrumentation used in remote sensing techniques includes bistatic systems and unistatic systems.

### BISTATIC SYSTEMS

Early bistatic design (see the top of Figure 5.13.2) placed the light source and the receiver at opposite ends of the area to be monitored. Precise alignment, to assure that the receiver gets the full strength of the transmitted signal, is often a problem. Therefore, two separate electrical sources are usually required to operate these systems (Shelley 1991).

### UNISTATIC SYSTEMS

A new unistatic design (see the bottom of Figure 5.13.2), developed by MDA Scientific, uses a single telescope that acts as both source and receiver. The IR beam traverses the area being monitored and returns to the receiver from an array of cubed mirrors, or retro-reflectors, on the opposite end of the field.

These clusters collect and refocus the beam and, unlike flat-faced mirrors, need not be precisely aligned to achieve near-perfect reflection along a light beam's original path.

This design makes the unistatic system easier to set up and reduces error during analysis.

## LIMITATIONS

With open-path systems, sophisticated, meteorological modeling software is necessary to integrate information about regional topography and moment-to-moment changes in atmospheric conditions. Such modeling programs are still in the early stages. Therefore, discrete-point sampling is needed to confirm optical sensing results. Another shortcoming of using open-path systems is the assumption that the distribution of molecules in the beam is homogeneous. Path-averaging assumptions can underestimate a localized problem.

Despite some remaining problems, the use of perimeter monitoring is rising for documenting cumulative emissions over process facilities. The EPA is developing procedures to demonstrate equivalence with reference test methods for use with some toxic gases (Schwartz, Sample, and McIlvaine 1994). These procedures are required before regulatory agencies and industry can adopt optical techniques.

# *Pollutants: Minimization and Control*

## **5.14 POLLUTION REDUCTION**

---

---

The CAA of 1970 establishes primary and secondary standards for criteria pollutants. Primary standards protect human health, while secondary standards protect materials, crops, climate, visibility, and personal comfort. The standard for total suspended particulates (TSP) is an annual geometric mean of  $75 \mu\text{g}/\text{m}^3$  and a maximum 24 hr average of  $260 \mu\text{g}/\text{m}^3$ . This standard is currently being reviewed by the U.S. EPA for possible change.

Prevention of air pollution from industrial operations starts within the factory or mill. Several alternatives are available to prevent the emission of a pollutant including:

- Selecting process inputs that do not contain the pollutant or its precursors
- Operating the process to minimize generation of the pollutant
- Replacing the process with one that does not generate the pollutant
- Using less of the product whose manufacture generates the pollutant
- Removing the pollutant from the process effluent.

### **Raw Material Substitution**

Removing some pollutants involves simply substituting materials which perform equally well in the process but which discharge less harmful products to the environment. This method of air pollution reduction usually produces satisfactory control at a low cost.

Typical examples are the substitution of high-sulfur coal with low-sulfur coal in power plants. This substitution requires little technological change but results in a substantial pollution reduction. Changing to a fuel like natural gas or nuclear energy can eliminate all sulfur emissions as well as those of particulates and heavy metals. However, natural gas is more expensive and difficult to ship and store than coal, and many people prefer the known risks of coal pollution than the unknown risks of nuclear power. Coal gasification also greatly reduces sulfur emissions. Another example is substituting gasoline with ethanol or oxy-

genated fuels in internal combustion engines. This substitution reduces the  $\text{O}_3$  pollution in urban areas. Alternative energy sources, such as wind or solar power, are being explored and may become economically feasible in the future.

### **Process Modification**

Chemical and petroleum industries have changed dramatically by implementing automated operations, computerized process control, and completely enclosed systems that minimize the release of materials to the outside environment.

A process modification example is industry reducing the oxidation of  $\text{SO}_2$  to  $\text{SO}_3$  by reducing excess air from  $\sim 20\%$  to  $<1\%$  when burning coal, resulting in reduced sulfuric acid emissions. However, this process change has increased fly ash production.

Powders and granulated solids are widely used in industry. Handling these materials at locations such as transfer points or bagging and dumping operations generates dust that can affect worker health. Plinke et al. (1991) found that the amount of dust generated by an industrial process depends on the size distribution of the dust, the ratio of impaction forces that disperse the dust during material handling, and the cohesion properties of the dust, such as moisture content. The implication is that by modifying both the material handling processes and the properties of the powders, the dust generated can be reduced.

Similar approaches are being used in municipal trash incinerators which emit carcinogenic dioxins. By adjusting the temperature of incineration, dioxin emissions can be prevented.

### **Marketing Pollution Rights**

Some economists view absolute injunctions and rigid limits as counterproductive. They prefer to rely on market mechanisms to balance costs and effects and to reduce pollution. Corporations can be allowed to offset emissions by

buying, selling, and banking pollution rights from other factories at an expected savings of \$2 to 3 billion per year. This savings may make economic sense for industry and even protect the environment in some instances, but it may be disastrous in some localities.

## Demand Modification

Demand modification and lifestyle changes are another way to reduce pollution. To combat smog-causing emissions, some districts in California have proposed substantial lifestyle changes. Aerosol hair sprays, deodorants, charcoal lighter fluid, gasoline-powered lawn mowers, and drive-through burger stands could be banned. Clean-burning, oxygenated fuels or electric motors would be required for all vehicles. Car-pooling would be encouraged, and parking lots would be restricted.

# 5.15 PARTICULATE CONTROLS

---

---

## Control Equipment

If waste reduction is not possible, either by process or material change, waste particulate material must be removed from the process air stream. Selecting the type of control equipment depends largely on the characteristics of the particulate material to be removed. Factors such as the physical form of the particulates (whether solid or liquid), particle size and size distribution, density and porosity of the particulates, and particle shape (spheres, fibers, or plates) affect particle behavior.

Control equipment can be divided into three broad classes: gravitational and inertial collectors, electrostatic precipitators (ESPs), and filters. Included in the category of gravitational and inertial collectors are wet and dry scrubbers, gravity settling chambers, and cyclone collectors. ESPs include both single and two-stage units. Finally, filters encompass a variety of media ranging from woven and nonwoven fabric, fiber, and paper media. In addition to media, filters are often classified according to the method of cleaning.

## Particulate Size

Although particulate material varies in both size and composition, certain particle types are usually associated with a range of particle sizes. For example, particulate mater-

## Gas Cleaning Equipment

Industry controls air pollution with equipment that removes contaminants at the end of the manufacturing process. Many such devices exist and are described in the next sections. These devices display two characteristics: the size and cost of the equipment increase with the volume of gas cleaned per unit of time, and the cost of removing a contaminant rises exponentially with the degree of removal. The degree of pollutant removal is described as collection efficiency, while the operating cost depends on the pressure drop across the unit and its flow capacity.

—*Gurumurthy Ramachandran*

## Reference

Plinke, M.A.E., D. Leith, D.B. Holstein, and M.G. Boundy. 1991. Experimental examination of factors that affect dust generation. *Am. Ind. Hyg. Assoc. J.* 52, no. 12:521–528.

ial produced by crushing or grinding or resuspended from settled dusts is generally made up of particles with diameters larger than 1  $\mu\text{m}$ . On the other hand, particulate material produced by condensation or gas-phase chemical reactions is comprised of many small particles, all much smaller than 1  $\mu\text{m}$  in diameter. [Figure 5.15.1](#) illustrates typical particle diameters for a variety of substances, including particulates such as beach sand and pollens. For comparison, this figure also includes the size range for types of electromagnetic radiation, estimates of gas molecule diameters, size ranges for fogs, mists and raindrops, and ranges for inspirable particles.

## Other Factors

Generally, particle size is the most important factor in the selection of a collector since the range of particle sizes to be collected strongly affects the expected cost and efficiency. In some instances, other factors such as serviceability or the pressure drop across the collector are the most important factors. [Table 5.15.1](#) lists the characteristics of various particulate removal equipment and compares some of these features. For the most part, the collection devices that are the least expensive to install and operate are also the least efficient.

[Table 5.15.2](#) also compares the collection characteristics and total annual costs of various air cleaning equip-

## 5.16 PARTICULATE CONTROLS: DRY COLLECTORS

### Gravity Settling Chambers

**FEATURE SUMMARY**

**Pressure Drop**

Less than 0.5 in of water

**Operating Temperatures**

Up to 1000°C

**Applications**

Precleaners for removing dry dust produced by grinding in cement and lime kilns, grain elevators, rock crushers, milling operations, and thermal coal dryers

**Dust Particle Sizes**

Greater than 50 μm

Settling chambers serve as preliminary screening devices for more efficient control devices. These chambers remove large particles from gas streams by gravity. The chambers slow the gas sufficiently to provide enough time for particles to collect (Leith, Dirgo, and Davis 1986). Figure 5.16.1 shows a chamber of length L, width W, and height H. A mass balance for an infinitesimal slice dL yields:

$$V_g H W C = V_g H W (C - dC) + W dL (-V_{ts}) C \quad \mathbf{5.16(1)}$$

where:

$V_g$  = the uniform gas velocity

$V_{ts}$  = the particle terminal settling velocity

$C$  = particle concentration in the slice dL

This equation assumes that the particles are well-mixed in every plane perpendicular to the direction of air flow due to lateral turbulence. This assumption is reasonable because even at low velocities, gas flow in industrial-scale settling chambers is turbulent. Rearranging Equation 5.16(1) and integrating between the two ends of the chamber yields the collection efficiency of the chamber as:

$$\eta = 1 - \exp \left[ \frac{-V_{ts} L}{V_g H} \right] \quad \mathbf{5.16(2)}$$

The terminal settling velocity is as follows:

$$V_{ts} = \frac{\rho_p d^2 C_c g}{18\mu} \quad \mathbf{5.16(3)}$$

where:

$\rho_p$  = the particle density

$d$  = the particle diameter

$\mu$  = the viscosity of the medium

$C_c$  = the Cunningham slip correction factor

FIG. 5.16.1 Schematic diagram of settling chamber with complete lateral mixing due to turbulence.

Equation 5.16(2) shows that settling chambers have high collection efficiency for low gas velocities, high terminal settling velocities, and large ratios of chamber length to height. Thus, gas velocities are usually below 3 m/sec, which has the added benefit of preventing reentrainment. A large L/H ratio ensures a long residence time and a short vertical distance for the particle to travel to be collected. The equation yields high terminal settling velocities for large particle sizes, therefore, these devices efficiently remove particles greater than 50  $\mu\text{m}$  in diameter.

Settling chambers are characterized by low capital costs and low pressure drop ( $\sim 0.5$  in water gauge [w.g.]). They can be used under temperature and pressure extremes ( $\sim 1000^\circ\text{C}$  and  $\sim 100$  atm). Settling chambers are used as precleaners to remove dry dusts produced by grinding, e.g. in coal dryers, grain elevators, and rock crushers.

## Cyclones

### FEATURE SUMMARY

#### Types of Designs

Reverse flow, or straight through, with tangential, scroll, and swirl vane entries

#### Gas Flow Rates

50 to 50,000  $\text{m}^3/\text{hr}$

#### Pressure Drop

Between 0.5 and 8.0 in of water

#### Operating Temperatures

Up to  $1000^\circ\text{C}$

#### Applications

Cement and lime kilns, grain elevators, milling operations, thermal coal dryers, and detergent manufacturing

#### Dust Particle Sizes

Greater than 5  $\mu\text{m}$

#### Partial List of Suppliers

Advanced Combustion Systems Inc.; Alfa-Laval Separation Inc.; Bayliss-Trema Inc.; Beckert and Heister Inc.; Clean Gas Systems

Inc.; Dresser Industries Inc.; Ducon Environmental Systems; Emtron Corp.; Fisher-Klosterman Inc.; Hough International Inc.; HVAC Filters Inc.; Interel Environmental Technologies Inc.; Joy Technologies Inc.; Quality Solids Separation Co.; Thiel Air Technologies Corp.; United Air Specialists Inc.; Wheelabrator Inc.

Cyclones operate by accelerating particle-laden gas in a vortex from which particles are removed by centrifugal force. One of the most widely used dust collecting devices, cyclones are inexpensive to construct and easy to maintain because they do not have any moving parts. Although cyclones are inefficient for collecting particles smaller than 5  $\mu\text{m}$  in diameter, they operate with low to moderate pressure drops (0.5 to 8.0 in w.g.).

Cyclones can be constructed to withstand dust concentrations as high as  $2000 \text{ g/m}^3$ , gas temperatures as high as  $1000^\circ\text{C}$ , pressures up to 1000 atm, and corrosivity. Such conditions are encountered in the pressurized, fluidized-bed combustion of coal, where cyclones are an economic control option. In addition, cyclones are used to control emissions from cement and lime kilns, grain elevators, grain drying and milling operations, thermal coal dryers, and detergent manufacturing.

Various cyclone designs have been proposed; however the reverse-flow cyclone is the type most commonly used for industrial gas cleaning. Figure 5.16.2 shows the dimensions of a reverse-flow cyclone. Dust-laden gas enters the cyclone at the top; the tangential inlet causes the gas to spin. After entry, the gas forms a vortex with a high tangential velocity that gives particles in the gas a high centrifugal force, moving them to the walls for collection. Below the bottom of the gas exit duct, the spinning gas gradually migrates to the cyclone axis and moves up and out the gas exit. Thus, the cyclone has an outer vortex moving downward and an inner vortex flowing upward (Dirgo and Leith 1986). Collected dust descends to the duct outlet at the bottom of the cone.

Cyclone dimensions are usually expressed as multiples of the diameter  $D$ . The dimension ratios  $a/D$ ,  $b/D$ ,  $D_c/D$ ,

FIG. 5.16.2 Dimensions of a reverse-flow cyclone.

$S/D$ ,  $h/D$ ,  $H/D$ , and  $B/D$  allow cyclones which differ in size to be compared. Table 5.16.1 gives some standard designs.

## GAS FLOW PATTERNS

Understanding and characterizing the performance of a cyclone requires knowledge of the gas flow patterns within. The overall gas motion consists of two vortices: an outer vortex moving down and an inner vortex moving up.

According to Barth (1956), the boundary between the outer and inner vortices, called the *cyclone core*, is the cylindrical extension of the gas exit duct.

Gas flow is three dimensional and can be described in terms of three velocity components—tangential, radial, and axial. Ter Linden (1949) made the first systematic measurements of the velocity field inside a cyclone. In recent years, laser doppler velocimetry (Kirch and Löffler 1987) and digital imaging (Kessler and Leith 1991) have yielded more accurate measurements of the three velocity components.

## TANGENTIAL GAS VELOCITY

Early theoretical treatments of cyclone flow patterns (Lissman 1930; Rosin, Rammler, and Intelman 1932) described the relationship between the tangential gas velocity  $V_t$  and the distance  $r$  from the cyclone axis as:

$$V_t r^n = \text{constant} \quad 5.16(4)$$

The vortex exponent  $n$  is  $+1$  for an ideal liquid and  $-1$  for rotation as a solid body, while the usual range for  $n$  is from 0.5 to 0.9 (Ter Linden 1949; Shepherd and Lapple 1939; First 1950).

Equation 5.16(4) implies that tangential velocity increases from the walls to the cyclone axis where it reaches infinity. Actually, in the outer vortex, tangential velocity increases with decreasing radius to reach a maximum at the radius of the central core. In the inner vortex, the tangential velocity decreases with decreasing radius. Figure 5.16.3 shows Iozia and Leith's (1989) anemometer measurements of tangential velocity. Measurements by Ter Linden (1949) show similar velocity profiles.

## RADIAL AND AXIAL GAS VELOCITY

Radial gas velocity is the most difficult velocity component to measure experimentally. Figure 5.16.4 shows Kessler and Leith's (1991) measurements of radial velocity profiles in a cyclone. Despite some uncertainty in the measurements, some trends can be seen. Radial flow velocity increases toward the center of the cyclone due to the conservation of mass principle. A tendency also exists for the maximum radial velocity in each cross section to decrease with decreasing cross-sectional height.

Figure 5.16.5 shows the axial gas velocity in a reverse-flow cyclone. The gas flows downward near the cyclone wall and upward near the cyclone axis. The downward velocity near the wall is largely responsible for transporting dust from the cyclone wall to the dust outlet.

## MODELING GAS FLOWS

The fluid dynamics of a cyclone are complex, and modeling the detailed flow pattern involves solving the strongly

coupled, nonlinear, partial differential equations of the conservation of mass and momentum. Boysan, Ayers, and Swithenbank (1982) have developed a mathematical model of gas flow based on the continuity and momentum conservation principles, accounting for the anisotropic nature of turbulence and its dissipation rate. The velocity

and pressure profiles of their model agree remarkably with the experimental measurements of Ter Linden (1949). However, as they suggest, the information obtained from such modeling is more detailed than that required by a process design engineer.

### COLLECTION EFFICIENCY

*Collection efficiency*  $\eta$  is defined as the fraction of particles of any size that is collected by the cyclone. The plot of collection efficiency against particle diameter is called a *fractional or grade efficiency curve*.

Determining the path of the particles in the gas flow field is essential to estimate the collection efficiency. When all external forces except drag force are neglected, the equation of motion for a small particle is expressed in a Lagrangian frame of reference as:

$$\begin{aligned} \frac{du_p}{dt} &= -\left(\frac{1}{8m_p} C_D \pi d^2 \rho_p\right) (u_p - u - u') |u_p - u - u'| \\ \frac{dv_p}{dt} &= \frac{w_p^2}{r} - \left(\frac{1}{8m_p} C_D \pi d^2 \rho_p\right) (v_p - v - v') |v_p - v - v'| \\ \frac{dw_p}{dt} &= 2 \frac{w_p}{r} v_p - \left(\frac{1}{8m_p} C_D \pi d^2 \rho_p\right) \\ &\quad \times (w_p - w - w') |w_p - w - w'| \end{aligned} \tag{5.16(5)}$$

where:

- $u_p, v_p, w_p$  = the components of the particle velocities in the  $z, r,$  and  $\theta$  directions
- $u, v, w$  = the gas velocities in the same directions
- $u', v',$  and  $w'$  = the fluctuating components of the gas velocities
- $d_p$  = the particle diameter
- $\rho_p$  = the particle density
- $C_D$  = the drag coefficient
- $m_p$  = the particle mass

In addition to Equations 5.16(5), the following equation applies:

$$\frac{dz}{dt} = u_p; \quad \frac{dr}{dt} = v_p; \quad \text{and} \quad \frac{d\theta}{dt} = \frac{w_p}{r} \tag{5.16(6)}$$

Boysan, Ayers, and Swithenbank (1982) used a stochastic approach whereby the values of  $u', v',$  and  $w'$ , which pre-

**FIG. 5.16.5** Axial gas velocity in a reverse-flow cyclone.

vail during the lifetime of a fluid eddy in which the particle is traversing, are sampled assuming that these values possess a Gaussian probability distribution. They used the lifetime of the fluid eddy as a time interval over which the gas velocity remains constant. This assumption allowed the direct solution of the equations of motion to obtain local, closed-form solutions. They obtained the values of  $z$ ,  $r$ , and  $\theta$  by a simple stepwise integration of the equation of the trajectory. Many random trajectories were evaluated, and a grade efficiency curve was constructed based on these results. The results agreed with the experimental results of Stairmand (1951).

Kessler and Leith (1991) approximated the drag force term using Stokes' law drag for spheres. They solved the equations of motion numerically using backward difference formulas to solve the stiff system of differential equations. They modeled the collection efficiency for a single, arbitrarily sized particle by running several simulations for that particle. For each particle size, the ratio of collected particles to total particles described the mean of a binomial distribution for the probability distribution. Figure 5.16.6 shows this curve, three other grade efficiency models (Barth [1956], Dietz [1981], and Iozia and Leith [1990]), and the direct measurements of Iozia and Leith.

Early collection efficiency treatments balanced the centrifugal and drag forces in the vortex to calculate a *critical particle* size that was collected with 50 or 100% efficiency. The tangential velocity of the gas and the particle were assumed to be equal, and the tangential velocity was given by the vortex exponent law of Equation 5.16(4). As previously shown, the maximum tangential velocity,  $V_{\max}$

occurs at the edge of the central core. The average inward radial velocity at the core edge is as follows:

$$V_r = -\frac{Q}{2\pi r_{\text{core}}(H - S)} \quad 5.16(7)$$

For particles of the critical diameter, the centrifugal and drag forces balance, and these static particles remain suspended at the edge of the core. Larger particles move to the wall and are collected, while smaller particles flow into the core and out of the cyclone. Barth (1956) and Stairmand (1951) used different assumptions about  $V_{\max}$  to develop equations for the critical diameter. Collection efficiencies for other particle sizes were obtained from a separation curve—a plot that relates efficiency to the ratio of particle diameter to the critical diameter. However, theories of the critical particle type fail to account for turbulence in the cyclone (Leith, Dirgo, and Davis 1986); moreover, a single separation curve is not universally valid.

Later theories attempted to account for turbulence and predict the entire fractional efficiency curve (Dietz 1981; Leith and Licht 1972; Beeckmans 1973). Of these, the theory by Leith and Licht (1972) has been frequently used; however, some of the assumptions on which the theory is based have been invalidated. As with most efficiency theories, the interactions between particles is not taken into account. The assumption of complete turbulent mixing of aerosol particles in any lateral plane has been proven untrue.

Iozia and Leith (1989) used experimental data to develop an equation to predict the *cut diameter*  $d_{50}$ , which is the particle size collected with 50% efficiency. Their empirical equations are as follows:

FIG. 5.16.6 Measured collection efficiency from studies by Barth, Dietz, and Iozia and Leith and modeled collection efficiency by Kessler and Leith.

$$d_{50} = \left( \frac{9\mu Q}{\pi z_c \rho_p V_{\max}^2} \right)^{1/2} \quad 5.16(8)$$

where:

$$V_{\max} = 6.1 V_i \left( \frac{ab}{D^2} \right)^{0.61} \left( \frac{D_e}{D} \right)^{-0.74} \left( \frac{H}{D} \right)^{-0.33} \quad 5.16(9)$$

where  $V_i$  is the inlet gas velocity, and  $z_c$  is the core length which depends on core diameter  $d_c$  as follows:

$$d_c = 0.52D \left( \frac{ab}{D^2} \right)^{-0.25} \left( \frac{D_e}{D} \right)^{1.53} \quad 5.16(10)$$

When  $d_c < B$ , the core intercepts the cyclone wall, and the following equation applies:

$$z_c = (H - S) - \left( \frac{H - h}{D - 1} \right) \left( \frac{d_c}{B} - 1 \right) \quad 5.16(11)$$

When  $d_c < B$ , the core extends to the bottom of the cyclone, and the following equation applies:

$$z_c = (H - S) \quad 5.16(12)$$

Iozia and Leith (1989, 1990) also developed the following logistic equation for the fractional efficiency curve:

$$\eta = \frac{1}{1 + \left( \frac{d_{50}}{d} \right)^\beta} \quad 5.16(13)$$

where the parameter  $\beta$  is estimated from the cut size  $d_{50}$ , and the geometry of the cyclone is as follows:

$$\ln(\beta) = 0.62 - 0.87 \ln(d_{50}(\text{cm})) + 5.21 \ln\left(\frac{ab}{D^2}\right) + 1.05 \left( \ln\left(\frac{ab}{d^2}\right) \right)^2 \quad 5.16(14)$$

The preceding model describes collection efficiencies significantly better than other theories.

## PRESSURE DROP

A cyclone pressure drop results from the following factors (Shepherd and Lapple 1939):

1. Loss of pressure due to gas expansion as it enters the cyclone
2. Loss of pressure due to vortex formation
3. Loss of pressure due to wall friction
4. Regain of rotational kinetic energy as pressure energy

Factors 1, 2, and 3 are probably the most important. Inoya (1953) showed that increasing wall roughness decreases the pressure drop across the cyclone probably by inhibiting vortex formation. If this assumption is true, then energy consumption due to vortex formation is more important than wall friction. First (1950) found that wall friction is not an important contributor to pressure drop.

Devices such as an inlet vane, an inner wall extension of the tangential gas entry within the cyclone body to a position close to the gas exit duct, and a cross baffle in the gas outlet lower the pressure drop (Leith 1984). However, such devices work by suppressing vortex formation and decrease collection efficiency as well. Designing cyclones for low pressure drop without attaching devices that also lower collection efficiency is possible.

Cyclone pressure drop has traditionally been expressed as the number of inlet velocity ( $v_i$ ) heads  $\Delta H$ . The following equation converts velocity heads to pressure drop  $\Delta P$ :

$$\Delta P = \Delta H \left( \frac{1}{2} \rho_g v_i^2 \right) \quad 5.16(15)$$

The value of  $\Delta H$  is constant for a cyclone design (i.e., cyclone dimension ratios), while  $\Delta P$  varies with operating conditions.

Many analytical expressions for determining  $\Delta H$  from cyclone geometry are available (Barth 1956; First 1950; Shepherd and Lapple 1940; Stairmand 1949; Alexander 1949). None of these expressions predicts pressure drop accurately for a range of cyclone designs; predictions differ from measured values by more than a factor of two (Dirgo 1988). Further, evaluations of these models by different investigators produced conflicting conclusions as to which models work best.

Dirgo (1988) and Ramachandran et al. (1991) developed an empirical model for predicting pressure drop, which was developed through statistical analysis of pressure drop data for ninety-eight cyclone designs. They used stepwise and backward regression to develop the following expression for  $\Delta H$  based on cyclone dimension ratios:

$$\Delta H = 20 \left( \frac{ab}{D_e^2} \right) \left\{ \frac{\left( \frac{S}{D} \right)}{\left( \frac{H}{D} \right) \left( \frac{h}{D} \right) \left( \frac{B}{D} \right)} \right\}^{1/3} \quad 5.16(16)$$

This model made better predictions of pressure drop than the models of Barth (1956), First (1950), Shepherd and Lapple (1940), Stairmand (1949), and Alexander (1949).

## DUST LOADING

Increasing inlet dust loading,  $C_i$  ( $\text{g}/\text{cm}^3$ ), increases collection efficiency and decreases pressure drop. Briggs (1946) quantified the influence of dust loading on pressure drop as follows:

$$\Delta P_{\text{dusty}} = \frac{\Delta P_{\text{clean}}}{1 + 0.0086 C_i^{1/2}} \quad 5.16(17)$$

The following equation (Whiton 1932) gives the effect on efficiency of changing the inlet loading from  $C_{i1}$  to  $C_{i2}$ :

$$\frac{100 - \eta_1}{100 - \eta_2} = \left( \frac{C_{i2}}{C_{i1}} \right)^{0.182} \quad 5.16(18)$$

## CYCLONE DESIGN OPTIMIZATION

Cyclone design usually consists of choosing an accepted standard design or a manufacturer's proprietary model that meets cleanup requirements at a reasonable pressure drop. However, investigators have developed analytical procedures to optimize cyclone design, trading collection efficiency against pressure drop.

Leith and Mehta (1973) describe a procedure to find the dimensions of a cyclone with maximum efficiency for a given diameter, gas flow, and pressure drop. Dirgo and Leith (1985) developed an iterative procedure to improve cyclone design. While holding the cyclone diameter constant, their method alters one cyclone dimension and then searches for a second dimension to change to yield the greatest collection efficiency at the same pressure drop.

They selected the gas outlet diameter  $D_e$  as the primary dimension to vary. This variation changed the pressure drop. Then, they varied the inlet height  $a$ , inlet width  $b$ , and gas outlet duct length  $S$ , one at a time, to bring pressure drop back to the original value. They predicted the  $d_{50}$  for each new design from theory. The new design with the lowest  $d_{50}$  became the baseline for the next iteration. In the next iteration, they varied  $D_e$  again with the three other dimensions to find the second dimension change that most reduced  $d_{50}$ . They continued iterations until the predicted reduction in  $d_{50}$  from one iteration to the next was less than one nanometer.

Ramachandran et al. (1991) used this approach with the efficiency theory of Iozia and Leith, Equations 5.16(8)–5.16(14), and the pressure drop theory of Dirgo, Equation 5.16(16), to develop optimization curves. These curves predict the minimum  $d_{50}$  and the dimension ratios of the optimized cyclone for a given pressure drop (see Figures 5.16.7 and 5.16.8).

To design a cyclone, the design engineer must obtain the inlet dust concentration and size distribution and other design criteria such as gas flow rate, temperature, and particle density, preferably by stack sampling. When a cyclone is designed for a plant to be constructed, stack testing is impossible, and the design must be based on data obtained from similar plants. Once the size distribution of the dust is known, the design engineer chooses a value of  $d_{50}$ . For each size range, the engineer calculates the collection efficiency using Equation 5.16(13). The overall efficiency is calculated from the following equation:

$$\eta_{\text{overall}} = \sum_i f_i \eta_i \quad 5.16(19)$$

where  $f_i$  is the fraction of particles in the  $i^{\text{th}}$  size range. By trial and error, the engineer chooses a value of  $d_{50}$  to

obtain the required overall efficiency. This  $d_{50}$  is located on the optimization curve (e.g., for  $H = 5D$ ) of Figure 5.16.7, and the pressure drop corresponding to this  $d_{50}$  is found. Figure 5.16.8 gives the cyclone dimension ratios. The cyclone diameter is determined from the following equation:

$$D_2 = D_1 \left( \frac{\rho_{p2} Q_2}{\rho_{p1} Q_1} \right)^{1/3} \quad 5.16(20)$$

where  $D_1$ ,  $\rho_{p1}$ , and  $Q_1$  are the cyclone diameter (0.254 m), particle density ( $1000 \text{ kg/m}^3$ ), and flow ( $0.094 \text{ m}^3/\text{sec}$ ) of the cyclone optimized in Figure 5.16.8; and  $\rho_{p2}$  and  $Q_2$  are the corresponding values for the system being designed. The following equation gives the design pressure drop:

$$\Delta P_2 = \Delta P_1 \left( \frac{Q_2 D_1^2}{Q_1 D_2^2} \right)^2 \quad 5.16(21)$$

where  $\Delta P_1$  is the pressure drop from Figure 5.16.7 corresponding to the chosen  $d_{50}$ .

If the pressure drop  $\Delta P_2$  is too high, then the design engineer should explore other options, such as choosing a taller cyclone as the starting point or reducing the flow through the cyclone by installing additional cyclones in parallel. These options, however, increase capital costs. The design engineer has to balance these various factors.

## Filters

### FEATURE SUMMARY

#### Types of Filter Media

Paper, woven fabric with a low air/cloth ratio, felted fabric with high air/cloth ratio

#### Fibers

Glass, Teflon, Nomex, dacron, orlon, nylon, wool, cotton, and dynel

#### Cleaning Methods

Reverse flow, pulse jet, and various shaking methods including manual, mechanical, and sonic

#### Partial List of Suppliers

Aeropulse, Inc.; Airguard Industries Inc.; Air Sentry, Inc.; Amco Industries Inc.; Amco Engineering Co.; BGI Inc.; Dresser Industries Inc.; Dustex Corp.; Emtrol Corp.; Environmental Elements Inc.; Esstee Mfg. Co., Inc.; Flex-Cleen Corp.; Fuller Co.; General Filters Inc.; Great Lakes Filter, Filpaco Div.; Hough International, Inc.; HVAC Filters Inc.; Interel Environmental Technologies Inc.; Kimbell-Bishard; Mikropul Environmental Systems; North American Filter Co.; Perry Equipment Corp.; Purolator Products Air Filtration Co.; Science Applications International Co.; Stamm International Group; Standard Filter Corp.; TFC Corp.; Tri-Dim Filter Corp.; Trion Inc.; United McGill Corp.; Wheelabrator Air Pollution Control; Zelcron Industries, Inc.; Zurn Industries Inc.

## FIBER FILTERS

Fiber bed filters collect particles within the depth of the filter so that a dust cake does not build up on the filter surface. Fiber sizes range from less than  $1\ \mu\text{m}$  to several hundred  $\mu\text{m}$ . The materials used for fibrous filters include

cellulose, glass, quartz, and plastic fibers. Fiber beds are used as furnace filters, air conditioning filters, and car air filters. They are also used for sampling in air pollution and industrial hygiene measurements. The collected particles cannot generally be cleaned from the bed, so these filters must be replaced when the pressure drop becomes too high.

## Filtration Theory

The basis of this theory is the capture of particles by a single fiber. The single-fiber efficiency  $\eta_{\text{fiber}}$  is defined as the ratio of the number of particles striking the fiber to the number of particles that would strike the fiber if streamlines were not diverted around the fiber. If a fiber of diameter  $d_f$  collects all particles contained in a layer of thickness  $y$ , then the single-fiber efficiency is  $y/d_f$  (see Figure 5.16.9).

The general approach involves finding the velocity field around an isolated fiber, calculating the total collection efficiency of the isolated fiber due to the mechanisms of particle deposition, expressing the influence of neighboring fibers (interference effects) by means of empirical corrections, and finally obtaining the overall efficiency of a filter composed of many fibers. The following equation relates the overall efficiency of a filter composed of many fibers in a bed  $E$  to the single-fiber efficiency:

$$E = 1 - \exp \left[ \frac{-4\eta_{\text{fiber}}\alpha L}{\pi d_f(1 - \alpha)} \right] \quad 5.16(22)$$

where:

- $\alpha$  = the solidity or packing density of the filter
- $L$  = the filter thickness
- $d_f$  = the fiber diameter

Note that even if  $\eta_{\text{fiber}} = 1$ , the total filter efficiency can be low if  $\alpha$  is low or the filter thickness is small. The derivation of this equation assumes that particles are well-mixed in every plane perpendicular to the gas flow direction, no particles are reentrained into the gas stream, all fibers are perpendicular to the gas flow direction, and the gas has a uniform velocity.

FIG. 5.16.9 Single-fiber collection efficiency.

## Filtration Mechanisms

As air passes through a filter, the trajectories of particles deviate from the streamlines due to various mechanisms, most important of which are interception, inertial impaction, diffusion, gravity, and electrostatic forces. The radiometric phenomena such as thermophoresis and diffusiophoresis are usually negligible. The single-fiber efficiency  $\eta_{\text{fiber}}$  is approximated as the sum of the efficiencies due to each of the preceding mechanisms acting individually as follows:

$$\eta_{\text{fiber}} = \eta_{\text{inter}} + \eta_{\text{impaction}} + \eta_{\text{diffusion}} + \eta_{\text{gravity}} + \eta_{\text{elec}} \quad 5.16(23)$$

The maximum value of the single-fiber efficiency is 1.0; so if several of the mechanisms have large efficiencies, their sum cannot exceed unity.

### Interception

Particles are collected when the streamline brings the particle center to within one particle radius from the fiber surface. This effect is described by a dimensionless interception parameter  $R$ , which is the ratio of particle diameter  $d_p$  to fiber diameter as follows:

$$R = \frac{d_p}{d_f} \quad 5.16(24)$$

Assuming Kuwabara flow,  $\eta_{\text{inter}}$  is given by the following equation:

$$\eta_{\text{inter}} = \frac{1 + R}{2Ku} \left[ 2\ln(1 + R) - 1 + \alpha + \left( \frac{1}{1 + R} \right)^2 \left( 1 - \frac{\alpha}{2} \right) - \frac{\alpha}{2} (1 + R)^2 \right] \quad 5.16(25)$$

where  $Ku$  is the Kuwabara hydrodynamic factor given by the following equation:

$$Ku = -\frac{1}{2} \ln \alpha - \frac{3}{4} + \alpha - \frac{\alpha^2}{4} \quad 5.16(26)$$

Interception is independent of the flow velocity around a fiber.

### Inertial Impaction

A particle, because of its inertia, may be unable to adjust to the rapidly changing curvature of streamlines in the vicinity of a fiber and may cross the streamlines to hit the fiber. The dimensionless number used to describe this effect is the Stokes number, which is the ratio of particle stopping distance to fiber diameter as follows:

$$\text{Stk} = \frac{\tau U}{d_f}, \quad \text{where } \tau = \frac{1}{18} d_p^2 \frac{(\rho_p - \rho_m)}{\mu} C_c \quad 5.16(27)$$

where:

- $C_c$  = the Cunningham slip correction factor
- $U$  = the free-stream velocity (cm/sec)
- $\mu$  = the viscosity of the medium (poise)
- $\rho_p$  and  $\rho_m$  = the densities of the particle and medium, respectively (gm/cc)

The slip correction factor is given by the equation  $C_c = 1 + [2\lambda(1.257)/d_p]$  where  $\lambda$  is the mean free path of gas molecules and is equal to  $0.071 \mu\text{m}$  for air molecules at  $25^\circ\text{C}$  and  $d_p > 2\lambda$ .

Stechkina, Kirsch, and Fuch (1969) calculated the inertial impaction efficiency for particles using the Kuwabara flow field as follows:

$$\eta_{\text{impaction}} = \frac{1}{(2Ku)^2} \times [(29.6 - 28\alpha^{0.62})R^2 - 27.5R^{2.8}] \text{Stk} \quad 5.16(28)$$

Inertial impaction is a significant collection mechanism for large particles, high gas velocities, and small-diameter fibers.

### Brownian Diffusion

Very small particles generally do not follow streamlines but wobble randomly due to collisions with molecules of gas. Random Brownian motion causes incidental contact between a particle and the fiber. At low velocities, particles spend more time near fiber surfaces, thus enhancing diffusional collection. A dimensionless parameter called the Peclet number  $Pe$  is defined as a ratio of convective transport to diffusive transport as follows:

$$Pe = \frac{d_c U}{D} \quad 5.16(29)$$

where:

- $d_c$  = the characteristic length of the collecting medium
- $U$  = the average gas velocity
- $D$  = the diffusion coefficient of the particles as follows:

$$D = \frac{kTC_c}{3\pi\mu d_p} \quad 5.16(30)$$

where:

- $k$  = the Boltzman constant ( $1.38 \times 10^{-16}$  erg/ $^\circ\text{Kelvin}$ )
- $T$  = the absolute temperature
- $\mu$  = the viscosity of the medium (poise)
- $d_p$  = the particle diameter

Lee and Liu (1982a,b) use a boundary layer model commonly used in heat and mass transfer analysis with a flow field around multiple cylinders that account for flow interference due to neighboring fibers as follows:

$$\eta_{\text{diffusion}} = 2.58 \frac{1 - \alpha}{Ku} Pe^{-2/3} \quad 5.16(31)$$

## Gravitational Settling

Particles deviate from streamlines when the settling velocity due to gravity is sufficiently large. When flow is downward, gravity increases collection; conversely, when flow is upward, gravity causes particles to move away from the collector resulting in a negative contribution. Gravity is important for large particles at low flow velocities. The dimensionless parameter for this mechanism is as follows:

$$Gr = \frac{V_{ts}}{U} \quad 5.16(32)$$

where  $U$  is the free stream velocity and  $V_{ts}$  is the settling velocity. The single-filtration efficiency due to gravity is as follows:

$$\eta_{gravity} = \frac{Gr}{1 + Gr} \quad 5.16(33)$$

## Electrostatic Forces

Aerosol particles can acquire an electrostatic charge either during their generation or during flow through a gas stream. Likewise, the filter fibers can acquire a charge due to the friction caused by a gas stream passing over them. The following three cases can occur:

### 1. Charged Particle–Charged Fiber

$$\eta_{elec} = \frac{4Qq}{3\mu d d_f V_g} \quad 5.16(34)$$

where  $Q$  is the charge per unit length of the fiber and  $q$  is the charge on the particle.

### 2. Charged Fiber–Neutral Particle

$$\eta_{elec} = \frac{4}{3} \left( \frac{-1}{+1} \right) \left( \frac{d^2 Q^2}{d_f^3 \mu V_g} \right) \quad 5.16(35)$$

where  $\epsilon$  is the dielectric constant of the particle.

### 3. Charged Particle–Neutral Fiber

$$\eta_{elec} = \sqrt{\frac{\epsilon - 1}{\epsilon + 1}} \left( \frac{q^2}{3\pi\mu d d_f^2 V_g (2 - \ln Re)} \right)^{1/2} \quad 5.16(36)$$

where  $\mu$  is the viscosity of the medium and  $Re$  is the Reynold's number given by  $(d_f V_g \rho_g) / \mu$ .

## Pressure Drop of Fibrous Filters

The following equation gives the pressure drop for fibrous filters (Lee and Ramamurthi 1993):

$$\Delta P = \frac{16\eta\alpha UL}{Kud_f^2} \quad 5.16(37)$$

The measured pressure drop across a filter is used with Equation 5.16(37) to determine the effective fiber diameter  $d_f$  for use in the filtration efficiency theory, previously described (Lee and Ramamurthi 1993). Predicting the pres-

sure drop for real filters is not straightforward. Comparing the measured pressure drop and calculated pressure drop based on an ideal flow field indicates how uniformly the media structure elements, such as fibers or pores, are arranged.

## FABRIC FILTERS (BAGHOUSES)

Baghouses separate fly ash from flue gas in separate compartments containing tube-shaped or pocket-shaped bags or fabric filters. Baghouses are effective in controlling both total and fine particulate matter. They can filter fly ash at collection efficiencies of 99.9% on pulverized, coal-fired utility boilers. Other baghouse applications include building material dust removal, grain processing, oil mist recovery in workplace environments, soap powders, dry chemical recovery, talc dust recovery, dry food processing, pneumatic conveying, and metal dust recovery.

The main parameters in baghouse design are the pressure drop and air-to-cloth ratio. Pressure drop is important because higher pressure drops imply that more energy is required to pull gas through the system. The *air-to-cloth ratio* determines the unit size and thus, capital cost. This ratio is the result of dividing the volume flow of gas received by a baghouse by the total area of the filtering cloth and is usually expressed as acfm/ft<sup>2</sup>. This ratio is also referred to as the *face velocity*. Higher air-to-cloth ratios mean less fabric, therefore less capital cost. However, higher ratios can lead to high pressure drops forcing energy costs up. Also, more frequent bag cleanings may be required, increasing downtime. Fabric filters are classified by their cleaning method or the direction of gas flow and hence the location of the dust deposit.

## Inside Collectors

During filtration, as shown in Figure 5.16.10, dusty gas passes upward into tubular or pocket-shaped bags that are closed at the top. Tubular bags are typically 10 m tall and 300 mm in diameter. A dust cake builds on the inside bag surface during filtration. Clean gas passes out through the filter housing. Filtration velocities are about 10 mm/sec (2 cfm/ft<sup>2</sup>). Many bags in a compartment act in parallel, and a fabric filter usually comprises several compartments.

Two cleaning techniques are used with inside collectors: reverse flow and shaking. In reverse flow, as shown in Figure 5.16.10, filtered gas from the outlets of other compartments is forced backward through the bags. Between the support rings, this reverse flow causes the bags to partially collapse causing the dust cake on the inside to deform, crack, and partially dislodge. A framework of rings keeps the bags open during cleaning. After a few minutes, the reverse gas stops, and filtration resumes. Cleaning is usually performed offline. Typical air-to-cloth ratios are 2

cfm/ft<sup>2</sup>, and dust cake weights range from 0.5 to 1.5 lb/ft<sup>2</sup>. The pressure drop across the fabric and dust cake with reverse flow is 0.5 to 1.0 in w.g. Some inside collectors used for oil mist recovery are not cleaned but are replaced when they become saturated with oil.

When equilibrium is established, the forces acting to remove the residual dust cake must equal those tending to retain it (Carr and Smith 1984). The removing forces are mechanical flexing and deformation, aerodynamic pressure, gravity, erosion, and acceleration by snapping the bags. Forces acting to retain the dust cake are adhesion and cohesion. *Adhesion* refers to the binding forces between particles and fibers when they contact each other; whereas *cohesion* refers to the bonding forces that exist between the collected particles. Forces acting to remove the residual dust cake increase with thickness or weight of the dust cake, while those tending to retain it decrease or remain the same. Thus, when equilibrium is achieved, a residual dust cake is established.

In shaking, the bag tops are connected to an oscillatory arm, causing the dust on the inside bag surfaces to separate from the fabric and fall into the hopper. Shaking is usually used in conjunction with reverse-gas cleaning. Although bags in shake and deflate units contain no anti-collapse rings, they retain a nominally circular cross section because the reverse-gas flow is low. The shaking force is applied to the tops of the bags causing them to sway and generating traveling waves in them. Deformation of the bags is significant in dislodging the dust cake.

Bags made from woven fabrics are generally used for these filters. Most large filters cleaned by reverse flow collect fly ash at coal-fired plants (Noll and Patel 1979). Bags are usually made of glass fiber to withstand the hot flue gases. Bag lifetime has exceeded 20,000 hr for woven bags. The long life is due to the low filtration velocity and infrequent cleaning (Humphries and Madden 1981). Filter problems in the utility industry are caused by improper bag specifications, installation, or tensioning. Other problems are related to *bag blinding*, a gradual, irreversible increase in pressure drop.

## Outside Collectors

As shown in Figure 5.16.11, in outside collectors, dusty gas flows radially inward through cylindrical bags held open by a metal frame inside them. The bags are typically 3 m tall and 200 mm in diameter. Dust collects on the outside bag surfaces. Clean gas passes out of the top of each bag to a plenum.

Cleaning outside collectors usually involves injecting a pulse of compressed air at the outlet of each bag. This pulse snaps the bag open and drives the collected dust away from the bag surface into the hopper. Because pulse-jet cleaning takes a fraction of a second, it can be done on-line without interrupting the gas flow to a compartment.

Pulse-jet filters generally use thick felt fabrics to reduce dust penetration even when the dust cake is not thick. Filtration velocities through a pulse-jet filter are several times higher than through a reverse gas filter; therefore, pulse-jet filters can be smaller and less expensive. Operating at high filtration velocities can lead to an excessive pressure drop, dust penetration, and fabric wear. These filters are most commonly used to control industrial dust.

Pulse-jet cleaning can be ineffective when the dust is fine. The particles are driven beneath the fabric surface and are not easily removed. As fine dust accumulates below the surface, the pressure drop across the filter gradually increases. If the pressure drop becomes too high, the blinded bags must be replaced. With online cleaning of pulse-jet filters, as little as 1% of the dust on a bag can fall to the hopper after each cleaning pulse (Leith, First, and Feldman 1977).

## Pressure Drop

The pressure drop is the sum of the pressure drop across the filter housing and across the dust-laden fabric (Leith and Allen 1986). The pressure drop across the housing is proportional to the square of the gas-flow rate due to turbulence. The pressure drop across the dust-laden fabric is

FIG. 5.16.10 Reverse-gas flow cleaning in inside collectors.

FIG. 5.16.11 Pulse-jet cleaning in outside collectors.

the sum of the pressure drop across the clean fabric and the pressure drop across the dust cake as follows:

$$\Delta P = \Delta P_f + \Delta P_d = K_1 v + K_2 v w \quad 5.16(38)$$

where:

- $v$  = the filtration velocity
- $K_1$  = the flow resistance of the clean fabric
- $K_2$  = the specific resistance of the dust deposit
- $w$  = the fabric dust areal density

$K_1$  is related to Frazier permeability, which is the flow through a fabric in  $\text{cfm}/\text{ft}^2$  of fabric when the pressure drop across the fabric is 0.5 in w.g. as follows:

$$K_1 (\text{Pa s m}^{-1}) = \frac{24590}{\text{Frazier Permeability}(\text{cfm}/\text{ft}^2 \text{ at } 0.5 \text{ in w.g.})} \quad 5.16(39)$$

The following equation determines the dust loading adding to the fabric between cleanings  $w_0$ :

$$w_0 = C_{in} v t \quad 5.16(40)$$

where:

- $C_{in}$  = the dust inlet concentration
- $t$  = the time between cleanings

Dividing Equation 5.16(38) by  $v$  gives the filter drag as follows:

$$S = \frac{\Delta P}{v} = K_1 + K_2 w \quad 5.16(41)$$

Figure 5.16.12 shows a plot of drag  $S$  versus  $w$ . Equation 5.16(41) assumes that the increase in drag with increasing areal density is linear; however, the increase is linear only after a dust cake has formed. Therefore, Equation 5.16(41) can be rewritten as follows in terms of the extrapolated residual areal dust density after cleaning  $w_R$  and the effective drag  $S_E$ .

$$S = S_E + K_2(w - w_R) \quad 5.16(42)$$

FIG. 5.16.12 Pressure drop and drag for a fabric filter versus areal density of the dust deposit.

### Evaluation of Specific Resistance $K_2$

The Kozeny–Carman relationship (Billings and Wilder 1970; Carman 1956) is often used to describe pressure drop across a dust deposit. Rudnick and First (1978) showed that the Happel (1958) cell model corrected for slip flow gives better  $K_2$  estimates than the Kozeny–Carman relationship for a dust cake with no interaction between the fabric and cake. All theoretical models for  $K_2$  are sensitive to dust deposit porosity and dust particle size distributions. Porosity cannot usually be estimated correctly and varies with filtration velocity, humidity, and other factors. Whenever possible,  $K_2$  should be measured rather than calculated from theory. Leith and Allen (1986) suggest that the dust collected on a membrane filter and  $K_2$  should be calculated from the increase in pressure drop ( $\Delta P_2 - \Delta P_1$ ) with filter weight gain ( $M_2 - M_1$ ) as follows:

$$K_2 = \left( \frac{A}{v} \right) \left[ \frac{(\Delta P_2 - \Delta P_1)}{(M_2 - M_1)} \right] \quad 5.16(43)$$

where  $A$  is the surface area of the membrane filter.

### Cleaning Fabric Filters

Dennis and Wilder (1975) present a comprehensive study on cleaning mechanisms. For a dust cake to be removed from a fabric, the force applied to the cake must be greater than the forces that bond the cake to the fabric. The major factors that combine to create both adhesion and cohesion are van der Waals, coulombic and induced dipole electrostatic forces, and chemical reactions between the gas and the dust. Capillary forces caused by surface tension are important under high relative humidity conditions.

The following equation calculates the drag across a single bag:

$$S = \frac{1}{\sum_{i=1}^n \left( \frac{a_i}{S_i} \right)} \quad 5.16(44)$$

where  $a_i$  is the  $i^{\text{th}}$  fraction of the total bag area and  $S_i$  is the drag through that area (Stephan, Walsh, and Herrick 1960). Substituting the values  $a_i$  and  $S_i$  for the cleaned and uncleaned portions in Equation 5.16(44) calculates the drag for the entire filter. When the local filtration velocity through each bag area (which depends on local drag) is used, the additional dust collected on each area over time can be determined. This collection in turn changes the local drag. This procedure allows an iterative prediction of pressure drop versus time.

### Cleaning Inside Collectors

The factors responsible for cake removal in inside collectors have received little attention. Cake rupture due to fabric flexing is the primary cleaning mechanism. The other main mechanism is the normal stress to the cake from reverse pressurization.

Shaker filters use a motor and an eccentric cam to produce the cleaning action. Cleaning depends on factors such as bag shape and support, rigidity, bag tension, shaker frequency, and shaker amplitude. The following equation gives the acceleration a developed by the shaker arm:

$$a = 4\pi^2 f^2 l_d \quad 5.16(45)$$

where:

- $f$  = the frequency of shaking
- $l_d$  = the amplitude of the sinusoidal motion

Modeling the transfer of motion to the bags is analogous to a vibrating string, whereby a wave travels down the bag and is reflected from its end. If the reflected wave reaches the arm at the same time that the next wave is produced, resonance occurs; this time is when the transfer of cleaning energy to the bag is optimum.

### Pulse-Jet Cleaning

Leith and Ellenbecker (1980b) use Equation 5.16(38) as the basis of a model to predict pressure drop across a pulse-jet cleaned filter. Their model assumes that the fraction of the dust deposit removed by a cleaning pulse is proportional to the separation force applied and that impulse and conservation of momentum determine bag motion as follows:

$$\Delta P = K_v v^2 + \frac{P_s + K_1 v - \sqrt{(P_s - K_1 v)^2 - 4w_o v \left( \frac{K_2}{K_3} \right)}}{2} \quad 5.16(46)$$

where  $K_v$  depends on the pressure drop characteristics of the venturi at the top of each bag. Typically,  $K_v = 57500 \text{ Pa s}^2/\text{m}^2$ . The value  $P_s$  is the pressure within the bag generated by the cleaning pulse, and it depends on venturi design as well as pulse pressure  $P$  as follows:

$$P_s (\text{Pa}) = 164 [P (\text{kPa})]^{0.6} \quad 5.16(47)$$

The values  $K_1$  and  $w_o$  are from Equations 5.16(39) and 5.16(40), respectively. The term  $(K_2/K_3)$  is a constant that depends on the interaction of the dust and the fabric.

An environmental engineer can use Equation 5.16(46) to estimate the pressure drop of an existing filter when the operating conditions change. When the pressure drop under the initial operating conditions is known, the engineer can use Equation 5.16(46) to determine  $(K_2/K_3)$ . Then, using this value of  $(K_2/K_3)$ , the engineer can determine the pressure drop for other operating conditions.

### Collection Efficiency

The collection efficiency of a fabric filter depends on the interactions between the fabric, the dust, and the cleaning method. However, a clear understanding of these factors is not available, and existing models cannot be generalized beyond the data sets used in their development.

Impaction, diffusion, and interception in a dust cake are effective. Essentially all incoming dust is collected through a pulse-jet filter, with or without a dust cake. Nevertheless, some dust penetrates a fabric filter. It does so because gas bypasses the filter by flowing through pinholes in the dust cake or because the filter fails to retain the dust previously collected (seepage).

*Pinholes* form in woven fabrics at yarn intersections. With dust loading, some pinholes are bridged, while the gas velocity increases through open pinholes. Incoming particles bounce through pinholes rather than collect. A disproportionately high fraction of gas flows through unbridged pinholes due to their lower resistance. As the fabric flexes during cleaning, some dust particles dislodge and recollect deeper in the fabric. After several cycles of dislodgment and recollection, the particles completely pass through the filter. Particle penetration by this mechanism is called *seepage*.

Dennis et al. (1977) and Dennis and Klemm (1979) developed a model for predicting effluent fly ash concentration with fabric loading for woven glass fabrics. However, their models contain empirical constants that may be inappropriate for other fabrics. Leith and Ellenbecker (1982) showed that seepage is the primary mechanism for penetration through a pulse-jet-cleaned felt fabric. They developed a model (Leith and Ellenbecker 1980a) for outlet flux  $N$  assuming that all incoming dust is collected by the filter and that seepage of previously collected particles through the fabric accounts for all the dust emitted once

the filter is conditioned. Seepage occurs as the bag strikes its supporting cage at the end of a cleaning pulse. The impact dislodges particles from the filter; the particles are then carried into the outlet gas stream. The following equation calculates the outlet flux:

$$N = \frac{kw^2v}{t} \quad 5.16(48)$$

where:

- N = the outlet flux
- w = the areal density of the dust deposit
- v = the filtration velocity
- t = the time between cleaning pulses to each bag
- k = a constant that depends on factors such as dust characteristics, fabric types, and length of filter service

Figure 5.16.13 plots the outlet flux measured in laboratory experiments against the flux predicted using Equation 5.16(48) with  $k = 0.002 \text{ m} - \text{s/kg}$ . These data are for different felt surfaces with different filtration velocities and different dusts. However, all data cluster about the same line.

Figure 5.16.14 plots the mass outlet flux against particle diameter for a pulse-jet filter. Comparatively little flux results from the seepage of small particles because of their small mass. The flux due to large particles is also little because they do not pass through the filter. Intermediate size particles contribute the most to the flux since they are large enough to have appreciable mass and small enough to seep

through. However, no theory exists to predict outlet flux as a function of particle size.

However, Christopher, Leith, and Symons (1990) evaluate mass penetration as a function of particle size. They developed the following empirical equation:

$$N = k \left( \frac{w^2v}{t} \right)^n \quad 5.16(49)$$

where the exponent n is given by:

$$n = 0.916(d_p)^{0.257} \quad 5.16(50)$$

where  $d_p$  is the particle diameter in  $\mu\text{m}$ .

The following equation gives model constant k:

$$k = a(d_p)^{4.82} \quad 5.16(51)$$

where  $a = 4.45 \times 10^{-6}$  for Ptfelaminated fabric and  $a = 2.28 \times 10^{-5}$  for untreated polyester felt fabric.

### Bag Design

Bags are chosen for temperature and chemical resistance, mechanical stability, and the ability to collect the dust cake and then allow it to be easily removed. In utility applications, fiberglass bags are used exclusively. For low temperature applications ( $<280^\circ\text{F}$ ), acrylic is an economical alternative.

Bag fabric research focuses on two broad objectives: improving performance and economics. Different weaves

Wool	G	Wool	P				

Notes: \*These fibers degrade in hot, moist atmospheres; Dacron is affected most, Nomex next, nylon the least.

†Glass is destroyed by gaseous HF at dew point temperatures.

These ratings are only a general guide: E = Excellent, G = Good, F = Fair, P = Poor.

and finishes for fiberglass are being studied, as well as alternative fabrics such as Teflon, Nomex, Ryton, and felted glass (see Table 5.16.2).

Bag weave is significant because different weaves produce different types of filter cakes. *Warp* is the system of yarns running lengthwise in a fabric, and *fill* is the system running crosswise. The style, weight, thickness, porosity, and strength are factors to consider in weave selection. Finishes are a lubricant against abrasion and protect against acid and alkali attack. Teflon, silicon, and graphite are the most popular finishes.

## 5.17

# PARTICULATE CONTROLS: ELECTROSTATIC PRECIPITATORS

---

---

### FEATURE SUMMARY

#### Types of Designs

Single- or two-stage

#### Applications

Single-stage units are used in coal-fired power plants to remove fly ash, cement kiln dust, lead smelter fumes, tar, and pulp and paper alkali salts. Two-stage units are used for air conditioning applications.

#### Flue Gas Limitations

Flow up to  $4 \times 10^6$  acfm, temperature up to 800°C, gas velocity up to 10 ft/sec, pressure drop is under 1 in w.g.

#### Treatment Time

2–10 sec

#### Power Requirement

Up to 17.5 W per  $\text{m}^3/\text{min}$

#### Dust Particle Size Range

0.01  $\mu\text{m}$  to greater than 1000  $\mu\text{m}$

#### Collection Efficiency

99.5 to 99.99%

#### Partial List of Suppliers

Electrostatic precipitation uses the forces of an electric field on electrically charged particles to separate solid or liquid aerosols from a gas stream. The aerosol is deliberately charged and passed through an electric field causing the particles to migrate toward an oppositely charged electrode which acts as a collection surface. Gravity or rapping the collector electrode removes the particles from the precipitator. Various physical configurations are used in the charging, collection, and removal processes.

ESPs are characterized by high efficiencies, even for small particles. They can handle large gas volumes with low pressure drops and can be designed for a range of temperatures. On the other hand, they involve high capital costs, take up a lot of space, and are not flexible after installation to changes in operating conditions. They may not work on particles with high electrical resistivity.

Commercial ESPs accomplish charging using a high-voltage, direct-current corona surrounding a highly charged electrode, such as a wire. The large potential gra-

dient near the electrode causes a corona discharge comprising electrons. The gas molecules become ionized with charges of the same sign as the wire electrode. These ions then collide with and attach to the aerosol particles, thereby charging the particles. Two electrodes charge the particles, and two electrodes collect the particles, with an electric field between each pair.

When the same set of electrodes is used for both charging and collecting, the precipitator is called a *single-stage precipitator*. Rapping cleans the collecting electrodes; thus, these precipitators have the advantage of continuous operation. The discharge electrode consists of a wire suspended from an insulator and held in position by a weight at the bottom. A power source supplies a large direct current (DC) voltage ( $\sim 50$  kV) which can be either steady or pulsed.

Parallel plate ESPs are more widely used in industry. Here, gas flows between two vertical parallel plates with several vertical wires suspended between them. The wires are held in place by weights attached at the bottom. These wires constitute the charging electrodes, and the plates are the collecting electrodes. Rapping the plate removes the collected dust; the dust gathers in a dust hopper at the bottom. Figure 5.17.1 shows a single-stage, parallel plate precipitator with accessories such as hoppers, rappers, wire weights, and distribution baffles for the gas.

If different sets of electrodes are used for charging and collecting, the precipitator is called a *two-stage precipitator* (see Figure 5.17.2). Cleaning involves removing the collecting plates and washing them or washing the collecting plates in place. In a two-stage ESP, the charging section is short, providing a short residence time, and the collection section is five or more times longer to provide sufficient time for collection (Crawford 1976). Two-stage ESPs are used in air conditioning applications, while single-stage ESPs are used in industrial applications where dust loadings are higher and space is available.

## Corona Generation

When the potential difference between the wire and plate electrodes increases, a voltage is reached where an electrical breakdown of the gas occurs near the wire. When gas molecules get excited, one or more of the electrons can shift to a higher energy level. This state is transient; once the excitation has ceased, the molecule reverts to its ground state, thereby releasing energy. Part of this energy converts

FIG. 5.17.1 Single-stage, parallel plate ESP with accessories.

to light. The bluish glow around the wire is the corona discharge. A different situation occurs when an electron or ion imparts additional energy on an excited molecule. This process causes a cascade or avalanche effect described next.

The space between the wire and the plate can be divided into an active and a passive zone (see Figure 5.17.3). In the active zone, defined by the corona glow discharge, electrons leave the wire electrode and impact gas molecules, thereby ionizing the molecules. The additional free electrons also accelerate and ionize more gas molecules. This avalanche process continues until the electric field decreases to the point that the released electrons do not acquire sufficient energy for ionization. The behavior of these charged particles depends on the polarity of the electrodes; a negative corona is formed if the discharge electrode is negative, and a positive corona is formed if the discharge electrode is positive.

In a negative corona, positive ions are attracted toward the negative wire electrode, and electrons are attracted toward the positive plate or cylinder electrode. Beyond the corona glow region, the electric field diminishes rapidly, and if electronegative gases are present, the gas molecules

become ionized by electron impact. The negative ions move toward the plate electrode. In the passive zone, these ions attach themselves to aerosol particles and serve as the principal means for charging the aerosol. The ion concentration is typically  $10^7$  to  $10^9$  ions/cm<sup>3</sup>.

The corona current, and therefore the charge density in the space between the electrodes, depends on factors such as the ionic mobility, whether the gas is electropositive or electronegative, and whether the corona is positive or negative. If the gas is electropositive with low electron affinity like N<sub>2</sub>, H<sub>2</sub>, or an inert gas, its molecules absorb few electrons. Thus, the current is predominantly electronic. Due to the higher mobility of electrons, the corona current is high. Conversely, an electronegative gas like O<sub>2</sub> has high electron affinity and absorbs electrons easily. Here, the current is due to negative ions, and thus the corona current is low due to the lower mobility of the gas ions.

When a corona is negative, the free electrons leaving the active zone are transformed into negative ions with a substantially lower mobility on their way to the plates. The negative charge carriers thus cover the first part of their path as fast, free electrons and the second part as slower ions; their average mobility is lower than that of free elec-

FIG. 5.17.2 Parallel plate, two-stage ESP.

trons but higher than that of the large ions. On the other hand, when a corona is positive, the positive charge carriers are large, slow ions by origin and retain this form throughout their motion. Consequently, a negative corona always has a higher corona current than a positive corona for an applied voltage.

Negative coronas are more commonly used in industrial applications, while positive coronas are used for cleaning air in inhabited spaces. A negative corona is accompanied by ozone generation and, therefore, is usually not

used for cleaning air in inhabited spaces. However, most industrial gas-cleaning precipitators use a negative corona because of its superior electrical characteristics which increase efficiency at the temperatures at which they are used.

### Current–Voltage Relationships

For a wire-in-cylinder configuration, the current–voltage relationship can be derived from Poisson’s equation as follows:

$$\nabla^2 V = -\frac{4\pi}{\epsilon_0} \rho_s \quad 5.17(1)$$

where:

$\rho_s$  = the space charge per unit volume  
 $\epsilon_0$  = the permittivity of the medium.

The equations in this treatment follow the electrostatic system of units (ESU). The value  $V$  is the electric potential which is related to the electric field  $\vec{E}$  as follows:

$$-\nabla V = \vec{E} \quad 5.17(2)$$

Thus, the relationship can be expressed as follows:

$$\nabla^2 V = \frac{\partial^2 V}{\partial r^2} + \frac{1}{r} \frac{\partial V}{\partial r} \quad 5.17(3)$$

In the presence of a charge sufficient to produce corona discharge, the preceding equations can be expressed as:

$$\frac{dE}{dr} + \frac{1}{r} E = -\frac{4\pi}{\epsilon_0} \rho_s \quad 5.17(4)$$

FIG. 5.17.3 Variation of field strength between wire and plate electrodes.

Assuming that the wire acts as an ion source, the current  $i$  applied to the wire is used to maintain the space charge as follows:

$$i = 2\pi r \rho_s Z E \quad 5.17(5)$$

where  $Z$  is the ion mobility. Substituting Equation 5.17(5) in 5.17(4) and solving the resultant differential equation yields the following equation:

$$E = \left( \frac{2i}{Z} + \frac{C^2}{r^2} \right)^{1/2} \quad 5.17(6)$$

where  $C$  is a constant of integration which depends on corona voltage, current, and the inner and outer cylinder diameters and  $r$  is the radial distance from the wire. For large values of  $i$  and  $r$ , Equation 5.17(6) reduces to  $E = (2i/Z)^{1/2}$ , implying a constant field strength over most of the cross section away from the inner electrode.

The following equation gives an approximation of the corona current  $i$  (White 1963):

$$i = V(V - V_0) \frac{2Z}{r_0^2 \ln \left[ \frac{r_0}{r_i} \right]} \quad 5.17(7)$$

where:

- $V$  = the operating voltage
- $V_0$  = the corona starting voltage
- $r_0$  and  $r_i$  = the radii of the cylinder and wire, respectively.

The value  $V_0$  can be estimated by use of the following equation:

$$V_0 = 100\delta r_i \left( 1 + \frac{0.3}{r_i} \right) \ln \left[ \frac{r_0}{r_i} \right] \quad 5.17(8)$$

where  $\delta$  is a correction factor for temperature and pressure as follows:

$$\delta = \frac{293}{T} \frac{P}{760} \quad 5.17(9)$$

The factor  $f$  is a wire roughness factor, usually between 0.5 and 0.7 (White 1963).

Equation 5.17(8) shows that reducing the size of the corona wire decreases the applied voltage necessary to initiate corona  $V_0$ . Decreasing the corona starting voltage increases the corona current for an applied voltage.

An analysis similar to that shown for wire-in-cylinder configuration can be applied to the parallel plate and wire electrode configuration. The equations are not as simple because the symmetry of the cylindrical precipitator simplifies the mathematics. The plate-type precipitator also has an additional degree of freedom—corona wire spacing. Qualitatively, if the corona wires are spaced close together, the system approaches the field configuration of a parallel plate capacitor, which yields a constant field strength in the interelectrode space. For an applied voltage, this configuration reduces the electric field near the

corona wire. Therefore, using smaller wires or spacing the wires farther apart increases the current density in a region.

In the presence of aerosol particles, the particles get charged with the same sign as the wire. This particle charging decreases the voltage gradient, and therefore the corona starting voltage has a higher value. Another effect is that the electric field is distorted and the electric field near the collector electrode increases due to image forces.

## Particle Charging

Two mechanisms are responsible for charging aerosol particles in an ESP: field charging and diffusion charging. Both mechanisms are active; however, each becomes significant for particles in different size ranges. Field charging is the dominant mechanism for particles with a diameter greater than  $1 \mu\text{m}$ , while diffusion charging predominates for particles with a diameter less than  $0.2 \mu\text{m}$ . In the intermediate region, both mechanisms contribute a significant charge.

### FIELD CHARGING

The presence of particles with a dielectric constant greater than unity causes a localized deformation in the electric field (see Figure 5.17.4). Gas ions travel along electric field lines, and because the lines intercept the particle matter, the ions collide with these particles and charge them. When the particle reaches a *saturation charge*, additional ions are repelled and charging stops. The amount of charge  $q$  on a particle is the product of the number of charges  $n$  and the electronic charge  $e$  ( $q = ne$ ). The following equation gives the rate of particle charging:

FIG. 5.17.4 Distortion of an electric field around an aerosol particle.

$$\frac{d\left(\frac{n}{n_s}\right)}{dt} = \pi N_i e Z \left(1 - \frac{n}{n_s}\right)^2 \quad 5.17(10)$$

On integration, this equation yields the number of charges on a particle as a function of time as follows:

$$n = n_s \left(\frac{t}{t + \tau}\right) \quad 5.17(11)$$

where  $n_s$  is the saturation charge given by  $(3\epsilon/\epsilon + 2)(d^2E/4e)$ . The saturation charge is the maximum charge that can be placed on a particle of diameter  $d$  by a field strength  $E$ . The value  $\epsilon$  is the dielectric constant of the particle. The value  $\tau_e$  is a time constant for the rapidity of charging and is equal to  $(1/\pi e Z_i N_i)$ , where  $Z_i$  is the ion mobility and  $N_i$  is the ion concentration.

## DIFFUSION CHARGING

Particles are charged by unipolar ions in the absence of an electric field. The collision of ions and particles occurs due to the random thermal motion of ions. If every ion that collides with a particle is retained, the rate of charging with respect to time is as follows:

$$\frac{dn}{dt} = \frac{\pi}{4} d^2 \bar{c} N_i \exp\left[-\frac{2ne^2}{dkT}\right] \quad 5.17(12)$$

For an initially uncharged particle, integrating this equation gives the number of charges gained due to diffusion charging as follows:

$$n = \left(\frac{dkT}{2e^2}\right) \ln\left[1 + \frac{\pi d \bar{c} e^2 N_i}{2kT} t\right] \quad 5.17(13)$$

where:

- $k$  = the Boltzman constant
- $T$  = the absolute temperature
- $e$  = the charge of one electron

Here,  $\bar{c}$  is the mean thermal speed of the ions and for a Maxwellian distribution is given by  $\sqrt{8kT/\pi m}$  where  $m$  is the ionic mass.

When both field and diffusion charging are significant, adding the values of the  $n$  calculated with Equations 5.17(11) and 5.17(13) is not satisfactory; adding the charging rates due to field and diffusion charging is better and gives an overall rate. This process yields a nonlinear differential equation with no analytic solution and therefore has to be solved numerically. An overall theory of combined charging agrees with experimental values but is computationally cumbersome.

## Migration Velocity

The following equation determines the velocity of a charged particle suspended in a gas and under the influence of an electric field by equating the electric and Stokes drag forces on the particle:

$$V_p = \frac{neEC_c}{3\pi\mu d} \quad 5.17(14)$$

Here,  $V_p$  is the particle migration velocity toward the collector electrode, and  $E$  is the collector electric field. The value for  $n$  depends on whether field or diffusion charging is predominant. Particles charged by field charging reach a steady-state migration velocity, whereas the migration velocity for small particles charged by diffusion charging continues to increase throughout the time that the dust is retained in the precipitator.

## ESP Efficiency

The most common efficiency theory is the Deutsch-Andersen equation. The theory assumes that particles are at their terminal electrical drift velocity and well-mixed in every plane perpendicular to the gas flow direction due to lateral turbulence. The theory also assumes plug flow through the ESP, no reentrainment of particles from the collector plates, and uniform gas velocity throughout the cross section. Collection efficiency is expressed as follows:

$$\eta = 1 - \exp\left[-\frac{V_p A}{Q_g}\right] \quad 5.17(15)$$

where  $A$  is the total collecting area of the precipitator and  $Q_g$  is the volumetric gas flow. The derivation of this equation is identical to that for gravity settling chambers except that the terminal settling velocity under a gravitational field is replaced with terminal drift velocity in an electric field.

The precipitator performance can differ from theoretical predictions due to deviations from assumptions made in the theories. Several factors can change the collection efficiency of an idealized precipitator. These factors include particle agglomeration, back corona, uneven gas flow, and rapping reentrainment.

Cooperman (1984) states that the Deutsch-Andersen equation neglects the role of mixing (diffusional and large-scale eddy) forces in the precipitator. These forces can account for the differences between observed and theoretical migration velocities and the apparent increase in migration velocity with increasing gas velocity. He postulates that the difference in particle concentration along the precipitator length produces a mixing force that results in a particle velocity through the precipitator that is greater than the gas velocity. At low velocities, the effect is pronounced, but it is masked at higher velocities. He presents a more general theory for predicting collection efficiency by solving the mass balance equation as follows:

$$D_1 \frac{\partial^2 C}{\partial x^2} + D_2 \frac{\partial^2 C}{\partial y^2} - V_g \frac{\partial C}{\partial x} + V_p \frac{\partial C}{\partial x} = 0 \quad 5.17(16)$$

where:

- $C$  = the particle concentration
- $D_1$  and  $D_2$  = the longitudinal and transverse mixing coefficients, respectively

$V_g$  = the gas velocity in the x direction  
 $V_p$  = the migration velocity in the y direction  
 (see Figure 5.17.5)

The initial conditions chosen are  $C(0,y) = C_0$ , and  $C(x,y) \rightarrow 0$  as  $y \rightarrow 0$ , where  $C_0$  is the particle concentration at the inlet. The first condition implies a constant concentration across the inlet, while the second condition states that an infinitely long precipitator has zero penetration.

The boundary conditions are  $D_2 \partial C / \partial y + V_p C = 0$  at the center plane, and  $D_2 \partial C / \partial y - f V_p C = 0$  at the boundary layer. The first condition states that the diffusional flux balances the flux due to migration velocity, and no net particle flux occurs across the center plane. The second condition contains a reentrainment factor  $f$ . This factor is an empirical parameter indicating what fraction of the particles that enter the boundary layer are later reentrained back into the gas stream. The complete analytic solution is fairly complicated, and therefore only the first term of the solution is used; but it yields sufficient accuracy as follows:

$$\eta = 1 - \exp \left[ \left( \frac{V_g}{2D_1} \right) - \sqrt{\left( \frac{V_g}{2D_1} \right)^2 + \left( \frac{D_2}{D_1} \right) \left( \frac{\lambda_1}{b} \right)^2 + \frac{V_p^2}{4D_1 D_2}} \right] L \quad 5.17(17)$$

$$\tan \lambda_1 = \frac{\beta}{\chi} \frac{2\lambda_1(1-f)}{\lambda_1^2 - (1-f) \frac{\beta^2}{\chi^2}}$$

$$\beta = \frac{bV_p}{2D_1}; \quad \chi = \frac{D_2}{D_1}$$

where  $b$  is the distance from the center line to the collector plate and  $\lambda_1$  is the smallest positive solution to the preceding transcendental equation.

The Deutsch-Andersen equation and other efficiency theories are limiting cases of this general theory. To use this exact theory, an environmental engineer has to first decide on appropriate mixing coefficients. For a large  $D_2$

(i.e., large transverse mixing), the equation for efficiency reduces to the following equation:

$$\eta = 1 - \exp \left[ \left( \frac{V_g b}{2D_1} \right) - \sqrt{\left( \frac{V_g b}{2D_1} \right)^2 + 2(1-f) \frac{V_p b}{2D_1}} \right] \frac{L}{b} \quad 5.17(18)$$

Expanding the square root term as a Taylor series up to the first three terms and rearranging gives the following equation:

$$\eta = 1 - \exp \left[ -(1-f) \left( 1 - \frac{V_p}{V_g^2} \right) \frac{D_1(1-f)}{b} \frac{V_p A_c}{Q_g} \right] \quad 5.17(19)$$

This equation is analogous to the Deutsch-Andersen equation except that two modifying factors are added. The  $(1-f)$  factor corrects for reentrainment, and the second factor is related to the diffusional transport in the gas flow direction that modifies the gas velocity. Cooperman (1984) suggests a value of 18,000 cm<sup>2</sup>/sec for  $D_1$ .

Thus, efficiency depends on longitudinal mixing as well as reentrainment.

## DUST RESISTIVITY

A major factor affecting ESP performance is the electrical resistivity of dust. If the resistivity is low (high conductivity), the charge on a particle leaks away quickly as particles collect on the plate. Thus, reentrainment becomes possible. As van der Waals' forces may be insufficient to bind the particles, the particles hop or creep through the precipitator. Conversely, if the particle resistivity is high, a charge builds on the collected dust. This charge reduces field strength, reducing ionization and the migration velocity of particles through the gas.

A plot of resistivity versus temperature shows a maximum resistivity between 250 and 350°F (see Figure 5.17.6). This relationship is unfortunate because operators cannot reduce the ESP temperature below 250°F without risking condensation of H<sub>2</sub>SO<sub>4</sub> on the plate surfaces.

FIG. 5.17.5 Top view of wire-plate precipitator.

FIG. 5.17.6 Variation of fly ash resistivity with coal sulfur content and flue-gas temperature.

Increasing the temperature above 350°F results in excessive heat loss from the stack.

Resistivity decreases with increased sulfur content in coal because of the increased adsorption of conductive gases on the fly ash. Resistivity changes were responsible for the increased fly ash emissions when power plants switched from high-sulfur coal to low-sulfur coal to reduce SO<sub>2</sub> emissions in the United States.

In some cases of high resistivity in dust, adding a conditioning agent to the effluent gases substantially reduces resistivity and enhances particle collection. Examples are adding SO<sub>3</sub> to gas from power generator boilers and NH<sub>3</sub> to gas from catalytic cracking units used in petroleum refining. The overall efficiency can increase from 80% before injection to 99% after injection.

## PRECIPITATOR DESIGN

Precipitator design involves determining the sizing and electrical parameters for an installation. The most important parameters are the precipitation rate (migration velocity), specific collecting area, and specific corona power (White 1984). In addition, the design includes ancillary factors such as rappers to shake the dust loose from the plates, automatic control systems, measures for insuring high-quality gas flow, dust removal systems, provisions for structural and heat insulation, and performance monitoring systems.

The design engineer should determine the size distribution of the dust to be collected. Based on this information, the engineer can calculate the migration velocity (also known as the precipitation rate)  $V_p$  using Equation 5.17(14) for each size fraction. The engineer calculates the number of charges on a particle  $n$  using Equation 5.17(11) or 5.17(13), depending on whether field or diffusion charging is predominant. Diffusion charging is the dominant charging mechanism for particles less than 0.2  $\mu\text{m}$ , while field charging is predominant for particles greater than 1  $\mu\text{m}$ . For particles of intermediate sizes, both mechanisms

are significant. The engineer can also calculate  $V_p$  empirically from pilot-scale or full-scale precipitator tests. The value  $V_p$  also varies with each installation depending on resistivity, gas flow quality, reentrainment losses, and sectionalization. Therefore, each precipitator manufacturer has a file of experience to aid design engineers in selecting a value of  $V_p$ . A high migration velocity value indicates high performance.

After selecting a precipitation rate, the design engineer uses the Deutsch-Andersen relationship, Equation 5.20(15) or 5.20(18), to determine the collecting surface area required to achieve a given efficiency when handling a given gas flow rate. If Equation 5.20(18) is used, the engineer can choose the value of the reentrainment factor  $f$  empirically from pilot-scale studies or previous experience or set it to zero as an initial guess. The quantity  $A/Q_g$  is called the specific collection area.

The corona power ratio is  $P_c/Q_g$ , where  $P_c$  is the useful corona power. The design engineer determines the power required for an application on an empirical basis. The power requirements are related to the collection efficiency and the gas volume handled. Figure 5.17.7 plots the collection efficiency versus the corona power ratio. At high efficiencies, large increments of corona power are required for small increments in efficiency. The precipitation rate (migration velocity) is related to corona power as follows:

$$V_p = \frac{kP_c}{A} \quad 5.17(20)$$

where  $k$  is an empirical constant that depends on the application. The Deutsch-Andersen equation can therefore be expressed as follows:

$$\eta = 1 - \exp\left[-\frac{kP_c}{Q}\right] \quad 5.17(21)$$

FIG. 5.17.7 Collection efficiency as a function of the corona power ratio.

**TABLE 5.17.1 RANGES FOR ESP DESIGN PARAMETERS**

<i>Parameter</i>	<i>Range of Values</i>
Precipitation rate $V_p$	1.0–10 m/min
Channel width $D$	15–40 cm
Specific collection area $\frac{\text{Plate Area}}{\text{Gas Flow}}$	0.25–2.1 m <sup>2</sup> /(m <sup>3</sup> /min)
Gas velocity $u$	1.2–2.5 m/sec
Aspect ratio $R = \frac{\text{Duct Length}}{\text{Height}}$	0.5–1.5 (Not less than 1 for $\eta > 99\%$ )
Corona power ratio $\frac{\text{Corona Power}}{\text{Gas Flow}} = \frac{P_c}{Q}$	1.75–17.5 W/(m <sup>3</sup> /min)
Corona current ratio $\frac{\text{Corona Current}}{\text{Plate Area}}$	50–750 $\mu\text{A}/\text{m}^2$
Plate area per electrical set $A_s$	460–7400 m <sup>2</sup>
Number of electrical sections $N_s$	
a. In the direction of gas flow	2–8
b. Total number of sections	1–10 bus sections/(1000 m <sup>3</sup> /min)
Spacing between sections	0.5–2 m
$L_{en}, L_{ex}$	2–3 m
Plate Height; Length	8–15 m; 1–3 m
<hr/>	
<i>Power Density versus Resistivity</i>	
<i>Ash Resistivity, ohm-cm</i>	<i>Power Density, W/m<sup>2</sup></i>
$10^4$ – $10^7$	43
$10^7$ – $10^8$	32
$10^9$ – $10^{11}$	27
$10^{11}$	22
$10^{12}$	16
$10^{13}$	10.8
<hr/>	
<i>Source: C.D. Cooper and F.C. Alley, 1986, Air pollution control: A design approach (Boston: PWS Publishers).</i>	

This relationship gives the corona power necessary for a given precipitation efficiency, independent of the precipitator design. The maximum corona power capability of the electrical sets should be considerably higher than the useful corona power.

The corona electrodes in large precipitators are subdivided into multiple groups or sections, referred to as bus sections. These sections are individually powered by separate rectifier sets to reduce the effects of sparking and better match the corona voltages and currents to the electrical characteristics of the gas and dust. The degree of sectionalization is expressed as the number of sections per 1000 m<sup>3</sup>/min. This parameter is a measure of the precipitator's ability to absorb corona power from the electrical sets. ESP performance improves with sectionalization. This improvement may be due to better electrode alignment and accurate spacing (White 1977). Sectionalization also implies that the unit is operational even if a few bus sections are taken offline.

Table 5.17.1 gives the range of some design parameters. A design engineer can specify the basic geometry of an ESP using the information in the table.

The following equation determines the total number of channels in parallel or the number of electrical sections in a direction perpendicular to that of gas flow  $N_d$ :

$$N_d = \frac{Q}{uDH} \quad 5.17(22)$$

where:

- Q = the volumetric gas flow rate
- u = the linear gas velocity
- D = the channel length (plate separation)
- H = the plate height

The overall width of the precipitator is  $N_d D$ . The overall length of the precipitator is as follows:

$$L_0 = N_s L_p + (N_s - 1)L_s + L_{en} + L_{ex} \quad 5.17(23)$$

where:

- $N_s$  = the number of electrical sections in the direction of flow
- $L_p$  = the plate length

$L_s$  = the spacing between the electrical sections  
 $L_{en}$  and  $L_{ex}$  = the entrance and exit section lengths, respectively.

The following equation determines the number of electrical sections  $N_s$ :

$$N_s = \frac{RH}{L_p} \quad 5.17(24)$$

where  $R$  is the aspect ratio.

When the number of ducts and sections have been specified, the design engineer can use the following equation to calculate the actual area:

$$A_a = 2HL_p N_s N_d \quad 5.17(25)$$

The preceding procedure provides a rational basis for determining the plate area, total power, and degree of sectionalization required.

# 5.18 PARTICULATE CONTROLS: WET COLLECTORS

### FEATURE SUMMARY

#### Types of Designs

Low or high energy

#### Limitations

Low efficiency and liquid waste disposal for low-energy designs; operating costs for high-energy designs

#### Loadings

0.1 to 100 g/m<sup>3</sup>

#### Pressure Drop

Low energy—0.5 to 2 cm H<sub>2</sub>O; high energy—2 to 100 cm H<sub>2</sub>O

#### Overall Efficiency

Low energy—high for >10 μm; high energy—high for >1 μm

A particulate scrubber or wet collector is a device in which water or some other solvent is used in conjunction with inertial, diffusion, or other forces to remove particulate matter from the air or gases. The scrubbing process partially mimics natural processes where dust-laden air is cleaned by rain, snow, or fog. The first industrial scrubbers attempted to duplicate this natural cleaning, with dusty air ascending through a rain of liquid droplets in a

large, vertical tube. Subsequent developments reduced the space requirements for scrubbers.

The first patent for a particle scrubber design was issued in Germany in 1892, and the first gas scrubber with rotating elements was patented about 1900. Venturi scrubbers were developed just after World War II, mainly in the United States, and represented a breakthrough in scrubber design (Batel 1976).

## General Description

In the scrubbing process, gas containing dust particles contacts a scrubbing liquid (often water). Here, some of the dust particles are captured by the scrubbing liquid. The scrubbing liquid can also condense on the dust particles, forming liquid droplets which are more easily removed than the dry dust particles. Finally, the mist droplets, which may or may not contain dust particles, are removed in an entrainment separator. [Figure 5.18.1](#) schematically shows the process. The primary collection mechanisms for particle removal are inertial impaction, interception, diffusion or diffusiophoresis, and electrical attraction. At times, other mechanisms, such as those listed in [Table 5.18.1](#), are involved in collection. However, in all cases, the dominant mechanism is inertial impaction followed by diffusion.

Scrubbers can be divided into three categories. In the first category, the scrubbing liquid is a spray, and collection occurs when particles are embedded by impaction in the scrubbing liquid surface (see part [a](#) in [Figure 5.18.2](#)). In the second category, collection occurs by impingement

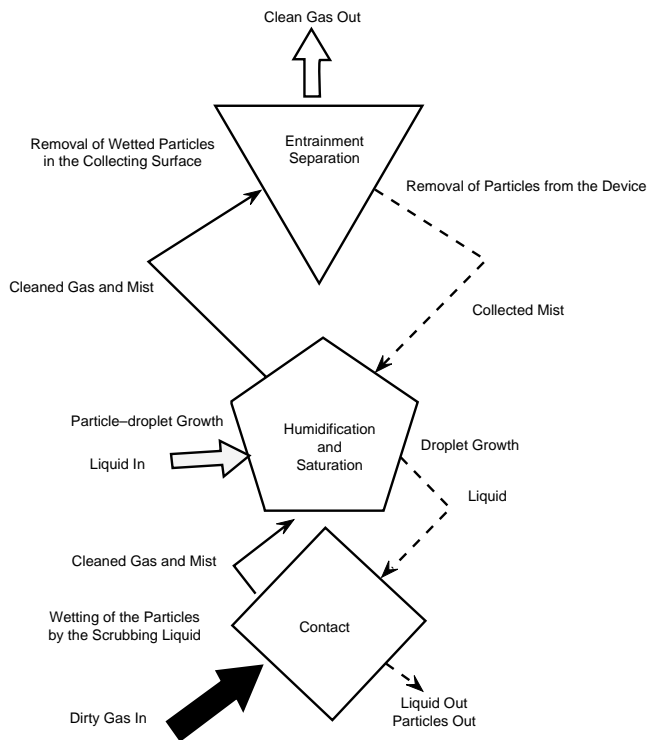

FIG. 5.18.1 Schematic diagram of scrubbing process.

on a wetted surface (see part b of Figure 5.18.2). Finally, in the third category, particle-laden air is bubbled through the scrubbing liquid, and particles are removed by impingement (see part c of Figure 5.18.2).

The main factor influencing a scrubber's efficiency is the size of the dust particles being removed. Scrubber collection efficiency also varies with scrubber design and operating conditions. Figure 5.18.3 shows examples of typical grade efficiency curves. Because of the efficiency variation due to particle size, collection efficiency is often expressed as a function of one particle size, the *50% cut diameter*, that is, the particle diameter for which collection efficiency is 50% (Calvert et al. 1972; Calvert 1974, 1977). The rationale for this definition is that the grade efficiency curve for all scrubbing is steepest at the 50% point, and for estimating purposes this curve is considered to be a step function—all particles greater than this size are collected, all smaller are not (see dotted line on Figure

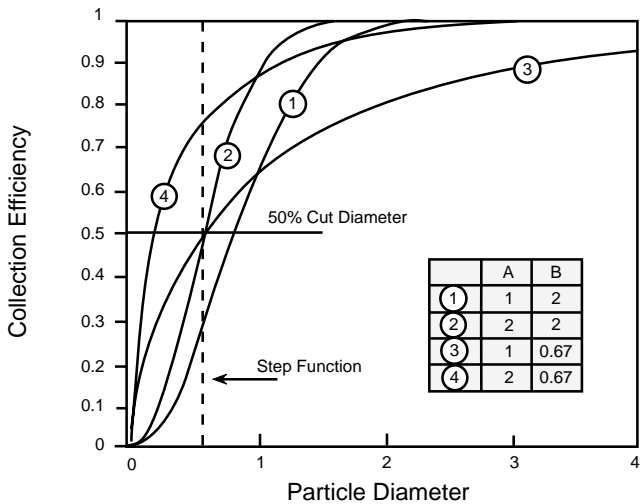

FIG. 5.18.3 Typical grade efficiency curves as computed from Efficiency =  $\exp(-Ad_{pa}^B)$ .

5.18.3). Because collection efficiency is also a function of particle density, the concept of the aerodynamic particle diameter must be considered. The aerodynamic diameter of an aerosol particle is the diameter of a unit density sphere (density =  $1 \text{ g/cm}^3$ ) which has the same settling velocity as the particle. With this definition, the relationship of a spherical particle of diameter  $d_s$  and density  $\rho$  to its aerodynamic diameter  $d_a$  is expressed as:

$$d_a = d_s(\rho C_c)^{1/2} \quad 5.18(1)$$

For particles with diameters of several micrometers or less, a slip correction term  $C_c$  must be included in the aerodynamic diameter conversion as follows:

$$C_c = 1 + \frac{2\lambda}{d_s} \left[ 1.257 + 0.400 \exp\left(-\frac{1.1d_s}{2\lambda}\right) \right] \quad 5.18(2)$$

The term  $d_s$  is the dust particle diameter, and  $\lambda$  is the mean free path of gas molecules. For air at  $20^\circ\text{C}$ ,  $\lambda$  has a value of  $0.0687 \mu\text{m}$ .

## Scrubber Types

Over the years, many scrubber designs have been developed based on the three preceding scrubbing processes. Some representative examples are described next.

FIG. 5.18.2 Schematic illustration of various scrubbing mechanisms.

FIG. 5.18.4 Example of preformed spray unit.

### SPRAY COLLECTORS—TYPE I

With spray-type units, particles are collected on liquid droplets within the scrubbing unit. The liquid droplets are formed either by atomization, where the flow rate of the scrubbing liquid and pressure in the atomizing nozzle control the droplet size and number, or by the moving gas stream, which atomizes and accelerates the resulting droplets.

#### Preformed Spray

With a preformed spray, droplets are formed by a nozzle and are then sprayed through the dust-laden air (see Figure 5.18.4). Removal of the dust is primarily by impaction, although diffusion and diffusiophoresis can also contribute to particle collection. Spray scrubbers, taking advantage of gravitational settling, achieve cut diameters around 2  $\mu\text{m}$ , with high-velocity sprays capable of reducing this lower limit to about 0.7  $\mu\text{m}$  (aerodynamic diameter) (Calvert et al. 1972).

#### Gas-Atomized Spray

With a gas-atomized spray, high-velocity, particle-laden gas atomizes liquid into drops, and the resulting turbulence and velocity difference between droplets and particles enhances particle-droplet collisions and hence particle removal (see Figure 5.18.5). Typical gas velocities range from 60 to 120 m/sec (200–400 f/sec), and the pressure drop in these units is relatively high. A typical example of this type of unit is the venturi scrubber. Venturi scrubbers have achieved cut diameters down to 0.2  $\mu\text{m}$  (Calvert 1977).

### Centrifugal Scrubbers

With centrifugal scrubbers, the scrubbing liquid is sprayed into the gas stream at the same time the unit is imparting a spinning motion to the mixture of particles and droplets (see Figure 5.18.6). The result is a centrifugal deposition of the particle-droplet mixture on the outer walls of the scrubber. Depending on the amount of scrubbing liquid used, the collection efficiency is good for particles down to about 1 to 2  $\mu\text{m}$  diameter (aerodynamic) (Calvert et al. 1972). The tangential velocities in these units should not

FIG. 5.18.5 Examples of gas-atomized spray unit.

FIG. 5.18.7 Plate scrubbers.

FIG. 5.18.8 Massive packing and fibrous packing scrubbers.

exceed 30 m/sec to prevent reentrainment of the droplet-particle mixture.

## IMPINGEMENT ON A WETTED SURFACE—TYPE II

With impingement on a wetted surface, collection occurs by impingement. These scrubbers include plate scrubbers and scrubbers with massive packing or fibrous packing.

### Plate Scrubbers

Plate scrubbers have plates or trays mounted within a vertical tower at right angles to the axis of the tower (see Figure 5.18.7). Gas flows from the bottom of the tower up through slots, holes, or other perforations in the plates where mixing with the scrubbing liquid occurs. Collection efficiency increases as the cut diameter decreases. A cut diameter of about  $1\ \mu\text{m}$  (aerodynamic diameter) is typical for  $\frac{1}{8}$ -in holes in a sieve plate (Calvert et al. 1972). Calvert (1977) points out that increasing the number of plates does not necessarily increase collection efficiency. Once particles around the size of the cut diameter are removed, adding more plates does little to increase collection efficiency.

### Massive Packing

Packed-bed towers packed with crushed rock or various ring- or saddle-shaped packings are often used as gas scrubbers (see a in Figure 5.18.8). The gas-liquid contact can be crossflow, concurrent, or countercurrent. Collection efficiency rises as packing size falls. According to Calvert (1977), a cut diameter of about  $1.5\ \mu\text{m}$  (aerodynamic) can be achieved with columns packed with 1-in Berl saddles or Raschig rings. Smaller packings give higher efficiencies; however, the packing shape appears to have little importance.

### Fibrous Packing

Beds of fibers (see part b in Figure 5.18.8) are also efficient at removing particles in gas scrubbers. Fibers can be made from materials such as steel, plastic, or even spun glass. With small diameter fibers, efficient operation is achieved. Efficiency increases as the fiber diameter decreases and also as gas velocity increases. The collection is primarily by impaction and interception. Diffusion is important for small particles, although to increase diffusional collection, lower gas velocities are necessary. Cut diameters can be as low as  $1.0$  to  $2.0\ \mu\text{m}$  (aerodynamic) or in some cases as low as  $0.5\ \mu\text{m}$  (aerodynamic) (Calvert et al. 1972). A major difficulty with fibrous beds is that they are prone to plugging; even so, they are widely used.

## BUBBLING THROUGH SCRUBBING LIQUID—TYPE III

In scrubbers that bubble gas through a scrubbing liquid, the particulate-containing gas is subjected to turbulent mixing with the scrubbing liquid. Droplets form by shear forces, or the dust particles are impacted directly onto the scrubbing liquid. Droplets are also formed by motor-driven impellers (that are either submerged or in the free air of the scrubber). These impellers serve not only to form small droplets but also to enhance impaction of the dust particles.

### Baffle and Secondary-Flow Scrubbers

These units remove particulates from an air stream by continually changing the flow direction and velocity as the gas flows through the unit (see Figure 5.18.9). This motion results in intimate particle mixing in the gas and the spray droplets of scrubbing liquid. Zig-zag baffles or louvers are examples of how flow direction and velocity are altered internally. With these units, cut diameters as low as 5 to 10  $\mu\text{m}$  can be achieved with low pressure drops. Plugging can be a problem with some heavy particle loadings.

### Impingement and Entrainment Scrubbers

With this type of scrubber design, the particle-gas mixture is bubbled through or skimmed over the scrubbing liquid surface which atomizes some droplets and mixes the particles with the scrubbing liquid (see Figure 5.18.10). Both particle impaction on the liquid surface and on the atomized drops and some diffusion contribute to particle collection, which is effective with high-velocity entrainment for cut diameters down to 0.5  $\mu\text{m}$  (aero-

FIG. 5.18.9 Baffle-type scrubber.

dynamic diameter). The pressure drop for this class of device is high.

### Mechanically Aided Scrubbers

With mechanically aided scrubbers, a motor-driven device in the scrubber produces spray droplets and mixes the incoming gas and scrubbing liquid more intimately (see Figure 5.18.11). The motor-driven device can be a fan with the scrubbing liquid introduced into the fan rotor, or it can be a paddle arrangement (disintegrator) in the scrubbing liquid that produces droplets. These units have cut diameters down to 2.0  $\mu\text{m}$  (aerodynamic), or even 1.0  $\mu\text{m}$  for some disintegrator designs (Calvert et al. 1972).

### Fluidized- (Moving) Bed Scrubbers

Fluidized-bed scrubbers are similar to packed-bed units except that the packing material is light enough to float in the gas stream (see Figure 5.18.12). The packing material expands to about twice its original depth. This expansion intimately mixes the particulates and scrubbing liquid and permits effective collection down to cut diameters of 1  $\mu\text{m}$  (aerodynamic) (Calvert 1977).

FIG. 5.18.10 Impingement scrubber.

FIG. 5.18.11 Mechanically aided scrubber.

FIG. 5.18.12 Fluidized- or mobile-bed scrubber.

### SCRUBBERS USING A COMBINATION OF DESIGNS

Besides the preceding basic scrubber types, a number of scrubber designs use two or more of the collection mechanisms in Table 5.18.1. With a process known as flux force/condensation scrubbing (Calvert and Jhaveri 1974), collection phenomena such as diffusiophoresis or thermophoresis combine with condensation to improve particle removal. This process uses steam to increase the deposition of scrubbing liquid on the dust particles by condensation, making the resulting dust-liquid droplets easier to remove. Temperature gradients or concentration fluxes enhance particle collection. This process is particularly attractive if the incoming dusty gas stream is hot and humid. Otherwise, the process is more costly than more conventional scrubber designs.

Another approach enhances scrubber collection efficiency using electrostatics. The electrostatics can take the form of wet ESPs, charged-dust/grounded-liquid scrubbers, charged-drop scrubbers, or charged-dust/charged-liquid scrubbers (Calvert 1977).

### Factors Influencing Collection Efficiency

The collection efficiency of the scrubbing process depends on having high velocities between the dust particles and

9.	Thermophoretic force
10.	Diffusiophoresis force

the collecting liquid (Overcamp and Bowen 1983). These high velocities enhance the impaction efficiency. Because fine particles rapidly attain the velocity of their surroundings, continually mixing the dirty air stream with the collecting liquid is necessary for good impaction, and short distances between the particles and the collecting surface are required for efficient diffusive collection (Nonhebel 1964).

Considering all collection mechanisms in an ideal scrubber, Figure 5.18.13 shows the shape of a typical efficiency versus particle diameter curve for impaction plus diffusion. In the figure a minimum collection efficiency is apparent that is typical of the low efficiency in the transition from impaction collection processes to diffusion-related processes. Above this minimum, efficiency varies roughly as a function of the dust particle diameter squared, and below it roughly as  $(1/d^2)$  (Reist 1993). Efficiency is approximately proportional to particle density. As might be expected, because of the variety of scrubbing configurations available, no one collection mechanism is dominant, and no single approach determines all scrubber performance (Crawford 1976).

### CONTACTING POWER RULE

Through experience, investigators have observed that scrubber efficiency for similar aerosols, regardless of scrubber design, is related to the power consumed by the scrubber in making the liquid-particle contact. Thus, scrubber grade efficiency appears to be a function of power input. Scrubbers are high-energy devices. That is, in general, the higher the energy input per unit volume of gas treated, the more efficient the scrubber is for smaller sized particle collection. Also, higher power inputs imply smaller scrubbing liquid drop sizes and more turbulence.

Semrau (1960) shows that the efficiency of any scrubber for similar aerosols is strongly affected by the power

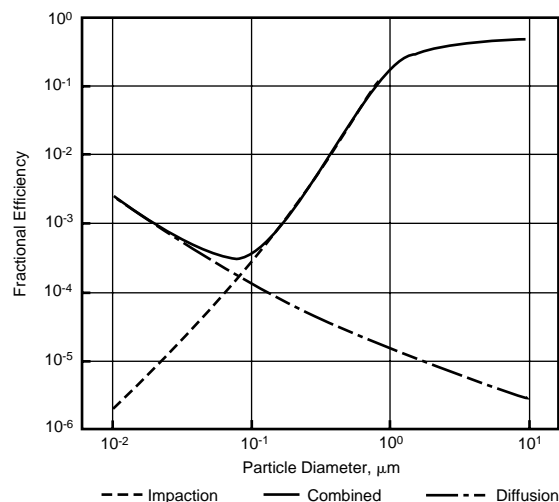

FIG. 5.18.13 Fractional efficiency for combined impaction and diffusion.

dissipated in operating the scrubber (termed *contacting power*) and little affected by scrubber size, geometry, or the manner in which the power is applied.

In this text, contacting power is the power per unit of the gas volumetric flow rate used in contacting the aerosol to be cleaned. This power is ultimately dissipated as heat. The power per unit of the gas volumetric flow rate is considered an effective friction loss and represents friction loss across the scrubbing unit, neglecting losses due to kinetic energy changes in the flowing gas stream or losses due to equipment operating dry (Semrau 1960, 1977).

Contacting power is stated in the following contacting power rule:

$$N_t = \alpha P_T^\gamma \quad 5.18(3)$$

where  $N_t$  is the number of transfer units. Transfer units are related to the fractional collection efficiency as follows:

$$= 1 - e^{-N_t} \quad 5.18(4)$$

In Equation 5.18(3), the terms  $\alpha$  and  $\gamma$  are empirical constants that depend on the properties of the dust being collected. Table 5.18.2 lists the values for  $\alpha$  and  $\gamma$  for various dust plus scrubber combinations. The contacting power  $P_T$  is calculated from the following equation (Semrau 1960):

$$P_T = P_G + P_L + P_M \quad 5.18(5)$$

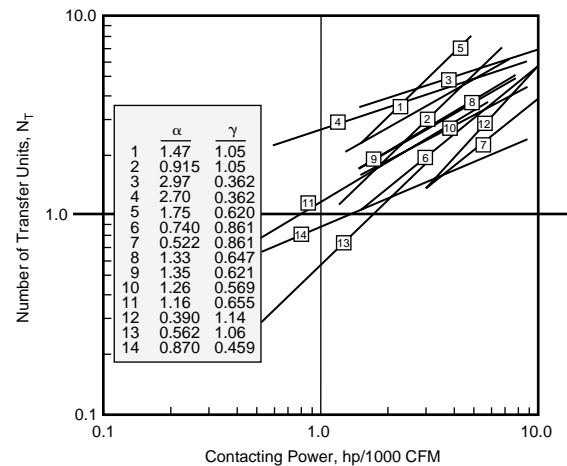

where:

- $P_G$  = the power input required to overcome the gas pressure drop across the collector
- $P_L$  = the power input required to produce droplets through the spray nozzles
- $P_M$  = the power input required to drive any rotor, if present.

Figure 5.18.14 plots  $N_T$  as a function of contacting power for various dusts. In the preceding equations, the power terms are expressed in kWhr/1000 m<sup>3</sup>. Table 5.18.2 gives the factors for converting power to either hp/1000 cfm, or effective friction loss (inches or centimeters of water).

Using the contacting power approach is best when some knowledge of the scrubber's performance for a specific

aerosol is available. For example, when pilot plant designs are scaled up to full-size units for a dust control problem, contacting power is helpful in predicting the overall efficiency of the new, full-size unit. Or, if a scrubbing unit is to be replaced with a new and different design, the contacting power approach is helpful in estimating the performance of the new unit. However, in determining contacting power, a design engineer must insure that only the portion of energy input representing energy dissipated in scrubbing is used (Semrau 1977). Also, little data exists relating gas-phase and mechanical contacting power. Since the contacting power approach is an empirical approach, extrapolating the results into areas with little data requires caution.

TABLE 5.18.2 FORMULAS FOR PREDICTING CONTACTING POWER

	Symbol	Metric Units <sup>b</sup>	Dimensional Formula
Effective friction loss	$F_E$	cm H <sub>2</sub> O	$\Delta p^a$
Gas phase contacting power	$P_G$	kWh/1000 m <sup>3</sup>	$0.02724 F_E$
Liquid phase contacting power	$P_L$	kWh/1000 m <sup>3</sup>	$0.02815 \rho_f (Q_L/Q_G)^c$
Mechanical contacting power	$P_M$	kWh/1000 m <sup>3</sup>	$16.67 (W_s/Q_G)^c$
Total contacting power	$P_T$	kWh/1000 m <sup>3</sup>	$P_G + P_L + P_M$

Notes: <sup>a</sup>The effective friction loss is approximately equal to the scrubber pressure loss  $\Delta p$ .

<sup>b</sup>1.0 kWh/1000 m<sup>3</sup> = 2.278 hp/1000 ft<sup>3</sup>/min

<sup>c</sup>This quantity is actually power input and represents an estimate of contacting power;  $Q_L$  is in l/min,  $Q_G$  is in m<sup>3</sup>/min, and  $W_s$  is net mechanical power input in kW.

## USE OF THE AERODYNAMIC CUT DIAMETER

Because of the variety of parameters involved, accurately designing a scrubber for an installation without prior knowledge of scrubber performance at that or a similar installation is difficult. Factors such as air flow rate, scrubbing liquid flow rate, inlet gas temperature, scrubbing liquid temperature, relative humidity, concentration, size and size distribution of the aerosol in the incoming gas, scrubber droplet size and size distribution, and the type of scrubber can confound the design engineer and cloud the design process. Even so, some equations are available to make initial estimates for scrubber design.

Dust size distributions are often represented by log-normal distributions; that is, the particle frequency for a given diameter is distributed according to a normal curve when plotted against the logarithm of the particle diameter. Then, similar to the standard deviation of a normal distribution, the geometric standard deviation of a log-normal distribution measures the spread of the distribution. With a log-normal distribution having a geometric standard deviation of  $\sigma_g$ , 67% of all particles have diameters between the size ranges  $d_g/\sigma_g$  and  $\sigma_g d_g$ . Equation 5.18(6) gives the form of the log-normal distribution:

$$\int_0^d f(x)dx = \int_0^d \frac{1}{x \ln \sigma_g (2\pi)^{0.5}} \exp \left[ -\frac{(\ln x - \ln d_g)^2}{2 \ln^2 \sigma_g} \right] dx \quad 5.18(6)$$

where:

- $d_g$  = the geometric median diameter
- $\sigma_g$  = the geometric standard deviation
- $x$  = any particle diameter of interest.

Thus, the right side of Equation 5.18(6) gives on integration the fraction of particles whose diameters are less than or equal to  $x$ . Integrating between limits of  $x = 0$  to  $\infty$  gives a result of 1, and between limits of  $x = 0$  to  $d_g$ , a result of 0.5.

Two particle size distributions must be considered in scrubber design. Besides the size distribution of the dust to be collected, the grade efficiency must also be considered when the collector operates under specific conditions. As previously discussed, according to Calvert et al. (1972), the grade efficiency can be effectively represented by the *aerodynamic cut diameter*  $d_{ac}$ . If  $d_{ac} = d_g$ , a collection efficiency of 50% is estimated; if  $d_{ac} = d_g/\sigma_g$ , the estimated collection efficiency is 84%. Hence, for any level of efficiency and a log-normal aerosol, the use of Equation 5.18(6) determines the equivalent  $d_{ac}$ .

Figure 5.18.15 represents an integrated form of Equation 5.18(6) which gives any collection efficiency (50% or greater) as a function of the ratio  $d_{ac}/d_g$  with  $\sigma_g$  as a parameter. Thus, for example, if a collection efficiency of 99% is needed for a log-normal, unit-density aerosol with  $d_g = 5.0 \mu\text{m}$  and  $\sigma_g = 2$ , Figure 5.18.15 shows that a multiplication factor of about 0.2 is indicated. The required  $d_{ac}$  is then  $5 \times 0.2 = 1 \mu\text{m}$ .

FIG. 5.18.15 Cleaning efficiency as a function of the multiplication factor for log-normal particle distributions of various skewness.

## DETERMINATION OF $d_{ac}$ AS A FUNCTION OF SCRUBBER OPERATING PARAMETERS

A number of theoretical equations estimate scrubber performance with reasonable accuracy for a specific scrubber type.

### Venturi

Calvert (1970) and Calvert et al. (1972) considered the venturi scrubber and developed the following equation for collection efficiency :

$$= \exp \left[ -\frac{2Q_L u_G \rho_L d_d}{55Q_G \mu_G} F(K_{pt}, f) \right] \quad 5.18(7)$$

where:

- $Q_L/Q_G$  = the volumetric flow ratio of liquid to gas
- $u_G$  = the gas velocity in cm/sec
- $\rho_L$  = the density of the liquid in gm/cm<sup>3</sup>
- $\mu_G$  = the viscosity of the liquid in poises
- $d_d$  = the drop diameter in cm
- $f$  = an operational factor which ranges from 0.1 to 0.3, but is often taken as 0.25

The term  $f$  includes the influence of factors such as collection by means other than impaction, variation in drop sizes, loss of liquid to venturi walls, particle growth by condensation, and degree of utilization of the scrubbing liquid.

The following equation gives function  $F(K_{pt}, f)$ :

$$F(K_{pt}, f) = \left[ 0.7 + K_{pt} f - 1.4 \ln \left( \frac{K_{pt} f + 0.7}{0.7} \right) - \frac{0.49}{K_{pt} f + 0.7} \right] \frac{1}{K_{pt}} \quad 5.18(8)$$

where  $K_p$  is defined as:

$$K_p = \frac{v_r d_a^2}{9\mu_G d_d} \quad 5.18(9)$$

The term  $v_r$  represents the relative velocity between the dust particle and the droplet, and  $d_a$  is the aerodynamic particle diameter as defined in Equation 5.18(1). The average liquid droplet diameter  $d_d$  is given by the empirical equation of Nukiyama and Tanasawa (1938) as:

$$d_d = \frac{50}{u_G} + 91.8 \left( \frac{Q_L}{Q_G} \right)^{1.5} \quad 5.18(10)$$

The drop diameter  $d_d$  is expressed in units of centimeters (cm), and the gas velocity  $u_G$  in cm/sec.

When  $\beta = 0.5 = 50\%$ , Equation 5.18(7) can be solved for  $d_a = d_{ac}$  for a variety of  $Q_L/Q_G$  ratios. The solutions to these calculations are plotted as shown Figure 5.18.16. For these calculations,  $k = 0.25$ ,  $\mu_G = 1.82 \times 10^{-4}$  poises, and  $u_G = v_r$  with  $u_G$  as a parameter ranging from 5 m/sec to 15 m/sec. Figure 5.18.16 can then be used to estimate  $d_{ac}$  for venturi scrubber operation at different  $Q_L/Q_G$  ratios and different throat velocities.

Rudnick et al. (1986) evaluated three widely used venturi scrubber equations (Calvert [1970], Yung et al. [1978], and Boll [1973]) and compared the equations with experimental data. They concluded that Yung's model, a modification of the Calvert model, predicts data better than the other two. However, the difference was not that great, and since the Yung model is complicated, the Calvert model remains useful for a first approximation of venturi scrubber performance.

The pressure drop across a venturi scrubber (in centimeters of water) can be estimated from the following equation (Leith, Cooper, and Rudnick 1985):

FIG. 5.18.16 Predicted venturi performance. (Adapted from S. Calvert, J. Goldshmid, D. Leith, and D. Mehta, 1972, *Scrubber handbook*, Riverside, Calif.: Ambient Purification Technology, Inc.)

$$\Delta p = 1.02\rho_L \frac{Q_L}{Q_G} u_{Gt}^2 \left[ \beta \left( 1 - \frac{u_{Gf}}{u_{Gt}} \right) + \left( \frac{u_{Gf}}{u_{Gt}} \right)^2 \right] \quad 5.18(11)$$

The term  $u_{Gf}$  is the gas velocity at the exit of the venturi, and  $u_{Gt}$  is the gas velocity in the throat. The term  $\beta$  can be estimated from the following equation:

$$\beta = 2(1 - X^2 + \sqrt{X^4 - X^2}) \quad 5.18(12)$$

and  $X$  is defined as follows:

$$X = 1 + 3L_t C_D \rho_G / (16d_d \rho_L) \quad 5.18(13)$$

where  $L_t$  is the throat length, and  $C_D$  is the drag coefficient, which can be estimated up to a flow Reynolds number of about 1000 by the following equation:

$$C_D = \frac{24}{Re} (1 + 0.15Re^{0.687}) \quad 5.18(14)$$

Above this Reynolds number, the drag coefficient is estimated by  $C_D = 0.44$ . The Reynolds number is given by the following equation:

$$Re = \frac{u_G d \rho_g}{\mu_G} \quad 5.18(15)$$

### Countercurrent Spray Tower

For a countercurrent spray tower as shown in Figure 5.18.4, the following equation estimates the collection efficiency (Calvert 1968):

$$\eta = 1 - \exp \left[ - \frac{3Q_L v_{d/g} Z \eta_d}{2Q_G v_{d/w} d_d} \right] \quad 5.18(16)$$

where:

- $v_{d/g}$  = the velocity of the droplets relative to the gas
- $v_{d/w}$  = the velocity of the droplets relative to the walls  
( $v_{d/w} = v_{d/g} + v_{g/w}$ )
- $Z$  = the height or length of the scrubber in cm

The following equation gives  $\eta_d$ :

$$\eta_d = \left( \frac{Stk}{Stk + 0.7} \right)^2 \quad 5.18(17)$$

The following equation gives the Stokes number  $Stk$ :

$$Stk = \frac{d_a^2 \rho_p v_{a/g}}{9\mu_G d_d} \quad 5.18(18)$$

### Impingement and Entrainment-Type Scrubber

For this type of unit (see Figure 5.18.10), the efficiency can be estimated from the following equation (Calvert et al. 1972):

$$\eta = 1 - \exp \left[ - \frac{2\Delta p d_d}{55u_G \mu_G} F(K_{pt}, f) \right] \quad 5.18(19)$$

Usually a value of 0.25 is chosen for  $f$ . According to Schiffer and Hesketh (1983), the drop diameter  $d_d$  is about

one-third that calculated from Equation 5.18(10). The pressure drop in these units is given by the following equation:

$$\Delta p = \frac{\rho_L Q_L u_G}{A} \quad 5.18(20)$$

where A is the collecting area, defined as the total surface area of the collecting elements perpendicular to the gas flow direction.

## 5.19 GASEOUS EMISSION CONTROL

---

---

This section presents some options for reducing the emission of pollutants. It focuses on the complex series of processes and phenomena generally grouped under acid rain. Acid rain is associated with the release of sulphur and nitrogen oxides into atmosphere via the burning of fossil fuels. The deposition of sulfur and nitrogen compounds is one of the most pressing large-scale air pollution problems.

The options presented are based on general pollution prevention techniques. This section focuses on source control via technology changes. Source reduction measures aim at long-term reduction, while other options can limit pollution during unfavorable conditions.

### Energy Source Substitution

This option includes the transition to solar energy, nuclear energy, and other methods of obtaining energy. Of the pollutants generated by burning fuels, the emission of sulfur oxides and ash are directly attributable to fuel composi-

tion. Using the right fuel can cut sulfur dioxide and ash emissions. This option means switching to coal with lower sulfur content or replacing coal with gaseous fuel or desulfurized fuel oils. The sulfur in heavy fuel oils can be removed in a high-pressure catalytic reactor, in which hydrogen combines with the sulfur to form hydrogen sulfide which is then recovered.

An alternative to using lower-sulfur coal is to remove some of the sulfur in the coal (see [Figure 5.19.1](#)). Sulfur in the form of discrete iron pyrite crystals can be removed because they have different properties from the organic coal matrix in which they are embedded. This difference makes separation by physical processing possible. The key economic factor is the cost of the losses of combustible material which occur during the cleaning process. To date, none of the coal cleaning processes have been proven commercially successful. Their attractiveness is also diminished by their inability to recover, on average, more than half the sulfur content (e.g., the pyritic fraction) of the fuel (Bradshaw, Southward, and Warner 1992).

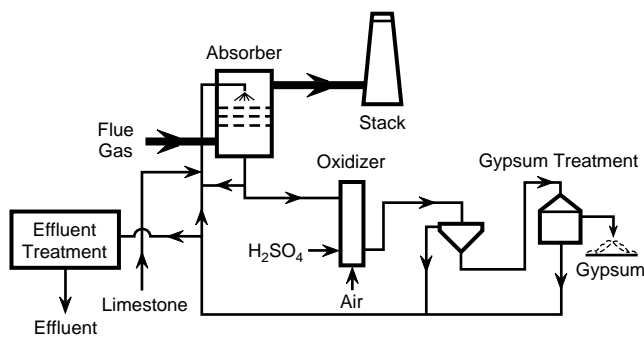

FIG. 5.19.1 Schematic diagram of a limestone-gypsum FGD plant.

Nitrogen oxides form at firebox temperatures by the reaction of the oxygen and nitrogen in the air and fuel. The thermal fixation of atmospheric nitrogen and oxygen in the combustion air produces *thermal*  $NO_x$ , while the conversion of chemically bound nitrogen in the fuel produces *fuel*  $NO_x$ .

For natural gas and light distillate oil firing, nearly all  $NO$  emissions result from thermal fixation. With residual fuel oil, the contribution of fuel-bound nitrogen can be significant and in some cases predominant. This contribution is because the nitrogen content of most U.S. coals ranges from 0.5 to 2% whereas that of fuel oil ranges from 0.1 to 0.5%. The conversion efficiencies of fuel mixture to  $NO_x$  for coals and residual oils have been observed between 10 and 60% (U.S. EPA 1983). Figure 5.19.2 shows the possible fates of fuel nitrogen. One option of reducing  $NO_x$  is to use low-nitrogen fuel.

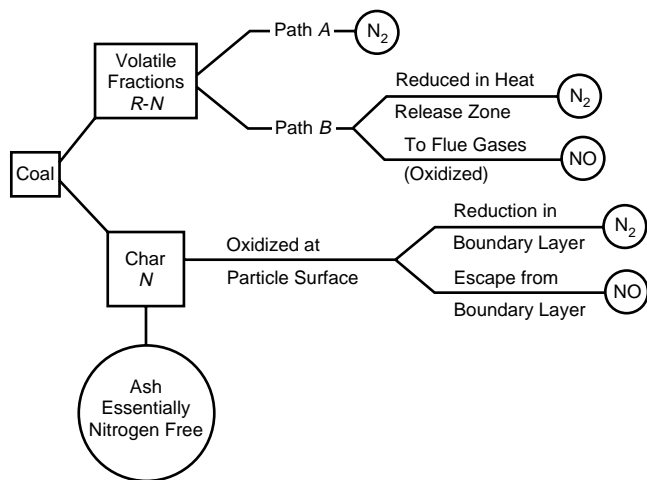

FIG. 5.19.2 Possible fates of nitrogen contained in coal. (Reprinted, with permission, from M.P. Heap et al., 1976, The optimization of burner design parameters to control  $NO$  formation in pulverized coal and heavy oil flames, *Proceedings of the Stationary Source Combustion Symposium—Vol. II: Fuels and Process Research Development*, EPA-600/2-76-152b [Washington, D.C.: U.S. EPA].

## Process Modifications

The formation rates of both thermal  $NO_x$  and fuel  $NO_x$  are kinetically or aerodynamically limited, with the amount of  $NO_x$  formed being less than the equilibrium value (Wark and Warner 1981). Combustion conditions dominate the formation rate of  $NO_x$ , and modifying the combustion process can suppress it. Rapidly mixing oxygen with the fuel promotes both thermal and fuel  $NO_x$  formation.

MacKinnon (1974) developed a kinetic model from experimental studies of a heated mixture of  $N_2$ ,  $O_2$ , and air as well as air. His kinetic equations provide insight to the strategies for controlling the formation of thermal  $NO_x$  as follows:

- The peak temperature should be reduced.
- The gas residence time at the peak temperature should be reduced.
- The oxygen concentration in the highest temperature zone should be reduced.

Regardless of the mechanisms, several general statements can be made about fuel  $NO_x$ . It depends highly on the air/fuel ratio. The percent conversion to fuel  $NO_x$  declines rapidly with an increasing fuel equivalent ratio. (The *fuel equivalent ratio* is a multiple of the theoretical fuel/air ratio and is the inverse of the stoichiometric ratio. The stoichiometric ratio is unity when the actual air/fuel ratio equals the theoretical air to fuel needed for complete combustion.) The fuel equivalent ratio primarily affects the oxidation of the volatile R-N fraction (where R represents an organic fragment) rather than the nitrogen remaining in the char. The degree of fuel-air mixing also strongly affects the percent conversion of fuel nitrogen to  $NO_x$ , with greater mixing resulting in a greater percent conversion.

## COMBUSTION CONTROL

Several process modifications can reduce  $NO_x$  formation. Table 5.19.1 summarizes the commercially available  $NO_x$  control technologies as well as their relative efficiencies, advantages and disadvantages, applicability, and impacts.

The simplest combustion control technology is the *low-excess-air* (LEA) operation. This technology reduces the excess air level to the point of some constraint, such as carbon monoxide formation, flame length, flame stability, and smoke. Unfortunately, the LEA operation only moderately reduces  $NO_x$ .

## Off-Stoichiometric Combustion (OSC)

OSC, or staged combustion, combusts fuel in two or more stages. The primary flame zone is fuel-rich, and the secondary zones are fuel-lean. This combustion is achieved through the following techniques. These techniques are generally applicable only to large, multiple-burner, combustion devices.

**TABLE 5.19.1 SCREENING POTENTIAL NO<sub>x</sub> CONTROL TECHNOLOGIES**

<i>Technique</i>	<i>Description</i>	<i>Advantages</i>	<i>Disadvantages</i>	<i>Impacts To Consider</i>	<i>Applicability</i>	<i>NO<sub>x</sub> Reduction</i>
LEA	Reduces oxygen availability	Easy operational modification	Low NO <sub>x</sub> reduction potential	High carbon monoxide emissions, flame length, flame stability	All fuels	1–15%
OSC a. BOOS b. OFA c. Air Lances	Staged combustion, creating fuel-rich and fuel-lean zones	Low operating cost, no capital requirement required for BOOS	a. Typically requires higher air flow to control carbon monoxide b. Relatively high capital cost c. Moderate capital cost	Flame length, forced draft fan capacity, burner header pressure	All fuels; Multiple-burner devices	30–60%
LNB	Provides internal staged combustion, thus reducing peak flame temperatures and oxygen availability	Low operating cost, compatible with FGR as a combination technology to maximize NO <sub>x</sub> reduction	Moderately high capital cost; applicability depends on combustion device and fuels, design characteristics, and waste streams	Forced-draft fan capacity, flame length, design compatibility, turndown flame stability	All fuels	30–50%
FGR	Up to 20–30% of the flue gas recirculated and mixed with the combustion air, thus decreasing peak flame temperatures	High NO <sub>x</sub> reduction potential for natural gas and low-nitrogen fuels	Moderately high capital cost, moderately high operating cost, affects heat transfer and system pressures	Forced-draft fan capacity, furnace pressure, burner pressure drop, turndown flame stability	Gas fuels and low-nitrogen fuels	40–80%
W/SI	Injection of steam or water at the burner, which decreases flame temperature	Moderate capital cost, NO <sub>x</sub> reductions similar to FGR.	Efficiency penalty due to additional water vapor loss and fan power requirements for increased mass flow	Flame stability, efficiency penalty	Gas fuels and low-nitrogen fuels	40–70%
RAPH	Air preheater modification to reduce preheat, thereby reducing flame temperature	High NO <sub>x</sub> reduction potential	Significant efficiency loss (1% per 40°F)	Forced-draft fan capacity, efficiency penalty	Gas fuels and low-nitrogen fuels	25–65%
SCRI	Catalyst located in flue gas stream (usually upstream of air heater) promotes reaction of ammonia with NO <sub>x</sub>	High NO <sub>x</sub> removal	Very high capital cost, high operating cost, extensive ductwork to and from reactor required, large volume reactor must be sited, increased pressure drop may require induced-draft fan or larger forced-draft fan, reduced efficiency, ammonia sulfate removal equipment for air heater required, water treatment of air heater wash required	Space requirements, ammonia slip, hazardous waste disposal	Gas fuels and low-sulfur liquid and solid fuels	70–90%
SNCR—Urea Injection	Injection of urea into furnace to react with NO <sub>x</sub> to form nitrogen and water	Low capital cost, relatively simple system, moderate NO <sub>x</sub> removal, nontoxic chemical, typically low energy injection sufficient	Temperature dependent, design must consider boiler operating conditions and design, NO <sub>x</sub> reduction may decrease at lower loads	Furnace geometry and residence time, temperature profile	All fuels	25–50%
SNCR—Ammonia Injection	Injection of ammonia into furnace to react with NO <sub>x</sub> to form nitrogen	Low operating cost, moderate NO <sub>x</sub> removal	Moderately high capital cost; ammonia handling, storage, vaporization	Furnace geometry and residence time, temperature profile	All fuels	25–50%

The *burner-out-of-service* (BOOS) technique terminates the fuel flow to selected burners while leaving the air registers open. The remaining burners operate fuel rich, thereby limiting oxygen availability, lowering peak flame temperatures, and reducing NO<sub>x</sub> formation. The unreacted products combine with the air from the terminated fuel burners to complete burnout before exiting the furnace.

Installing *air-only* (OFA) ports above the burner zone also achieves staged combustion. This technique redirects a portion of the air from the burners to the OFA ports. A variation of this concept, *lance air*, has air tubes installed around the periphery of each burner to supply staged air.

### Combustion Temperature Reduction

Reducing the combustion temperature effectively reduces thermal NO<sub>x</sub> but not fuel NO<sub>x</sub>. One way to reduce the temperature further is to introduce a diluent, as in *flue gas recirculation* (FGR). FGR recirculates a portion of the flue gas back into the windbox. The recirculated flue gas, usually 10–20% of the combustion air, provides sufficient dilution to decrease NO<sub>x</sub> emissions.

An advantage of FGR is that it can be used with most other combustion control methods. However, in retrofit applications, FGR can be expensive. In addition to requiring new large ducts, FGR may require major modifications to fans, dampers, and controls.

*Water or steam injection* (W/SI) is another method that works on the principle of combustion dilution, similar to FGR. In addition, W/SI reduces the combustion air temperature. In some cases, W/SI is a viable option when moderate NO<sub>x</sub> reductions are required for compliance.

### OTHER MODIFICATIONS

*Reduction of the air preheat temperature* (RAPH) is another viable technique for cutting NO<sub>x</sub> emissions. This technique lowers the peak flame temperatures, thereby reducing NO<sub>x</sub> formation. The thermal efficiency penalty, however, can be substantial.

Post-combustion control techniques such as SCR and SNCR by ammonia or urea injection are described in Section 5.24.

The techniques of OSC, FGR, and RAPH can be effectively combined. The OSC techniques, namely LEA and two-stage combustion, reduce the quantities of combustion gases reacting at maximum temperature, while FGR and RAPH directly influence the maximum level of combustion temperatures. The reductions obtained by combining individual techniques are not additive but multiplicative. However, the combined conditions necessary to achieve such low levels of oxides are not compatible with operational procedures.

Figure 5.19.3 summarizes the NO<sub>x</sub> control technology choices. An environmental engineer can use this figure and Table 5.19.1 to identify the potential control technologies for boilers and process heaters. After identifying the applicable technologies, the engineer must conduct an economic analysis to rank the technologies according to their cost effectiveness. Management can then select the optimum NO<sub>x</sub> control technology for a specific unit.

## Design Feature Modifications

Several design feature modifications also reduce NO<sub>x</sub> emissions including modified burners, burner location and spacing, tangential firing, steam temperature control, air and fuel flow patterns, and pressurized fluidized-bed combustion.

### MODIFIED BURNERS

While SCR and SNCR control NO<sub>x</sub> emissions by treating the NO<sub>x</sub> after it has been formed in the combustion reaction, modifications to the combustion equipment or burners also significantly reduces NO<sub>x</sub> formation. Using such modified burners has a number of advantages, the major ones being simplicity and low cost. At the same time, since burners are the primary component of a furnace, implementing new ones should be tried cautiously.

### Stage-Air Burners

Staged-air burner systems divide incoming combustion air into primary and secondary paths. All fuel is injected into

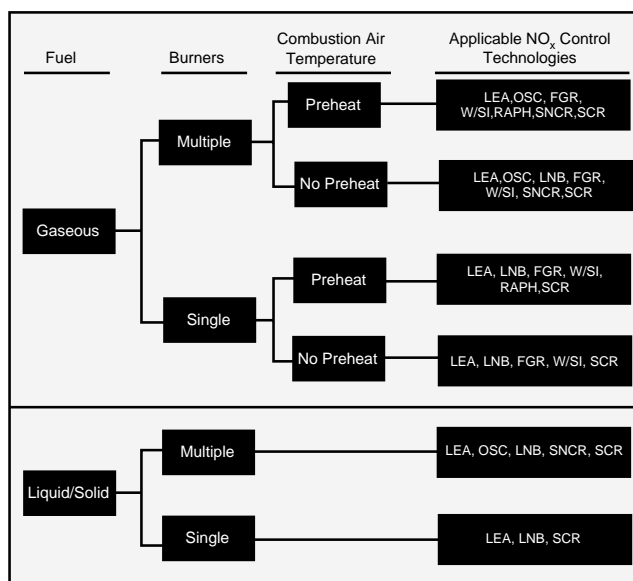

FIG. 15.9.3 Guidelines to identify potential NO<sub>x</sub> control technologies. (Reprinted, with permission, from A. Garg, 1994, Specify better low-NO burners for furnaces, *Chem. Eng. Prog.* [November].)

the throat of the burner and is combined with the primary air, which flows through the venturi and burns (see the right side of Figure 5.19.4).

Staged-air burners are simple and inexpensive, and  $\text{NO}_x$  reductions as high as 20 to 35% have been demonstrated (Garg 1992). These burners are most suitable for forced-draft, liquid-fuel applications and lend themselves to external, flue gas circulations. The main disadvantage of these burners is the long flames, which must be controlled.

### Staged-Fuel Burners

In staged-fuel burners, fuel is injected into the combustion zone in two stages, thus creating a fuel-lean zone and delaying completion of the combustion process. This lean combustion reduces peak flame temperatures and reduces thermal  $\text{NO}_x$ . The remainder of the fuel-gas is injected into the secondary zone through secondary combustion nozzles (see the left side of Figure 5.19.4).

The combustion products and inert gases from the primary zone reduce the peak temperatures and oxygen concentration in the secondary zone, further inhibiting thermal  $\text{NO}_x$  formation. Some of the  $\text{NO}_x$  formed in the first stage combustion zone is reduced by the hydrogen and carbon monoxide formed in the staged combustion.

Staged-fuel burners can reduce  $\text{NO}_x$  emissions by 40–50% (Garg 1994). The flame length of this type of burner is about 50% longer than that of a standard gas burner. Staged-fuel burners are ideal for gas-fired, natural-draft applications.

### Ultra-Low- $\text{NO}_x$ Burners

Several designs combine two  $\text{NO}_x$  reduction steps into one burner without any external equipment. These burners typically incorporate staged air with internal FGR or staged fuel with external FGR. In the staged-fuel burners with internal FGR, the fuel-gas pressure

FIG. 5.19.4 OFC achieved by air staging or fuel staging. (Reprinted, with permission, from Garg, 1994.)

induces recirculation of the flue gas (see Figure 5.19.5), creating a fuel-lean zone and reducing oxygen partial pressure.

In staged-air burners with internal FGR, fuel mixes with part of the combustion air, creating a fuel-rich zone. The high-pressure atomization of liquid fuel or fuel gas creates FGR. Pipes or parts route the secondary air in the burner block to complete combustion and optimize the flame profile.

Air or fuel-gas staging with internal FGR can reduce NO<sub>x</sub> emissions by 55 to 75%. The latter design can be used with liquid fuels, whereas the former is used mostly for fuel-gas applications.

Low-NO<sub>x</sub> burners have been installed in a variety of applications in both new and revamped plants. Table 5.19.2 summarizes the performance of several of these installations.

FIG. 5.19.5 Combining staged fuel burners with internal FGR. (Reprinted, with permission, from A. Garg, 1992, Trimming NO<sub>x</sub> from furnaces, *Chem. Eng. Prog.* [November].)

## BURNER LOCATIONS AND SPACING

NO<sub>x</sub> concentrations vary with burner type, spacing, and location in coal-fired generation plants. Cyclone burners are known for their highly turbulent operations and result in high-level emissions of NO<sub>x</sub> in these plants.

The amount of heat released in the burner zone seems to have a direct effect on NO<sub>x</sub> concentrations (see Figure 5.19.6). The OFC reduction techniques are the most effective for larger generating units with larger burners. These techniques are effective since essentially all NO is formed in the primary combustion zone, and as the burner size increases, the primary zone becomes less efficient.

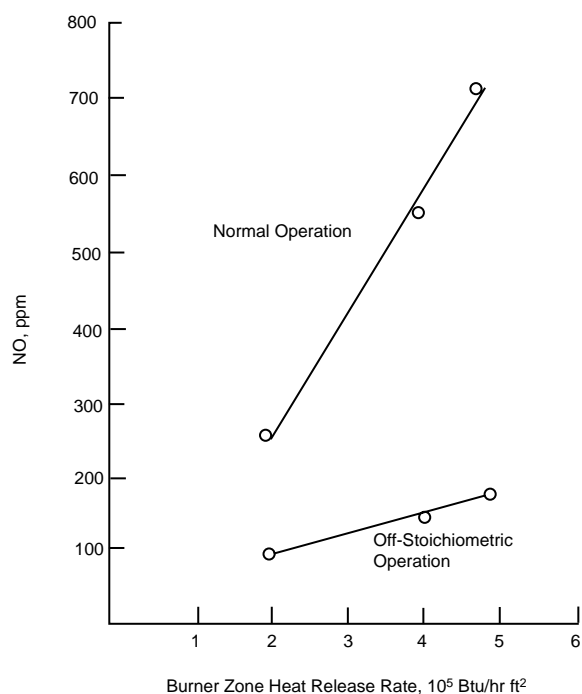

FIG. 5.19.6 Effect of nitric oxide concentrations with increasing burner zone heat release rate: 480 MW unit, natural gas fuel.

TABLE 5.19.2 APPLICATIONS OF LNB BURNERS

Heater Application	Burner Type	NO <sub>x</sub> Emission Level, ppm
Crude, vacuum, and coker heaters (cabin)	Forced-draft, staged fuel, preheated air	60
Vertical cylindrical refinery heaters	Natural-draft, staged-fuel, with internal FGR	25
Down-fired hydrogen reformer	Induced-draft, staged-fuel-gas	60*
Vertical cylindrical refinery heaters	Forced-draft, staged-fuel, with internal FGR, preheated air	60
Upfired ethane cracker	Natural-draft, staged-fuel	85

Source: A. Garg, 1994, Specify better low-NO<sub>x</sub> burners for furnaces, *Chem. Eng. Prog.* (January).

Notes: \*With steam injection.

Different burner spacing has essentially no effect on the  $\text{NO}_x$  concentration in boiler emissions when the boilers are at full-load operations. However, at a reduced load, closer burner spacing results in higher  $\text{NO}_x$  releases because close burner spacing inhibits effective bulk recirculation into the primary combustion zone.

The distribution of air, through the primary air ducts located immediately above and below the fuel nozzles and through the secondary air ducts located immediately above and below the primary ducts, can be used as a means to reduce  $\text{NO}_x$  emissions.

## TANGENTIAL FIRING

In tangential firing, the furnace is used as a burner, resulting in a lower flame temperature and in a simultaneous reduction (as much as 50 to 60% compared with conventional firing methods) in  $\text{NO}_x$  emissions.

## STEAM TEMPERATURE CONTROL

Product gas recirculation, burner tilt, and high excess air are techniques for steam temperature control. The burner tilt and high excess air increase the  $\text{NO}_x$  formation. Changing the burner tilt from an angle inclined  $30^\circ$  downstream from horizontal to  $10^\circ$  upstream increases the  $\text{NO}_x$  concentration from 225 ppm to 335 ppm (Shah 1974).

## AIR AND FUEL FLOW PATTERNS

For effective use of the OFA technique, uniform air and fuel flow to the burners is essential. High CO concentrations, localized in a small zone of the furnace exhaust gas, occur when one burner operates at a rich fuel-air mode. Reducing the high CO concentration involves increasing excess air or decreasing the degree of OFA, both of which increase the  $\text{NO}_x$  emissions. Therefore, the effective solution is to reduce the fuel flow to the burner.

## PRESSURIZED FLUIDIZED-BED COMBUSTION

Mixing an adsorbent (e.g. limestone) directly into the fluidized bed in which coal is burned achieves direct sulfur dioxide control (see Figure 5.19.7). Fluidization is achieved via the combustion air that enters the base of the bed (Halstead 1992). Environmental engineers can apply this basic concept in several ways to meet the needs of chemical industries as well as power generation plants.

The potential advantages of fluidized-bed combustion are as follows:

- Lower combustion temperature resulting in less fouling and corrosion and reduced  $\text{NO}_x$  formations
- Fuel versatility including range of low-grade fuels, such as char from synthetic fuel processing

FIG. 5.19.7 Pressurized fluidized-bed combustion system.

- Higher thermal efficiency including high heat release and heat transfer
- Waste solids in dry form

The potential disadvantages are as follows:

- Large particulate loading in the flue gas
- Potentially large amounts of solid waste, which are  $\text{SO}_2$  absorbent.

## Pollution Monitoring

Continuous stack and ambient monitoring provides the information needed to formulate strategies for pollutant control (see Sections 5.9, 5.11, and 5.12). In Osaka, Japan, telemeters monitoring pollutant emissions from factories and stations sampling ambient quality perform environmental monitoring. An environmental monitoring system uses remote-sensing by earth-observing satellites and an environmental information system to forecast the environmental impact of pollution.

A procedure change can ease the effects of sulfur or nitrogen oxide pollution. Automatic changes can be made during high levels of ambient pollution. For example, the Tennessee Valley Authority (TVA) has been switching to low-sulfur fuels during adverse meteorological conditions.

## 5.20

# GASEOUS EMISSION CONTROL: PHYSICAL AND CHEMICAL SEPARATION

---

---

Major air pollutants are gases such as carbon monoxide, nitrogen oxides, sulfur oxides, and VOCs. Generally, the pollutant concentrations in waste air streams are relatively low, but emissions can still exceed the regulatory limits. Removing air pollutants is achieved by the following methods:

- Absorption by a liquid solution
- Condensation of pollutants by cooling the gas stream
- Absorption on a porous adsorbent
- Chemical conversion of pollutants into harmless compounds

Sometimes methods are combined to treat a feed stream. For example, the absorption of SO<sub>2</sub> can be performed in an absorber using an aqueous lime solution. The key step in the separation is absorption although reactions occur between the SO<sub>2</sub> and lime in the absorber. Therefore, this SO<sub>2</sub> separation is considered *absorption*.

Choosing the air pollutant removal method depends mostly on the physical and chemical properties of the pollutant and the conditions (i.e., temperature, pressure, volume, and concentration) under which the pollutant is treated. The methods chosen for reducing air pollution must not increase pollution in other sectors of the environment. For example, transferring the air pollutant into liquid or solid absorption agents that subsequently contaminate the environment is not a solution to the problem.

### Absorption

Absorption is a basic chemical engineering operation and is probably the most well-established gas control technique. It is used extensively in the separation of corrosive, hazardous, or noxious pollutants from waste gases. The major advantage of absorption is its flexibility; an absorber can handle a range of feed rates.

Absorption, also called scrubbing, involves transferring pollutants from a gas phase to a contacting solvent. The transfer occurs when the pollutant partial pressure in the gas phase is higher than its vapor pressure in equilibrium with the solvent. To maximize the mass-transfer driving force (i.e., the difference in pollutant concentration between the gas and liquid phase), the absorber generally operates in a countercurrent fashion.

Absorption systems can be classified as physical absorption and absorption with a chemical reaction. In physical absorption, the pollutants are dissolved in a solvent and can be desorbed for recovery. The absorption of ammonia by water or the absorption of hydrocarbon by oil are typical examples.

If a solvent to absorb a significant quantity of the pollutant cannot be found, a reactant mixed with the solvent can be used. The pollutants must first be absorbed into the liquid phase for the reaction to occur. In this case, the pollutant concentration in the liquid is reduced to a low level. As a result, high absorption capacity is achieved.

The reaction can be reversible or irreversible. Typical reversible reactions are H<sub>2</sub>S/ethanolamines, CO<sub>2</sub>/alkali, carbonates, and some flue gas desulfurization (FGD) systems. The reversible reactions allow the pollutants to be recovered in a concentrated form and the solvent to be recycled to the absorber. If the reactions are irreversible, the reaction products must be disposed or marketed (e.g. ammonium sulfate). A few FGD systems are irreversible (vide infra).

### ABSORPTION OPERATIONS

Absorption systems design involves selecting a solvent and the design of the absorber.

## Solvent Selection

Solubility is the most important consideration in the selection of a solvent for absorption. The higher the solubility, the lower the amount of solvent required to remove a given amount of pollutants. The solvent should also be relatively nonvolatile to prevent an excessive carryover in the gas effluent. Other favorable properties include low flammability and viscosity, high chemical stability, acceptable corrosiveness, and low toxicity and pollution potential. The final selection criterion is an economic comparison with other control technologies.

## Absorber Design

Any gas-liquid contactors that promote the mass transfer across the phase boundary can be used in absorption operations. The most popular devices are spray, packed, and tray columns as well as venturi scrubbers. For gas pollution control, the combination of high gas flowrate and low pollutant concentration suggests that the absorber should exhibit a low pressure drop. The mass-transfer efficiency of the absorber determines the height of the column, but it is not as important a consideration as the pressure drop. Clearly, spray and packed columns are the best devices to satisfy the preceding criteria. Spray columns are used where fouling and low pressure drops are encountered. The design of a spray column is straightforward and is detailed in other publications (Kohl 1987). The packed column is the device used most often.

Two types of packings are used for absorption: random packing and structured packing. Table 5.20.1 shows a list of packing suppliers. Structured packing tends to be proprietary, and the design procedure is normally obtained from suppliers. Random packings (e.g., Pall rings and Intalox saddles) can be purchased from several suppliers,

and the system design procedure is published. Table 5.20.2 shows the properties of typical random packings.

As a general rule, randomly packed columns have the following characteristics (Strigle 1987):

- A pressure drop between 2 and 5 cm H<sub>2</sub>O/m of packed depth
- Air velocity between 1.7 and 2.4 m/sec for modern, high-capacity plastic packings
- An inlet concentration of pollutants below 0.5% by volume
- A superficial liquid rate in the range of 1.35 to 5.5 L/m<sup>2</sup> · sec

Figure 5.20.1 is a schematic diagram of a typical packed column installation.

## Design Procedure

In designing a packed column, the design engineer must consider the solvent rate, column diameter, and column height.

### SOLVENT RATE

Once the feed and effluent specifications are established, the design engineer can calculate the minimum solvent rate. The minimum rate is the rate below which separation is impossible even with a column of infinite height. The engineer calculates flowrates as illustrated in Figure 5.20.2. The mole fraction of the pollutant in the solvent ( $X_T$ ) and effluent gas ( $Y_T$ ) at the top of the column as well as that in the feed gas ( $Y_B$ ) are known. A straight line is drawn from ( $X_T, Y_T$ ) to intercept the equilibrium line at  $Y_B$ . The slope of this line represents the ratio of the minimum solvent rate to the feed gas rate.

The normal operating solvent rate should be 30 to 70% above the minimum rate.

**COLUMN DIAMETER**

Since the pressure drop directly impacts the operating cost for the blower to deliver the feed gas, the design engineer should choose the tower diameter to meet the pressure drop specification. Figure 5.20.3 shows the value for a widely used correlation for the pressure drop calculation. The correlation includes a parameter, packing factor F<sub>p</sub>, which is a constant for a given packing size and shape (Fair 1987). The value of F<sub>p</sub> can be obtained from Table 5.20.2. With known physical properties and flowrates for the liquid and gas streams, the engineer first determines the specific gas rate G, kg/m<sup>2</sup> · sec in the column and then calculates the column cross-sectional area by dividing the total gas flowrate (G<sub>T</sub>, kg/s) by G.

In cases where the pressure drop is not a prime consideration (e.g., treatment of a pressurized process stream), the column can be designed to operate at 70–80% of flooding rate. For packings below 2.5 cm size, the design engineer can use the flooding line shown in Figure 5.20.3 to calculate the flooding rate. If the packing is larger than 3.7 cm, the following empirical equation determines the pressure drop at flooding (McCabe 1993):

**FIG. 5.20.2** Calculation of minimum solvent rates for two different shapes of equilibrium line.

**FIG. 5.20.3** Generalized correlation for the calculation of pressure drops in packed columns.

$$\Delta P_{\text{flood}} = 0.307 F_P^{0.7} \quad 5.20(1)$$

Using Figure 5.20.3, the engineer can then calculate the  $G$  value and hence the required column diameter.

#### COLUMN HEIGHT

The required height of an absorption column is determined primarily by the degree of pollutant removal and the mass-transfer characteristics of the system. The degree of pollu-

tant removal can be represented by the number of transfer units (NTU) which is a function of the average driving force for mass transfer and the degree of separation as follows:

$$NTU = \int_{y_T}^{y_B} \frac{dy}{y - y^*} \quad 5.20(2)$$

where  $y$  and  $y^*$  are the mole fraction of the pollutant in the gas phase and in equilibrium with the contacting solvent, respectively. The mass-transfer characteristics include

the fluid properties, operating conditions, and column internal parameters. The following equation expresses these effects:

$$\text{HTU} = \text{Height of a Transfer Unit} = \frac{G}{K_y a} \quad 5.20(3)$$

where  $K_y$  is the overall mass-transfer coefficient and  $a$  is the effective interfacial area available for mass transfer. The required column height  $H$  can then be calculated from the following expression:

$$H = \text{HTU} \cdot \text{NTU} = \frac{G}{K_y a} \int_{y_T}^{y_B} \frac{dy}{y - y^*} \quad 5.20(4)$$

McCabe (1993) provide the derivation of the preceding equations. To solve Equation 5.20(4), the design engineer must specify  $y_B$  and  $y_T$  and obtain  $G$  from the column diameter calculations,  $y^*$  from the equilibrium relationship, and  $K_y a$  from engineering correlations. The values for  $y^*$  for physical absorption are available from Henry's law equation as follows:

$$y^* = \frac{H}{P_T} x \quad 5.20(5)$$

where  $H$  is the Henry's law constant and  $P_T$  is the total pressure. The accuracy of estimating column height depends mostly on the  $K_y a$  correlation chosen for the calculation. In mass-transfer operations,  $K_y$  can be broken down to the mass-transfer coefficient in the gas phase  $k_y$  and in the liquid phase  $k_x$ . This two-resistance theory is widely accepted (McCabe 1993) and leads to the following relationships:

$$\frac{1}{K_y} = \frac{1}{k_y} + \frac{m}{k_x} \quad \text{and } y^* = mx \quad 5.20(6)$$

These relationships assume that the resistances to mass transfer in the gas and liquid phases occur in series, and the gas-liquid interface does not contribute significant resistance to the mass transfer. If  $k_y$  is much greater than  $k_x/m$ , then  $K_y \cong m/k_x$ , and the rate of absorption is controlled by the liquid-phase transfer. On the other hand, if  $k_y \ll k_x/m$ , then the system is gas-phase controlled. To some extent, the value of  $m$  or  $H$  controls the phase control mechanism. For a soluble system (e.g., absorption of  $\text{NH}_3$  by water), the value of  $m$  is small, and thus the mass transfer is gas-phase controlled. For a  $\text{CO}_2$ /water system, the value of  $m$  is large, and the absorption is liquid-phase controlled.

The calculations also require estimating the effective interfacial area  $a$ . The area  $a$  is generally smaller than the geometric area of the packing because some packing area is not wetted and some area is covered by a stagnant, liquid film that is already saturated with the pollutant (i.e., inactive for mass transfer).

Onda, Takeuchi, and Okumoto (1968) have expressions for the individual mass-transfer coefficients  $k_x$  and  $k_y$  as well as the effective interfacial area  $a$ , and the de-

rived values can be used in the absence of experimental data. The equations are as follows:

$$k_y \left( \frac{RT}{a_p D_G} \right) = 5.23 \left( \frac{G}{a_p \mu_G} \right)^{0.7} (Sc_G)^{1/3} (a_p d_p)^{-2} \quad 5.20(7)$$

$$k_x \left( \frac{\rho_L}{g \mu_L} \right)^{1/3} = 0.0051 \left( \frac{L}{a_p \mu_L} \right)^{2/3} (Sc_L)^{-1/2} (a_p d_p)^{0.4} \quad 5.20(8)$$

where:

- $L$  = mass flowrate of liquid ( $\text{kg/sec} \cdot \text{m}^2$ )
- $G$  = mass flowrate of gas ( $\text{kg/sec} \cdot \text{m}^2$ )
- $D_G$  = diffusion coefficient ( $\text{m}^2/\text{sec}$ )
- $Sc_L$  = Schmidt number,  $(\mu_L/\rho_L D_L)$
- $k_y$  = gas-phase mass-transfer coefficient ( $\text{kmol}/\text{N} \cdot \text{s}$ )
- $k_x$  = liquid-phase mass-transfer coefficient ( $\text{m/s}$ )
- $\rho_L$  = density of liquid ( $\text{kg}/\text{m}^3$ )
- $\mu_L$  = viscosity of liquid ( $\text{N} \cdot \text{s}/\text{m}^2$ )
- $d_p$  = effective packing diameter (the diameter of a sphere with equal surface area)
- $a_p$  = dry outside surface area of packing

In this model,  $a$  is assumed to equal  $a_w$ , the wetted area of the packing, and is calculated by the following equation:

$$a = a_w \left\{ 1 - \exp \left[ -1.45 (Re_L)^{-0.1} (Fr_L)^{-0.05} (We_L)^{0.2} \left( \frac{\sigma}{\sigma_c} \right)^{-0.75} \right] \right\} \quad 5.20(9)$$

where:

- $a$  = the effective interfacial area for mass transfer ( $\text{m}^2/\text{m}^3$ )
- $a_w$  = wetted area of packing
- $\sigma_c$  = a critical surface tension = 61 dyn/cm for ceramic packing, 75 dyn/cm for carbon steel packing, and 33 dyn/cm for polyethylene packing
- $Re_L$  =  $L/a_p \mu_L$
- $Fr_L$  =  $a_p L^2 / (g \rho_L)^2$
- $We_L$  =  $L^2 / a_p \rho_L$
- $Sc_L$  =  $\frac{\mu_L}{\rho_L D_L}$
- $Sc_G$  =  $\frac{\mu_G}{\rho_G D_G}$

Absorption with a chemical reaction in the liquid phase is involved in most applications for gas control. Reaction in the liquid phase reduces the equilibrium partial pressure of the pollutant over the solution, which increases the driving force for mass transfer. If the reaction is irreversible, then  $y^* = 0$ , and the NTU is calculated as follows:

$$\text{NTU} = \int_{y_T}^{y_B} \frac{dy}{y - y^*} = \ln \frac{y_B}{y_T} \quad 5.20(10)$$

A further advantage of the reaction is the possible increase in the liquid-phase mass-transfer coefficient  $k_x$  and the effective interfacial area  $a$ . Perry and Green (1984) describe the design methods in detail.

## COMMERCIAL APPLICATIONS

Most commercial applications of absorption for gas control fall into two categories: regenerative and nonregenerative systems. For regenerative systems, the solvent leaving the absorber is enriched in pollutant. This mixture is normally separated by distillation. The solvent is then recycled back to the absorber, and the pollutant can be recovered in a concentrated form. Regeneration is possible when the absorber uses a physical solvent or a solvent containing compounds that react reversibly with the pollutant. The recovery of  $H_2S$  from hydrocarbon processing using an amine as the solvent is a major application of regenerative absorption. Figure 5.20.4 shows a typical flowsheet.

For the capture of  $H_2S$  and volatile sulfur compounds (e.g., thiols, COS, and  $CS_2$ ) released during the transportation of sour liquids, a portable system is required. Am-gas Scrubbing Systems Ltd. (Calgary, Canada) manufactures both portable and stationary units that use 26% aqueous ammonia. The spent solution oxidizes to form ammonium sulfate, which is recovered from the spent absorbent and can be marketed as fertilizer. Alternate absorbents for portable units include basic hypochlorite (bleach) solutions, but the stability of the solution decreases with consumption of the base as the  $H_2S$  is absorbed. A complicating factor in the use of basic fluid absorbent systems is that  $CO_2$  is also a weak acid and is absorbed to sequentially form bicarbonate ( $HCO_3^-$ ) and carbonate ( $CO_3^{2-}$ ) ions, thereby consuming the absorbent.

The absorption of  $SO_2$  by dimethylaniline from off-gases at copper, zinc, lead, and nickel smelters is another application. The desorbed  $SO_2$  produces  $H_2SO_4$ . The  $SO_2$  concentration in the off-gases is approximately 10%.

For nonregenerative or throwaway systems, irreversible reactions occur in the liquid phase. The reagents in the solvent are consumed and must be replenished for absorption efficiency. The resulting products are discarded. Typical examples are the absorption of acid gases by caustic solutions. Nonregenerative systems are economical only when the reagents are inexpensive or the volume involved is small.

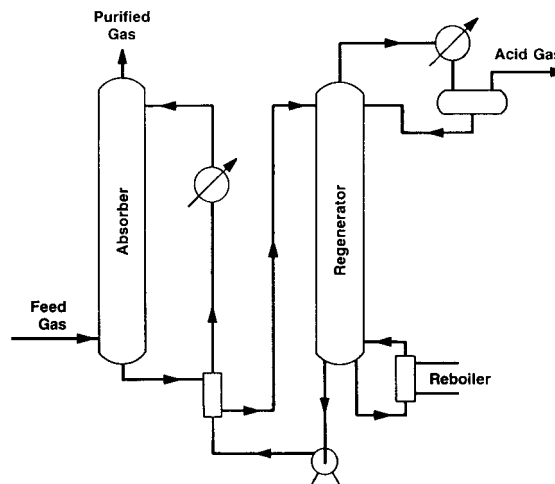

FIG. 5.20.4 Flowsheet for the recovery of  $H_2S$  using amine as a solvent.

TABLE 5.20.3 FLUE GAS DESULFURIZATION PROCESSES

Process Generics	Process Operations	Active Material	Key Sulfur Product
Throwaway processes			
1. Lime or limestone	Slurry scrubbing	CaO, $CaCO_3$	$CaSO_3/CaSO_4$
2. Sodium	$Na_2SO_3$ solution	$Na_2CO_3$	$Na_2SO_4$
3. Dual alkali	$Na_2SO_3$ solution, regenerated by CaO or $CaCO_3$	$CaCO_3/Na_2SO_3$ or CaO/NaOH	$CaSO_3/CaSO_4$
4. Magnesium promoted-lime or limestone	$MgSO_3$ solution, regenerated by CaO or $CaCO_3$	$MgO/MgSO_4$	$CaSO_3/CaSO_4$
Regenerative processes			
1. Magnesium oxide	$Mg(OH)_2$ slurry	MgO	15% $SO_2$
2. Sodium (Wellman-Lord)	$Na_2SO_3$ solution	$Na_2SO_3$	90% $SO_2$
3. Citrate	Sodium citrate solution	$H_2S$	Sulfur
4. Ammonia	Ammonia solution, conversion to $SO_2$	$NH_4OH$	Sulfur (99.9%)
Dry processes			
1. Carbon adsorption	Adsorption at 400°K, reaction with $H_2S$ to S, reaction with $H_2$ to $H_2S$	Activated carbon/ $H_2$	Sulfur
2. Spray dryer	Absorption by sodium carbonate or slaked lime solutions	$Na_2CO_3/Ca(OH)_2$	$Na_2SO_3/Na_2SO_4$ or $CaSO_3/CaSO_4$

The most important application of absorption for gas control technology is FGD. Because flue gas from power plants contributes about two-thirds of the U.S. emissions, large efforts have been spent on developing an effective control technology. Currently, several hundred FGD systems are in commercial operation. The absorption can be regenerative or nonregenerative as well as wet or dry; in effect, four categories of FGD processes exist. Table 5.20.3 lists the processes in use. The following sections describe the most important FGD processes.

### Nonregenerative Systems

Most FGD systems are nonregenerative. The reagents used in the absorber are alkaline compounds that react with  $\text{SO}_2$ . Most well-established technology (see Figure 5.20.5) is based on limestone and lime. Other processes are based on  $\text{NaOH}$ ,  $\text{Na}_2\text{CO}_3$ , and  $\text{NH}_4\text{OH}$ . Since lime and limestone are the most inexpensive and abundant reagents, they are used in about 75% of the installed FGD systems. In this process, the reaction products are  $\text{CaSO}_3$  and  $\text{CaSO}_4$  in a sludge form that must be disposed. These systems can remove 90% of the  $\text{SO}_2$  in the flue gases. Although lime is more reactive than limestone, it is more expensive; therefore, lime is not used as widely as limestone.

The main drawback of lime- and limestone-based FGD systems is scaling and plugging of the column internals. This problem is eliminated in the dual alkali system (see Figure 5.20.6) by absorption with a  $\text{Na}_2\text{SO}_3/\text{Na}_2\text{SO}_4$  solution which is then sent to a separate vessel where lime or limestone and some  $\text{NaOH}$  are introduced. The lime or limestone precipitates the sulfite and sulfate and regenerates  $\text{NaOH}$  for reuse in the absorption column. The major disadvantage of this process is the loss of soluble sodium salts into the sludge which may require further treatment. As a result, this process is not used as widely as the lime and limestone process.

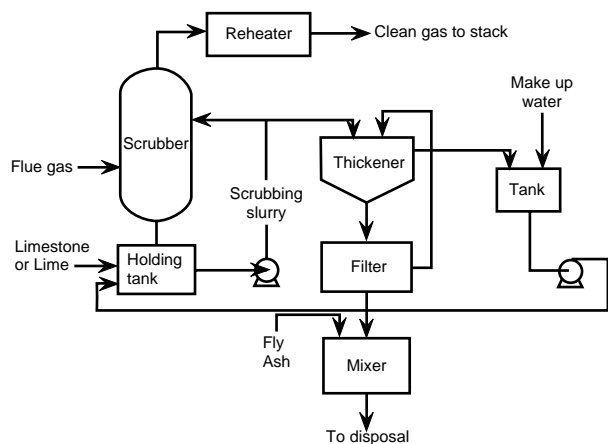

FIG. 5.20.5 Schematic flow diagram of a limestone-based FGD system.

### Regenerative Systems

Regenerative processes have higher costs than throw-away processes. However, regenerative processes are chosen when disposal options are limited. Regenerative processes produce a reusable sulfur product. In Japan, where the government mandates FGD, regenerative processes are used almost exclusively.

The Wellman-Lord process is the most well-established regenerative process which uses an aqueous sodium sulfite solution as the solvent. Figure 5.20.7 is a schematic diagram of the Wellman-Lord process. This process consists of the four following subprocesses:

**Flue gas pretreatment.** In this subprocess, flue gas from an ESP is blown through a venturi prescrubber. The prescrubber removes most of the remaining particles and any existing  $\text{SO}_3$  and  $\text{HCl}$ , which upset the  $\text{SO}_2$  absorption chemistry. The prescrubber also cools and humidifies the flue gas. A liquid purge stream from the prescrubber removes the solids and chlorides.

**$\text{SO}_2$  absorption by sodium sulfite solution.** In the  $\text{SO}_2$  absorber tower, the flue gas from the prescrubber contacts the aqueous sodium sulfite, and the  $\text{SO}_2$  is absorbed and reacted with  $\text{Na}_2\text{SO}_3$  in the liquid to form sodium bisulfite. Since excess  $\text{O}_2$  is always present, some of the  $\text{Na}_2\text{SO}_3$  oxidizes to  $\text{Na}_2\text{SO}_4$ ; some of the  $\text{Na}_2\text{SO}_3$  reacts with the residual  $\text{SO}_3$  to form  $\text{Na}_2\text{SO}_4$  and sodium bisulfite. The sodium sulfate does not further  $\text{SO}_2$  absorption. A continuous purge from the bottom of the absorber prevents excessive sulfate buildup. Since the absorber bottom is rich in bisulfite, most of the stream is routed for further processing.

**Purge treatment.** Part of the liquid stream leaving the absorber is sent to the chiller and crystallizer, where the less soluble, sodium sulfate crystals are formed. The slurry is centrifuged, and the solids are dried and discarded. The bisulfite-rich, centrifugal material is returned to the process.

**Sodium bisulfite regeneration.** The remaining part of the liquid stream from the absorber is sent to a heated evap-

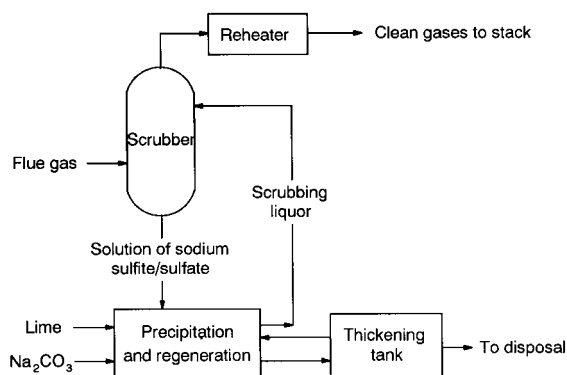

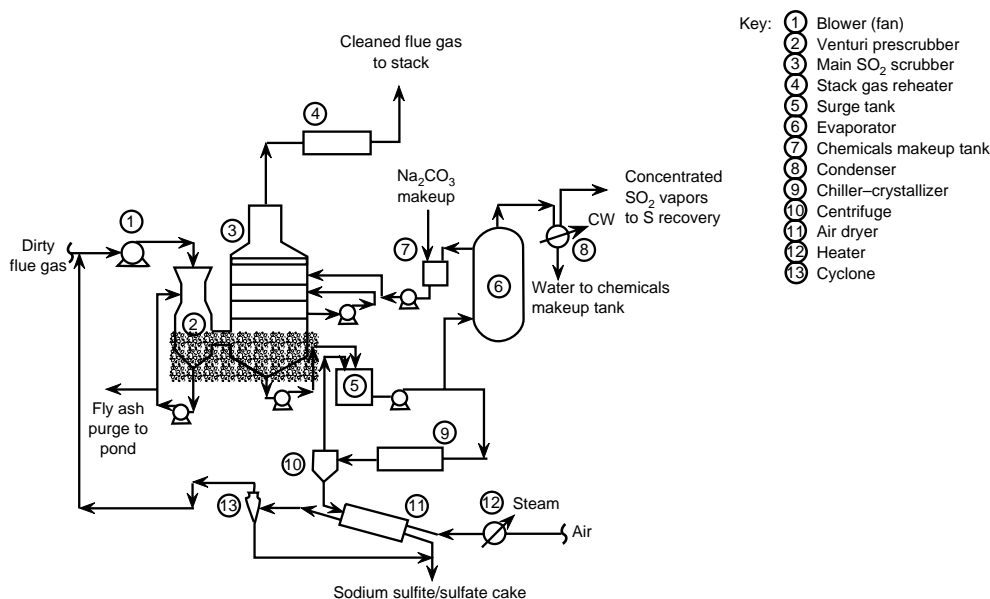

FIG. 5.20.6 Schematic diagram of a dual alkali FGD system.

**FIG. 5.20.7** Schematic process flow diagram of the Wellman-Lord SO<sub>2</sub> scrubbing and recovery system. (Reprinted from U.S. Environmental Protection Agency (EPA), 1979.)

orator and crystallizer, where sodium bisulfite is decomposed to Na<sub>2</sub>SO<sub>3</sub> and SO<sub>2</sub>. The gas stream contains 85% SO<sub>2</sub> and 15% H<sub>2</sub>O, thus the SO<sub>2</sub> can be used as feed stock for producing S or sulfuric acid. To replace the lost Na<sub>2</sub>SO<sub>3</sub>, this subprocess adds soda ash (Na<sub>2</sub>CO<sub>3</sub>) to make up sodium. The Na<sub>2</sub>CO<sub>3</sub> reacts readily with SO<sub>2</sub> in the absorber tower to give sodium sulfite.

Surface condensers are normally shell and tube type and should be set vertically. Vapor should only condense inside the tubes. This arrangement prevents a stagnant zone of inert gas (air) that might blanket the heat transfer surfaces. Figure 5.20.8 shows a typical surface condenser. The feed gas enters the top of the condenser and flows concurrently downward with the condensate.

## Condensation

In cases where pollutants have low vapor pressures, condensation is effective for removing a significant part of the vapor. The condenser works by cooling the feed gas to a temperature below the dew point of the feed gas. Although condensation can also occur by increasing the pressure without changing the temperature, this method is seldom used for the control of air pollution.

Because condensation is a simple process and the design techniques for condensers are well-established, condensation is also used as a pretreatment process for reducing the load and operating problems of other pollution control devices.

Cooling water is the most commonly used coolant although brine solutions are also used when low temperatures are required.

Two types of condensers are surface and contact condensers. Surface condensers are used when the coolant and pollutant form a miscible mixture. This mixture must be further separated (e.g., by distillation) for recovery of the pollutants. If the coolant is immiscible with the pollutants, contact condensers are used because phase separation is a relatively easy operation. However, the coolant is not contaminated to the extent of causing water pollution problems.

**FIG. 5.20.8** Surface condenser.

Contact condensers are much smaller and less expensive than surface condensers. In the design shown in Figure 5.20.9, part of the coolant is sprayed into the gas space near the top of the condenser. This design is similar to the spray column used in absorption. The remainder of the coolant is directed into a discharge throat to complete the condensation. The pressure regain in the downstream cone of the venturi is often sufficient to eliminate the need for a pump or a barometric leg.

Because the coolant required to operate contact condensers is ten to twenty times that for surface condensers, the latter is the predominate device used in air pollution control applications. The design of a surface condenser is based on complete resistance to heat transfer on the condensing side in the layer of condensate. A mean condensing coefficient is calculated from appropriate correlations. Calculating the overall heat transfer coefficient and the log-mean temperature driving force estimates the required heat transfer area. Many engineering textbooks (Perry and Green 1984) provide additional design details.

## Adsorption

Adsorption is a separation process based on the ability of adsorbents to remove gas or vapor pollutants preferentially from a waste gas stream (Yang 1987; Kohl and Riesenfeld 1985). The process is particularly suitable when pollutants are (1) noncombustible, (2) insoluble in liquids, or (3) present in dilute concentration.

The mechanism of adsorption can be classified as either physical adsorption or chemisorption. In physical adsorption, gas molecules adhere to a solid surface via van der Waals forces. The process is similar to the condensation of a vapor. It is a reversible process. Desorption occurs by lowering the pressure, increasing the temperature, or purging the adsorbent with an inert gas. In chemisorp-

FIG. 5.20.9 Contact condenser.

tion, gas molecules are adsorbed by forming chemical bonds with solid surfaces. This process is sometimes irreversible. For example, oxygen chemisorbed on activated carbon can only be desorbed as CO or CO<sub>2</sub>. Chemisorbed spent adsorbents cannot normally be regenerated under mild temperatures or vacuum.

## ADSORPTION ISOTHERM

For a particular single gas–solid combination, one of five types of adsorption isotherm is found (see Figure 5.20.10). In separation processes, the favorable isotherms, types 1 and 2 are most frequently encountered.

From considering kinetics for a single gas impacting a uniform solid surface and adsorbing without chemical change, Langmuir (1921) deduced that the fraction of a surface covered by a monolayer varies with the partial pressure of the adsorbate  $P_a$ . The following equation gives the mass of adsorbate adsorbed per unit mass of adsorbent  $m_a$ :

$$m_a = \frac{k_1 P_a}{k_2 P_a + 1} \quad 5.20(11)$$

where  $k_1$  and  $k_2$  are constants. Equation 5.20(11) is known as the Langmuir isotherm, and the shapes are types 1 and 2 in Figure 5.20.10.

Assuming that the number of sites of energy  $Q$  ( $N_Q$ ) is related to a base value for  $Q$ ,  $Q_0$ , as follows:

$$N_Q = ae^{-Q/Q_0} \quad 5.20(12)$$

then Equation 5.21(11) reduces to the following approximation:

$$\Theta = \text{const.} P^{1/n} \quad 5.20(13)$$

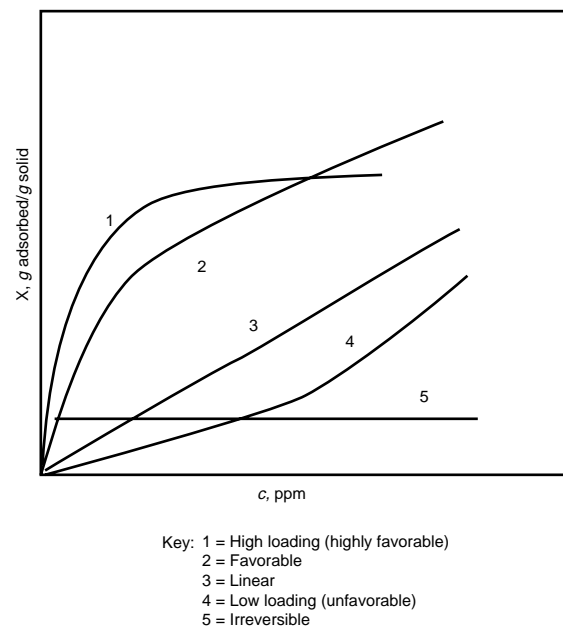

FIG. 5.20.10 Adsorption loading profiles.

When expressed as the volume of adsorbate adsorbed per unit mass of adsorbent  $\nu$ , as follows:

$$\nu = kP^{1/n} \quad 5.20(14)$$

or expressed in terms of concentration in the gas phase  $c$  and at the adsorbent surface  $w$ , as follows:

$$c = \alpha w^\beta \quad 5.20(15)$$

the expression is known as the Freundlich isotherm. For a binary, or higher, mixture in which the components compete for surface sites, the expression is more complex (Yang 1987). Table 5.20.4 gives the values for parameters  $k$  and  $n$  in the Freundlich isotherm for selected adsorbates.

Ideally, an adsorbent adsorbs the bulk of a pollutant from air even when that material is in low concentration. The adsorption profile for such behavior is called *favorable* and is shown as curves 1 and 2 in Figure 5.20.10. If high concentrations must be present before significant quantities are adsorbed (curve 4), the profile is called *unfavorable adsorption*.

As a pollutant is adsorbed onto the adsorbent, the concentration in the air stream falls. The adsorbent continues to adsorb the pollutant from the air stream until it is close to saturation. Thus, as the air stream passes through a bed of adsorbate, the pollutant concentration varies along the bed length. This adsorption wave progresses through the bed with time (see Figure 5.20.11). At time  $t_1$ , the bed is fresh, and essentially all pollutant is adsorbed close to the entrance of the bed. At time  $t_2$ , the early part of the bed is saturated, but the pollutant is still effectively adsorbed. At time  $t_3$ , a small concentration of pollutant remains in the air stream at the exit. When the pollutant concentration at the exit meets or exceeds the limiting value, the bed is spent and must be replaced or regenerated. For some

pollutants, the breakthrough of detectable amounts of pollutants is unacceptable. To avoid exceeding acceptable or regulated limits for pollutant concentrations in exit gases, replacing or regenerating adsorbent beds well before the end of the bed's lifetime is essential.

The profiles shown in Figure 5.20.11 are for a single pollutant in an air stream. An adsorber normally operates in a vertical arrangement to avoid bypassing gases. For multiple pollutants, the process is more complex as each pollutant can exhibit different behavior or competition can occur between pollutants for adsorption sites (Yang 1987; Kast 1981). The bed design must be able to adsorb and retain each pollutant.

## ADSORPTION EQUIPMENT

The major industrial applications for adsorption processes have both environmental and economic objectives. The abatement of air pollution includes removing noxious and odorous components. Additionally, adsorption is used for the recovery of solvents and reagents, such as carbon disulfide, acetone, alcohol, aliphatic and aromatic hydrocarbons, and other valuable materials, from effluent streams (Kast 1981).

Typically, a process in which the adsorbate is recovered uses temperature swing adsorption (TSA), pressure swing adsorption (PSA), or continuous or periodic removal of the adsorbent from the system (Kast 1981). The TSA and PSA technologies are normally used only for the removal of high concentrations of adsorbate. For the majority of environmental applications, small concentrations must be removed from air, and continuous or periodic removal technologies are more appropriate.

**TABLE 5.20.4 FREUNDLICH ISOTHERM PARAMETERS FOR SOME ADSORBATES**

Adsorbate	Temperature (K)	$k \times 100$	$n$	Partial Pressure (Pa)
Acetone	311	1.324	0.389	0.69–345
Acrylonitrile	311	2.205	0.424	0.69–103
Benzene	298	12.602	0.176	0.69–345
Chlorobenzene	298	19.934	0.188	0.69–69
Cyclohexane	311	7.940	0.210	0.69–345

### Periodic Removal

This system is the simplest to design or build but is not necessarily the most efficient or cost-effective to operate. Essentially, the adsorbate is left in a fixed-bed or fluidized-bed adsorber until the adsorptive capacity of the bed is approached. Then, the adsorbate is removed for destruction, disposal, or regeneration. A new adsorbent is then charged to the system. For systems in which either the adsorbent or adsorbate is hazardous or contact with air is deleterious, this method presents issues requiring expensive solutions. Further, during changeover of the spent adsorbent, the adsorber is not used. Therefore, a minimum of two adsorber units is necessary for any plant in continuous operation.

### Continuous Removal

By simultaneously introducing and removing adsorbent, this system achieves continuous operation. This system requires the bed, or the material in the bed, to be in continuous motion. A fixed-bed can rotate so that the fraction of the bed exposed to the feed stream is continuously charged. The spent adsorbent then rotates to a separate zone where the system regenerates it either by flushing with a carrier gas, contact with a reagent, or desorption of the adsorbate by sweeping with a hot gas. Because the adsorbent is necessarily porous, no significant reverse pressure differential exists between the feed and flushing systems.

A solid adsorbent cascading through the feed gas can be continuously removed from the base of the adsorber unit. Regenerated adsorbent can then be recycled to the unit.

### TSA

When the bond between the adsorbent and adsorbate is strong (i.e., chemisorption), regenerating the adsorbent requires elevated temperatures and purging with a nonadsorbing gas. If this process occurs in the adsorber unit, a TSA process is used. For continuous processing, a minimum of three adsorber units are required for economic operation: at least one in operation, one undergoing regeneration, and one cooling down following regeneration. Typically, the gas flushing the unit that is cooling down is then passed through the bed undergoing regeneration. A heater ensures that the flush gas is at a temperature to effect desorption. The effluent stream is then cooled, and if the adsorbate is to be recovered, the flush gas and adsorbate are separated by physical methods (distillation, condensation, or decanting). Regeneration can also require additional steps, including physical or chemical treatment, washing, and drying.

### PSA

When the adsorption capacity of an adsorbent is a function of pressure or one component in a gaseous mixture

is preferentially adsorbed at high pressures, PSA can be used for gas separation. Essentially, a bed of adsorbent in one unit is initially exposed to the gas mixture at a high pressure. The feed stream is then diverted to another unit, while the initial unit is vented or flushed at a lower pressure. A significant fraction of the adsorbate desorbs, and the bed in this unit is regenerated and reused following repressurization.

For each of these systems, more than one bed is required for continuous operations to accommodate regeneration of spent material and servicing. The setup required is similar to that shown in Figure 5.20.12.

## ADSORBER DESIGN

In adsorber design, a design engineer must have knowledge about adsorbents, the adsorbent operation, and the regeneration operation.

### Adsorbents

Favorable properties of an adsorbent include good thermal stability; good mechanical integrity, especially for use in a continuous removal or fluidized-bed system; high surface area and activity; a large capacity for adsorption; and facile regeneration. In some cases, the spent adsorbent must be disposed of, in which case it must be inexpensive and environmentally benign or of commercial value following minor processing.

Activated carbon and the series of microporous aluminosilicates known as zeolites are important adsorbents. Table 5.20.5 presents the properties of the widely used zeolites. Because water vapor is not considered an air pollutant, the adsorption capacity of a zeolite for water is not a benefit.

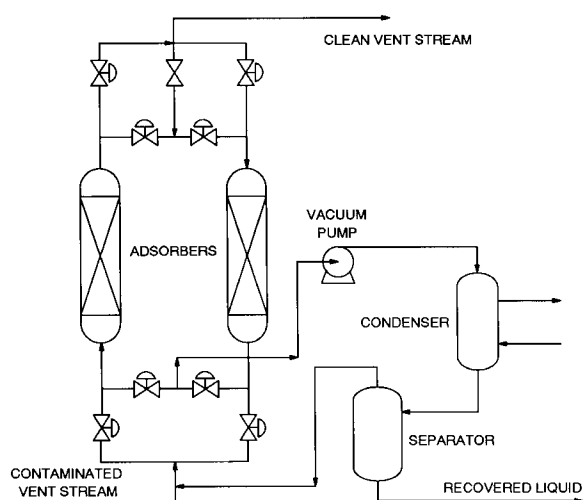

FIG. 5.20.12 Activated carbon system for solvent recovery using modified PSA. (Data from AWD Technologies, Inc., 1993, *Hydrocarbon processing* [August]:76.)

Activated carbon is a highly porous adsorbent with a high capacity for a range of adsorbates (see Table 5.20.6).

Thermal or vacuum desorption permits the recovery of several adsorbates from both zeolites and activated carbon. Thus, these materials are valuable for the recovery of fugitive reagents or solvents. Flushing with water removes inorganic adsorbates such as  $\text{SO}_2$  adsorbed on carbon but the carbon must be dried before reuse. Figure 5.20.13 shows a zeolite-based adsorption system for solvent vapors.

## Adsorbent Selection

In selecting an adsorbent, the design engineer must ensure that the adsorption isotherm is favorable. If the adsorption isotherm is unfavorable, the loading is low, and the process is rarely economic. Irreversible adsorption should be avoided unless regeneration is not required.

If the feed gas is at an elevated temperature, cooling the gas stream may be required. The cost of cooling is significant and should be included in cost estimates.

Some adsorbates decompose in adsorption or regeneration. Many decomposition products (e.g., from chlorinated hydrocarbons, ketones, and acetates) are acidic and can corrode the system. They also need an additional separation step if the recovered adsorbate is valuable.

Using an adsorbent system for continuous solvent recovery from a vent stream requires using multiple beds. Regeneration of the adsorbent and recovery of the solvent can be accomplished by several means, including PSA (see Figure 5.20.12). Alternatively, a system can recover the solvent by sequentially steam treating the spent adsorbate to remove the adsorbed solvent, drying the carbon with hot air, and cooling the bed to the operating temperature. The number of beds required depends on the effective time-on-stream of the adsorbent bed and the time required to regenerate the carbon. The determination of these parameters is described next. Table 5.20.7 shows typical operating parameters for adsorbers.

## Adsorption Operation

The design and operation of an adsorber requires knowledge of the adsorption isotherm, mass transfer, and axial dispersion of adsorbates. Heat transfer is also significant at high pollutant concentrations. Generally, if the feed rate is less than  $12 \text{ m}^3/\text{sec}$ , purchasing an adsorber package from a reputable supplier is more economical than custom building a unit.

Figure 5.20.14 shows the operation of a typical adsorber. For an ideal breakthrough curve, all the pollutant fed in time  $t_s$  is adsorbed. During this time period, the concentration on the adsorbent surface increases from the initial value  $w_0$  to the saturation (or equilibrium) value  $w_s$ . Thus, the following equation applies for a feed gas with linear velocity  $u_0$  and concentration  $c_0$ :

$$t_s = \frac{LB_s(w_s - w_o)}{u_o c_o} \quad 5.20(16)$$

where L and P<sub>s</sub> are the bed length and the bulk density of the adsorber, respectively. For new and completely regenerated adsorbents, w<sub>o</sub> = 0.

The actual breakpoint time t is always less than t<sub>s</sub>. If the adsorption zone is small compared to the bed length L, most of the adsorbent is used.

In an ideal case of no mass-transfer resistance and no axial dispersion, the adsorption zone becomes zero, i.e., t = t<sub>s</sub>. However, since mass-transfer resistance always exists, the practical operating capacity is normally 25–50% of the theoretical isotherm value.

**FIG. 5.20.13** Zeolite-based adsorption system for solvent vapors. The large wheel in the middle of the unit adsorbs vapors and is simultaneously regenerated.

In a fixed, cylindrical bed adsorber, the adsorption zone shown in Figure 5.20.14 moves down the column at a nearly constant pattern. The shape and velocity of the adsorption zone are influenced by the adsorption isotherm. For Freundlich-type adsorption, in which c<sub>o</sub> = αw<sub>s</sub><sup>β</sup> as expressed in Equation 5.20(15), the following equation gives velocity of the adsorption zone:

$$u_{ad} = \frac{u_o}{\rho_s} (\alpha)^{1/\beta} (c_o)^{\beta-1/\beta} \quad 5.20(17)$$

and the following equation expresses the height of the adsorption zone:

$$z = \frac{u_o}{K} \int_0^1 \frac{d\gamma}{\gamma - \gamma^\beta}; \quad \gamma = c/c_o \quad 5.20(18)$$

where K is the overall gas–solid mass-transfer coefficient (s<sup>-1</sup>) and c is the breakthrough concentration set by the

FIG. 5.20.14 Adsorber operation.

design engineer ( $\text{kg}/\text{m}^3$ ) to meet the environmental standards. The value of the integral on the right side of Equation 5.20(18) is undefined for limits of 0 and 1. However, taking limits close to these values (e.g., 0.01 and 0.99) defines the integral and solves the equation. The breakthrough time  $t_\beta$  is then as follows:

$$t_\beta = L - \frac{z}{u_{\text{ad}}} \quad 5.20(19)$$

These design equations estimate operating time before breakthrough occurs. The accuracy of the calculations depends on the estimation of  $K$ , which is determined by the combination effect of diffusion external to the adsorbent, in the pores and on the pore surface, as well as axial dispersion. Predictions of  $K$  values from existing mass-transfer correlations are available but often are unreliable. Thus, adsorber designs are generally based on laboratory data. The scale-up then involves using the same adsorbent size and superficial gas velocity.

For longer beds, the column height of the adsorption zone is a small fraction of the bed length. A longer bed leads to better utilization of the adsorbent. The longer bed also results in a lower degree of backmixing (i.e., higher mass-transfer coefficient). However, proper design is required to avoid an excessive pressure drop. The energy consumption for a blower to overcome a pressure drop is a significant part of the overall operating cost. In the absence of experimental data, the Ergun equation or

FIG. 5.20.15 Canister adsorption system used to remove trace contaminants from air. (Reprinted, with permission, from Balston, Inc.)

equations provided by adsorbent suppliers (e.g., UOP) can provide an estimate. The Ergun equation is as follows:

$$\frac{\Delta P}{L} = \frac{(1 - \epsilon)^2 G^2}{g_c^3 d_p \rho_G} \left[ 1.75 + \frac{150(1 - \epsilon) \mu_G}{d_p G} \right] \quad 5.20(20)$$

where:

- $\Delta P$  = pressure drop,  $\text{lb}_f/\text{ft}^2$
- $L$  = bed depth, ft
- $g_c$  = gravitational constant,  $4.17 \times 10^8 \text{ lb}_m = \text{ft}/\text{lb}_f - \text{h}^2$
- $\epsilon$  = void fraction
- $\rho_G$  = gas density,  $\text{lb}_m/\text{ft}^3$
- $G$  = superficial gas velocity,  $\text{lb}_m/\text{ft}^2 - \text{h}$
- $\mu_G$  = gas viscosity,  $\text{lb}_m/\text{ft}^2 - \text{h}$
- $d_p$  = particle diameter, ft

For nonspherical particles,  $d_p$  is defined as the equivalent diameter of a sphere having the same specific surface (external area of the particle/bed volume) as the particle.

When the pressure drop across the adsorbent bed must be small, the shape of both the bed and, consequently, the adsorption wave are different from those for a cylindrical packed adsorber. Figure 5.20.15 shows an example of using a canister-type bed for low pressure drop operations.

### Regeneration Operation

For continuous operation, when breakthrough occurs, the adsorbent has reached its operating capacity. The adsorption operation must then be performed in another, unsaturated bed. The spent adsorbent is regenerated unless it is

used in the treatment of very dilute gases or in specialty applications such as medical uses or gas masks. The most common fluids used in regeneration are hot air and steam. During regeneration, the equations for calculating the velocity and height of the desorption zone can be derived from the Freundlich isotherm ( $c_R = \alpha_R w_s^{\beta_R}$ ) similar to Equations 5.20(17), 5.20(18), and 5.20(19) as follows:

$$c_R = \alpha_R \left( \frac{c_o}{\alpha} \right)^{\beta_R/\beta} \quad 5.20(21)$$

where subscript R refers to regeneration.

Theoretical predictions are not reliable and should be treated as estimates only. Laboratory data may not be available for scale-up because simulating the conditions for a large adiabatic bed is difficult using a small column. For the regeneration of carbon, the reverse flow of steam at 105 to 110°C is often used. The regeneration stops soon after the temperature front reaches the exit, and the typical steam consumption is 0.2 to 0.4 kg/kg carbon. Under these conditions, the carbon is not free of adsorbate. However, prolonging the desorption period is not economic because an excessive amount of steam is required to remove the remaining adsorbate due to the unfavorable shape of the tail of the desorption wave.

If the regeneration time is longer than the adsorption time, three or more beds are required to provide continuous operation.

## Chemical Conversion

Removing air pollutants by chemical conversion is used for VOCs, hydrogen sulfide, and nitrogen oxides.

### VOCs

When the concentration of VOCs in an air stream must be eliminated or severely reduced, the VOC can be destroyed thermally or catalytically by oxidation. For thermal destruction technologies, see Section 5.21. The VOCs include hydrocarbons (gasoline vapor, solvents, and aromatics), halogenated organics (solvents and vinyl chloride monomer), oxygenates (ketones, esters, and aldehydes), and odorous compounds (amines, mercaptans, and others from the effluent treatment or food processing) (see Table 5.20.8) (Spivey 1987). The oxidation products are carbon dioxide, water, and an acidic component (HX [X = Cl, Br, I]) from halocarbons; SO<sub>x</sub> from sulfur compounds; NO<sub>x</sub> from amines, nitriles, and nitrogen heterocycles; and P<sub>2</sub>O<sub>5</sub> from phosphorus compounds. Excess oxygen ensures

that oxidation is complete and that partial oxidation products (which can be pollutants) are not formed. Scrubbing with a mild basic aqueous solution removes the acidic component in the tail streams.

The oxidation of a VOC is exothermic. However, because a VOC is present only as a dilute component, the reaction heat is insufficient to maintain the temperature required for oxidation. Therefore, additional heating is required, or a catalyst must be used that enables total oxidation at lower temperatures (see Table 5.20.8).

Most catalytic operations also require elevated temperatures to ensure a complete reaction at a suitably fast rate. Therefore, either the catalyst bed is heated, or the feed stream is preheated. Inlet gas streams are kept 50–150°C higher than the ignition temperatures (Nakajima 1991). When the preheating uses an internal flame, the process is complex, involving both the products of combustion in the flame and processes occurring at the catalyst. The operating parameters (temperature and space velocity) for an application depend on the destructibility of the VOC (see Table 5.20.9).

In a typical application, more than one VOC is destroyed. Frequently, oxidation at a catalyst is competitive under stoichiometric or partial oxidation conditions, or one VOC inhibits catalytic oxidation of another. Using excess oxygen in air overcomes these problems. A range of parameters applies in catalytic oxidation for VOC destruction. These parameters depend on the application (Spivey 1987).

### Mechanisms

The oxidation of a VOC (S) at a catalyst can involve a species at the surface and in the vapor phase. The

Langmuir–Hinshelwood mechanism (Scheme 1) requires the adsorption of each species at nearby sites and subsequent reaction and desorption.

The Mars–van Krevelen mechanism of catalytic oxidations (Scheme 2) explicitly requires a redox process in which oxygen is consumed from the catalyst surface by reaction with the VOC and then is replenished by oxygen from the vapor phase.

The Eley–Rideal mechanism (Scheme 3) is similar to the Mars–van Krevelen mechanism except that the products are formed from adsorbed oxygen and the VOC in the gas phase.

As these schemes show, for metal or nonreducible oxide catalysts, excess oxygen in the gas phase means that the catalyst surface is well-covered with oxygen and that little if any VOC is adsorbed. Thus, the Eley–Rideal mechanism is expected to be important. For metal oxide catalysts containing readily reducible metals, the Mars–van Krevelen mechanism is important.

Metal oxides that are n-type semiconductors are rich in electrons and are generally not highly active as oxidation catalysts. Vanadium pentoxide is the notable exception. In contrast, p-type semiconductors are conductive because of the electron flow into positive holes. The electron-deficient surfaces of such metal oxides readily adsorb oxygen, and if the adsorption is not too strong, they are active catalysts. Insulators, which are inexpensive and not friable or

thermally unsuitable, have values as supports for more expensive, catalytically active metal oxides or noble metals.

For all mechanisms, a key factor is the strength of the interaction between the surface and the oxygen (atom, molecule, or ion) required for oxidation of the VOC. If the oxygen is too tightly bound to a surface, that surface is not highly active as a catalyst. Similarly, if the interaction is too weak, the surface coverage with oxygen is low, and the catalytic activity is consequently diminished. Various thermodynamic properties are considered as the parameter that best represents the strength of adsorption. For metals, the initial heat of oxygen adsorption is a reasonable choice (Bond 1987). For metal oxides, the reaction enthalpy for reoxidation of the used catalyst (Mars-van Krevelen mechanism) is considered the most representative (Satterfield 1991). The maximum rate for VOC oxidation over an oxide catalyst is estimated to occur when the reaction enthalpy for reoxidation of the catalyst is one-half of the reaction enthalpy for total oxidation of the VOC. Thus, the selection of a catalyst for an application depends strongly on the nature of the VOC to be destroyed, and the conditions depend on the destructibilities of the VOC (see Table 5.20.9).

Complete oxidation of each VOC in a multicomponent stream is ensured with high temperatures and excess oxygen, and mixed-oxide catalysts are frequently used. The mixed oxides, especially when promoted with alkali or alkaline earth metal oxides, frequently have activities that are different from the combination of properties of the components, and in general the activities are higher. This phenomenon probably arises from two factors: the availability and mobility of the different forms of available oxygen and the accessibility of different binding sites with various energy levels.

More than one type of surface oxygen species can be involved: adsorbed dioxygen ( $O_2$ ), ions ( $O^{2-}$ ;  $O_2^{2-}$ ), or radical ions ( $O^-$ ;  $O_2^-$ ) on the surface or incorporated into the lattice of the catalyst. Sachtler (1970) and Sokolovskii (1990) review the roles of various forms of adsorbed oxygen.

## Kinetics

The following equations summarize the steps required for destruction of a VOC by an Eley-Rideal mechanism:

where  $[ ]$  represents a surface site and  $[S_{a,i}]$  represents the  $i$ th in a series of partially oxidized species  $S_a$  at the surface of the catalyst. The following rate expression is derived from the preceding mechanism:

FIG. 5.20.16 Overall reaction rate. (Reprinted, with permission, from D.L. Trimm, 1991, *Catalytic combustion*, Chap. 3 in *Studies in inorganic chemistry 1991* 11:60.)

$$r = \frac{k_a P_{O_2} P_{VOC}}{k_b P_{O_2} + v k_c P_{VOC}} \quad 5.20(26)$$

where  $k_a$ ,  $k_b$ , and  $k_c$  are constants and  $v$  is the stoichiometric coefficient of oxygen in the overall oxidation reaction of the VOC. Under conditions of excess oxygen where  $k_b P_{O_2} \gg v k_c P_{VOC}$ , this equation reduces to the following approximate form:

$$r \cong k P_{VOC} \quad 5.20(27)$$

For most applications, the kinetics are described by the following fractional power expression:

$$r = k_b P_{O_2}^a P_{VOC}^b \quad 5.20(28)$$

in which  $a$  and  $b$  are fractional coefficients with values close to zero and unity, respectively.

The oxidation of a VOC can occur at the catalyst surface and in the gas phase. The overall reaction rate is the sum of these two components and is a strong function of temperature (see Figure 5.20.16) (Prasad 1984, Trimm 1991). The catalytic oxidation of hydrocarbons over supported metal catalysts is thought to occur via dissociative chemisorption of the VOC, followed by reaction with coadsorbed oxygen at the surface and then desorption of the combustion products (Chu and Windawi 1996). The rate determining step in this Langmuir-Hinshelwood type of mechanism is hydrogen abstraction from the VOC. Thus the ease of oxidation of the VOC is directly related to the strength of the C-H bond. Methane is more difficult to oxidize than other paraffins, aromatics, or olefins, and oxygenates are relatively easier to oxidize.

## Reactors

The reactor's heat requirement heat arises mainly from the need to preheat the inlet gases or to heat the catalyst bed. For efficient operation of a catalytic oxidation system, the exhaust heat must be recovered and used to preheat the feed, as shown in Figure 5.20.17 for a system manufac-

**FIG. 5.20.17** Schematic diagram of catalytic process with burner. (Reprinted, with permission, from Salem Engelhard.)

tured by Salem Engelhard (South Lyon, Mich.). The residual heat is recovered by a secondary heat exchanger and used for area heating or other purposes requiring low-grade energy.

In some cases, destruction of all VOCs and intermediates requires a higher operating temperature than that required to combust a single VOC (see [Figure 5.20.18](#)).

The waste gases from several chemical, printing, or related industries contain mixtures of halogenated and non-halogenated VOCs. Converting each VOC requires a combination of catalysts. Further, scrubbing the effluent from the reactor is necessary to remove the acidic components generated. As an example of such a system, the catalytic solvent abatement (CSA) process designed and marketed by Tebodin V.B. is shown in [Figure 5.20.19](#).

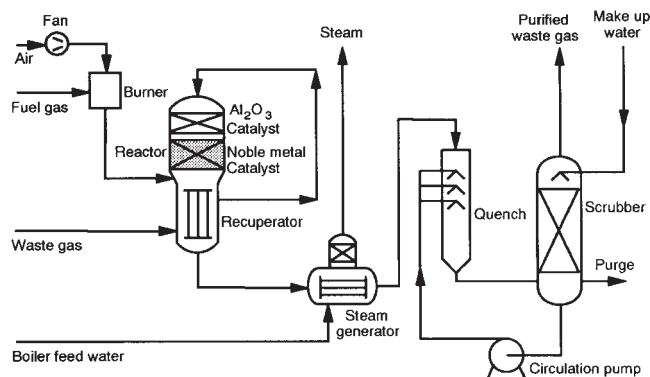

**FIG. 5.20.18** Conversion curves for VOC destruction using a catalytic incinerator. (Data from Brown Engineering, Seattle, Wash; Johnson Matthey, Catalytic Systems Division, Wayne, Pa.)

The heat for a catalytic incinerator can be applied directly to the catalyst bed, rather than from a burner. The swingtherm system (see [Figure 5.20.20](#)) manufactured by Mo-Do Chemetics, Ltd. (Vancouver, Canada and Ornskolsvik, Sweden) uses dual beds at a temperature of 300–350°C. The air stream is fed at 60°C and is heated by contacting a ceramic at 320°C. It then passes through a platinum-based catalyst. The exothermal VOC oxidation raises the temperature of the gases to 350°C. The gases then pass through the other bed to heat the ceramic rings; the effluent gases are cooled to 90°C. When the second reactor is warmed to 320°C, the inflow is reversed. The flow reversal occurs every 2–5 min. For VOC concentrations below 300 ppm, auxiliary heating is required.

## HYDROGEN SULFIDE

Large sources of hydrogen sulfide (H<sub>2</sub>S) are treated as a resource from which sulfur is recovered. The normal recovery is to oxidize a part of the H<sub>2</sub>S to sulfur dioxide (SO<sub>2</sub>) and then react H<sub>2</sub>S and SO<sub>2</sub> over an alumina-based catalyst in the Claus process as follows:

**FIG. 5.20.19** CSA system. (Data from Tebodin B.V., The Hague, the Netherlands.)

FIG. 5.20.20 Swingtherm process. (Reprinted, with permission, from *Chemical Engineering*, 1993 [October]:153.)

$H_2S$  is initially removed from a source, such as sour natural gas, by dissolution in an alkanolamine solvent. However, for low concentrations of  $H_2S$  in air, this method is not sufficiently effective for total removal of  $H_2S$  (Kohl and Riesenfeld 1985). Instead, the  $H_2S$  is either oxidized completely to  $SO_2$ , and then the system removes the  $SO_2$  by scrubbing or capture, or it is captured by reaction with solid or liquid-phase adsorbents.

For stationary units, any liquid or solid base reacts with  $H_2S$ . Magnetite ( $Fe_3O_4$ ), limestone ( $CaCO_3$ ), lime ( $CaO$ ), zinc carbonate ( $ZnCO_3$ ), and zinc oxide ( $ZnO$ ) are each effective, and  $Fe_3O_4$ ,  $CaO$ , and  $ZnO$  are used commercially.

Table 5.20.10 lists the major adsorbents for  $H_2S$ . The main advantage of using these solutions is to reduce high  $H_2S$  concentrations in gas streams. Table 5.20.11 lists the advantages and disadvantages of these adsorbents. Using solid adsorbents or dry conversion technology is frequently necessary to remove  $H_2S$  at the ppm level. Table 5.20.10 also shows examples of dry oxidation technologies. The use of solid adsorbents is expensive; therefore, for air streams containing large amounts of  $H_2S$ , both scrubbing and adsorption are used in sequence.

The market for  $H_2S$  is small compared to that for sulfur or sulfuric acid. Thus, regeneration of  $H_2S$  removed by adsorption from air streams is performed only occasionally. Several proven technologies are available for the dry oxidation of  $H_2S$  to sulfur.

## Dry Oxidation

The dry oxidation process using iron oxide is inexpensive but not pleasant or simple to operate. The following equation empirically gives the suitable box sizes (Steere Engineering Co.):

$$A = \frac{GS}{3000(D + C)} \quad 5.20(30)$$

where:

- A = cross-section through which gas passes on its way through any one box in the series
- G = maximum amount of gas to be purified, scf/hr
- S = a correction factor for the hydrogen sulfide content of the inlet gas
- D = the total depth of the oxide, ft through which the gas passes consecutively in the purifier set. In boxes with split flow where half the gas passes through each layer, the area exposed to the gas is twice the cross-sectional area of the box, while D is the depth of one layer of oxide.
- C = the factor: 4 for 2 boxes, 8 for 3 boxes, and 10 for 4 boxes, respectively
- 3000 = a constant

From Equation 5.20(30), the following equation gives the maximum amount of gas which can be purified by a unit:

$$G = \frac{3000(D + C)A}{S} \quad 5.20(31)$$

**TABLE 5.20.10 ADSORBENTS FOR HYDROGEN SULFIDE**

<i>Liquid Adsorbents</i>	<i>Trade or Generic Names</i>	<i>Source</i>	<i>Comments</i>
Alkanolamines:			
Monoethanolamine	MEA	Dow, U.S.A.	Moderately selective
Diethanolamine	DEA	Dow, U.S.A.	Moderately selective
Triethanolamine	TEA	Dow, U.S.A.	Selective
N-methyldiethanolamine	MDEA	Dow, U.S.A.	Selective
Diisopropanolamine	DIPA	Dow, U.S.A.	Selective
Aqueous potassium carbonate	Hot Carbonate		Moderately selective
Aqueous tripotassium phosphate			Selective
Alkazid process			
Dialkylglycine sodium salt	DIK Solution		Selective
Sodium alanine solution	M Solution		Moderately selective
Sodium phenolate solution	S Solution		Not selective
Aqueous Ammonia			
+Air/hydroquinone	Perox		Recovers as sulfur
+Air	Am-gas	Am-gas, Canada	Recovers as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>
Aqueous Sodium Carbonate			
+Quinoline sulfonate salt and sodium metavanadate	Stretford	W.C. Holmes and Company, U.K.	Recovers as sulfur
+Naphthaquinone sulfonate salt	Takahax	Tokyo Gas Co. and Nittetsu Chemical Engineers Co.	Recovers as sulfur
Aqueous zinc acetate			
Aqueous calcium acetate			
+Heat to decompose product			Precipitates ZnS
Iron Oxide	Dry Box		Ca(SH) <sub>2</sub> soluble;
+Controlled reoxidation			CaS precipitates
Zinc Oxide, ZnO			Sulfur recovery, for ppm H <sub>2</sub> S streams
			Useful for ppm H <sub>2</sub> S; only mod. selective
			Product releases H <sub>2</sub> S on decomp.
Calcium oxide, CaO	Lime		oxidizes to sulfate
Copper, Cu			
(or other metals)			Reagent, not adsorbent; forms CuS and H <sub>2</sub> , but requires expensive regeneration

Table 5.20.12 tabulates the values of S. The values for the factor C are based on the number of boxes in the series being used at the time of operation and on the assumption that the flow is reversed during purification.

The designer must use the appropriate size of iron oxide particles for the required pressure drop across the bed. The empirical relationship was developed for one system (Prasad 1984) and can be used as an approximation for similar systems:

$$\Delta P = 3.14d^{-0.61} \quad 5.20(32)$$

Perry (1984) recommends an allowable pressure drop of 1–2 psi/ft at 800–1000 psig and linear gas velocities of 5–10 ft/min. Typical operating conditions are shown in Table 5.20.13.

### Activated Carbon Process

Activated carbon is an effective catalyst for the oxidative conversion of H<sub>2</sub>S in hydrocarbon gas streams to elemental sulfur under mild conditions. I.G. Farbenindustrie developed the first process to exploit this capability. Such a unit may process up to 200,000 cu ft/hr of water–gas, with a pressure drop of 25 in of water.

### Reactions of H<sub>2</sub>S and SO<sub>2</sub>

The Sulfreen process designed by Lurgi (Germany) and Elf Aquitaine (France) reduces residual sulfur compounds in tail gases from Claus plants for sulfur recovery from natural gas. Alumina or carbon catalysts

**TABLE 5.20.11 TECHNICAL ADVANTAGES AND DISADVANTAGES FOR AMINES USED AS H<sub>2</sub>S ADSORBENTS**

<i>Amine</i>	<i>Advantages</i>	<i>Disadvantages</i>
MEA	Known technology Low cost (approximately \$1.6/kg) Simple regeneration. 20–30% solution has low freezing point (to –50°C).	Some degradation by CO <sub>2</sub> , COS, and CS <sub>2</sub> requires use of make-up. May need addition of foaming prevention agents. Some corrosion effects.
DEA	Known technology. Low cost. Simple regeneration. Better H <sub>2</sub> S selectivity than MEA.	Some degradation. Slightly higher cost than MEA. May need foam prevention agent.
TEA	Known technology. Low cost (approximately \$1.4/kg). Simple regeneration. Highly selective to H <sub>2</sub> S. Less degradation. 40% solution has reasonable freezing point (–32°C).	Approximately twice as expensive as MEA, based on adsorption capacity. Minimum (fluid) operating temperature is higher than for MEA.
MDEA or DIPA	Highest selectivity to H <sub>2</sub> S. Lowest regeneration temperature; hence energy savings. Lower heat of reaction Lower corrosion effects. Low vaporization losses. Not degraded by COS or CS <sub>2</sub> . Higher initial costs are offset by reduced make-up costs.	Higher initial cost for amine. If an MDEA or DIPA regeneration plant is not nearby, a regeneration unit is required.

are used, and efficiencies as high as 90% can be attained for streams containing 1.50% H<sub>2</sub>S and 0.75% SO<sub>2</sub>. Similar technologies are used in the cold-bed adsorption process, developed by AMOCO Canada Petroleum Company Ltd., and the MCRC sulfur recovery process, licensed by Delta Engineering Corporation (USA). Sulfur recoveries up to 99% are attainable for each of these processes.

### Oxidation to Oxides of Sulfur

An alternative strategy in sulfur recovery is the oxidation to oxides of sulfur. For treating air with low concentrations of H<sub>2</sub>S, this strategy does not require finding a market for small amounts of sulfur produced, and it can remove any adsorbed products from the catalyst bed thermally or by flushing with water.

The Katasulf process (Germany) for cleaning gas streams for domestic use can operate in various configurations. Depending on the pollutants and their concentrations in the feed gas, a prewasher may be necessary in addition to the main gas washer for SO<sub>2</sub> removal from gases exiting the catalyst chamber. Other applications use side-stream or split-stream arrangements. In each case, the catalyst is activated carbon, alumina, or a combination of two of three metals (iron, nickel, and copper) and operates close to 400°C. The Katasulf process is effective for H<sub>2</sub>S and NH<sub>3</sub> removal and can be operated to reduce HCN and organic sulfur compounds.

### NITROGEN OXIDES

The major stationary sources of nitrogen oxide (NO<sub>x</sub>) emissions come from the combustion of fossil fuels. The

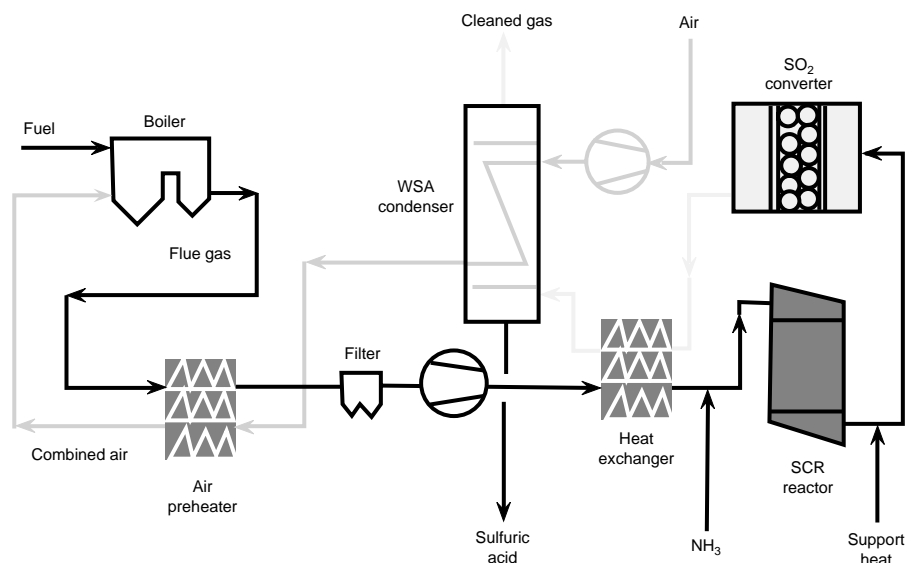

FIG. 5.20.22 SNOX process for combined treatment of  $\text{NO}_x$  and  $\text{SO}_x$ .

flue gas usually contains 2–6% oxygen and a few hundred ppm of  $\text{NO}_x$ , which consists of 90–95% NO and 5–10%  $\text{NO}_2$ . The only viable postcombustion process for  $\text{NO}_x$  emission control is chemical conversion to  $\text{N}_2$  by a reducing agent. Several gases can be used for this purpose including methane, hydrogen, carbon monoxide, and ammonia. However, because the flue gas contains much more than  $\text{O}_2$  than  $\text{NO}_x$ , the reducing agent must selectively react with  $\text{NO}_x$  rather than  $\text{O}_2$  to minimize its consumption (Environment Canada: Task Force Report 1989; Nakatsuji 1991). To date, many commercial installations based on the selective reduction of  $\text{NO}_x$  by  $\text{NH}_3$  can remove about

80% of  $\text{NO}_x$  in the flue gas. The governing equations for the ammonia-based technology are as follows:

The first two reactions dominate when the flue gas is heated to about  $1000^\circ\text{C}$ . Above  $1100^\circ\text{C}$ , Equation 5.20(35) becomes significant leading to the unwanted formation of NO. If the temperature is below  $800^\circ\text{C}$ , the reaction rate is too low for practical use. Thus, the process

Notes: This list is not comprehensive. The authors have attempted to provide current information but recognize that data may have changed. Inclusion of a company in this list is not an endorsement of that company's products and should not be construed as such.

is temperature sensitive. With the use of a suitable catalyst, the NO<sub>x</sub> reduction can be carried out at 300–400°C, a temperature normally available in a flue gas system. This process is called Selective Catalytic Reduction (SCR). Figure 5.20.21 is a schematic diagram for the SCR process. In this process, at least 1% O<sub>2</sub> should be present in the flue gas, thus it is suitable for boiler and furnace applications. Several simple catalytic and noncatalytic systems are in commercial operation at several sites (see Table 5.20.14).

Under ideal reaction conditions, one mole of NH<sub>3</sub> is required to convert one mole of NO; however, in practice, one mole of NH<sub>3</sub> reduces about 0.8–0.97 moles of NO<sub>x</sub>. The excess NH<sub>3</sub> is required because of the side reaction with O<sub>2</sub> and incomplete mixing of the ammonia with the flue gas. Much of the ammonia slip ends up in the fly ash, and the odor can become a problem when the ash is sent to a landfill or sold to cement plants.

The SCR processes are simple, requiring only a proper catalyst and an ammonia injection system. The catalysts currently in use are TiO<sub>2</sub>-based which can be mixed with vanadium or molybdenum and tungsten oxides. These catalysts eliminate the formation of ammonium bisulfate which can plug the downstream equipment, a problem in earlier SCR systems.

A new Shell de-NO<sub>x</sub> catalyst comprises vanadium and titanium, in high oxidation states, impregnated onto silica with a high surface area (300 m<sup>2</sup>/g). The data for a commercial and semicommercial operation indicate consistent performance for periods up to one year (Groeneveld et al. 1988). The catalyst is deactivated by high concentrations of SO<sub>2</sub>, but the poisoning is reversible with heating. A version of this process is installed to control dust-containing flue gas. This process employs a parallel passage system in which the flue gas permeates through the catalyst separating into passages for feed and purified streams.

The Shell technology is being developed for other applications. In particular, a lateral flow reactor is being developed which demonstrates a low pressure drop. The design of this reactor should allow for convenient installation and maintenance (Groeneveld et al. 1988).

Flue gases, especially from coal-burning boiler units or power generation, contain both NO<sub>x</sub> and SO<sub>x</sub>, with fly ash and metal-containing particulates. Processes have been developed that convert the NO<sub>x</sub> to nitrogen, which is vented, and the SO<sub>x</sub> to sulfuric acid, which is removed by scrubbing. Figure 5.20.22 is a schematic of the SNOX process (Haldor Topsøe A/S, Denmark). This process recovers up to 95% of the sulfur in the SO<sub>x</sub> as sulfuric acid and reduces 95% of the NO<sub>x</sub> to free nitrogen. All fly ash and metals are essentially captured.

Table 5.20.15 is a recent list of catalyst suppliers, and Table 5.20.14 lists the manufacturers of environmental technologies (Environmental Processes '93 1993).

## 5.21

# GASEOUS EMISSION CONTROL: THERMAL DESTRUCTION

---

---

This section addresses the thermal destruction of gaseous wastes. These wastes are predominantly VOC-containing. The principal methods are thermal combustion and incineration and flaring, although a number of new technologies are emerging. First, this section provides an overview of these methods including major technological and some cost considerations. Then, it cites several examples of industries that employ these technologies to achieve destruction and removal efficiencies (DREs) in excess of 98% and low products of incomplete combustion (PIC) emissions.

Next this section reviews the thermodynamic and kinetic fundamentals that form the basis of thermal incineration and illustrates the principles with two sample calculations. Most of this section is devoted to the design considerations of thermal incinerators; the remaining section is allocated to flares and the emerging technologies.

### Overview of Thermal Destruction

The principal methods for thermal destruction include thermal combustion and incineration, flaring, and other emerging technologies.

### THERMAL COMBUSTION AND INCINERATION

Thermal combustion and incineration is the principal approach used for VOCs (usually expressed in concentration terms) but is equally applicable to liquids and solids with sufficient heat content. This technique is different from catalytic destruction, which is discussed in Section 5.20. From a global mass balance and energy balance point of view, the design and implementation of a thermal incinerator is straightforward. Thermal efficiencies can be estimated closely with CO<sub>2</sub> and H<sub>2</sub>O as the principal products. For dilute streams, achieving the required temperature may require auxiliary fuel.

In the area of PIC-formation, global approaches become unworkable. Environmental engineers may have to use detailed measurement techniques to verify emission types and levels not only from the combustion process but also for the pollution control equipment.

Thermal destruction is simplest when (at least theoretically) CO<sub>2</sub> and H<sub>2</sub>O are the expected products. The process becomes more complicated when hetero atoms (i.e., N, S, and Cl) or inorganics are involved, especially if

corrosive products (i.e., HCl and SO<sub>2</sub>) are formed. The dividing line between gaseous and liquid wastes is not always sharp because liquid wastes can contain many species of high-vapor pressure and gaseous wastes can carry liquid residues in droplet form.

The main variables controlling the efficiency of a combustion process are temperature, time, and turbulence; the three Ts of combustion. At a constant combustion chamber temperature, the DRE, defined in terms of the following equation:

$$\text{DRE \%} = \frac{\text{VOC}_{\text{in}} - \text{VOC}_{\text{out}}}{\text{VOC}_{\text{in}}} \times 100 \quad 5.21(1)$$

increases with residence time; increasing the temperature increases the DRE at a constant time. At efficient combustion temperatures, the rate can become mixing limited.

Modern thermal oxidation systems can accomplish +99% DRE for capacities ranging from 1000–500,000 cfm and VOC concentrations of 100–2000 ppmv. Typical residence times are 1 sec or less at temperatures of 1300–1800°F. Inlet VOC concentrations above 25% of the lower explosion limit (LEL) are generally avoided due to the potential explosion hazards. Temperatures near 1800°F and long residence times can lead to elevated nitrogen oxide levels, which may have to be controlled separately (if lowering the combustion temperature is not feasible).

Thermal incinerators are usually coupled to two types of thermal energy recovery systems: regenerative and recuperative. Both methods transfer the heat content of the combustion exhaust gas stream to the incoming gas stream (Ruddy and Carroll 1993). In a regenerative system, an inert material (such as a dense ceramic) removes heat from the gases exiting the furnace. Such a ceramic storage bed eventually approaches the temperature in the combustor, consequently reducing the heat transfer. Therefore, the hot exhaust stream contacts a cooler bed, while the incoming gas stream passes through the hot bed.

As shown in Figure 5.21.1, the VOC-laden gas stream enters bed #1 which warms this gas stream by transferring heat from a previous cycle. Some VOCs are destroyed here, but most of them are oxidized in the combustion chamber. The flue gases from this combustion exit through bed #2 and transfer most of their enthalpy in the process. Within seconds of a heating and cooling cycle, the beds are switched, and the incoming stream now enters bed #2. Consequently, a near steady-state operation is approached,

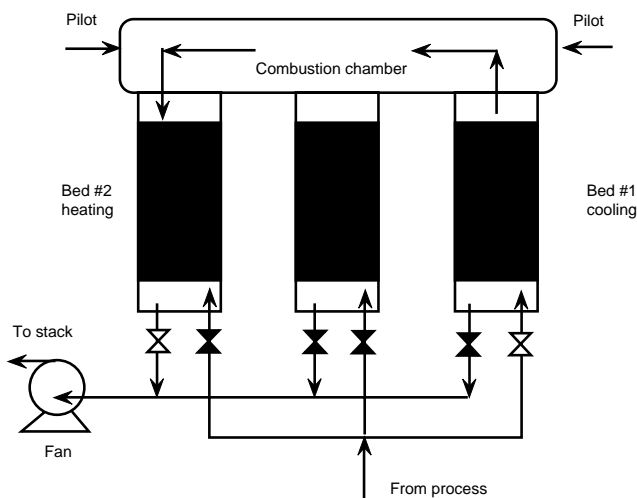

FIG. 5.21.1 Diagram of a regenerative thermal oxidizer.

FIG. 5.21.2 Recuperation-type afterburner.

and more heat can be recovered from these systems than from a typical thermal incinerator (about 70%). Using multiple beds can lead to heat recoveries to 95%. The need for any auxiliary fuel depends on the potential thermal energy of the VOC-laden stream.

Recuperative thermal oxidation systems typically use a shell-and-tube design heat exchanger to recover heat from the flue gases for heating the incoming gases. Operating temperatures are reached quickly in these systems. Recuperative heat exchange is also more suited to cyclic operations and variations in VOC feed rates and concentrations. Figure 5.21.2 is a schematic of such a system.

Table 5.21.1 summarizes the emission sources, VOC categories, and typical operating parameters (flow rates and concentrations), as well as the cost aspects of thermal VOC control technologies.

## FLARING

Flaring is the process of disposing of industrial and other combustible waste gas streams via a visible flame (flare). The flame can be enclosed in a chimney or stack.

Flares are widely used for the disposal of waste gases from several industrial processes, including process start ups, shutdowns, and emergencies. These processes are characterized by variable or intermittent flow. Flares are principally used where the heating value cannot be economically recovered. Applications include petroleum production, blast furnace and coke oven combustible gases, industrial chemical production, and landfills. Refinery

TABLE 5.21.1 THERMAL VOC CONTROL TECHNOLOGIES

Technology	Emission Source	VOC Category	Emission Rate Volumetric (scfm)	VOC (ppmv)
Thermal oxidation <sup>a</sup>	PV, ST TO, WW	AHC, HHC A, K	<20,000 w, w/o HR ≥20,000 w HR	20-1000 w/o HR ≥1,000 w HR
Flaring	PV, ST, TO, WW, F	AHC, A, K

flares are typically elevated and steam-assisted. Flares can be open or enclosed and burn with a type of diffusion flame. Auxiliary fuel may have to be added to support flare combustion.

### EMERGING TECHNOLOGIES

Numerous emerging technologies have been used or proposed for the thermal destruction of wastes, more so for liquid and solid wastes than for gaseous wastes. The reason is clear: most gaseous wastes that are candidates for thermal destruction carry large quantities of inert diluents (CO<sub>2</sub>, H<sub>2</sub>O, and N<sub>2</sub>), whereas some of these emerging technologies are energy intensive because they operate at high temperatures.

Some of these technologies have been available for decades and will probably not find widespread application. However, some technologies combine thermal destruction with the formation of a useful product. Consequently, product formation enhances the advantages of thermal incineration, in which energy recovery is the chief economic benefit.

Preconcentration (adsorption and desorption or absorption and desorption) can be a suitable pretreatment to one of these techniques, though rarely practiced. Also, numerous emerging technologies are not thermal in nature. Table 5.21.2 lists several emerging technologies based primarily on the availability of practical and theoretical information but not restricted to gaseous wastes.

### Source Examples

Hundreds of processes emitting VOCs are candidates for thermal destruction. This section presents several diverse

examples. The *Air Pollution Engineering Manual* (1992) provides more detail on process descriptions and emissions.

### PETROLEUM INDUSTRY

The major segments of this industry are exploration and production, transportation, refining, and marketing. Each of these segments consists of facilities and processes that emit VOCs. These emissions can be handled by a variety of thermal destruction techniques, principally flares, incinerators, and boilers.

The refining step includes numerous processes and potential emission sources, such as crude separation, light hydrocarbon processing, middle and heavy distillate processing, residual hydrocarbon processing, and auxiliary processes. Emissions are classified as process point and process and area fugitive emissions (pumps, valves, fittings, and compressors). Fugitive emissions can be a substantial fraction. Table 5.21.3 summarizes estimates of major aromatic hydrocarbons and butadiene emissions from various point and fugitive sources.

Thermal incineration controls continuous VOC emissions; this method is preferred (to flaring) when hetero atoms are in the VOCs, such as Cl and S that lead to corrosive products. The application of thermal incineration to processes of varying flows and concentrations are more problematical. A large safety factor must be employed (not to exceed 25% of the LEL). On the other hand, if the concentrations are too low, auxiliary fuel is required.

### CHEMICAL WOOD PULPING

The major gaseous emissions in this industry are odorous, total reduced sulfur (TRS) compounds, characteristic of Kraft pulp mills. The principal components are hydrogen sulfide (H<sub>2</sub>S), methyl mercaptan (CH<sub>3</sub>SH), dimethyl sulfide ((CH<sub>3</sub>)<sub>2</sub>S), and dimethyl disulfide ((CH<sub>3</sub>)<sub>2</sub>S<sub>2</sub>). In addition, emissions of noncondensable gases such as acetone and methanol are common. Emissions from uncontrolled sources, such as digester and evaporator, relief, and blow

**TABLE 5.21.3 ESTIMATED EMISSIONS FROM PETROLEUM REFINERY**

<i>Chemical</i>	<i>Point, tn/yr</i>	<i>Fugitive, tn/yr</i>	<i>Total, tn/yr</i>
Benzene	114	29	142
Toluene	437	111	548
Xylene (total)	31	1751	1782
Butadiene	3	1	4
Trimethyl benzene (1,2,4)	310	141	452

*Source:* Air Pollution Management Association, 1992, *Air pollution engineering manual*, edited by A.J. Buonicore and W.T. Davis (New York: Van Nostrand Reinhold).

gases, are expressed in lb/tn of air-dried pulp. Emissions also arise from black liquor oxidation tower vents.

Kraft pulp mills that began construction or modification after September 24, 1976 are subject to the new source performance standards (NSPS) for particulate matter and TRS emissions. Also, in 1979, the U.S. EPA issued retrofit emission guidelines to control TRS emissions at existing facilities not subject to the NSPS.

Today, combustion controls most major and minor sources of TRS emissions (National Council of the Paper Industry for Air and Stream Improvement 1985). Most commonly, existing combustors, such as power boilers and lime kilns, are used as well as specifically dedicated incinerators. The principal oxidation product is sulfur dioxide; a caustic scrubber is often installed after the incinerator to neutralize that gas. Two types of noncondensable gases are produced by the Kraft pulping process: low volume, high concentration (LVHC) and high volume, low concentration (HVLC). The latter can be burnt only in a boiler capable of accepting such large gas volumes without disrupting the unit's efficiency.

## LANDFILL GAS EMISSIONS

The major component of landfill gas is methane; less than 1% (by volume) consists of nonmethane organic compounds. Air toxics detected in landfills include such compounds as benzene, chlorobenzene, chloroform, TSRs, tetrachloroethylene and toluene, and xylenes (Air and Waste Management Association 1992). Landfill gas is generated by chemical and biological processes on municipal solid waste (MSW). The gas generation rate is affected by parameters such as the type and composition of the waste, the fraction of biodegradable materials, the age of the waste, the moisture content and pH, and the temperature. Anaerobic decomposition can produce internal temperatures to 37°C (98.6°F); gas production rates are highest for moisture contents of 60–78%.

Control measures are usually based on containment combined with venting and collection systems. Low permeability solids for cover and slurry walls reduce the landfill gas movement. Capping is the process that uses a cover soil of low permeability and low porosity.

Gases can be vented or collected. Collection systems consist of several vertical and/or horizontal recovery wells that collect and convey gas within the landfill via a piping header system to a thermal oxidizer such as a flare. Blowers or compressors are used for this purpose. Gas collection efficiencies for active landfills with capping and gas collection can reach 90%.

The principal thermal destruction method for landfill gas is flaring. Emissions from landfill gas flares are a function of the gas flow rates, the concentration of the combustible component (which determines the temperature), and the residence time required. These emissions are esti-

mated from combustion calculations; they are generally not measured.

## RENDERING PLANTS

Thermal destruction methods are often applied to odorous emissions. Rendering plants are prime examples of an odorous emission. In these plants, animal and poultry by-products are processed to produce fallow, grease, and protein meals. Batch and continuous processes are used. Other sources (National Council of the Paper Industry for Air and Stream Improvement 1985; Prokop 1985) describe these processes in detail.

In a batch cooker system (the basic rendering process), cookers are charged with raw material; a cook is made under controlled time, temperature, and pressure conditions; the cooked material is discharged; and the cycle is repeated. Under continuous conditions, the raw material is charged to the cooker.

The principal odorous emissions from these processes are N- and S-containing organic compounds, which are listed in Table 5.21.4. Additional compounds include higher molecular weight organic acids, pyrazines, alcohols, and ketones. These compounds are mostly noncondensibles and arise under the cooking conditions (~220°F). The type of raw material and its age have a significant effect on the odor intensity. Continuous systems tend to be enclosed and have a greater capability of confining odors. In the batch process, the steam rate varies between 450–900 ft<sup>3</sup> min<sup>-1</sup>. Steam is subsequently condensed and cooled to below 120°F. Odorous noncondensibles range in odor intensity from 5000–10<sup>6</sup> odor units/scf; the volumetric emission rate of noncondensibles varies between 25–75 ft<sup>3</sup> min<sup>-1</sup>.

Since rendering plants use boilers for steam generation and drying, odor control by incineration usually uses the existing boilers. The following factors should be considered when boiler incineration of odor-intense effluents is implemented:

- Excess air at odor pickup points should be avoided
- If possible, the odor-containing stream should be used as primary combustion air
- Moisture and particle concentrations should be low
- High-intensity odors must contact the furnace flame
- Sufficient residence time at T > 1200°F must be provided in existing boilers.

In addition, the use of an existing boiler for odor incineration must conform to engineering, safety, and insurance requirements. Sections 5.26 and 5.27 provide more information on odor and its control.

## Combustion Chemistry

Thermal incineration is based on combustion chemistry including stoichiometry and kinetics. These fundamentals and sample calculations are described next.

**TABLE 5.21.4 ODOROUS COMPOUNDS IN RENDERING PLANT EMISSIONS**

Compound Name	Formula	Molecular Weight	Detection Threshold (ppm, v/v)	Recognition (ppm, v/v)

## STOICHIOMETRY

The starting basis of thermal incineration is the complete combustion of a hydrocarbon to carbon dioxide and water in air as follows:

This equation accounts for all major atoms. If the VOC contains Cl, S, or N in appreciable amounts, these components must be accounted for in the stoichiometry; usually HCl, SO<sub>2</sub>, and NO are combustion products. If the components of a mixture are known, equations can be written for each species; if the components are not known, an apparent chemical formula can be based on the weight percents of each combustible element (e.g., C, H, N, and S).

Any oxygen in VOCs (alcohols and ketones) is subtracted from the stoichiometric oxygen requirements. The formation of thermal NO (from nitrogen in the air) is not accounted for in stoichiometric combustion equations; only when nitrogen is present in the fuel-VOC mixture is NO formation (from fuel or VOC N) accounted for stoichiometrically.

For dilute gas streams, achieving high-DRE and low-PIC emissions (not accounted for in the combustion stoichiometry) requires auxiliary fuel to maintain a minimum temperature and residence time.

Using excess air is common practice. This use is expressed in terms of the air/fuel ratio (mass based) or the equivalence ratio, defined as  $\phi$  as follows:

$$\phi = \frac{(\text{VOC/oxygen})_{\text{actual}}}{(\text{VOC/oxygen})_{\text{stoichio}}} \quad 5.21(3)$$

## SAMPLE CALCULATION #1

A hazardous chlorinated hydrocarbon is combusted in air according to the following stoichiometry:

Calculate the stoichiometric HCl mole fraction for  $x = 6$ ,  $y = 3$ , and  $z = 2$ . If the combustion is conducted in a way that leads to 4 oxygen mole % in the stack gas, what is the equivalence ratio; if, under these conditions, the DRE is 99.99%, what is the emitted C<sub>6</sub>H<sub>3</sub>Cl<sub>2</sub> concentration?

## SOLUTION

Total moles in stack gas: 32.125; mole fraction HCl = 0.062

If E = excess oxygen, then by stoichiometry, 6.25E oxygen is in the product gases. Therefore, the following equation applies:

$$0.04 = \frac{6.25E}{32.125 + 6.25E + 6.25 \times 3.78E}$$

Solving, E = 0.254; then

$$(\text{oxygen})_{\text{actual}} = 6.25 + 6.25 \times 0.254 = 7.84$$

$$\phi = \frac{1/7.84}{1/6} = 0.765$$

1 mole C<sub>6</sub>H<sub>3</sub>Cl<sub>2</sub> in \* 0.0001 mole C<sub>6</sub>H<sub>3</sub>Cl<sub>2</sub>

1 mole  $C_6H_3Cl_2$  in \* 0.0001 mole  $C_6H_3Cl_2$   
 Total moles out = 32.125 + 7.589 = 39.714

$$\frac{0.0001}{39.714} \times 10^6 = 2.52 \text{ ppm}$$

## KINETICS

Stoichiometry cannot account for finite DRE and PIC concentrations. Global kinetics can address only the former. Finite DRE can be expressed as a fractional conversion as follows:

$$\ln \frac{C_{\text{vocf}}}{C_{\text{voci}}} = -kt = \ln(1 - \text{DRE}) \quad 5.21(4)$$

where  $k$  is a (pseudo) first-order rate coefficient  $s^{-1}$ . The product of rate and residence time determines the conversion (i.e., a high DRE is achieved only by a sufficiently high rate [high temperature] and sufficient residence time).

This presentation implies a plug-flow reactor and irreversibility; the latter is usually a good assumption in combustion reactions. Some evidence exists that a modified model incorporating an ignition-delay time gives a better fit to experimental data (Lee et al. 1982).

In Equation 5.21(4), the dimensionless group  $-kt$  presents the natural log of the unreacted fraction. Conversion increases rapidly with an increase in  $kt$ . This product implies a batch reactor. For a flow reactor (plug flow),  $t$  is replaced by  $\bar{t}$ , the mean residence time, defined as  $V/Q$  (reactor volume divided by the volumetric flow rate at a constant density) or  $L/\bar{u}$  for tubular reactors ( $L$  = reactor/combustor length;  $\bar{u}$  = average velocity).

Some reported data shows evidence that continuously stirred tank reactors (CSTR), or perfect mixer, behavior occurs at high conversion (Hemsath and Suhey 1974). The following equation expresses this behavior:

$$\frac{C_{\text{vocf}}}{C_{\text{voci}}} = \left( \frac{1}{1 + k\bar{t}} \right) \quad 5.21(5)$$

Composite behavior is sometimes an explanation for the observed results, i.e., a model consisting of a plug-flow reactor followed by one or more CSTRs.

In all combustion reactions, some CO is always formed. The following two-step global model accounts for this formation:

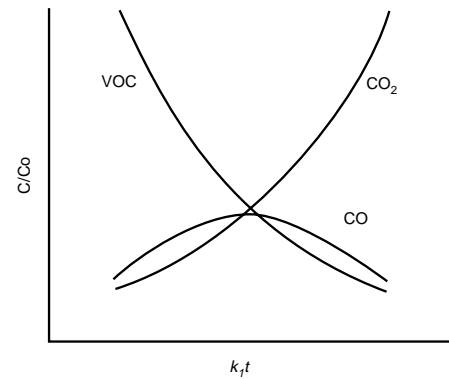

where, assuming excess oxygen, the following equations apply:

$$r_{\text{VOC}} = -k_1 (\text{VOC}) \quad 5.21(7)$$

$$r_{\text{CO}} = -k_1 (\text{VOC}) - k_2 (\text{CO}) \quad 5.21(8)$$

$$r_{\text{CO}_2} = k_2 (\text{CO}) \quad 5.21(9)$$

Qualitatively, the resulting concentration dependence is of the form shown in Figure 5.21.3. Under typical incinera-

key:  
 $c$  = Concentration at time  $t$  or exit concentration  
 $C_0$  = Initial concentration  
 $k_1 t$  = Product of rate coefficient  $\times$  time, where  $t$  can be taken as the residence time at a given temperature

FIG. 5.21.3 Qualitative relationship between VOC, CO, and  $CO_2$  concentration as a function of  $k_1 t$ .

tion conditions, the preceding chemical sequence is irreversible. Using  $C_{\text{VOC}}(t=0) = C_{\text{VOC},i}$  and  $C_{\text{CO},i} = C_{\text{CO}_2,i} = 0$ , the solution of Equations 5.21(7) to 5.21(9) is as follows:

$$\frac{C_{\text{VOC},t}}{C_{\text{VOC},i}} = \exp(-k_1 t) \quad 5.21(10)$$

$$\frac{C_{\text{CO},t}}{C_{\text{VOC},i}} = \frac{1}{1 - \frac{k_2}{k_1}} (\exp(-k_2 t) - \exp(-k_1 t)) \quad 5.21(11)$$

$$\frac{C_{\text{CO}_2,t}}{C_{\text{VOC},i}} = 1 - \exp(-k_1 t) - \frac{1}{1 - \frac{k_2}{k_1}} (\exp(-k_2 t) - \exp(-k_1 t)) \quad 5.21(12)$$

This scheme can account for variable levels of CO in the exit gases, depending on the VOCs, temperature, and residence time. This analysis does not account for other PICs; usually when CO is low, other PICs are low also. Since the rate coefficients  $k_1$  and  $k_2$  are the Arrhenius-type and are strongly temperature-dependent, temperature is the critical variable.

### SAMPLE CALCULATION #2

The incineration of VOCs requires a minimum residence time at a specified temperature to achieve a certain DRE. Given the global rate expression of Equation 5.21(2) and a pseudo-first-order rate coefficient  $k_1 = A \exp(-E/RT)$ , where  $E = 45 \text{ Kcal mole}^{-1}$ ,  $A = 1.5 \times 10^{11} \text{ s}^{-1}$ ,  $R = \text{gas constant} = 2 \times 10^{-3} \text{ Kcal mole}^{-1} \text{ K}^{-1}$ , and  $T = \text{temperature K}$ , would 1 sec at 1000 K (1341°F) be sufficient to achieve a DRE of 99.99%?

$$k_1 = 1.5 \times 10^{11} \exp\left(-\frac{45}{2 \times 10^{-3} \times 10^3}\right) = 25.4 \text{ s}^{-1}$$

**SOLUTION**

For 1 sec,  $k_1t = 25.4$  and  $\exp(-25.4) \ll 0.0001$ ; therefore, 1 sec is sufficient to achieve a DRE of 99.99%.

**Design Considerations**

This section discusses the design considerations for thermal incinerators, flares, and other emerging technologies.

**THERMAL INCINERATORS**

Katari et al. (1987a and b) summarize incineration techniques for VOC emissions. Particularly useful are a table on the categorization of waste gas streams (see Table 5.21.5) and a flow chart that determines the suitability of a waste gas stream for incineration and the need for auxiliaries. The categorization includes the % oxygen, VOC content vis-a-vis LEL, and heat content. Thus, a mixture of VOC and inert gas with zero or a negligible amount of oxygen (air) and a heat content  $>100 \text{ Btu scf}^{-1}$  ( $3.7 \text{ MJ m}^{-3}$ ) can be used as a fuel mixed with sufficient oxygen for combustion (see category 5 in Table 5.21.5).

Figure 5.21.4 is a schematic of the incineration system. Waste gas from the process, auxiliary fuel (if needed), and combustion air (if needed) are combined in the combustion chamber under conditions (i.e., time, temperature, and turbulence) to achieve minimum conversion (DRE  $>99\%$ ). The temperature inside the combustion chamber should be well above the ignition temperature (1000–1400°F) of

most VOCs; residence times of 0.3–1.0 sec may be sufficient. If higher DREs are required ( $>99.99\%$ ), both residence time and temperature may have to be increased depending on the VOC composition. This increase is also necessary the more nonuniform (in terms of VOC components) the waste gas stream is.

The majority of industrial waste gases for thermal destruction fall under category 1 of Table 5.21.5. The following parameters must be quantified (see Figure 5.21.4):

Heat content of the waste gas and  $T_p$  from process ( $T_p$  5  $T_w$ , if no heat exchanger is used)

The % LEL (VOC content and types)

The waste gas volumetric flow rate  $T_w$

TE required based on the necessary DRE

The nature of the VOCs in the waste gas stream determine the temperature ( $T_E$ ) at the exit of the combustor (not equal to the adiabatic flame temperature).

The composition of the waste gases determines the combustion air requirements; required temperatures and flow rates determine the auxiliary fuel requirements, furnace chamber size, and heat exchanger capacity. The suggested temperatures are 1800°F for 99% DREs at approximately 1 sec residence time. Applicable incinerator types include liquid injection, rotary kiln, fixed-hearth, and fluidized-beds (of which several variants exist). Dempsey and Oppelt (1993) describe these units in more detail. Although these authors principally address hazardous waste, their article

**TABLE 5.21.5 CATEGORIZATION OF WASTE GAS STREAMS**

<i>Category</i>	<i>Waste Gas Composition</i>	<i>Auxiliaries and Other Requirements</i>
1	Mixture of VOC, air, and inert gas with $>16\% \text{ O}_2$ and a VOC content $<25\%$ LEL (i.e., heat content $<13 \text{ Btu/ft}^3$ )	Auxiliary fuel is required. No auxiliary air is required.
2	Mixture of VOC, air, and inert gas with $>16\% \text{ O}_2$ and a VOC content between 25 and 50% LEL (i.e., heat content between 13 and 26 $\text{Btu/ft}^3$ )	Dilution air is required to lower the heat content to $<13 \text{ Btu/ft}^3$ . (Alternative to dilution air is installation of LEL monitors.)
3	Mixture of VOC, air, and inert gas with $<16\% \text{ O}_2$	This waste stream requires the same treatment as categories 1 and 2 except the portions of the waste gas used for fuel burning must be augmented with outside air to bring its $\text{O}_2$ content to about 16%.
4	Mixture of VOC and inert gas with zero to negligible amount of $\text{O}_2$ (air) and $<100 \text{ Btu/ft}^3$ heat content	This waste stream requires direct oxidation with a sufficient amount of air.
5	Mixture of VOC and inert gas with zero to negligible amount of $\text{O}_2$ (air) and $>100 \text{ Btu/ft}^3$ heat	This waste stream requires premixing and use as a fuel.
6	Mixture of VOC and inert gas with zero to negligible amount of $\text{O}_2$ and heat content insufficient to raise the waste gas to the combustion temperature	Auxiliary fuel and combustion air for both the waste gas VOC and fuel are required.

**Temperature:**

- $T_p$  = Waste gas from process
- $T_w$  = Waste gas leaving heat exchanger or entering combustion chamber
- $T_{AF}$  = Auxiliary fuel
- $T_A$  = Combustion air
- $T_E$  = Flue gas
- $T_S$  = Flue gas leaving heat exchanger or stack temperature

FIG. 5.21.4 Schematic diagram of incinerator system.

is a comprehensive review that includes regulatory aspects, current practice, technology, emissions and their measurements, control parameters, performance indicators, and risk assessment.

In thermal incinerators,  $T_w$  is usually below 1000–1100°F (to avoid preignition); as  $T_w$  increases, auxiliary fuel requirements can decrease. For a system with a recuperative heat exchanger,  $T_w$  can be calculated as follows:

$$T_w = T_p + \eta (T_E - T_p) \quad 5.21(13)$$

where  $\eta$  represents the efficiency of the heat exchanger (see Figure 5.21.2). Standard heat transfer texts provide the equations for estimating  $\eta$  as well as the requisite material and energy balances.

If the wastes to be destroyed contain chlorine, higher temperatures may be required, and APCD needs increase, specifically the necessity to control HCl emissions. In addition, the PIC mix is more complex when organochlorine compounds are present and may require the application of Appendix VIII compound sampling techniques. Dempsey and Oppelt summarize these methods in a table.

CEMs are often used (or are required) for combustion gas components such as CO, CO<sub>2</sub>, O<sub>2</sub>, NO<sub>x</sub>, and THC, one or more of which serves as a performance indicator. Again, if chlorinated compounds are combusted, continuous monitoring of HCl can be necessary. The methodology is the same as for CO and CO<sub>2</sub>, namely NDIR. Nitrogen-containing compounds can form NO<sub>x</sub>, S-containing compounds lead to SO<sub>2</sub> and perhaps some SO<sub>3</sub>, P-containing compounds lead to P<sub>2</sub>O<sub>5</sub> (a highly corrosive compound), and Br-, F-, and I-compounds form the corresponding acids.

Gaseous hazardous waste can lead to higher molecular weight PICs; for example, the combustion of methyl chloride (while yielding mainly CO<sub>2</sub> and HCl) can also lead to species such as chloroethanes and chlorobenzenes.

## FLARES

Figure 5.21.5 shows an example of an enclosed flare, as used in landfill gas disposal. A multiple-head, gas burner is mounted at ground level inside a refractory-lined, combustion chamber that is open at the top. Enclosed flares have better combustion efficiencies than elevated flares, and emission testing is more readily performed. Typical minimum performance parameters include 0.3 sec residence time at 1000°F and CO < 100 ppm. Most refinery flares are elevated and steam assisted (see Figure 5.21.6). The steam promotes turbulence, and the induction of air into the flare improves combustion. The amount of steam required depends partly on the C/H ratio of the VOCs to be destroyed; a high ratio requires more steam to prevent a smoking flare.

U.S. EPA studies (Joseph et al. 1983; McCrillis 1988) identify several parameters important to flare design: flare head design, flare exit velocity, VOC heating value, and whether the flame is assisted by steam or air. They acquired the data from a specially constructed flare test facility. For a given flare head design, they found that the flame stability (the limit of flame stability is reached when the flame propagation speed is exceeded by the gas velocity) is a function of the fuel (VOC), gas velocity at the flare tip, and the lower heating value (LHV) of the fuel. For a given velocity, a minimum LHV is required for stable combustion. A combustion efficiency of >98% is maintained as long as the ratio of the LHV to the minimum LHV required for stable combustion is >1.2. Below that value, the DRE drops rapidly.

Gas (VOC) composition has a major influence on the stability limit. Figure 5.21.7 illustrates this influence with the results from the EPA flare test facility. Particularly interesting is the difference between methyl chloride (MeCl), propane (Prop), and butadiene (But) at a given exit velocity. The figure shows that with most gases, an increase in the flare exit velocity must be accompanied by an in-

FIG. 5.21.5 Typical enclosed flare. (Adapted from John Zinc Inc., General arrangement drawing model ZTOF enclosed flare.)

FIG. 5.21.6 Steam-assisted elevated flare system.

**FIG. 5.21.7** Flame stability limits for different gas mixtures flared without pilot assist from a 3-in open-pipe nozzle.

crease in the heating value of the waste to maintain a stable flame. For Cl-containing compounds, the flame stability should correlate with the H/Cl ratio.

Stone et al. (1992) outline design procedures for flares. The U.S. EPA requirements for flares are specified in 40 CFR Section 60.18. The requirements are for steam-assisted, air-assisted, and nonassisted flares. For steam-assisted, elevated flares, the following points must be addressed:

An exit velocity at the flare tip <60 ft/sec (for 300 Btu/scf gas streams) and <40 ft/sec (for >1000 Btu/scf gas streams). Between 300–1000 Btu/scf, the following equation applies:

$$\log V_{\max} = \frac{\text{NHV} + 1214}{852} \quad 5.21(14)$$

where  $V_{\max}$  = the maximum permitted velocity and NHV = the net heating value (BTU/scf)

Absence of visible emissions (5 min exception period for any 2 consecutive hr)

Presence of a flame at all times when venting occurs

NHV not less than 300 Btu/scf.

## EMERGING TECHNOLOGIES

This section discusses the design considerations for emerging technologies including molten salt oxidation, molten

metal reactions, molten glass, plasma systems, and corona destruction.

### Molten Salt Oxidation

Molten salt technology is an old technology. The process combines combustible wastes and air in a molten salt batch (which can be a single component such as sodium carbonate or a mixture) within a molten salt reactor, usually constructed of ceramic or steel. Typical temperatures are 1500–1900°F and several seconds of residence time for the gas phase.

An attractive feature is the heating value of the fuel which should be sufficient to maintain the salt medium in the molten state. Consequently, this technology is best applied to combustible liquid and solid wastes, rather than gaseous wastes, as the latter are usually too dilute. Another attractive aspect is the neutralization of acidic species, such as HCl and SO<sub>2</sub>, which form from Cl- or S-containing wastes.

### Molten Metal Reactions

Much higher temperatures are possible for a molten metal bath (primarily iron), up to 3000°F. This technology works best for wastes that are low in oxygen, leading to an off-gas composed primarily of CO and H<sub>2</sub>. A molten metal bath requires large heat input by induction; the resulting

temperatures are high enough to break all chemical bounds, leading to extremely high DREs. Any downstream emissions are usually the result of recombination reactions rather than incomplete destruction.

This process is most advantageous for concentrated liquid and solid wastes. Dilute gaseous wastes place high demands on the energy inputs.

A potential advantage for both molten salt and molten metal technology is their application to wastes containing quantities of toxic metals. However, both technologies require extensive downstream particle control.

### Molten Glass

This technology has been championed by Penberthy Eletromelt International, Seattle, Washington. It is based on charging waste (combustible or noncombustible) continuously to a pool of molten glass in an electric furnace. This approach is primarily attractive for ash-forming wastes; these ashes are melted into the glass, and the resulting composites are stable (resistant to leaching).

Although gaseous wastes do not contribute ash, the temperatures in these furnaces are sufficiently high (>2300°F) to achieve high DRE and low PIC levels. The residence time for the molten glass phase is long (hours), but the residence time for the gas phase is much shorter.

### Plasma Systems

A plasma incinerator burns waste in a pressurized stream of preheated oxygen. Because temperatures can reach 5000°F, applying this technology to dilute streams is prohibitive. Such a system consists of a refractory-lined, water-cooled preheater, where a fuel is burned to heat oxygen to about 1800°F. This preheater is followed by the combustion chamber, where the waste and oxygen are mixed and auto-ignition occurs. From here, the gases pass into a residence chamber, where the destruction is completed at maximum temperature, followed by a quench chamber, a scrubber to remove acid gases, and a stack.

At plasma temperatures, the degree of dissociation of molecules is high, consequently reactivity increases; reaction rates are much higher than at normal incinerator temperatures. The high combustion efficiencies that are achievable lead to a compact design. High heat recovery is also possible. Thus, these systems lend themselves to a portable design.

### Corona Destruction

The EPA has been researching VOC and air toxic destruction since 1988 (Nunez et al. 1993). This work features a fixed-bed packed with high dielectric-constant pellets, such as barium titanate, that are energized by an AC voltage applied through stainless steel plates at each end of the bed. The destruction efficiencies for VOCs such as

benzene, cyclohexane, ethanol, hexane, hexene, methane, methylene chloride, methyl ethyl ketone, styrene, and toluene is predicted from the ionization potential and bond type for these compounds. The EPA studies did not report PICs; DREs ranged from 15% (methane) to ~100% (toluene) for concentrations of 50–250 ppmv. One advantage of this process is that it operates at ambient temperatures and appears not to be sensitive to poisoning by S and Cl compounds, as catalytic systems are.

A cost comparison with carbon adsorption and catalytic and thermal incineration is favorable. However, the results presented were based on a bench-scale system only; scaleup is clearly required for further engineering evaluation.

## Conclusions

For the foreseeable future, thermal oxidation remains the principal methodology whereby emissions of gaseous and particle-bound pollutants are minimized and heat is recovered. The combustion and incineration approach is primarily viable for dilute streams where selective recovery is difficult and economically infeasible. Proposed expenditures in this technology continue to be high (see Table 5.21.1).

Where wastes are well characterized and contain no chlorine, few problems are encountered. Thermal destruction is a mature technology. Future improvements include enhanced energy recovery, smaller sizes, and continuous monitors for compliance. The presence of chlorine and other hetero atoms that lead to corrosive products (e.g., HCl) impose constraints on the material choices, gas cleanup, and monitoring requirements. The chlorine level entering the unit should be closely controlled so that downstream cleanup is efficient. In some cases, monitoring for PICs, including polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/F), is required.

Flares will come under increasing scrutiny in the future, and performance improvements will be required. No routine methods are available to measure emissions from flares. PIC inventories are inadequate. However, in regions where flaring is common, VOC emissions are expected to impact the photochemical smog potential of the atmosphere; hence, these emissions must be described in more detail.

—Elmar R. Altwicker

## 5.22

# GASEOUS EMISSION CONTROL: BIOFILTRATION

---

---

The biological treatment of VOCs and other pollutants has received increasing attention in recent years. Biofiltration involves the removal and oxidation of organic compounds from contaminated air by beds of compost, peat, or soil. This treatment often offers an inexpensive alternative to conventional air treatment technologies such as carbon adsorption and incineration.

The simplest biofiltration system is a soil bed, where a horizontal network of perforated pipe is placed about 2 to 3 ft below the ground (Bohn 1992) (see [Figure 5.22.1](#)). Air contaminants are pumped through the soil pores, adsorbed on the surface of the moist soil particles, and oxidized by microorganisms in the soil.

### Mechanisms

Biofiltration combines the mechanism of adsorption, the washing effect of water (for scrubbing), and oxidation. Soils and compost have porosity and surface areas similar to those of activated carbon and other synthetic adsorbents. Soil and compost also have a microbial population of more than 1 billion antimycetes (microorganism resembling bacteria and fungi) per gram (Alexander 1977). These microbes oxidize organic compounds to carbon dioxide and water. The oxidation continuously renews the soil beds adsorption capacity (see [Figure 5.22.2](#)).

Another distinction is that the moisture in the waste gas stream increases the adsorption capacity of water-soluble gases and is beneficial for the microbial oxidation on which the removal efficiency of biofilters depends. Conversely, the moisture adsorbed by synthetic adsorbents reduces

their air contaminant adsorption capacity and removal efficiency. In addition, biofilter beds also adsorb and oxidize volatile inorganic compounds (VICs) to form calcium salts.

Gases in air flowing through soil pores adsorb onto or, as in GC, partition out on the pore surfaces so that VOCs remain in the soil longer than the carrier air. Soil-gas partition coefficients indicate the relative strengths of retention. The coefficients increase with VOC molecular weight and the number of oxygen, nitrogen, and sulfur functional groups in the VOC molecules. In dry soils, the coefficients for VOCs have been reported from 1 for methane to 100,000 for octane. However, under moist conditions, because of the water-soluble nature, the soil-gas partition coefficient for octane is probably a thousand, and acetaldehyde is around several thousand (Bohn 1992).

The biofilter's capacity to control air contaminants depends on the simultaneous operation of both adsorption and regeneration processes. Thus, overloading the system through excessive air flow rates can affect the biofilter's removal efficiency so that adsorption rates are lower than the rates at which chemicals pass through the filter. Once all adsorption sites are occupied, removal efficiency diminishes rapidly.

A second limiting factor is the microbial regeneration rate of the adsorbed chemical, which must equal or exceed the adsorption rate. Toxic chemicals can interfere with microbial processes until a bacterial population develops that can metabolize the toxic chemical. Biofilter bed acidity also reduces the removal efficiency because the environment for soil bacterial is inhospitable. In most cases

**FIG. 5.22.1** Soil bed. A biofilter consists of a bed of soil or compost, beneath which is a network of perforated pipe. Contaminated air flows through the pipe and out the many holes in the sides of the pipe (enlarged detail), thereby being distributed throughout the bed.

Adsorption of ammonia (NH<sub>3</sub>), hydrogen sulfide (H<sub>2</sub>S), and other odors on the soil particle surface.

**REGENERATION REACTIONS**

*Odorous hydrogen sulfide is oxidized to odorless sulfate*

*Ammonia is dissolved in water and oxidized to odorless nitrate*

*Bacteria oxidize odorous volatile organics to odorless carbon dioxide and water*

**FIG. 5.22.2** Adsorption of odors and regeneration of active sites.

of biofilter failure, the limiting factor is filter overloading rather than microbiological processes because of the great diversity and number of soil bacteria.

After start up, biofilter beds require an adaptation time for the microbes to adapt to a new air contaminant input and to reach steady state. For rapidly biodegradable compounds, the adaptation time is no more than several hours. As the biodegradability decreases, the adaptation time can take weeks. After start up, the bed is resistant to shock load effects. Table 5.22.1 summarizes the biodegradability of various gases.

### Fixed-Film Biotreatment Systems

Most biological air treatment technologies are fixed-film systems that rely on the growth of a biofilm layer on an inert organic support such as compost or peat (biofilters) or on an inorganic support such as ceramic or plastic (biotrickling filters). For both systems, solid particles must be removed from waste gases before the gases enter the system; particulates plug the pores. Both systems are best suited for treating vapor streams containing one or two major compounds. When properly designed, biofilters are well suited for treating streams that vary in concentration from minute to minute.

**TABLE 5.22.1 GASES CLASSIFIED ACCORDING TO DEGRADABILITY**

<i>Rapidly Degradable VOCs</i>	<i>Rapidly Reactive VICs</i>	<i>Slowly Degradable VOCs</i>	<i>Very Slowly Degradable VOCs</i>
Alcohols	H <sub>2</sub> S	Hydrocarbons*	Halogenated hydrocarbons†
Aldehydes	NO <sub>x</sub>	Phenols	Polyaromatic hydrocarbons
Ketones	(but not N <sub>2</sub> O)	Methyl chloride	CS <sub>2</sub>
Ethers	SO <sub>2</sub>		
Esters	HCl		
Organic acids	NH <sub>3</sub>		
Amines	PH <sub>3</sub>		
Thiols	SiH <sub>4</sub>		
Other molecules containing O, N, or S functional groups	HF

*Notes:* \*Aliphatics degrade faster than aromatics such as xylene, toluene, benzene, and styrene.  
 †Such as TCE, TCA, carbon tetrachloride, and pentachlorophenol.

Figure 5.22.3 is a schematic diagram of a biofiltration system. A biofiltration system uses microorganisms immobilized in the form of a biofilm layer on an adsorptive filter substrate such as compost, peat, or soil. As a contaminated vapor stream passes through the filtered bed, pollutants transfer from the vapor to the liquid biolayer and oxidize. More sophisticated enclosed units allow for the control of temperature, bed moisture content, and pH to optimize degradation efficiency. At an economically viable vapor residence time (1 to 1.5 min), biofilters can be used for treating vapor containing about 1500 µg/l of biodegradable VOCs.

**FIG. 5.22.3** Biofilter schematic diagram. (Reprinted, with permission, from A.P. Togna and B.R. Folsom, 1992, Removal of styrene from air using bench-scale biofilter and biotrickling filter reactors, Paper No. 92-116.04, *85th Annual Air & Waste Management Association Meeting and Exhibition, Kansas City, June 21-26.*)

Figure 5.22.4 is a schematic diagram of a biotrickling filter for treating VOCs (Hartman and Tramper 1991). Biotrickling filters are similar to biofilters but contain conventional packing instead of compost and operate with recirculating liquid flowing over the packing. Only the recirculating liquid is initially inoculated with a microorganism, but a biofilm layer establishes itself after start up. The automatic addition of acid or base monitors and controls the pH of the recirculating liquid.

The pH within a biofilter is controlled only by the addition of a solid buffer agent to the packing material at the start of the operation. Once this buffering capacity is exhausted, the filtered bed is removed and replaced with fresh material. For the biodegradation of halogenated contaminants, biofilter bed replacement can be frequent. Therefore, biotrickling filters are more effective than biofilters for the treatment of readily biodegradable halogenated contaminants such as methylene chloride.

Biotrickling filters, possibly because of higher internal biomass concentrations, offer greater performance than biofilters at higher contaminant loadings. At a 0.5-min vapor residence time, the maximum concentration of styrene that can be degraded with 90% efficiency using biotrickling filters is two times greater than what can be degraded using biofilters.

### Applicability and Limitations

Biofiltration has been used for many years for odor control at slaughter houses in Germany, the Netherlands, the United Kingdom, and Japan and to a limited extent in the United States. Recently, many wastewater and sludge treatment facilities have used biofilters for odor control purposes. The use of biofilters to degrade more complex air contaminants from chemical plants has occurred only

within the last few years. Table 5.22.2 lists some chemical process industry CPI applications.

Biotrickling filters are more effective than biofilters for the treatment of readily biodegradable halogenated contaminants such as methylene chloride. Biofiltration can be unsuitable for highly halogenated compounds such as TCE, TCA, and carbon tetrachloride because they degrade slowly aerobically.

The limiting factors of soil-bed treatments are biodegradability of the waste and the permeability and chemistry of the soil. Because these factors vary, the design of soil beds is site-specific. For VIC removal, the lifetime of the bed depends on the soil's capacity to neutralize the acids produced. Any complex mixture with widely

different chemical, physical, and biodegradable properties, such as petroleum hydrocarbon vapors, can require more than one optimized biofilter or biotrickling filter in series.

# Fugitive Emissions: Sources and Controls

## 5.23

### FUGITIVE INDUSTRIAL PARTICULATE EMISSIONS

This section is concerned with the dust generated in processing operations that is not collected through a primary exhaust or control system. Such emissions normally occur within buildings and are discharged to the atmosphere through forced- or natural-draft ventilation systems.

Industrial fugitive emissions contribute more than 50% of the total suspended and inhalable emissions (Cowherd and Kinsey 1986). In addition, these particulates frequently contain toxic or hazardous substances.

#### Sources

Most dry processing operations generate dust. Generation points include the following:

- Dumping of materials
- Filling of materials
- Drying of materials
- Feeding or weighing of materials
- Mechanical conveying of materials
- Mixing or blending of materials
- Pneumatic conveying of materials
- Screening or classifying of materials
- Size reduction of materials
- Bulk storage of materials
- Emptying of bulk bags

Generally, these materials are finely divided products that are easily airborne, resulting in sanitation problems and possibly fire or explosions.

#### Emission Control Options

Fugitive particulates can be controlled by three basic techniques: process modification, preventive measures, and add-on capture and removal equipment.

#### PROCESS MODIFICATION

Changing a process or operation to reduce emissions can be more practical than trying to control the emissions. For example, a pneumatic conveyance system eliminates the

emission problems of a conveyor belt, which can require any or all preventive procedures (i.e., enclosures, wet suppression, housekeeping of spilled materials, and stabilization of materials) and add-on equipment. Another solution is to use new intermediate bulk containers (IBCs), such as shown in Figure 5.23.1.

#### PREVENTIVE MEASURES

Housekeeping provides numerous beneficial results of good operation and maintenance (O&M). Good O&M includes the prevention of process upsets and defective equipment, prompt cleanup of spillage before dust becomes airborne, the partial or complete enclosure or shielding of dust sources.

Water, a water solution of a chemical agent, or a micron-sized foam can be applied to the surface of a partic-

FIG. 5.23.1 Inverted IBCs elevated to the third floor for charging reactors, eliminating worker exposure to hazardous P<sub>2</sub>S<sub>5</sub>. (Reprinted, with permission, from B.O. Paul, 1994, Material handling system designed for 1996 regulations, *Chemical Processing* [July].)

ulate-generating material. This measure prevents (or suppresses) the fine particles contained in the material from leaving the surface and becoming airborne. The chemical agents used in wet suspension can be either surfactants or foaming agents. Figure 5.23.2 shows a suppression system at a crusher discharge point.

The use of foam injection to control dust from material handling and processing operations is a recently developed method to augment wet suppression techniques. The foam is generated by a proprietary surfactant compound added to a small quantity of water, which is then vigorously mixed to produce a small-bubble, high-energy foam in the 100 to 200  $\mu\text{m}$  size range. The foam uses little liquid volume and when applied to the surface of a bulk material, wets the fines more effectively than untreated water does. Foam has been successfully used in controlling the emissions from belt transfer points, crushers, and storage-pile load-ins.

### CAPTURE AND REMOVAL

Most industrial process, fugitive particulate emissions are controlled by capture and collection or industrial ventilation systems. These systems have three primary components:

- A hood or enclosure to capture emissions that escape from the process
- A dry dust collector that separates entrained particulates from the captured gas stream
- A ducting or ventilation system to transport the gas stream from the hood or enclosure to the APCD

Before designing a dust collection system, the environmental engineer must thoroughly understand the process

FIG. 5.23.2 Wet suppression system at a crusher discharge point. (Reprinted from C. Cowherd, Jr. and J.S. Kinsey, 1986, *Identification, assessment, and control of fugitive particulate emissions*, EPA-600/8-86-023, Research Triangle Park, N.C.: U.S. EPA.)

and its operations and the requirements of operating personnel. The engineer must evaluate the materials in the dust in addition to the particle size and define the characteristics of the material including the auto-ignition temperature, explosive limits, and the potential for electrostatic buildup in moving these materials. The engineer must locate the pickup and select the components to be used in the system.

Each operation generates various amounts of dust. The environmental engineer uses the amount of dust, the particle size, and the density of the dust in determining the capture velocity of the dust, which affects the pickup or hood design. Normal capture velocity is a function of particle size and ranges from 6 to 15 ft/sec (Opila 1993). In practice, the closer the hood is to the dust source, the better the collection efficiency is and the less air is needed for the collection process. The engineer should design enclosures and hoods at suitable control velocities to smooth the air flow. Examples of dust collection follow (Kashdan, et al. 1986):

A bag tube packer (see Figure 5.23.3) where displaced air is treated from the feed hopper supplying the packer, from the bag itself, and from the spill hopper below the bagger for any leakage during bag filling

Open-mouth bag filling (see Figure 5.23.4) where the dust pickup hood collects the air displaced from the bag

Barrel or drum filling (see Figure 5.23.5) that uses a dust pickup design with the same contour of the drum being filled. The pickup is designed for a single drum diameter; the design becomes complicated if 15, 30, and 55 gal drums are filled at the same filling station. The height and diameter of these drums vary affecting the capture velocity of the air.

The pickup of dust created when material flows down a chute onto a conveyor belt (see Figure 5.23.6)

The pickup points required for dust-free operation of a flatdeck screen (see Figure 5.23.7)

FIG. 5.23.6 Dust pickup for chute discharging onto a belt conveyor. (Reprinted, with permission, from Opila, 1993.)

A slot-type hood used with a ribbon mixer (see [Figure 5.23.8](#))

Maintaining the conveying velocity throughout the collection system is important. If conveying velocities are too low, saltation (deposition of particles within a duct) occurs until the duct is reduced to a point where conveying velocity is obtained. This material buildup can be trou-

TABLE 5.23.1 MINIMUM AIR VELOCITIES IN DUCTS TO PREVENT DUST SETTLING

Type of Dust	Velocity, ft/min
Low density (gases, vapors, smoke, flour, lint)	2000
Medium-low density (grain, sawdust, plastic, rubber)	3000
Medium-high density (cement, sandblast, grinding)	4000
High-density (metal turnings, lead dust)	5000

## 5.24

### FUGITIVE INDUSTRIAL CHEMICAL EMISSIONS

This section is concerned with unintentional equipment leaks of VOCs from industrial plants. The quantity of these fugitive emissions is hard to measure, but in some cases they account for 70 to 90% of the air emissions from chemical manufacturing operations (U.S. EPA 1984). Many of these emissions contain HAPs.

#### Sources

Fugitive emissions are unintentional releases (leaks) from sources such as valves, pumps, compressors, pressure-relief valves, sampling connection systems, open-ended lines, and flanges as opposed to point-source emissions from stacks, vents, and flares.

Table 5.24.1 compares the fugitive emissions from these sources in terms of source emissions factors and total source contributions of VOCs. A count of all equipment multiplied by the emission factors estimates the total emissions.

Fugitive emissions do not occur as part of normal plant operations but result from the following:

- Malfunctions
- Wear and tear
- Lack of proper maintenance
- Operator error
- Improper equipment specifications
- Improper installation
- Use of inferior technology
- Externally caused damage

Fugitive emissions can be significantly reduced with the adoption of improved technology, maintenance, and operating procedures.

#### Source Controls

Good O&M has a significant influence on lowering the fugitive emissions and includes the following:

- Daily inspection for leaks by plant personnel
- Immediate leak repair
- Installation of gas detectors in strategic plant locations, with sample analysis performed regularly
- Monitoring of vibration in rotating machinery

**TABLE 5.24.1 COMPARISON OF FUGITIVE EMISSIONS FROM EQUIPMENT TYPES**

<i>Equipment Type</i>	<i>Process Fluid</i>	<i>Emission Factor, kg/hr</i>	<i>Percent of Total VOC Fugitive Emissions</i>
Valve	Gas or vapor	0.0056	47
	Light liquid	0.0071	
	Heavy liquid	0.00023	
Pump	Light liquid	0.0494	16
	Heavy liquid	0.0214	
Compressor	—	0.228	4
Pressure-relief valve	Gas or vapor	0.1040	9
Sampling connection	—	0.0150	3

Minimization of pipe and connector stresses caused by the vibration of pumps and compressors  
 Inspection and testing of relief-valves and rupture disks for leaks  
 Reduction in the number and volume of samples collected for control purposes  
 Inspection and periodic replacement of seals and gaskets  
 Because the emission control of equipment-related sources is unit-specific, this section discusses the control techniques by source category.

## VALVES

Except for check and pressure-relief valves, industrial valves need a stem to operate. An inadequately sealed stem is a source of fugitive gas emissions. Valves with emissions greater than 500 ppmv are considered *leakers*. The 500-ppmv-limit threshold can place excessive demands on many low-end valves. Figure 5.24.1 shows the primary maintenance points for a packed, stemmed valve. The cost of keeping these valves in compliance can be expensive over time compared to another valve of greater initial cost.

The following special valves are designed to control fugitive emissions:

Bellows-type stems for both rising stem and quarter-turn valves show almost zero leakage and require no maintenance during their service life (Gumstrup 1992). However, because bellows seals are more costly than packed seals, they are typically used in lethal and hazardous service. Figure 5.24.2 shows a typical design of a bellows-sealed valve.

Diaphragm valves and magnetically actuated, hermetically sealed control valves are two other valves least prone

**FIG. 5.24.1** Primary maintenance points for a valve stem. (Reprinted from U.S. Environmental Protection Agency, 1984, *Fugitive VOC emissions in the synthetic organic chemicals manufacturing industry*, EPA 625/10-84/004, Research Triangle Park, N.C.: U.S. EPA, Office of Air Quality and Standards.)

**FIG. 5.24.2** Typical design of a bellows-sealed valve.

**FIG. 5.24.3** Typical design of diaphragm valves. (Reprinted from U.S. EPA, 1984.)

to leaking. Figure 5.24.3 shows a typical diaphragm valve.

For services not requiring zero leakage on rising and rotary valve stem seals, a new group of improved packed seals is available. Most new seals claim to reduce fugitive emissions to a maximum leakage of less than 100 ppmv (Ritz 1993). Gardner (1991) discusses other types of valves for emission control.

## PUMPS

The failure of a sealant where a moving shaft meets a stationary casting is a source of fugitive gas emissions. Figure

FIG. 5.24.4 Typical design of a packed, sealed pump shaft. (Reprinted from U.S. EPA, 1984.)

5.24.4 shows the possible leak area. Lubricants between the rotating shaft and the stationary packing control the heat generated by friction between the two materials.

The following techniques can hold fugitive emissions to a minimum:

Equipping pumps with double, mechanical seals that have liquid buffer zones and alarms or automatic pump shut-offs for seal failures (see Figure 5.24.5). The effective use of mechanical seals requires closed tolerances. Shaft vibration and misalignment induce radial forces and movement, which can damage both seals and bearings. The primary causes of radial shaft motion include poor alignment of the shaft with the motor connected to the pump, poor baseplate installation, incorrect operating conditions, and loose or failed bearings (Clark and Littlefield 1994). Continuously coating bearings with lubricants keeps the surfaces free of debris.

Using canned-motor pumps (see Figure 5.24.6). These units are closed-couple designs in which the cavity housing the motor rotor and the pump casing are interconnected. As a result, the pump bearings run in the process liquid, and all seals are eliminated.

Adopting diaphragm and magnetic-drive pumps. These two pumps do not require a sealant to control leakage.

Adams (1992) discusses the selection and operation of mechanical seals.

## COMPRESSORS

The standard for compressors requires (1) using mechanical seals equipped with a barrier fluid system and control degassing vents or (2) enclosing the compressor seal area and venting emissions through a closed-vent system to a control device. These systems provide control efficiencies approaching 100% (Colyer and Mayer 1991).

Most concepts to control fugitive emissions from pumps

FIG. 5.24.5 Two arrangements of dual mechanical pump seals. (A) Back-to-back arrangement; (B) tandem arrangement (Reprinted from U.S. EPA, 1984).

apply to compressors. Likewise, analyzing the vibration characteristics anticipates pending problems.

## PRESSURE-RELIEF DEVICES

Figure 5.24.7 shows a pressure-relief valve and rupture device to control fugitive emissions. This device does not allow any emissions until the pressure is large enough to rupture the disk. The pressure-relief valve opens at a set pressure and then reseats when the pressure returns to below the set value.

Reseating the pressure-relief device after a discharge is often a source of a fugitive emission. The source can vary from a single improper reseating to a continuous failure because of a degraded seating element. Like other valves, pressure-relief valves with emissions greater than 500 ppmv above background are considered leakers.

An alternative to rupture disks and other techniques that achieve less than 500 ppmv above background is for plants to vent pressure-relief devices to a closed-vent system connected to a control device.

## SAMPLING CONNECTION SYSTEMS

MACT consists of closed-purge sampling, closed-loop sampling, and closed-vent vacuum systems in the rules for sampling connections. These systems are described as follows:

FIG. 5.24.6 Chempump canned-motor pump.

A closed-purge sampling system eliminates emissions due to purging either by returning the purge material directly to the process or by collecting the purge in a system that is not open to the atmosphere for recycling or disposal.

A closed-loop sampling system also eliminates emissions due to purging by returning process fluid to the process

through an enclosed system that is not directly vented to the atmosphere.

A closed-vent system captures and transports the purged process fluid to a control device.

Figure 5.24.8 shows two such systems.

### OPEN-ENDED LINES

Enclosing the open end of a valve or line with a cap, plug, or a second valve eliminates emissions except when the line is used for draining, venting, or sampling operations. The control efficiency associated with these techniques is approximately 100% (Colyer and Mayer 1991).

### FLANGES AND CONNECTORS

Flanges are significant sources of fugitive emissions, even at well-controlled plants, due to the large number of flanges and connectors. In most cases, tightening the flange bolts on the flanged connectors, replacing a gasket, or correcting faulty alignment of a surface eliminates a leak. The use of all welded construction minimizes the number of flange joints and screwed connections.

Unsafe-to-monitor connectors can expose personnel to imminent hazards from temperature, pressure, or explosive conditions. During safe-to-monitor periods, plant personnel should monitor these connectors, especially the critical ones, as frequently as possible using leak detectors.

### AGITATORS

Limited screening data indicate that agitators are a significant source of emissions. Agitators are technologically similar to pumps so emissions are controlled using seal technology. However, agitators have longer and larger diameter shafts than pumps and produce greater tangential loading. Therefore, the performance of pump seal systems cannot estimate agitator seal performance. A leak from an

FIG. 5.24.7 Pressure-relief valve mounted on a rupture disk device.

agitator is defined as a concentration of 10,000 ppmv or greater.

## 5.25 FUGITIVE DUST

Fugitive dust that deposits large particles on buildings, vehicles, and materials is a nuisance. Inhalation of dust can be debilitating, especially when the dust contains toxic elements and minerals. In addition, fugitive dust reduces visibility.

Fugitive dust consists of geological material suspended into the atmosphere by wind action and by human activities. Most of this dust soon deposits within a short distance of its origin, yet a portion of it can be carried many miles by atmospheric winds.

### Sources

Table 5.25.1 shows the approximate emissions of fugitive dust from manmade sources in the United States for

1990. These estimates are derived from standardized U.S. EPA emission factors that relate soil characteristics, meteorological conditions, and surface activities to emission rates. These estimates do not include all potential emitters (for example, natural dust emissions, such as wind devils, are omitted as are many from industrial activities). Mass emissions are restricted to particles that are less than 10 μm.

### Prevention and Controls

Table 5.25.2 is a partial listing of control techniques for reducing dust emissions from various sources. Table 5.25.3 presents an approximate categorization of control system capabilities. When more than one control technique can be used in series, the combined efficiency is estimated by a series function.

Partially or completely closing off the source from the atmosphere to prevent wind from entraining the dust can effectively reduce emissions. Frequently, confinement plus suppression is an optimum combination for effective, economical dust control.

### WIND CONTROL

Preventing the wind from entraining dust particles is accomplished by keeping the wind from blowing over materials. This prevention involves confinement or wind control. Tarps that cover piles are a wind control procedure for storage piles, truck, railcars, and other sources (see Figure 5.25.1).

A variation of the source enclosure method to control fugitive dust emissions involves applying wind fences (also referred to as windscreens). Porous wind fences significantly reduce emissions from active storage piles and exposed ground areas. The principle of a windscreen is to provide a sheltered region behind the fence line where the mechanical turbulence generated by ambient winds is significantly reduced. The downwind extent of the protected region is many times the physical height of the fence. This sheltered region reduces the wind erosion potential of the exposed surface in addition to allowing gravitational settling of larger particles already airborne. Figure 5.25.2 is a diagram of a portable windscreen used at a coal-fired power plant.

For unpaved routes and ditches, special fabrics placed over exposed surfaces prevent dust from becoming air-

borne from wind or machinery action. These fabrics are referred to as *road carpets*, and alternatively they prevent erosion by rain runoff.

## WET SUPPRESSION

Wet suppression systems apply either water, a water solution of a chemical agent, or a micron-sized foam to the surface of a particulate-generating material. This measure prevents (or suppresses) the fine particles in the material from leaving the surface and becoming airborne.

The chemical agents used in wet suppression systems are either surfactants or foaming agents for materials handling and processing operations or various dust palliatives applied to unpaved roads. In either case, the chemical agent agglomerates and binds the fines to the aggregate surface, thus eliminating or reducing its emission potential.

In agricultural fields, electrostatic foggers provide electrostatically charged water droplets that agglomerate suspended particles, thereby increasing the particle size and deposition velocity.

## VEGETATIVE COVER

Vegetation reduces wind velocity at the surface and binds soil particles to the surfaces. Of course, an area with vegetative cover should not be disturbed after planting (U.S. EPA 1977). Likewise, tilling implements, orientations, and frequencies should aim to limit the suspension of surface dust in agricultural fields.

**TABLE 5.25.5 IMPLEMENTATION ALTERNATIVES FOR CHEMICAL STABILIZATION OF AN UNPAVED ROAD**

<i>Cost Elements</i>	<i>Implementation Alternatives</i>
Purchase and ship chemical	Ship in railcar tanker (11,000–22,000 gal/tanker) Ship in truck tanker (4000–6000 gal/tanker) Ship in drums via truck (55 gal/drum)
Store chemical	Store on plant property In new storage tank In existing storage tank Needs refurbishing Needs no refurbishing In railcar tanker Own railcar Pay demurrage In truck tanker Own truck Pay demurrage In drums
Prepare road	Store in contractor tanks Use plant-owned grader to minimize ruts and low spots Rent contractor grader Perform no road preparation
Mix chemical and water in application truck	Put chemical in spray truck Pump chemical from storage tank or drums into application truck Pour chemical from drums into application truck, generally using forklift
Apply chemical solution via surface spraying	Put water in application truck Pump from river or lake Take from city water line Use plant-owned application truck Rent contractor application truck

## CHEMICAL STABILIZATION

Dust from unpaved roads or uncovered areas can be reduced or prevented by chemical stabilization. Chemical suppressants can be categorized as salts, lignin sulfonates, wetting agents, petroleum derivatives, and special mixtures. Manufacturers generally provide information for typical applications, dilution and application rates, and costs. Table 5.25.4 is a partial list of chemical stabilizers.

Table 5.25.5 lists alternatives for implementing chemical stabilization of an unpaved road.

# Odor Control

## 5.26

### PERCEPTION, EFFECT, AND CHARACTERIZATION

#### Odor Terminology

An odor is a sensation produced by chemical stimulation of the chemoreceptors in the olfactory epithelium in the nose. The chemicals that stimulate the olfactory sense are called *odorants* although people frequently refer to them as *odors*.

Several dimensions of human responses to the odor sensation can be scientifically characterized. These dimensions are threshold, intensity, character, and hedonic tone.

#### THRESHOLD

Threshold, or detectability, refers to the theoretical minimum concentration of odorant stimulus necessary for perception in a specified percentage of the population, usually the mean. A threshold value is not a fixed physiological fact or a physical constant but is a statistical point representing the best estimate from a group of individual scores. Two types of thresholds can be evaluated: detection and recognition.

The *detection threshold* is the lowest concentration of odorant that elicits a sensory response in the olfactory receptors of a specified percentage, usually 50%, of the population being tested (see Figure 5.26.1). The detection threshold is the awareness of an odor without necessarily recognizing it.

The *recognition threshold* is the minimum concentration recognized as having a characteristic odor quality by a specified percentage of the population, usually 50%. It differs from the detection threshold because it is the point at which people can describe a specific odor character to the sensory response.

In the measurement of environmental odors, which are generally complex mixtures of compounds, the threshold is not expressed as a concentration level. Instead, the threshold is expressed as dilution-to-threshold ratios (D/T); it is dimensionless. A D/T ratio of 100 means that a given volume (i.e., 1 cu ft) of odorous air requires 100 volumes (i.e., 100 cu ft) of odor-free air to dilute it to threshold, or a barely detectable odor. This concept is shown in Figure

FIG. 5.26.1 Odor threshold ratio.

5.26.1 where a 50% panel response occurs at 235 D/T for one sample and 344 D/T for the other sample.

Over the years, many terms have been used to express the concentration of odor including the following:

**ODOR UNIT**—one volume of odorous air at the odor threshold; often the volume is defined in terms of cubic feet as follows:

$$\frac{\text{odor units}}{\text{cu ft}} = \frac{\text{volume of sample diluted to threshold (cu ft)}}{\text{original volume of sample (cu ft)}} \quad 5.26(1)$$

**ODORANT QUOTIENT**—Expressed by the following equation. The Z is for Zwaardermaker who was the earliest investigator to use dilution ratios for odor measurement (ASTM 1993).

$$Z_t = \frac{C_o}{C_t} = \frac{\text{odorant concentration of a sample}}{\text{odorant concentration at threshold}} \quad 5.26(2)$$

Both odor units/cu ft and  $Z_t$  are dimensionless and are synonyms of the D/T; the odor unit is a unit of volume and is not a synonym of D/T (ASTM 1993; Turk 1973).

Another term, the *odor emission rate*, is often used to describe the severeness of the downwind impact, i.e., the problem a typical odor source creates at downwind locations. The odor emission rate, expressed in unit volume per minute, is the product of the D/T value of the odorous air and the air flowrate (cfm or its equivalent).

Listings of threshold values for pure chemicals are common in many environmental resource references. However, the reported threshold values are limited and vary as much as several orders of magnitude, suggesting that thresholds are limited in usefulness. However, a review of threshold value methodology finds that when threshold values are subjected to basic methodological scrutiny, the range of experimentally acceptable values is considerably reduced. Two recent documents of odor threshold reference guides are available. One published by the American Industrial Hygiene Association (1989) is based on a review for 183 chemicals with occupational health standards. The other document is published by the U.S. EPA (1992). It compiles odor thresholds for the 189 chemicals listed in the CAAAs.

## INTENSITY

Odor intensity refers to the perceived strength of the odor sensation. Intensity increases as a function of concentration. The relationship of the perceived strength (intensity) and concentration is expressed by Stevens (1961) as a psychophysical power function as follows:

$$S = K I^n \quad 5.26(3)$$

where:

- S = perceived intensity of the odor sensation
- I = physical intensity of stimulus (odorant concentration)
- n = constant
- K = constant

This equation can be expressed in logarithm as follows:

$$\log S = \log K + n \log I \quad 5.26(4)$$

where:

- n = slope
- K = y-intercept

Figure 5.26.2 shows an intensity function on logarithm coordinates of the standard odorant 1-butanol. The slope of the function, also called the *dose-response function*, varies with the type of odorant. Odor pollution control is concerned with the dose-response function, or the degree of dilution necessary to decrease the intensity. This function can be described by the slope. A low slope value indicates that the odor requires greater dilution for it to dissipate; a high slope value indicates that the intensity can be reduced by dilution more quickly. Compounds with low slope values are hydrogen sulfide, butyl acetate, and amines. Compounds with high slope values are ammonia and aldehydes. This function explains why hydrogen sulfide, butyl acetate, and amines can be detected far away from the odor origin. On the other hand, ammonia and aldehydes cause odor problems at locations near the origin.

## Category Scales

Category scales were the first technique developed to measure odor intensity. One widely used scale was developed for a 1930 study of odor used as gas alarms. The scale has the following six simple categories:

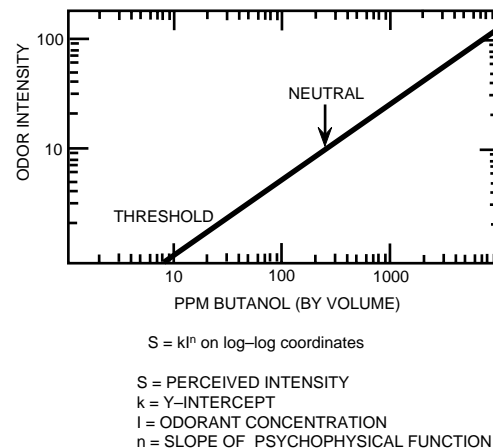

FIG. 5.26.2 Butanol reference scale.

- 0 No odor
- 1 Very faint odor
- 2 Faint odor
- 3 Easily noticeable odor
- 4 Strong odor
- 5 Very strong odor

The limitations of category scaling are that the number of categories to choose from is finite and they are open to bias through subjective number preferences or aversions.

### Magnitude Estimation

In magnitude estimation, observers create their own scales based on a specific reference point. The data from several observers is then normalized to the reference point. Magnitude estimation is a form of ratio scaling and has many advantages over category scaling (i.e., an unlimited range and greater sensitivity); however, it does require a more sophisticated observer and statistical analysis.

### Reference Scales

The reference scale for measuring odor intensity is standardized as ASTM Standard Practice E 544 (ASTM 1988). The method uses a standard reference odorant, 1-butanol, set in a series of known concentrations. The advantages of this method are that it 1) allows the comparison of subjective odor intensities between laboratories, 2) allows for odor control regulations to be expressed in terms of perceived intensity rather than odor thresholds, and 3) allows cross modality comparisons (i.e., sound and odor). One disadvantage is that some people find it difficult to compare odors that have a different odor character than the reference standard.

### CHARACTER

Another dimension of odor is its *character*, or what the odor smells like. ASTM publication DS 61 (Dravnieks 1985) presents character profiles for 180 chemicals using a 146 descriptor scale. The scale uses terms such as fishy, nutty, moldy, rancid, sewer, and ammonia. This dimension is useful in air pollution control for describing the source or process responsible for community odors because different odor characters are associated with various processes and industries. Table 5.26.1 provides a short list of the industrial odor character descriptions.

### HEDONIC TONE

*Hedonic tone*, also referred to as acceptability, is a category judgment of the relative pleasantness or unpleasantness of an odor. In the context of air pollution field work, the hedonic tone is often irrelevant. Perception of an odor is based on the combination of frequency of occurrence, odor character, and odor intensity. Even pleasant odors can become objectionable if they persist long enough.

**TABLE 5.26.1 INDUSTRIAL ODOR DESCRIPTORS**

<i>Odor Character Descriptor</i>	<i>Potential Sources</i>
Nail polish	Painting, varnishing, coating
Fishy	Fish operation, rendering, tanning
Asphalt	Asphalt plant
Plastic	Plastics plant
Damp earth	Sewerage
Garbage	Landfill, resource recovery facility
Weed killer	Pesticide, chemical manufacturer
Gasoline	Refinery
Airplane glue	Chemical manufacturer
Household gas	Gas leak
Rotten egg	Sewerage, refinery
Rotten cabbage	Pulp mill, sewage sludge
Cat urine	Vegetation

### Human Response to Odors and Odor Perception

Olfactory acuity in the population follows a normal bell curve distribution of sensitivity, ranging from hypersensitive to insensitive and anosmic (unable to smell). Individual odor threshold scores can be distributed around the mean value to several orders of magnitude.

Olfactory studies have revealed interesting information regarding odor perception. Two sensory channels are responsible for human detection of inhaled chemical substances in the environment. These are *odor perception* and the *common chemical sense* (CCS). Odor perception is a function of cranial nerve I, whereas the CCS is a function of cranial nerve V. The CCS is described as pungency and associated sensations such as irritation, prickliness, burning, tingling, and stinging. Unlike the olfactory structure, the CCS lacks morphological receptor structures and is not restricted to the nose or oral cavity (Cometto-Muñiz and Cain 1991).

Human responses to odor perception follow patterns associated with both the olfactory and the CCS functions. These are discussed next to facilitate the understanding of what prompts odor complaints and the difficulties associated with odor identification and measurement.

### SENSITIZATION, DESENSITIZATION, AND TOLERANCE OF ODORS

Repeated exposure to an odor can result in either an enhanced reaction described as sensitization or a diminished reaction defined as tolerance. When people become sensitized to an odor, the complaints regarding the odor can increase. On the other hand, tolerance of an odor can attribute to a person's unawareness of the continuous exposure to a potentially harmful substance. As an illustration of the complexity of odor perception, pungency stimulation shows an increased response to odors from a continuous or quickly repetitive stimulus during a short

term exposure. Also, a person can be more sensitive to one odorant than another. Such differences are often caused by repeated exposure to an odor. For example, tolerance is not uncommon for chemists or manufacturers who are exposed to an odorant daily over a period of years. Fatigue also affects odor perception; repeated exposure to an odorant can result in a desensitization to the odorant, where an observer can no longer detect an odor although it is strongly detectable by another.

## ODOR MIXTURES

An additional problem in odor identification is that ambient odors are generally mixtures of compounds in different concentration levels. A comparison of the perceived intensity of two chemicals presented alone at a concentration and the two chemicals in a mixture at the same concentrations usually shows that the perceived intensity of either chemical in the mixture is lower than it is alone. This response is known as hypoaddivitivity. On the other hand, the CCS responses show that the perception of the odor is mainly additive, i.e., equal in the mixture to the perception of either chemical alone (Cometto-Muñiz and Cain 1991).

Questions of safety with chemical mixtures are more successfully answered by experimentally determining the odor threshold of the mixture and then relating it to the chemical composition of the mixture. Some mixtures can contain a highly odorous but relatively nontoxic chemical together with a nonodorous but highly toxic chemical. The chemicals in a mixture can also disassociate through aging or different chemical processes, and the judgment of whether a toxic component is present can be incorrect if it is based solely on the detection of the odorous component. Assumptions about the relationship between odor and risk can only be made for specific cases for chemical mixtures.

## OTHER FACTORS AFFECTING ODOR PERCEPTION

Human response to odor is also based on the community, meteorology, and topography interactions. An odor with an acceptable hedonic tone and low intensity can generate complaints when the odor character is unfamiliar, causing concern with the toxicity. Conversely, some high intensities of hedonically unpleasant odors are tolerated because they are considered socially acceptable. Even pleasant odors, such as perfumes or roasting coffee, are considered objectionable if they persist for a long time or are frequently present.

Demographically, awareness of air pollution problems increases with education, income and occupational level, and age. Some of this awareness is also based on economic factors, such as property values.

## ODOR AND HEALTH EFFECTS

Odors can warn of potentially dangerous materials. The warning property of odor has long been recognized. In the Middle Ages, odors were held responsible for disease, rather than being the result of disease and poor hygiene. Physicians protected themselves by theoretically purifying the air in a sick room with perfumed water. In this century, the property of odor as a warning agent has been used on a worldwide scale through the addition of pungent odorants such as ethyl mercaptan to odorless natural gas. The perceived connection between odors and disease persists. With national attention focused on waste and chemical spills, in the absence of specific information to the contrary, the average person concludes that a bad smell is unhealthy.

The relationship between odor and health effects should be clarified. Many odorants are perceptible at concentrations far below harmful concentration levels. For example, hydrogen sulfide ( $H_2S$ ) has been detected at concentrations as low as 0.15 ppb, whereas the acceptable exposure limit or the threshold limit value–time-weighted average (TLV–TWA) recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) for this compound is 10 ppm, 6 orders of magnitude greater. Thus, the detection of the “rotten egg” character of  $H_2S$  is not necessarily an indicator of a potential health effect. Indeed, at concentrations near the TLV, the odor intensity of  $H_2S$  is unbearable. Similarly, the TLVs for creosol and ethyl acrylate are 4 orders of magnitude greater than their threshold values.

The nose is not a suitable screening device to determine the presence or the absence of a health risk. Although detecting an odor indicates that a chemical exposure has occurred, a more detailed sampling investigation should be conducted.

Studies that have reviewed community odor and health problems reveal that a variety of common ailments are related to chemical exposure. However, in most cases, the identified chemicals were well below the thresholds for toxicity. This evidence suggests that detecting unpleasant odors can cause adverse physiological and neurogenic responses such as nausea, stress, and low concentration levels and that these effects are a result of chemical exposure. Therefore, further studies are necessary to define allowable exposures and how they relate to odor detection.

By definition, chemicals that are hazardous to health are considered toxic whether odorous or not. They are therefore controlled under existing laws such as the Toxic Substances Act and the CAA and their related regulations.

# ODOR CONTROL STRATEGY

---

---

Odor control is similar to any other air pollution control problem. Choosing a new material with less odor potential, changing the process, using an add-on pollution control system such as a scrubber or an afterburner, or raising the stack height all achieve community odor control. However, since odor is a community perception problem, the control strategies must be more flexible. When the tolerance level of a community changes, the odor control requirements also change. In addition, unique local topography and weather mean that each odor control problem usually requires its own study. An adopted control strategy for a similar problem at another place may not be suitable under different circumstances.

As far as control strategy is concerned, eliminating the odor-causing source is always better than using add-on control equipment because the equipment can become an odor source itself. For example, when a fume incinerator controls solvent odor, the incinerator, if not properly operated, can produce incomplete combustion by-products with a more offensive odor and lower odor threshold than the original odor. When multiple sources are involved, the control effort should be targeted to sources with higher odor emission rates, lower slopes of the dose-response function, and unpleasant odor characters.

Odor control techniques fall into the following categories:

- Activated carbon adsorption
- Adsorption with chemical reaction
- Biofiltration
- Wet scrubbing
- Combustion
- Dispersion

This section discusses the advantages and disadvantages of each technique. The details of each approach to pollution abatement are covered in other sections of this handbook.

## Activated Carbon Adsorption

Activated carbon adsorption is a viable method in many odor control problems. Due to the nonpolar nature of its surface, activated carbon is effective in adsorbing organic and some inorganic materials. In general, organics having molecular weights over 45 and boiling points over 0°C are readily adsorbed.

The service life of activated carbon is limited by its capacity and the contaminating load. Therefore, provisions must be made for periodic renewal of the activated carbon. The renewal frequency is determined on the basis of performance deterioration (breakthrough) or according to a time schedule based on previous history or calculations of expected saturation. The exhausted carbon bed can be discarded or reactivated. Reactivation involves passing superheated steam through the carbon bed until sufficient material is desorbed. Recondensation of the material can recover it for reuse. This process is most suitable when only single compounds are involved. (Turk 1977).

## Adsorption with Chemical Reaction

Impregnating filter media such as granular activated carbon or activated alumina with a reactive chemical or a catalyst can convert the adsorbed contaminants to less odorous compounds. For example, an air filter medium consisting of activated alumina and potassium permanganate can remove odorous hydrogen sulfide, mercaptans, and other sulfur contaminants. Another approach, patented by Turk and Brassey, can remove hydrogen sulfide from oxygen containing gas. The process involves adding ammonia to the air stream containing hydrogen sulfide prior to its passage through activated carbon. The ammonia catalyzes the oxidation of hydrogen sulfide to elemental sulfur. Impregnating activated carbon with sodium or potassium hydroxide can also neutralize hy-

drogen sulfide and form elemental sulfur. Both the ammonia/granular activated carbon system and the caustic/granular activated carbon system perform better than unimpregnated carbon.

## Biofiltration

Biofiltration is an odor control technology that uses a biologically active filter bed to treat odorous chemical compounds. Materials such as soil, leaf compost, peat, and wood chips can be used for the filter bed. The filter bed provides an environment for microorganisms to degrade and ultimately remove the odorous chemical compounds.

Ideal operating requirements for a filter bed include high adsorption capacity, low pressure drop, high void fraction, high nutrient content, neutral to slightly alkaline pH, moderate temperatures, and adequate moisture content. Hydrogen sulfide, ammonia, and most organic components can be broken down in a biological filter, while most inorganic components cannot.

## Wet Scrubbing

Wet scrubbing is another widely used technology for odor control. Most wet scrubbers for odor control employ reactive chemicals. Reactive scrubbing involves the removal of odorous materials by neutralization, oxidation, or other chemical reactions. Odor removal by any liquid-gas process is a function of the solubility of the chemical compound in the liquid phase, the total effective gas-liquid contact area, the concentration of the odorous chemical compound in the gas stream, and the residence time of the gas stream in the scrubber.

Atomized mist scrubbers and packed scrubbers are both capable of providing large gas-liquid contact areas for gas absorption. In a mist scrubber, pneumatic nozzles use a high-velocity compressed air stream to atomize a chemical solution into 5- to 20- $\mu\text{m}$ -diameter drops, providing a

large contact area. Unlike packed scrubbers, mist scrubbers do not clog even if the gas stream contains large particles. In a packed scrubber system, the chemical solution is often recirculated. As a result, the water and chemical consumption is significantly reduced.

For more complex odor problems caused by a mixture of odorants, multiple stages of scrubbers utilizing different chemicals in each stage are often used. Figure 5.27.1 shows a multiple-stage scrubber installed to control odorous emissions from a wastewater sludge treatment facility. The system uses sulfuric acid in the first-stage, cocurrent, coarse-packing, packed-tower scrubber to remove ammonia and particulates; a caustic/hypochlorite solution in the second-stage, cocurrent, horizontal-mist scrubber to remove or reduce sulfur compounds and VOCs; and a weak caustic solution in the third-stage, cross-flow, packed-bed scrubber to remove the remaining odorants, especially those chlorine compounds generated in the second-stage scrubber. The control system also uses a 50-ft-tall stack to enhance the dilution of the remaining odorants during plume dispersion (Ponte and Aiello 1993).

## Combustion

Combustion is an effective technique for odor control. The odor control efficiency of a combustion system depends largely on the level of complete combustion. Incomplete combustion can actually increase an odor problem by forming more odorous chemical compounds. Three major factors influence the design principles for odor emission control: temperature, residence time, and mixing. All three factors are interrelated to each other, and variation in one can cause changes in the others. Generally, temperatures of 1200 to 1400°F and residence times of 0.3 to 0.5 sec with good mixing conditions effectively destroy the odorous chemical compounds in a combustion chamber. If moisture and corrosion are not of concern, facilities often use the boiler onsite for odorant destruction.

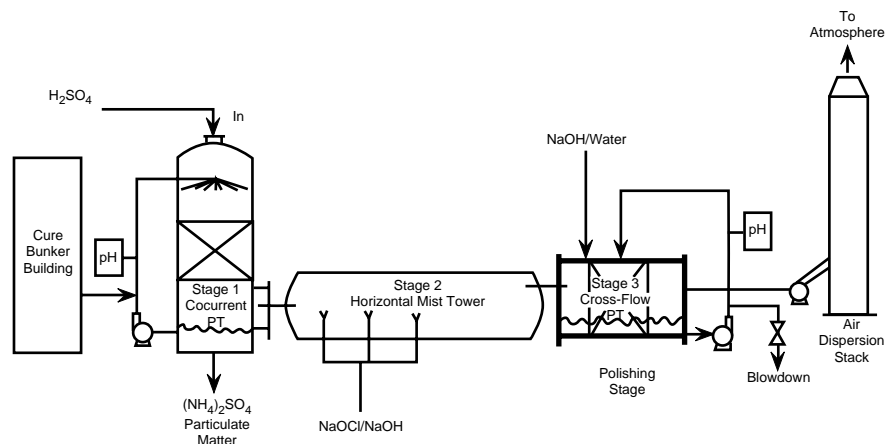

FIG. 5.27.1 Multiple-stage scrubber system schematic diagram.

FIG. 5.27.2 Wake effect and stack height.

## Dispersion

The use of elevated emission points can reduce the odorant concentration at downwind ground level because of dispersion or dilution. As shown in Figure 5.27.2, aerodynamic building wake effects often downwash emissions from rooftop sources. When the stack height is increased, emissions avoid the building wake, disperse at a higher level, and are diluted during transport before reaching the ground.

# Indoor Air Pollution

## 5.28 RADON AND OTHER POLLUTANTS

### PARTIAL LIST OF SUPPLIERS

Aircheck; Amersham Corporation; Electro-Mechanical Concepts, Inc.; Health Physics Associates, Ltd.; R.A.D. Service and Instruments Ltd.; Radon Inspection Service; Radon Testing Corporation of America; Ross Systems, Inc.; Scientific Analysis, Inc.; Teledyne Isotopes, Inc.; Terradex Corp.; University of Pittsburgh.

Growing scientific evidence indicates that the air within homes and other buildings can be more seriously polluted than outdoor air even in the largest and the most industrialized cities. For many people who spend 90% of their time indoors that indoor pollution can be unhealthy.

This section describes the source and effects of radon and other indoor pollutants and discusses techniques to improve the quality of indoor air.

### Radon

This section is concerned with radon including its source and effects and control techniques.

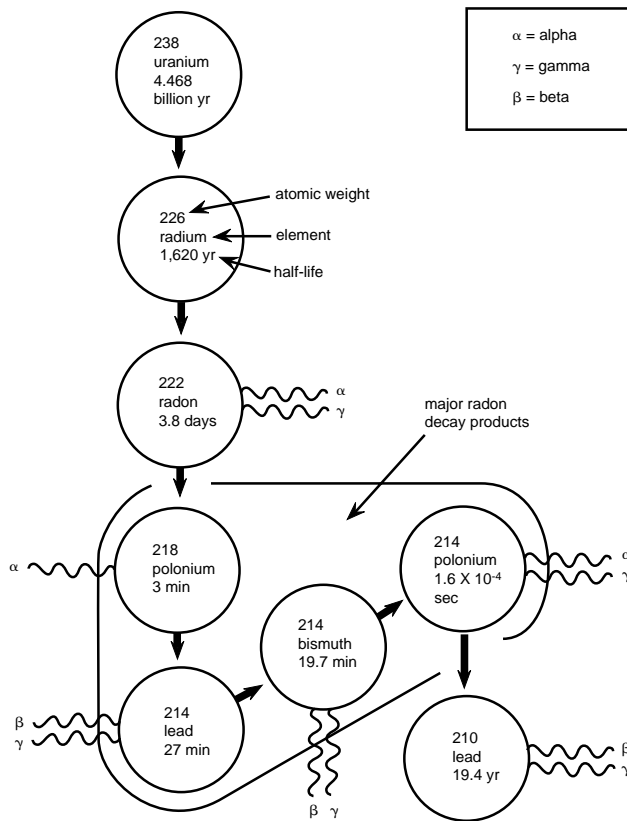

### SOURCE AND EFFECTS

Radon gas is produced by the decay of naturally occurring uranium found in almost all soils and rocks. Figure 5.28.1 shows the decay chain that transforms uranium into radon and its progeny. Radon is also found in soils contaminated with certain types of industrial waste, such as the by-products of uranium mining. Phosphate rock is a source of radon because deposits of phosphate often contain high levels of uranium, approximately 50 to 150 ppm.

A significant amount of radon is present in wells and soil in many parts of this country. Radon is commonly associated with granite bedrock and is also present in the natural gas and coal deposits in this rock. In its natural state, radon rises through airspace in the soil and enters a house through its basement, is released from agitated or boiled water, or escapes during natural gas use.

The most common pathways through which radon gas seeps in from the soil include cracks in concrete floors and walls, drain pipes, floor drains, sumps, and cracks or pores

**FIG. 5.28.1** Radium decay chart. About halfway through its decay sequence, uranium becomes a gas, radon, which as it disintegrates gives off radioactive particles of polonium, bismuth, and lead. Also noted is the half-life of each material—the time required for half of its radioactivity to dissipate.

in hollow block walls. Radon is drawn in by reduced air pressure, which results when the interior pressure drops below the pressure in the ground. This pressure drop is commonly caused by a warmer indoor climate; kitchen or attic exhaust fans; or consumption of interior air by furnaces, clothes dryers, or other appliances.

Radon is a colorless, odorless, almost chemically inert, radioactive gas. It is soluble in cold water, and its solubility decreases with increasing temperature. This characteristic of radon causes it to be released during water-related activities, such as taking showers, flushing toilets, and general cleaning.

Scientists and health officials express fears that the reduced infiltration of fresh air from the outside to increase energy efficiency is eliminating the escape route for radon and making a bad indoor pollution problem worse. Other factors to consider include the inflow rate of radon which depends on the strength of the radon source beneath the house and the permeability of the soil.

Since radon is naturally radioactive, it is unstable, giving off radiation as it decays. The radon decay products, radon progeny, or radon daughters, which are formed, cling to dust. If inhaled, the dust can become trapped in the lung's sensitive airways. As the decay products break down further, more radiation is released which can dam-

age lung tissue and lead to lung cancer after a period of ten to thirty years. Outside, radon dissipates quickly. However, in an enclosed space, such as a house, it can accumulate and cause lung cancer. Scientists believe that smoking increases any cancer risk from radon.

Figure 5.28.2 shows how the lung cancer risks of radon exposure compare to other causes of the disease. Scientists at the U.S. EPA estimate that if 100 individuals are exposed to a level of 4 picocuries per liter (pCi/l) over seventy years, between one and five of them will contract lung cancer. If these same individuals live in houses with levels of 200 pCi/l for only ten years, the number of anticipated lung cancer deaths would rise to between four and forty-two out of 100.

### Working Levels (WL) and pCi/l

By definition, a curie is the decay rate of one gram of radium—37 billion decays per sec. Radioactivity in the environment is usually measured in trillionth of a curie or a picocurie (pCi). With a concentration of 1 pCi/l of air,

**FIG. 5.28.2** Radon risk evaluation chart. This chart shows how the lung cancer risks of radon exposure compare to other causes of the disease. For example, breathing 20 pCi/l poses about the same lung cancer risk as smoking two packs of cigarettes a day. (Reprinted from U.S. Environmental Protection Agency.)

about 2 alpha particles are emitted per minute from radon atoms in each liter of air.

Another unit, the WL derived from mine regulations, is sometimes used. Actually, the WL is a measure of the concentration of radon daughters rather than of radon itself. Approximately, 1 pCi/l of radon gas is equivalent to 0.005 WL, or 1 WL is equivalent to about 200 pCi/l of radon gas.

## RADON DETECTION

The two most common radon testing devices are the charcoal canister and the alpha-check detector. Alpha-check detectors are ideal for making long-term measurements but are not suited for quick results (Lafavore 1987). A charcoal-adsorbent detector is the most practical approach for most. This test method is low-cost; the price for a single unit ranges from \$10 to 50 (Cohen 1987). However, a disadvantage of charcoal is its sensitivity to temperature and humidity.

Charcoal-adsorbent detectors consist of granules of activated charcoal that adsorb gases (including radon) to which they are exposed. When the charcoal is exposed long enough to become saturated, the canister is resealed and shipped back to a laboratory where the radioactivity is measured. The laboratory calculates the level of radon to which the device was exposed.

Ideally, testing should be done in the late fall or early spring when the house is closed and the heating system is not turned on. Less natural ventilation does not dilute the radon concentrations at these times. The next best times

are during winter months. Detectors that measure for three days or less require a closed-house procedure to start at least twelve hours before the test.

The detector should be placed in the lowest finished space in a spot where it is not disturbed. If the house has a basement, it should be placed there. The detector should be kept away from any sources of air movement, such as fire places and heating vents. To avoid the diluting effect of floor drafts, the tester should place the detector at least 20 in above the floor. The recommended exposure time for a radon detector is one to seven days.

The EPA recommends 4 pCi/l as the maximum acceptable indoor radon level. When the radon levels in a home range between 4 and 20 pCi/l, homeowners should take actions to reduce the air level within one to two years. If the level is between 20 and 200 pCi/l, action should be taken within several months. A reading above 200 pCi should be promptly reported and confirmed by the state department of environmental protection or department of public health.

## RADON CONTROL TECHNIQUES

Techniques to control radon in residence can be broadly classified as follows:

- Source removal (new construction considerations)
- Source control
- Sealing major radon source
- Sealing radon entry routes (see Figure 5.28.3)
- Subslab ventilation (Figure 5.28.4)

Key to Major Radon Entry Routes

### Soil Gas

- A Cracks in concrete slab
- B Cracks between poured concrete (slab) and blocks
- C Pores and cracks in concrete blocks
- D Slab-footing joints
- E Exposed soil, as in sump
- F Weeping tile
- G Mortar joints
- H Loose-fitting pipes

### Building Materials

- I Granite

### Water

- J Water

**FIG. 5.28.3** Major radon entry routes into detached houses (Reprinted from U.S. Environmental Protection Agency (EPA), 1986, *Reduction techniques for detached houses*, EPA 625/5-86/019, Research Triangle Park, N.C.: U.S. EPA.)

**FIG. 5.28.4** Individual pipe variation of subslab ventilation. (Reprinted from U.S. EPA, 1986.)

**FIG. 5.28.6** Two variations of wall ventilation: the baseboard method and the single-point pipe method.

- Drain-tile soil ventilation (Figure 5.28.5)
- Active ventilation of hollow block basement walls (see Figure 5.28.6)
- Avoidance of house depressurization
- Ventilation of indoor radon concentration
- Natural circulation
- Forced-air ventilation
- Heat recovery ventilation

However, the effectiveness of indoor air ventilation decreases with increased ventilation rates. Also, the radon source concentration and radon entry rate can reach a fi-

nite level where high ventilation rates are not productive (see Figure 5.28.7).

Table 5.28.1 summarizes the methods of reducing the radon level in a residence. No two houses have identical radon problems. Therefore, a routine method for reducing radon levels does not exist. Most homes usually require more than one of the nine methods listed to significantly reduce their radon levels. Before deciding on an approach, a homeowner should consider the unique characteristics of the house and consult a contractor specializing in the remediation of radon problems.

**FIG. 5.28.5** Drain-tile soil ventilation system draining to remote discharge area.

**FIG. 5.28.7** Effect of ventilation on indoor radon concentrations.

**TABLE 5.28.1 SUMMARY OF RADON REDUCTION TECHNIQUES**

<i>Method</i>	<i>Principle of Operation</i>	<i>House Types Applicable</i>	<i>Estimated Annual Average Concentration Reduction, %</i>	<i>Confidence in Effectiveness</i>	<i>Operating Conditions and Applicability</i>	<i>Estimated Installation and Annual Operating Costs</i>
Natural ventilation	Exchanges air causing replacement and dilution of indoor air with outdoor air by uniformly opening windows and vents	All <sup>a</sup>	90 <sup>b</sup>	Moderate	Opening windows and air vents uniformly around house  Air exchange rates up to 2 air changes per hour (ACH) attainable  Can require energy and comfort penalties and loss of living space use	No installation cost  Operating costs for additional heating range up to 3.4-fold increase from normal (0.25 ACH) ventilation conditions.
Forced-air ventilation	Exchanges air causing replacement and dilution of indoor air with outdoor air by fans located in windows or vent openings	All	90 <sup>b</sup>	Moderate	Continuous operation of a central fan with fresh air makeup, window fans, or local exhaust fans  Forced air ventilation used to increase air exchange rates to 2 ACH  Can require energy and comfort penalties and loss of living space use	Installation costs range up to \$150.  Operating costs range up to \$100 for fan energy and up to 3.4-fold increase in normal (0.25 ACH) heating energy costs <sup>c</sup> .
Forced-air ventilation with heat recovery	Exchanges air causing replacement and dilution of indoor air with outdoor air by a fan-powered ventilation system	All	90 <sup>b</sup>	Moderate to high	Continuous operation of units rated at 25–240 cfm  Air exchange increase from 0.25 to 2 ACH  In cold climates, recovery up to 70% of heat that would be lost through house ventilation without heat recovery	Installation costs range from \$400 to 1500 for 25–240-cfm units.  Operating costs range up to \$100 for fan energy plus up to 1.4-fold increase in heating costs assuming a 70% efficient heat recovery <sup>c</sup> .
Active avoidance of house depressurization	Provides clean makeup air to household appliances which exhaust or consume indoor air	All	0–10 <sup>e</sup>	Moderate <sup>f</sup>	Providing outside makeup air to appliances such as furnaces, fireplaces, clothes dryers, and room exhaust fans	Installation costs of small dampened ductwork are minimal.  Operating benefits can result from using outdoor air for combustion sources.
Sealing major radon sources	Uses gas-proof barriers to close off and exhaust or ventilate sources of soil-gas-borne radon	All	Local exhaust of the source can produce significant house-wide reductions.	Extremely case-specific	Sealing areas of major soil-gas entry such as cold rooms, exposed earth, sumps, or basement drains and ventilating by exhausting collected air to the outside	Most jobs are accomplished for less than \$100.  Operating costs for a small fan are minimal.

*Continued on next page*

**TABLE 5.28.1** *Continued*

<i>Method</i>	<i>Principle of Operation</i>	<i>House Types Applicable</i>	<i>Estimated Annual Average Concentration Reduction, %</i>	<i>Confidence in Effectiveness</i>	<i>Operating Conditions and Applicability</i>	<i>Estimated Installation and Annual Operating Costs</i>
Sealing radon entry routes	Uses gas-proof sealants to prevent soil-gas-borne radon-entry	All	30–90	Extremely case-specific	Sealing all noticeable interior cracks, cold joints, openings around services, and pores in basement walls and floors with appropriate materials	Installation costs range between \$300 and 500.
Drain-tile soil ventilation	Continuously collects dilutes and exhausts soil-gas-borne radon from the footing perimeter of houses	BB <sup>a</sup> PCB <sup>a</sup> S <sup>a</sup>	Up to 98	Moderate <sup>g</sup>	Continuous collection of soil-gas-borne radon using a 160-cm fan to exhaust a perimeter drain tile  Applicable to houses with a complete perimeter, footing level, drain tile system and with no interior block walls resting on subslab footings	Installation cost is \$1200 by contractor.  Operating costs are \$15 for fan energy and up to \$125 for supplemental heating.
Active ventilation of hollow-block basement walls	Continuously collects, dilutes, and exhausts soil-gas-borne radon from hollow-block basement walls	BB <sup>a</sup>	Up to 99+	Moderate to high	Continuous collection of soil-gas-borne radon using one 250-cm fan to exhaust all hollow-block perimeter basement walls  Baseboard wall collection and exhaust system used in houses with French (channel) drains	Installation costs for a single, suction-and-exhaust-point system is \$2500 (contractor-installed in unfinished basement). Installation cost for a baseboard wall collection system is \$5000 (contractor-installed in unfinished basement). Operating costs are \$15 for fan energy and up to \$125 for supplemental heating.
Subslab soil ventilation	Continuously collects and exhausts soil-gas-borne radon from the aggregate or soil under the concrete slab	BB <sup>a</sup> PCB <sup>a</sup> S <sup>a</sup>	80–90, as high as 99 in some cases	Moderate to high	Continuous collection of soil-gas-borne radon using one fan (~100 cfm, ≥0.4 in H <sub>2</sub> O suction) to exhaust aggregate or soil under slab  For individual suction point approach, roughly one suction point per 500 sq ft of slab area  Alternate approach of piping network under slab, permitting adequate ventilation without a power-driven fan	Installation cost for individual suction point approach is about \$2000 (contractor installed).  Installation costs for retrofit subslab piping network are over \$5000 (contractor installed). Operating costs are \$15 for fan energy (if used) and up to \$125 for supplemental heating.

## Other Indoor Pollutants

This section discusses the source and effects and control techniques for other indoor pollutants.

### SOURCE AND EFFECTS

Other indoor pollutants include asbestos, bioaerosols, carbon dioxide and carbon monoxide, formaldehyde, nitrogen oxides, ozone, inhalable particulates, and VOCs.

#### Asbestos

Asbestos is a silicate mineral fiber that is flexible, durable, and incombustible and makes good electrical and thermal isolators. It has been used as insulation for heating, water, and sewage pipes; sound absorption and fireproofing materials; roof, siding, and floor tiles; corrugated paper; caulking; putty; and spackle. In short, asbestos was used extensively in all types of construction until about 1960. Once released from its binding material (by erosion, vibration, renovation, or cleaning) the fibers can remain airborne for long periods.

#### Bioaerosols

Biological contaminants include animal dander, cat saliva, human skin scales, insect excreta, food remnants, bacteria, viruses, mold, mildew, mites, and pollen. The sources of these contaminants include outdoor plants and trees, people, and animals. Pollens are seasonal; fungal spores and molds are prevalent at high temperatures. A central air-handling system can distribute these contaminants throughout a building.

#### Carbon Dioxide and Carbon Monoxide

Carbon monoxide, a colorless, odorless, toxic gas formed by the incomplete combustion of fossil fuels, is the most prevalent and dangerous indoor pollutant. It results from poorly ventilated kitchens, rooms over garages, and unvented combustion appliances (stoves, ovens, heaters, and the presence of tobacco smoke).

#### Formaldehyde

Formaldehyde, the simplest of aldehydes, is a colorless gas that is emitted from various building materials, household products, or combustion processes. Indoor sources include pressed-wood products, including particle board, paneling, fiberboard, and wallboard; textiles, such as carpet backings, drapes and upholstery fabrics, linens, and clothing; urea-formaldehyde foam insulation; adhesives; paints; coatings; and carpet shampoos.

Minimal outgassing by each product can significantly increase the formaldehyde level when the ventilation rate

is low. Hot and humid conditions usually cause formaldehyde to outgas at a greater rate. Product aging diminishes its emission rate although in some cases, this process can take several years.

#### Nitrogen Oxides

Nitrogen oxides are combustion by-products produced by the burning of natural gas or oil in oxygen-rich environments such as kitchen stoves and ovens, furnaces, and unvented gas and kerosene heaters. When a fireplace or wood stove is used, some of these pollutants enter the room. Cracks in the stovepipe, downdrafts, or wood spillage from a fireplace can exacerbate the condition. Coal burning adds sulfur dioxide to the nitrogen oxides.

#### Ozone

Ozone is recognizable by its strong, pungent odor. Indoors, significant ozone can be produced by electrostatic copying machines, mercury-enhanced light bulbs, and electrostatic air cleaners. Poorly ventilated offices and rooms housing photocopying machines can accumulate significant levels of ozone.

#### Inhalable Particulates

Particulates are not a single type of pollutant; they describe the physical state of many pollutants—that is, all suspended solid or liquid particles less than a few hundred  $\mu\text{m}$  in size. Among the pollutants that appear as particulates are asbestos and other fibrous building materials, radon progeny, smoke, organic compounds, infectious agents, and heavy metals, such as cadmium in cigarette smoke.

Because of the diversity of particulates and their chemical nature, considering the adverse health effects of this category as a whole is not possible.

#### VOCs

VOCs are chemicals that vaporize readily at room temperature. High levels of organic chemicals in homes are attributed to aerosols, cleaners, polishes, varnishes, paints, pressed-wood products, pesticides, and others.

### CONTROL TECHNIQUES

The basic control techniques to improve the quality of indoor air are source removal, ventilation, isolation, and air cleaners.

#### Source Removal

This technique involves removing or modifying the source of pollution and replacing it with a low-pollution substi-

tute. Asbestos pipe insulation should be encased securely or replaced by nonasbestos pipe insulation if possible. Limiting the use of formaldehyde insulation, particle boards, carpets, fabric, or furniture containing formaldehyde can limit exposure to formaldehyde. Replacing kerosene and gas space heaters with electric space heaters can eliminate exposure to carbon dioxide, carbon monoxide, and nitrogen oxide. Biological contaminants and VOCs can be controlled by source removal.

## Ventilation

Increasing ventilation can remove the offending pollutants, such as VOCs, and dilute the remaining pollution to a safer concentration. For example, gas stoves can be fitted with range hoods and exhaust fans that draw the air and effluent in over the cooking surface and blow carbon dioxide, carbon monoxide, and nitrogen oxides outdoors. However, range hoods that use charcoal filters to clean the air and then revent it to the room are ineffective in controlling carbon dioxide, carbon monoxide, and nitrogen oxides. One solution is to open a window near the stove and fit it with a fan to blow out the pollutants.

Forced ventilation with window fans works the same as natural ventilation but insures a steadier and more reliable ventilation rate. Figure 5.28.8 shows heat exchangers that are the basis of a heat-recovery ventilation system.

One way to measure the success of a ventilation system is to use a monitor that detects carbon dioxide (a gas that causes drowsiness in excess amounts). If carbon dioxide levels are high, other pollutants are also likely to be present in excessive amounts. Monitors are available that trigger a ventilation system to bring in more fresh air when needed (Soviero 1992).

## Isolation

Isolating certain sources of pollution and preventing their emissions from entering the indoor environment is best. Formaldehyde outgassing from urea-formaldehyde foam insulation can also be partially controlled by vapor barriers; wallpaper or low-permeability paint applied to interior walls; and plywood coated with shellac, varnish, polymeric coatings, or other low-diffusion barriers. These barriers contain the formaldehyde outgasses, which are seemingly reabsorbed by their source rather than released into the home.

## Air Cleaners

The air cleaners for residential purposes are based on filtration, adsorption, and electrostatic precipitation as follows:

Filters made of charcoal, glass fibers, and synthetic materials are used to remove particles. Pollen or lint, which are relatively large particles, are easily trapped by most

**FIG. 5.28.8** Heat exchangers for heat-recovery ventilator. A heat-exchange element is the basis of a heat-recovery ventilator. Fresh outdoor air (1) is warmed as it passes through the exchanger and enters the house (2). Stale indoor air (3) leaving the house is cooled as it transfers heat to the exchanger and is vented outside (4). In the fixed-plate type, heat is transferred through plastic, metal, or paper partitions. The turning wheel of the rotary type picks up heat as it passes through the warm air path and surrenders heat to the cold air stream half a rotation later. Liquid refrigerant in the pipes of the heat-pipe type evaporates at the warm end and condenses at the cold end, transferring heat to the cold air.

filters. High-efficiency particulate air (HEPA) filters can remove particles larger than  $0.3 \mu\text{m}$ , which include bacteria and spores, but not viruses. Whereas filters trap larger particles, adsorbents react with the molecules. Three common adsorbents are activated charcoal, activated alumina, and silica gel. Adsorbents remove gases, such as formaldehyde, and ammonia.

**FIG. 5.28.9** Two-step precipitator.

Electrostatic air cleaners work by charging airborne particles with either a negative or positive electric charge. These charged particles gravitate to oppositely charged, special collector plates within the air cleaner. The technique is effective against dust, smoke particles, and some allergens. Figure 5.28.9 shows the operation principles of a two-step precipitator.

The National Aeronautics and Space Administration (NASA) studies have long indicated another simpler way to handle pollutants: household plants which absorb some toxins. The spider plant and philodendron, for example,

remove formaldehyde and carbon dioxide from indoor air (Soviero 1992).

---

### PARTIAL LIST OF SUPPLIERS

Altech; American Gas & Chemical Ltd; Bacharach Inc.; CEA Instruments Inc.; Coleman & Palmer Instrument Co.; Du Pont; Enmet Analytical Corp.; Gas Tech Inc.; Gilian; Lab Safety Supply; MDA Scientific Inc.; 3 M; National Draeger Inc.; Sensidyne Inc.; Sierra Monitor Inc.

OSHA requires employers to provide a safe and healthy working environment for employees. Of greatest concern are gases and vapors in the extremely toxic category, having TLV, permissible exposure limit (PEL), short-term exposure limit (STEL), or TLV-C values of 10 ppm or less. These standards are usually developed by the National Institute of Occupational Safety and Health (NIOSH).

This section focuses on exposure limits, continuous dosage sensors, and the material safety data sheet (MSDS), which contains standardized information about the properties and hazards of toxic substances.

## Exposure Limits

Table 5.29.1 lists some commonly occurring toxic components. The OSHA limits for many industrial chemicals are in 29 CFR 1910.1000 (OSHA 1989).

The NIOSH uses the following terms to describe exposure limits:

**ACTION LEVEL**—The exposure concentration at which certain provisions of the NIOSH-recommended standard must be initiated, such as periodic measurements of worker exposure, training of workers, and medical surveillance.

**CA**—A substance that NIOSH recommends be treated as a potential human carcinogen.

**CEILING**—A description usually used with a published exposure limit that refers to a concentration that should not be exceeded, even for an instant.

**IMMEDIATELY DANGEROUS TO LIFE OR HEALTH (IDLH)**—A level defined for respiratory protection that represents the maximum concentration from which, in the event of respiratory failure, a person can escape within 30 min without experiencing any impairing or irreversible health effects.

**PEL**—An exposure limit published and enforced by OSHA as a legal standard.

**RECOMMENDED EXPOSURE LIMIT (REL)**—The exposure recommended by NIOSH not to be exceeded.

**STEL**—The maximum concentration to which workers can be exposed for 15 min four times throughout the day with at least 1 hr between exposures.

**TWA**—The average time, over a work period, of a person's exposure to a chemical or agent determined by sampling for the contaminant throughout the time period.

## Occupational Exposure Monitoring

Table 5.29.2 lists selected workplace safety and health hazard standards. Monitoring can be accomplished through the use of color change badges, color detector tubes, and other monitoring techniques.

### COLOR CHANGE BADGES

Breathing zone monitoring can be performed via a small media (monitor) fastened to the worker's collar or lapel for periods of time corresponding to the STEL and TWA

**TABLE 5.29.1 TOXIC GASES AND VAPORS (10 PPM AND BELOW)**

<i>Name of Element or Compound</i>	<i>TLV-TWA, ppm</i>	<i>STEL, ppm</i>	<i>TLV-C, ppm</i>	<i>Human Carcinogenity Status</i>

<sup>b</sup>OSHA permissible exposure levels.

ing. The testor simply opens the detector tube, inserts it into the tube holder, and pulls a predetermined amount of sample air through the CDT. The color progression on the packed adsorption bed indicates the concentration of a particular toxic gas. Disposable CDTs are inexpensive, and some 250 different tubes are available. Table 5.29.4 lists some of the available tubes.

### OTHER MONITORING TECHNIQUES

Membrane filters with air sampling pumps monitor nuisance dust, lead silica, zinc, mineral oil, mist, and more.

The following activities are recommended for an employee exposure control program:

- Assign workers the correct monitors to determine their exposure level.
- Take enough samples to get an accurate, representative sampling.
- Evaluate the results to determine compliance with current OSHA standards.
- If the results show overexposure, determine the cause, and adjust the process and procedures of the task involved.
- If no overexposure is found, a decision should be made on the frequency of routine monitoring.
- Employees should be monitored for possible new exposures any time the process or procedure changes.
- Document all results.

**TABLE 5.29.4 FEATURES AND CAPABILITIES OF COLOR-CHANGING DOSIMETER TUBES**

<i>Description</i>	<i>Measuring Range (ppm)</i>	<i>Typical Applications</i>	<i>Shelf Life (yr)</i>
Ammonia (NH <sub>3</sub> )	50 to 900	Process control	3
Ammonia (NH <sub>3</sub> )	10 to 260	Industrial hygiene, leak detection	3
Benzene (C <sub>6</sub> H <sub>6</sub> )	5 to 200	Industrial hygiene	1
Carbon dioxide (CO <sub>2</sub> )	0.05 to 1.0%	Air contamination, concentration control	2
Carbon monoxide (CO)	10 to 250	Blast furnace, garage, combustion	1
Hydrogen sulfide (H <sub>2</sub> S)	100 to 2000	Industrial raw gases, metallurgy	3
Hydrogen sulfide (H <sub>2</sub> S)	3 to 150	Metal or oil refinery, chemical lab	3

## MSDSs

A major area that OSHA regulations address is the Hazard Communication Standard. The overall goal of the standard is to implement risk management and safety programs by regulated employers. According to the standard, employers must instruct employees on the nature and effects of the toxic substances with which they work, either in written form or in training programs. The instruction must include the following:

- The chemical and common name of the substance
- The location of the substance in the workplace
- Proper and safe handling practices
- First aid treatment and antidotes in case of overexposure
- The adverse health effects of the substance
- Appropriate emergency procedures
- Proper procedures for cleanup of leaks or spills
- Potential for flammability, explosion, and reactivity
- The rights of employees under this rule

Most of this information is available from the MSDS, 29 CFR 1910.1200, U.S. Department of Labor.

Employers must keep copies of MSDSs for each hazardous chemical in the workplace readily accessible to their employees. If the nature of the job is such that employees travel between different workplaces during a work shift, the MSDSs can be kept at a central location at the employer's primary facility.

## 6.1 THE PHYSICS OF SOUND AND HEARING

Sound can be defined as atmospheric or airborne vibration perceptible to the ear. *Noise* is usually unwanted or undesired sound. Consequently, a particular sound can be noise to one person and not to others, or noise at one time and not at other times. Sound loud enough to be harmful is called noise without regard to its other characteristics. Noise is a form of pollution because it can cause hearing impairment and psychological stress.

This section introduces the subject of sound in engineering terms and includes appended references which provide detailed back-up material. It includes the general principles of sound production and propagation, a description of the ear and its functions, a description of the effects of noise on the hearing apparatus and on the person, and an introduction to hearing measurement and hearing aids.

### Sound Production and Propagation

Audible sound is any vibratory motion at frequencies between about 16 and 20,000 Hz; normally it reaches the ear through pressure waves in air. Sound is also readily transmissible through other gases, liquids, or solids; its velocity depends on the density and the elasticity of the medium, while attenuation depends largely on frictional damping. For most engineering work, adiabatic conditions are assumed.

Sound is initially produced by vibration of solid objects, by turbulent motion of fluids, by explosive expansion of gases, or by other means. The pressures, amplitudes, and velocities of the components of the sound wave within the range of hearing are quite small. Table 6.1.1 gives typical values; the sound pressures referenced are the dynamic excursions imposed on the relatively constant atmospheric pressure.

In a *free field* (defined as an isotropic homogeneous field with no boundary surfaces), a point source<sup>o</sup> of sound produces spherical (Beranek 1954) sound waves (see Figure 6.1.1). If these waves are at a single frequency, the instantaneous sound pressure ( $P_{r,t}$ ) at a distance  $r$  and a time  $t$  is

$$P_{r,t} = [(V\sqrt{2}P)/r] \cos[\omega(t - r/t)] \text{ dynes/cm}^2 \quad 6.1(1)$$

where the term  $\sqrt{2}P$  denotes the magnitude of peak pressure at a unit distance from the source, and the cosine term represents phase angle.

In general, instantaneous pressures are not used in noise control engineering (though peak pressures and some non-sinusoidal pulse pressures are, as is shown later), but most sound pressures are measured in root-mean-square (RMS)

values—the square root of the arithmetic mean of the squared instantaneous values taken over a suitable period. The following description refers to RMS values.

For spherical sound waves in air, in a free field, RMS pressure values are described by

$$P_r = P_o/r \text{ dynes/cm}^2 \quad 6.1(2)$$

where  $P_r$  denotes RMS sound pressure at a distance  $r$  from the source, and  $P_o$  is RMS pressure at unit distance from the source. (Meters in metric units, feet in English units.) Acoustic terminology is based on metric units, in general, though the English units of feet and pounds are used in engineering descriptions.

A few other terms should be defined, and their mathematical relationships noted.

Sound intensity  $I$  is defined as the acoustic power  $W$  passing through a surface having unit area; and for spherical waves (see Figure 6.1.1), this unit area is a portion of a spherical surface. Sound intensity at a distance  $r$  from a source of power  $W$  is given by

$$I_r = W/4\pi r^2 \text{ watts/cm}^2 \quad 6.1(3)$$

Sound intensity is also given by

$$I_r = P_o^2/r^2 \rho c \text{ watts/cm}^2 \quad 6.1(4)$$

where  $\rho$  is the adiabatic density of the medium, and  $c$  is the velocity of sound in that medium. Similarly, the following equation gives the sound pressure if the sound is radiated uniformly:

$$P_r = (1/r)\sqrt{W\rho c/4\pi} \quad 6.1(5)$$

If the radiation is not uniform but has directivity, the term  $\rho c$  is multiplied by a directivity factor  $Q$ . To the noise-control engineer, the concept of intensity is useful principally because it leads to methods of establishing the sound power of a source.

The term  $\rho c$  is called the acoustic impedance of the medium; physically it represents the rate at which force can be applied per unit area or energy can be transferred per unit volume of material. Thus, acoustic impedance can be expressed as force per unit area per second (dynes/cm<sup>2</sup>/sec) or energy per unit volume per second (ergs/cm<sup>3</sup>/sec).

Table 6.1.1 shows the scale of mechanical magnitudes represented by sound waves. Amplitude of wave motion at normal speech levels, for example, is about  $2 \times 10^{-6}$  cm, or about 1 micro inch; while amplitudes in the lower part of the hearing range compare to the diameter of the hydrogen atom. Loud sounds can be emitted by a vibrat-

**TABLE 6.1.1 MECHANICAL CHARACTERISTICS OF SOUND WAVES**

	<i>RMS Sound Pressure</i> (dynes/cm <sup>2</sup> )	<i>RMS Sound Particle Velocity</i> (cm/sec)	<i>RMS Sound Particle Motion at</i> (1,000 Hz cm)	<i>Sound Pressure Level</i> (dB 0.0002 bar)
Threshold of hearing	0.0002	0.0000048	$0.76 \times 10^{-9}$	0
	0.002	0.000048	$7.6 \times 10^{-9}$	20

	$200 \times 10^3$	4800	$760 \times 10^{-3}$	180
Atmospheric pressure	$2000 \times 10^3$	48000	7.6	200

ing partition even though its amplitude is only a few micro inches.

**REFLECTION, DISPERSION, ABSORPTION, AND REFRACTION**

Sound traversing one medium is reflected when it strikes an interface with another medium in which its velocity is different; the greater the difference in sound velocity, the more efficient the reflection. The reflection of sound usually involves dispersion or scattering.

Sound is dispersed or scattered when it is reflected from a surface, when it passes through several media, and as it passes by and around obstacles. Thus, sound striking a building as plane waves usually is reflected with some dispersion, and plane waves passing an obstacle are usually somewhat distorted. This effect is suggested by Figure 6.1.1. The amount of dispersion by reflection depends on the relationship between the wavelength of the sound and the contour of the reflecting surface.

The absorption of sound involves the dissipation of its mechanical energy. Materials designed specifically for that purpose are porous so that as the sound waves penetrate, the area of frictional contact is large and the conversion of molecular motion to heat is facilitated.

Sound waves can be refracted at an interface between media having different characteristics; the phenomenon can be described by Snell's law as with light. Except for events taking place on a large scale, refraction is usually distorted by dispersion effects. In the tracking of seismic waves and undersea sound waves, refraction effects are important.

In engineering noise analysis and control, reflection, refraction, and dispersion have pronounced effects on directivity patterns.

**WAVE CHARACTER**

Since sound is a wave motion, it can be focussed by reflection (and less easily by refraction), and interference can

**FIG. 6.1.1** Sound sources. A point source at S produces a calculable intensity at a. The sound waves can set an elastic membrane or partition (like a large window) at W into vibration. This large source can produce roughly planar sound waves, which are radiated outward with little change in form but are distorted and dispersed as they pass the solid barrier B.

**FIG. 6.1.2** Reflection of sound waves. If the distance  $d$  between two parallel walls is an integral number of wavelengths, standing waves can occur. Interaction between direct waves from a source  $S$  and the reflected waves can produce interference.

occur, as can standing wave patterns. These effects are important in noise control and in auditorium acoustics. Another wave-motion phenomenon, the coincidence effect, affects partition behavior.

When two wave forms of the same frequency are superimposed, if they are inphase, they add and reinforce each other; while if they are of opposing phase, the resultant signal is their difference. Thus, sound from a single source combined with its reflection from a plane surface can produce widely varying sound levels through such interference. If reflective surfaces are concave, they can focus the sound waves and produce high sound levels at certain points. Dispersion often partially obscures these patterns.

Sound from a single source can be reinforced by reflection between two walls if their separation is a multiple of the wavelength; this standing-wave pattern is described by Figure 6.1.2.

These phenomena are important in auditorium design, but they cannot be ignored in noise control work. Reinforcement by the addition of signals can produce localized high sound levels which can be annoying in themselves and are also likely to produce mechanical vibrations—and thus new, secondary noise sources.

Random noise between parallel walls is reinforced at a series of frequencies by the formation of standing waves; this reinforcement partially accounts for the high noise level in city streets.

## ENERGY RELATIONSHIPS IN SOUND

The magnitudes most used to describe the energy involved in sound or noise are sound pressure and sound power. Pressure, either static (barometric) or dynamic (sound vibrations), is the magnitude most easily observed. Sound pressure is usually measured as an RMS value—whether this value is specified or not—but peak values are sometimes also used.

From the threshold of hearing to the threshold of pain, sound pressure values range from 0.0002 to 1000 or more dynes per square centimeter (Table 6.1.1). To permit this wide range to be described with equal resolution at all pressures, a logarithmic scale is used, with the decibel (dB) as its unit. Sound pressure level (SPL) is thus defined by

$$\text{SPL} = 20 \log_{10} (P/P_{\text{ref}}) \text{ dB} \quad \mathbf{6.1(6)}$$

where  $P$  is measured pressure, and  $P_{\text{ref}}$  is a reference pressure. In acoustic work this reference pressure is 0.0002 dynes/cm<sup>2</sup>. (Sometimes given as 0.0002 microbars, or 20 micronewtons/meter<sup>2</sup>. A reference level of 1 microbar is sometimes used in transducer calibration; it should not be used for sound pressure level.) Table 6.1.2 lists a few representative sound pressures and the decibel values of sound pressure levels which describe them.

This logarithmic scale permits a range of pressures to be described without using large numbers; it also represents the nonlinear behavior of the ear more convincingly. A minor inconvenience is that logarithmic quantities cannot be added directly; they must be combined on an energy basis. While this combining can be done by a mathematical method, a table or chart is more convenient to use; the accuracy provided by these devices is usually adequate.

Table 6.1.3 is suitable for the purpose; the procedure is to subtract the smaller from the larger decibel value, find the amount to be added in the table, and add this amount to the larger decibel value. For example, if a 76 dB value is to be added to an 80 dB value, the result is 81.5 dB (80 plus 1.5 from the table). If more than two values are to be added, the process is simply continued. If the smaller of the two values is 10 dB less than the larger, it adds less than 0.5 dB; such a small amount is usually ignored, but if several small sources exist, their combined effect should be considered.

The sound power of a source is important; the magnitude of the noise problem depends on the sound power. Sound power at a point (sound intensity) cannot be measured directly; it must be done with a series of sound pressure measurements.

The acoustic power of a source is described in watts. The range of magnitudes covers nearly 20 decimal places; again a logarithmic scale is used. The reference power level normally used is 10<sup>-12</sup> watt, and the sound power level (PWL) is defined by

$$\text{PWL} = 10 \log_{10} (W/10^{-12}) \text{ dB} \quad \mathbf{6.1(7)}$$

or, since the power ration 10<sup>-12</sup> means the same as -120 dB, the following equation is also correct:

$$\text{PWL} = 10 \log_{10} W + 120 \text{ dB} \quad \mathbf{6.1(8)}$$

In either case,  $W$  is the acoustic power in watts.

**TABLE 6.1.2 REPRESENTATIVE SOUND PRESSURES AND SOUND LEVELS**

<i>Source and Distance</i>	<i>Sound Pressure (dynes/cm<sup>2</sup>)</i>	<i>Sound Level (decibels 0.0002 μ bar)</i>
Saturn rocket motor, close by	1,100,000	195
Military rifle, peak level at ear	20,000	160
Jet aircraft takeoff; artillery, 2500'	2000	140
Planing mill, interior	630	130
Textile mill	63	110
Diesel truck, 60'	6	90
Cooling tower, 60'	2	80
Private business office	.06	50

<i>Source</i>	<i>Acoustic Power of Source</i>
Saturn rocket motor	30,000,000 watts
Turbojet engine	10,000 watts
Pipe organ, forte	10 watts
Conversational voice	10 microwatts
Soft whisper	1 millimicrowatt

Sound power levels are established through sound pressure measurements; in a free field, sound is radiated spherically from a point source, thus

$$PWL = SPL + 20 \log_{10} r + 0.5 \text{ dB} \quad \mathbf{6.1(9)}$$

For precise work, barometric corrections are required. In practical situations, a directivity factor must often be introduced. For example, if a machine rests on a reflecting surface (instead of being suspended in free space), reflection confines the radiated sound to a hemisphere instead of a spherical pattern, with resulting SPL readings higher than for free-field conditions.

Actual sound power values of a source, in watts, can be computed from PWL values using Equation 6.1(8).

In all cases, the units should be stated when sound pressure or sound power values are listed (dynes/cm<sup>2</sup>, watts), and the reference levels should be made known when

sound pressure levels or sound power levels are listed (0.0002 dynes/cm<sup>2</sup>, and 10<sup>-12</sup> watt).

## The Hearing Mechanism

Sound reaches the ear usually through pressure waves in air; a remarkable structure converts this energy to electrical signals which are transmitted to the brain through the auditory nerves. The human ear is capable of impressive performance. It can detect vibratory motion so small it approaches the magnitude of the molecular motion of the air. Coupled with the nerves and brain, the ear can detect frequency differences and combinations, magnitude, and direction of sound sources. It can also analyze and correlate such signals. A brief description of the ear and its functioning follows.

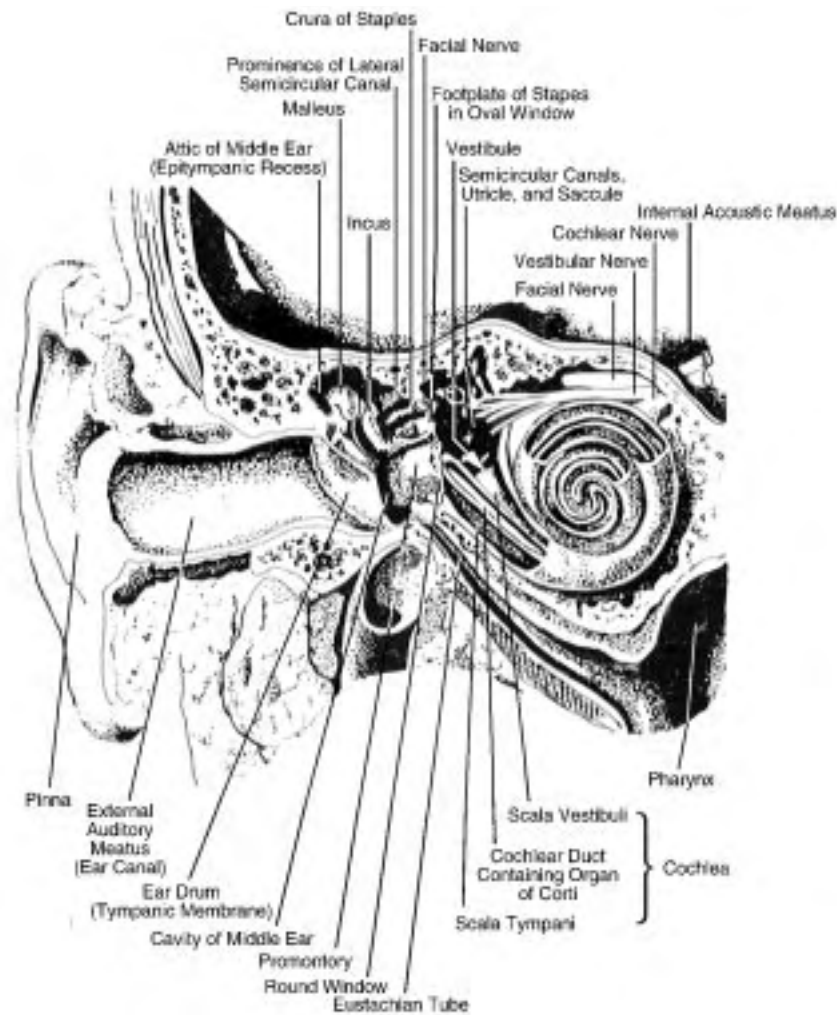

Figure 6.1.3 shows the anatomical division of the ear. The external human ear (called the auricle or the pinna) and the ear opening (the external auditory canal or meatus) are the only parts of the hearing system normally visible. They gather sound waves and conduct them to the eardrum and inner drum. They also keep debris and objects from reaching the inner ear.

The working parts of the ear include the eardrum and organs which lie behind it; they are almost completely surrounded by bone and are thus protected.

The sound transducer mechanism is housed in the middle ear (Figure 6.1.4). The eardrum or tympanic membrane is a thin, tough membrane, slightly oval in shape and a little less than 1 cm in mean diameter; it vibrates in response to sound waves striking it. The vibratory motion is transmitted through three tiny bones, the ossicles (the malleus, the incus, and the stapes; or the hammer, anvil, and stirrup), to the cochlea; it enters the cochlea at the oval window.

The ossicles are in an air-filled space called the middle ear; close to the middle ear are small muscles which act on them and on the tympanum. The principal function of the ossicles seems to be to achieve an impedance match between the external auditory canal and the fluid-filled cochlea. The principal function of the middle-ear muscles seems to be to control the efficiency of the middle ear by controlling tension of the eardrum and the mechanical advantage of the ossicles as a lever system. The middle ear is connected through the Eustachian tube with the nasal passages so that it can accommodate to atmospheric pressures; without this connection, changing atmospheric pressure would apply a steady force to the eardrum and prevent its free vibration.

The cochlea or cochlear canal functions as a transducer; mechanical vibrations enter it; electrical impulses leave it through the auditory nerve. The cochlea is a bone shaped like a snail, coiled two and one-half times around its own axis (Figure 6.1.3). It is about 3 cm long and 3 mm in di-

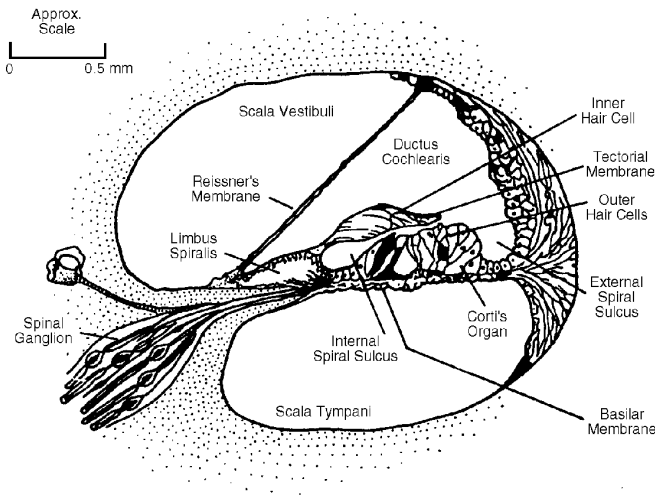

ameter at its largest part. It is divided along most of its length by the cochlea partition, which is made up of the basilar membrane, Reissner's membrane, and the organ of Corti.

A cross section through the cochlea (Figure 6.1.5) reveals three compartments: the scala vestibuli, the scala media, and the scala tympani. The scala vestibuli and the scala tympani are connected at the apex of the cochlea. They are filled with a fluid called perilymph in which the scala media floats. The hearing organ (organ of Corti) is housed in the scala media. The scala media contains a different fluid, endolymph, which bathes the organ of Corti.

The scala media is triangular in shape and is about 34 mm in length (Figure 6.1.5). Cells grow up from the basilar membrane. They have a tuft of hair at the end and are attached to the hearing nerve at the other end. A gelatinous membrane (tectoral membrane) extends over the hair cells and is attached to the limbus spiralis. The hair cells are embedded in the tectoral membrane.

**FIG. 6.1.4** The sound transducer mechanism housed in the middle ear. (Adapted from an original painting by Frank H. Netter, M.D., for *Clinical Symposia*, copyright by CIBA-GEIGY Corporation.)

**FIG. 6.1.5** Cross section through the cochlea.

Vibration of the oval window by the stapes causes the fluids of the three scala to develop a wave-like motion. The movement of the basilar membrane and the tectorial membrane in opposite directions causes a shearing motion on the hair cells. The dragging of the hair cells sets up electrical impulses which are transmitted to the brain in the auditory nerves.

The nerve endings near the oval and round windows are sensitive to high frequencies. Those near the apex of the cochlea are sensitive to low frequencies.

Another structure of the inner ear is the semicircular canals, which control equilibrium and balance. Extremely high noise levels can impair one's sense of balance.

The ear has some built-in protection; since it is almost entirely surrounded by bone, a considerable amount of mechanical protection is provided. The inner-ear mechanism

offers some protection against loud noises. The muscles of the middle ear (the tensor tympanus and stapedius) can reduce the ear's sensitivity to frequencies below about 1000 Hz when high amplitudes are experienced; this reaction is called the aural reflex. For most people, it is an involuntary muscular reaction, taking place a short time after exposure—0.01 second or so. For sounds above the threshold of pain, the normal action of the ossicles is thought to change; instead of acting as a series of levers whose mechanical advantage provides increased pressure on the eardrum, they act as a unit. Neither of these protective reactions operates until the conditions are potentially damaging.

## HEARING IMPAIRMENT

With the exception of eardrum rupture from intense explosive noise, the outer and middle ear are rarely damaged by noise. More commonly, hearing loss is a result of neural damage involving injury to the hair cells (Figure 6.1.6). Two theories are offered to explain noise-induced injury. The first is that excessive shearing forces mechanically damage the hair cells. The second is that intense noise stimulation forces the hair cells into high metabolic activity, which overdrives them to the point of metabolic failure and consequent cell death. Once destroyed, hair cells cannot regenerate.

## AUDIOMETRY PRINCIPLES

Audiometry is the measurement of hearing; it is often the determination of the threshold of hearing at a series of frequencies and perhaps for the two ears separately, though more detailed methods are also used. Audiometric tests are made for various reasons; the most common to determine the extent of hearing loss and for diagnosis to permit hearing aids to be prescribed.

In modern society a gradual loss in hearing is normal and occurs with increasing age; Figure 6.1.7 shows this condition. These curves show the average loss in a number of randomly selected men and women (not selected solely from noisy occupations), and these data are accepted as representing typical presbycusis conditions. (*Presbycusis* refers to the normal hearing loss of the elderly.) For all persons tested, the effect increases with age and is more pronounced at high frequencies than at low.

Men normally show the effect to a greater degree than women. In the last decade or so, women have experienced more presbycusis than formerly. Experts disagree as to whether noise is the predominant factor; but evidence shows that presbycusis and other processes of aging take place faster when noise levels and other social stresses are high. Another term, *sociocusis*, is being used to describe the hearing loss from exposure to the noises of modern society.

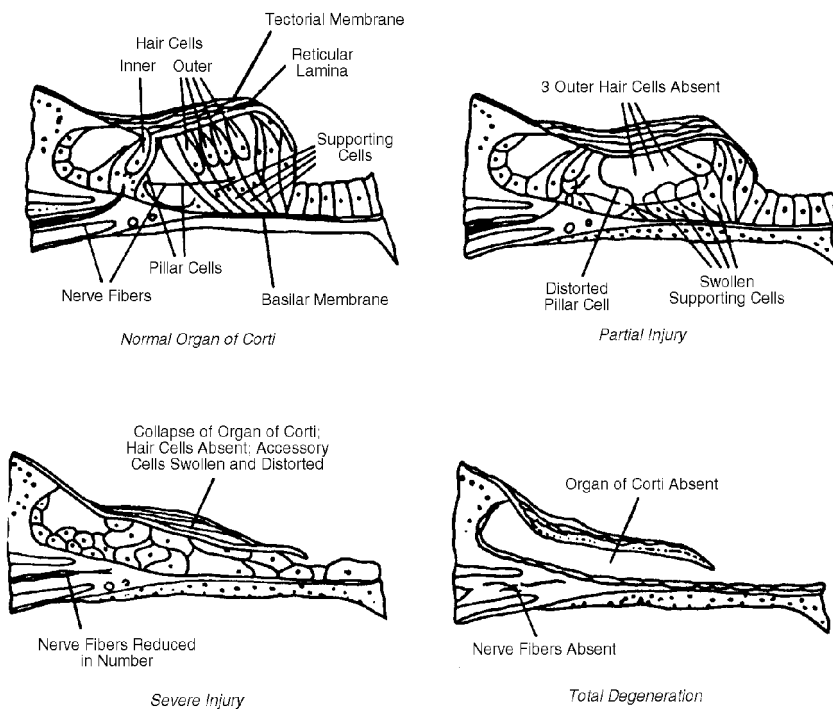

FIG. 6.1.6 Various degrees of injury to the hair cells.

FIG. 6.1.7 Normal presbycusis curves. Statistical analysis of audiograms from many people show normal losses in hearing acuity with age. Data for men are represented by solid lines; those for women by dotted lines.

Group surveys—of young men at college entrance examinations, for example—show increasing percentages of individuals whose audiograms look like those of men many years older. This indication is almost invariably of noise-induced hearing loss. If the audiogram shows losses not conforming to this pattern (conductive losses), more careful checking is indicated; such an audiogram suggests a congenital or organic disorder, an injury, or perhaps nervous damage. Group surveys are valuable in locating individuals who are experiencing hearing damage without realizing it; it is often not recognized until the subject begins to have difficulty in conversation. By this time irreparable damage occurred. Such tests are easily made using a simple type of audiometer.

As a part of a hearing-conservation program—either a public health or an industrial program—regular audio-

metric checks are essential. For this purpose, checking only threshold shift at several frequencies is common. The greatest value of these tests is that they are conducted at regular intervals of a few months (and at the beginning and the termination of employment) and can show the onset of hearing impairment before the individual realizes it.

A valuable use of the screening audiometric test is to determine temporary threshold shifts (TTS). Such a check, made at the end of a work period, can show a loss of hearing acuity; a similar test made at the beginning of the next work period can show if the recovery is complete. The amount and duration of TTS is somewhat proportional to the permanent threshold shift (PTS) which must be expected. Certainly if the next exposure to noise occurs before the ear has recovered from the last, the eventual result is permanent hearing impairment.

FIG. 6.1.8 Recording of audiometer data. Typical forms for recording audiometric data are either like the simplified table or like the audiometric curve. More data are normally included than are shown here.

## AUDIOMETRIC PRACTICES

A typical audiometer for this use consists of an audio-frequency source with amplifier, attenuator, and headset (air-conduction earphone, perhaps also a bone-conduction unit). The following are the standard test frequencies: 62, 135, 250, 500, 1000, 2000, 3000, 4000, 6000 and 8000 Hz. Not all of them are available on all audiometers. The sound output is adjusted so that at each frequency the level at the ear represents the hearing norm. Suitable controls are provided; a graphic recording device may also be used. To speed up group testing, more than one set of earphones can be provided.

The basic procedure is simple; for each ear and test frequency, the sound level is slowly raised until the subject hears the tone; the level reached is the threshold and is so recorded. Typical forms are shown in Figure 6.1.8; the lower form is graphic and shows the response of both ears superimposed. The upper is an abbreviated tabular form convenient for keeping permanent records of employees.

In routine testing in industrial locations, regular tests are made only at frequencies of 500, 1000, 2000, 4000, and 6000 Hz, with occasional tests over the entire range.<sup>1</sup> This abbreviated test takes less time than the comprehensive one; in addition, testing at the upper and lower extremes of frequency is difficult and subject to error. At the highest frequencies, problems of coupling between earphone and eardrum often occur. Differences or scatter of 5 dB in audiograms is not uncommon; it occurs except under the best laboratory conditions.

While an audiometric testing laboratory for the best types of clinical work is an elaborate installation, a facility for routine tests can be set up in an industrial plant occupying less than 100 square feet. It can be located in a first-aid station or even in a personnel office using a commercially available isolating booth for the audiometer and the subject.

Systematic differences in threshold levels have been found when one audiometric technique is changed to an-

other; these differences have been as large as 10 dB. Though some of these differences cannot be entirely explained, these points should be remembered: changes disclosed in a continuing series of audiograms are more likely to be reliable than any single audiogram, and uniformity and consistency in technique are essential.

## HEARING AIDS

As long as the cochlea and the auditory nerve survive, hearing loss can usually be compensated with an electronic hearing aid. Many of these are available. In principle, all are alike; a microphone picks up sound, an amplifier provides more energy, and an earpiece directs it to the hearing mechanism. Even if the eardrum and middle ear are damaged, a bone-conduction unit can often carry energy to the cochlea.

If the loss in hearing acuity is considerable, speech communication may no longer be satisfactory. In such circumstances (if not sooner), the use of a hearing aid should be considered. Loss in intelligibility is the usual result of loss in high-frequency sensitivity—which is often the result of continued exposure to noise. The frequency response of the hearing aid should be tailored to compensate for the specific deficiencies of the ear; if everything through the audible spectrum is simply made louder, the ear may be so affected by the low frequencies that no gain is realized in intelligibility.

1. In audiometric screening, a rule of thumb is that if the threshold at 500, 1000 and 2000 Hz is no higher than 25 dB, no hearing impairment is assumed since many normal people show this condition. If the subject's thresholds are above 40 dB, he needs amplification to hear speech properly. Obviously, this test does not check rate of hearing loss.

## 6.2 NOISE SOURCES

Noise is found almost everywhere, not just in factories. Thunder is perhaps the loudest natural sound we hear; it sometimes reaches the threshold of discomfort. Jet aircraft takeoffs are often louder to the listener. Some industrial locations have even louder continuous noise. Community noise is largely produced by transportation sources—most often airplanes and highway vehicles. Noise sources are also in public buildings and residences.

### Typical Range of Noise Levels

Variation in noise levels is wide. In rural areas, ambient noise can be as low as 30 dB; even in residential areas in or near cities, this low level is seldom achieved. In urban areas, the noise level can be 70 dB or higher for eighteen hours of each day. Near freeways, 90 to 100 dB levels are not unusual. Many industries have high noise levels. Heavy industries such as iron and steel production and fabricating and mining display high levels; so do refineries and chemical plants, though in the latter few people are exposed to the highest levels of noise. Automobile assembly plants, saw-mills and planing mills, furniture factories, textile mills, plastic factories, and the like often employ many people in buildings with high noise levels throughout. Hearing impairment of such employees is probable unless corrective measures are taken.

The construction industry often exposes its employees to hazardous noise levels and at the same time adds greatly to community noise. Community noise may not be high enough to damage hearing (within buildings) and yet have an unfavorable effect on general health.

Transportation contributes largely to community noise. The public may suffer more than the employees—the crew and passengers of a jetliner do not receive the high noise level found along the takeoff and approach paths. The drivers of passenger cars often are less bothered by their own noise than are their fellow drivers, and they are less annoyed than residents nearby for psychological reasons.

Noise levels high enough to be harmful in their immediate area are produced by many tools, toys, and other devices. The dentist's drill, the powder-powered stud-setting tool used in building, home workshop tools, and even hi-fi stereo headphones can damage the hearing of their users. They are often overlooked because their noise is localized.

Some typical noise sources are listed in [Table 6.2.1](#) and are classified by origin.

**TABLE 6.2.1 NOISE LEVELS FROM VARIOUS AREAS**

Noise Sources <sup>a</sup>	Noise Levels dB or 0.0002 $\mu$ bar
<i>Industrial</i>	
Near large gas-regulator, as high as	150

### Characteristics of Industrial Noise

Industrial noise varies in loudness, frequency components, and uniformity. It can be almost uniform in frequency response (white noise) and constant in level; large rotating machines and places such as textile mills with many machines in simultaneous operation are often like this. An automobile assembly line usually shows this steady noise with many momentary or impact noises superimposed on it. Other industries show continuous background noise at relatively low levels with intermittently occurring periods of higher noise levels.

Such nonuniform noises are likely to be more annoying and more fatiguing than steady noise, and they are more difficult to evaluate. The terms used to describe them are sometimes ambiguous. Usually the term *intermittent* refers to a noise which is *on* for several seconds or longer—perhaps for several hours—then *off* for a comparable time.

**TABLE 6.2.2 PULSE LOUDNESS COMPARED TO CONTINUOUS NOISE**

<i>Sound Press Level (SPL) Increase in Continuous Noise to Give Equal Loudness (dB)</i>	<i>Pulse Width (ms)</i>
25-30	0.02
19-22	1.0
13	5.0
10	10
4	50
2	100
0	500 or longer

The term *interrupted* usually has approximately the same meaning except that it implies that the *off* periods are shorter than the *on* periods. Intermittent or interrupted noises can be measured with a standard sound level meter and a clock or stopwatch.

Sounds whose duration is only a fraction of a second are called impulsive, explosive, or impact sounds. The terms are often used interchangeably for pulses of differing character, alike only in that they are short. They must be measured with instruments capable of following rapid changes or with instruments which sample and hold peak values.

The wave form of the noise can be modified appreciably by reflection before it reaches the ear, but it is usually described as either single-spike pulses or rapidly damped sinusoidal wave forms. Such wave forms can be evaluated fairly accurately by converting the time-pressure pattern into an energy spectrum and then performing a spectral analysis. A more accurate evaluation of the effect of intermittent but steady-level noise is possible through computation based on the ratio of on-to-off times.

The ear cannot judge the intensity of extremely short noise pulses or impact noises since it seems to respond more to the energy contained in the pulse than to its maximum amplitude. Pulses shorter than  $\frac{1}{20}$  second, therefore, do not sound as loud as continuous noise having the same sound pressure level; the difference is as much as 20 dB for a pulse 20 ms long. (See Table 6.2.2.) Thus, the ear can be exposed to higher sound pressures than the subject realizes from sensation alone; a short pulse with an actual sound pressure level of 155 to 160 dB might seem only at the threshold of discomfort, 130 to 135 dB for continuous noise. Yet this momentary pressure is dangerously near that at which eardrum rupture or middle-ear damage can occur.

Interruptions in continuous noise provide brief rest periods which reduce fatigue and the danger of permanent hearing impairment. Conversely, intermittent periods of high noise during otherwise comfortable work sessions are annoying and tend to cause carelessness and accidents.

Industrial noises also vary in their frequency characteristics. Large, slow-moving machines generally produce low-frequency noises; high-speed machines usually produce noise of higher frequency. A machine such as a large motor-generator produces noise over the entire audible frequency range; the rotational frequency is the lowest (1800 RPM produces 30 Hz) but higher frequencies from bearing noise (perhaps brush noise too), slot or tooth noise, wind noise, and the like are also present.

A few noise spectra are shown in Figure 6.2.1, in octave-band form. Curve No. 1 of a motor-generator set shows a nearly flat frequency response; it is a mixture of many frequencies from different parts of the machine. Curve No. 2, for a large blower, shows a predominantly low-frequency noise pattern; its maximum is around 100 or 120 Hz and can be caused by the mechanical vibration of large surfaces excited by magnetic forces. Curve No. 3 is for a jet plane approaching land; it contains much high-frequency energy and sounds like a howl or scream, while the blower noise is a rumble. Curve No. 4 describes the high-pitched noise caused by turbulence in a gas-reducing valve; it is mechanically connected to pipes which readily radiate in the range of their natural frequencies of vibration. Octave-band analyses have only rather broad resolution and are suited to investigate the audible sound characteristics; the mechanical vibrations causing the noise are best analyzed by a continuously variable instrument.

The radiating area of a source affects the amount of sound emitted; not only does the total amount of acoustic energy radiated increase roughly in proportion to the area in vibration, but a pipe or duct passing through a wall emits sound on both sides of the wall. The vibration amplitude can be only a few microinches yet produce loud sounds. If the natural frequency of an elastic member is near the frequency of the vibration, its amplitude can become large unless the member is damped or the driving force isolated.

## INDUSTRIAL NOISE SOURCES

In rotating and reciprocating machines, noise is produced through vibration caused by imperfectly balanced parts; bearing noise, wind noise, and other noises also exist. The amplitude of such noises varies with operating speed, usually increasing exponentially with speed. Noise frequencies cover a wide range since normally several harmonics of each fundamental are produced.

Electrical machines produce noise from magnetic as well as mechanical forces. Alternating current machines convert electrical to mechanical energy by cyclically changing magnetic forces which also cause vibration of the machine parts. These magnetic forces change in magnitude and direction as the machine rotates and air gaps and their magnetic reluctance change. The noise frequencies thus produced are related both to line frequency and its harmonics and to rotational speed. The entire pattern is quite com-

plicated. In nonrotating machines (transformers, magnetic relays, and switches), the noise frequencies are the line frequency and its harmonics and the frequencies of vibration of small parts which are driven into vibration when their resonant frequencies are near some driving frequency.

In many machines, more noise is produced by the material being handled than by the machine. In metal-cutting or grinding operations, much noise is produced by the cutting or abrading process and is radiated from both work-piece and machine.

Belt and screw conveyors are sometimes serious noise sources; they are large-area sources; their own parts vibrate and cause noise in operation, and the material they handle produces noise when it is stirred, dropped, or scraped along its path of motion. Vibration from conveyors is conducted into supports and building structure as well. Feeding devices, as for automatic screw machines, often rattle loudly.

Jiggers, shakers, screens, and other vibrating devices produce little audible noise in themselves (partly because their operating frequency is so low), but the material they handle produces much higher frequency noise. Ball mills, tumblers, and the like produce noise from the many impacts of shaken or lifted-and-dropped pieces; their noise frequencies are often low, and much mechanical vibration is around them.

Industry uses many pneumatic tools. Some air motors are quite noisy, others less so. Exhausting air is a major noisemaker, and the manner in which it is handled has much to do with the noise produced. Exhausting or venting any gas (in fact, any process which involves high velocity and pressure changes) usually produces turbulence and noise. In liquids, turbulent flow is noisy because of cavitation. Turbulence noise in gas is usually predominantly high frequency; cavitation noise in liquids is normally midrange to low frequency. Both types of noise can span several octaves in frequency range.

Gas and steam turbines produce high-frequency exhaust noise; steam turbines (for improved efficiency) usually exhaust their steam into a condenser; gas turbines sometimes feed their exhausts to mufflers. If such turbines are not enclosed, they can be extremely noisy; turbojet airplane engines are an example.

Impact noises in industry are produced by many processes; materials handling, metal piercing, metal forming, and metal fabrication are perhaps most important. Such noises vary widely because of machine design and location, energy involved in the operation, and particularly because of the rate of exchange of energy.

Not all industrial noises are within buildings; cooling towers, large fans or blowers, transformer substations, external ducts and conveyor housings, materials handling and loading, and the like are outside sources of noise. They often involve a large area and contribute to community noise. Bucket unloaders, discharge chutes, and carshakers, such as those used for unloading ore, coal, and gravel, pro-

duce noise which is more annoying because of its lack of uniformity.

Figure 6.2.2 summarizes a range of industrial plant noise levels at the operator's position. Table 6.2.3 gives some industrial equipment noises sources.

## MINING AND CONSTRUCTION NOISE

Both mining and construction employ noisy machines, but construction noise is more troublesome to the general public because of its proximity to urban and residential areas.

Motor trucks, diesel engines, and excavating equipment are used in both kinds of work. Welders and riveters are

**TABLE 6.2.3 INDUSTRIAL EQUIPMENT NOISE SOURCES**

<i>System</i>	<i>Source</i>

widely used in construction, especially in steel-framed buildings and shipbuilding. Pneumatic hammers, portable air compressors, loaders, and conveyors are used in both mining and construction. Crushing and pulverizing machines are widely used in mining and in mineral processing. A Portland cement plant has all of these plus ball or tube mills, rotary kilns, and other noisemakers as well. Highway and bridge construction use noisy earth-moving equipment; asphalt processing plants produce offensive fumes as well as burner noises; concrete mixing plants produce both dust and noise.

The actual noise-producing mechanisms include turbulence from air discharge; impact shock and vibration from drills, hammers, and crushers; continuous vibrations from shakers, screens, and conveyors; explosive noise; and exhaust turbulence from internal combustion engines.

## Transportation Noise

Motor vehicles and aircraft are estimated to cause more urban and community noise than all other sources combined, and 60 to 70% of the U.S. population lives in locations where such transportation noise is a problem. The number of workers exposed to hazardous noise in their daily work is estimated at between 5 and 15% of the population; most of them are also exposed to the annoying, sleep-destroying general urban noise.

Table 6.2.4 lists some typical values for aircraft, motor vehicles, railways, and subways. These values are not the absolute maximum but high typical values; actual noise

levels for motor vehicles, for example, are modified by the condition of the vehicle, condition of the pavement, manner of driving, tires, and surroundings. Both motor vehicles and aircraft are directional sources in that the location of the point of measurement affects the measured noise-level values.

Of all sources, aircraft noise probably causes the most annoyance to the greatest number of people. Airports are located near population centers, and approach and take-off paths lie above residential areas. Residential buildings are especially vulnerable to aircraft noise since it comes from above striking roofs and windows, which are usually vulnerable to noise penetration. The individual resident feels that he is pursued by tormenting noise against which he has no protection and no useful channel for protest.

Railway equipment has a high noise output but causes less annoyance than either highway and street traffic or air traffic. Railway noise is confined to areas adjacent to right-of-way, usually comes from extended sources, and is predictable. It is basically low frequency, thus less annoying than aircraft. Since railway equipment stays on its established routes, protection to residential areas is easily provided. Subway trains can be extremely annoying to their passengers; their noise levels are high; tunnel and station surfaces are highly reflective; and many passengers are present. Newer subway construction is less noisy than in the past (when 100 to 110 dBA was common). Subways, trolleys, and city buses all contribute considerably to urban noise and vibration.

**TABLE 6.2.4 TRANSPORTATION NOISES**

<i>Source<sup>a</sup></i>	<i>Levels (ref 0.0002 dynes/cm<sup>2</sup>)<sup>b</sup></i>	
4-engine turbojet, 400' altitude, takeoff	117 dBC	115 PNdB
4-engine turbofan, 400' altitude, approach	105 dBC	122 PNdB

Pumphouses and pipeline distributing terminals compare to other industrial locations, but the pipelines themselves present no noise problem.

### Urban Noise

The distribution patterns for urban noise are quite complex and differ from city to city; yet, in general, common factors describe them.

A noise base exists twenty-four hours per day, consisting of household noises, heating and ventilating noises, ordinary atmospheric noises, and the like; this noise base is usually of low level, from 30 to 35 dB. Here and there are somewhat louder sources of noise: electrical substations, powerplants, shopping centers with roof-mounted equipment, hotels, and other buildings which do not change with the night hours.

During the day and evening hours this base level increases because of increased residential activity and also because of general widespread city traffic. A new pattern appears: in busy downtown areas traffic is heavy, on thoroughways and main streets extremely dense traffic occurs during rush periods with heavy traffic continually, some factories are at work, etc. Noise levels in the streets can rise to 85 to 95 dB locally. An intermittent pattern is added from emergency vehicles, aircraft, and the like. The general noise level for the entire city can increase by 10 to 20 dB. The highest noise levels remain local; after a few blocks, the noise is attenuated through scattering and reflections among buildings, and the many sources blend into the general noise pattern.

The intermittent noise pattern is usually more disturbing than the steady pattern, especially at night. Measurements near main highways and freeways show general traf-

fic noise levels at a distance of 30 meters to be in the 65 to 80 dB range with frequent excursions up to 100 dB or even higher almost always caused by trucks but sometimes by motorcycles.

Only at the edges of urban areas does the noise level drop appreciably; and even there main highways, airports, and such can prevent a reduction. In most cities, no place is further than a few blocks from some part of the grid of principal streets carrying heavy traffic.

Important contributions are made by entertainment installations. These noise sources include music on streets and in shopping centers, amusement parks and racetracks, paging and public address systems, schools, athletic fields, and even discotheques where performances indoors are often audible several blocks away. Other offenders include sound trucks, advertising devices, and kennels or animal shelters.

Because noise sources are distributed over an urban area, the sound-power output of a source can be more informative than the noise level produced at a specific distance. Figure 6.2.3 lists some urban sources with their approximate sound-power ratings.

### Specific Noise Sources

Some noise sources are so intense, so widespread, or so unavoidable that they must be characterized as specific cases.

Pile driving and building demolition involve violent impacts and large forces and are often done in congested urban areas. Some piles can be sunk with less noisy methods, but sometimes the noise and vibration must simply be tolerated; however, these effects can be minimized and the working hours adjusted to cause the least disturbance.

Blasting for such construction can be controlled by the size of charges and protective mats. Some steel mill operations and scrap-handling operations are equally noisy and produce vibration but are normally not found near residential areas.

Sonic booms from aircraft extend over wide areas and affect many people. These noises are impulsive, and people respond to them as to other impulsive noises; the pressure levels are not high enough to be especially hazardous to hearing (maximums usually one to three pounds per square foot), but they can produce large total forces on large areas, for example, flat roofs.

Some air-bag protectors, designed to protect passengers in automobiles, can produce noise levels of 140 to 160 dB inside a closed car and, at the same time, sudden increases in atmospheric pressure at the ear. Teenagers who use headphones to listen to music often impose hazardous sound levels on their ears; they do not realize it, and no one else hears it. Hearing aids have been known to produce levels so high that in an attempt to gain intelligibility, actual harm is done. In these instances, the frequency response of the unit should produce the high levels only in the frequency range where they are needed.

In construction work, explosive-actuated devices can produce high noise levels at the operator's ear. Chain saws and other portable gasoline-powered tools are used close to the operator and, thus, their noise readily reaches the ear.

The dentist's drill, used several hours per day close to the ear, is a hearing hazard. Even musicians (especially in

military bands and in amplified rock-type music groups) have shown hearing losses after some time. Usually, of course, music is not continuous, and the intervals of rest for the ear are helpful.

Some special industrial processes, such as explosion-forming, shot-peening, and flame-coating, are so noisy that they must be performed in remote locations or behind walls. Many mining, ore-dressing, and other mineral-processing operations are performed in remote locations; but those employees who must be present must be protected.

## 6.3 THE EFFECTS OF NOISE

---

---

Human response to noise displays a systematic qualitative pattern, but quantitative responses vary from one individual to another because of age, health, temperament, and the like. Even with the same individual, they vary from time to time because of change in health, fatigue, and other factors. Variation is greatest at low to moderately high sound levels; at high levels, almost everyone feels discomfort. A detailed investigation of the physiological damage to human ears is difficult, but controlled tests on animals indicate the probable type of physiological damage produced by excessively high noise levels.

### Reactions to Noise

Specific physiological reactions begin at sound levels of 70 to 75 dB for a 1000 Hz pure tone. At the threshold of

such response, the observable reaction is slow but definite after a few minutes. These reactions are produced by other types of stimulation, so they can be considered as reactions to general physiological stress. First the peripheral blood vessels constrict with a consequent increase in blood flow to the brain, a change in breathing rate, changes in muscle tension, and gastrointestinal motility and sometimes glandular reactions detectable in blood and urine. Increased stimulation causes an increase in the reaction, often with a change in form. These reactions are sometimes called *N-reactions*—nonauditory reactions. If the stimulus continues for long, adaptation usually occurs with the individual no longer conscious of the reaction, but with the effect continuing. Auditory responses occur as well as these nonauditory or vegetative ones. If exposure is continued long enough, TTS can occur, and a loss of some

hearing acuity usually results with increasing age. Some workers refer to a “threshold of annoyance to intermittent noise” at 75 to 85 dB.

At a slightly higher level, and especially for intermittent or impulsive noise, another nonauditory response appears—the *startle effect*. Pulse rate and blood pressure change, stored glucose is released from the liver into the bloodstream (to meet emergency needs for energy), and the production of adrenalin increases. The body experiences a fear reaction. Usually psychological adaptation follows, but with changed physiological conditions.

At noise levels above 125 dB, electroencephalographic records show distorted brain waves and often interference with vision.

Most of these nonauditory reactions are involuntary; they are unknown to the subject and occur whether he is awake or sleeping. They affect metabolism; and since body chemistry is involved, an unborn baby experiences the same reactions as its mother. Sounds above 95 dB often cause direct reaction of the fetus without the brief delay required for the chemical transfer through the common bloodstream.

Most people find that under noisy conditions, more effort is required to maintain attention and that the onset of fatigue is quicker.

## AUDITORY EFFECTS

Within 0.02 to 0.05 seconds after exposure to sound above the 80 dB level, the middle-ear muscles act to control the response of the ear. After about fifteen minutes of exposure, some relaxation of these muscles usually occurs. This involuntary response of the ear—the auditory reflex—provides limited protection against high noise levels. It cannot protect against unanticipated impulsive sounds; it is effective only against frequencies below about 2000 Hz. And in any case, it provides only limited control over the entrance of noise. These muscles relax a few seconds after the noise ceases.

Following exposure to high-level noise, customarily a person has some temporary loss in hearing acuity and often a ringing in the ears (tinnitus). If it is not too great, this temporary loss disappears in a few hours. But if, for example, the TTS experienced in one work period has not been recovered at the start of the next work period, the effect accumulates; permanent hearing damage is almost certain if these conditions persist.

Important variables in the development of temporary and permanent hearing threshold changes include the following:

**Sound level:** Sound levels must exceed 60 to 80 dBA before the typical person experiences TTS.

**Frequency distribution of sound:** Sounds having most of their energy in the speech frequencies are more potent in causing a threshold shift than are sounds having most of their energy below the speech frequencies.

**Duration of sound:** The longer the sound lasts, the greater the amount of threshold shift.

**Temporal distribution of sound exposure:** The number and length of quiet periods between periods of sound influences the potentiality of threshold shift.

**Individual differences in tolerance of sound** may vary among individuals.

**Type of sound—steady-state, intermittent, impulse, or impact:** The tolerance to peak sound pressure is reduced by increasing the duration of the sound.

## PTS

A direct relationship exists between TTS and PTS. Noise levels that do not produce TTS after two to eight hours of exposure do not produce PTS if continued beyond this time. The shape of the TTS audiogram resembles the shape of the PTS audiogram.

Noise-induced hearing loss is generally first characterized by a sharply localized dip in the hearing threshold limit (HTL) curve at frequencies between 3000 and 6000 Hz. This dip commonly occurs at 4000 Hz (Figure 6.3.1). This dip is the *high frequency notch*.

The progress from TTS to PTS with continued noise exposure follows a fairly regular pattern. First, the high-frequency notch broadens and spreads in both directions. While substantial losses can occur above 3000 Hz, the individual does not notice any change in hearing. In fact, the individual does not notice any hearing loss until the speech frequencies between 500 and 2000 Hz average more than a 25 dB increase in HTL on the ANSI-1969 scale. The onset and progress of noise-induced permanent hearing loss is slow and insidious. The exposed individual is unlikely to notice it. Total hearing loss from noise exposure has not been observed.

## ACOUSTIC TRAUMA

The outer and middle ear are rarely damaged by intense noise. However, explosive sounds can rupture the tympanic membrane or dislocate the ossicular chain. The permanent hearing loss that results from brief exposure to a very loud noise is termed *acoustic trauma*. Damage to the outer and middle ear may or may not accompany acoustic trauma. Figure 6.3.2 is an example of an audiogram that illustrates acoustic trauma.

## Damage-Risk Criteria

A damage-risk criterion specifies the maximum allowable exposure to which a person can be exposed if risk of hearing impairment is to be avoided. The American Academy of Ophthalmology and Otolaryngology defines hearing impairment as an average HTL in excess of 25 dB (ANSI-1969) at 500, 1000, and 2000 Hz. This limit is called the *low fence*. Total impairment occurs when the

average HTL exceeds 92 dB. Presbycusis is included in setting the 25 dB ANSI low fence. Two criteria have been set to provide conditions under which nearly all workers can be repeatedly exposed without adverse effect on their ability to hear and understand normal speech.

## Psychological Effects of Noise Pollution

### SPEECH INTERFERENCE

Noise can interfere with our ability to communicate. Many noises that are not intense enough to cause hearing impairment can interfere with speech communication. The interference or *masking* effect is a complicated function of the distance between the speaker and listener and the frequency components of the spoken words. The speech interference level (SIL) is a measure of the difficulty in communication that is expected with different background noise levels. Now analysis talk in terms of A-weighted background noise levels and the quality of speech communication (Figure 6.3.3).

### ANNOYANCE

Annoyance by noise is a response to auditory experience. Annoyance has its base in the unpleasant nature of some sounds, in the activities that are disturbed or disrupted by noise, in the physiological reactions to noise, and in the responses to the meaning of the messages carried by the noise. For example, a sound heard at night can be more annoying than one heard by day, just as one that fluctuates can be more annoying than one that does not. A sound that resembles another unpleasant sound and is perhaps threatening can be especially annoying. A sound that is mindlessly inflicted and will not be removed soon can be

more annoying than one that is temporarily and regretfully inflicted. A sound, the source of which is visible, can be more annoying than one with an invisible source. A sound that is new can be less annoying. A sound that is locally a political issue can have a particularly high or low annoyance.

The degree of annoyance and whether that annoyance leads to complaints, product rejection, or action against an existing or anticipated noise source depend upon many

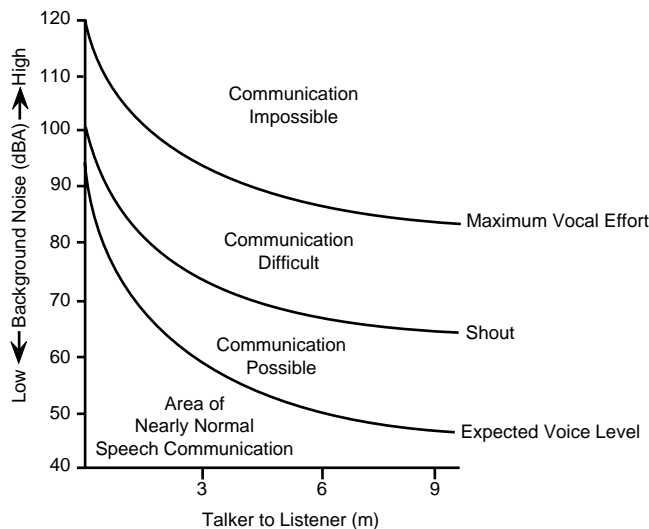

FIG. 6.3.2 An example audiogram illustrating acoustic trauma. (Reprinted, by permission, from W.D. Ward and Abram Gloger, 1961, A case of firecracker-induced hearing loss. *Laryngoscope* 71, Copyright by Laryngoscope.)

**FIG. 6.3.3** Quality of speech communication as a function of sound level and distance. (Reprinted from James D. Miller, 1971, *Effects of noise on people*, U.S. Environmental Protection Agency Publication No. NTID 300.7 [Washington, DC: U.S. Government Printing Office].)

factors. Some of these factors have been identified, and their relative importance has been assessed. Responses to aircraft noise have received the greatest attention. Less information is available concerning responses to other noises, such as those of surface transportation and industry and those from recreational activities. Many of the noise rating or forecasting systems in existence were developed to predict annoyance reactions.

### SLEEP INTERFERENCE

Sleep interference is a category of annoyance that has received much attention and study. Everyone has been awakened or kept from falling to sleep by loud, strange, frightening, or annoying sounds. Being awakened by an alarm clock or clock radio is common. However, one can get used to sounds and sleep through them. Possibly, environmental sounds only disturb sleep when they are unfamiliar. If so, sleep disturbance depends only on the frequency of unusual or novel sounds. Everyday experience also suggests that sound can induce sleep and, perhaps, maintain it. The soothing lullaby, the steady hum of a fan, or the rhythmic sound of the surf can induce relaxation. Certain steady sounds serve as an acoustical shade and mask disturbing transient sounds.

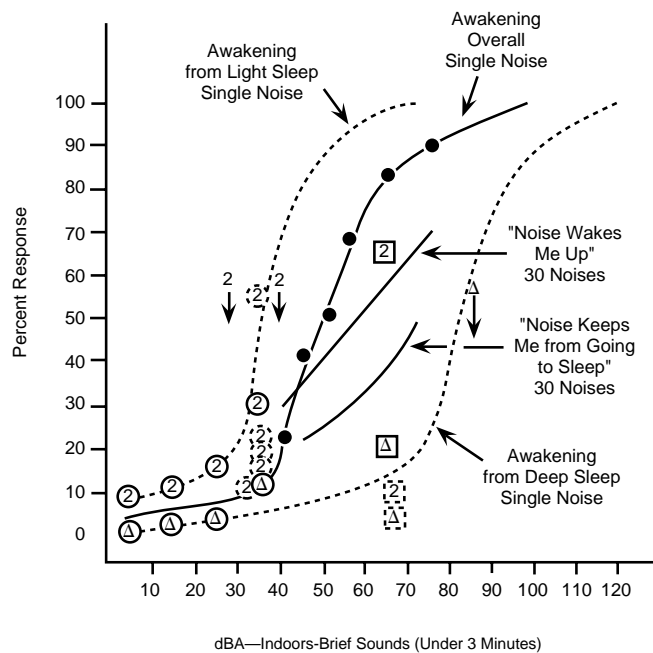

Common anecdotes about sleep disturbance suggest an even greater complexity. A rural person may have difficulty sleeping in a noisy urban area. An urban person may be disturbed by the quiet when sleeping in a rural area. And how is it that a parent wakes to a slight stirring of his or her child, yet sleeps through a thunderstorm? These observations all suggest that the relations between expo-

sure to sound and the quality of a night's sleep are complicated.

The effects of relatively brief noises (about three minutes or less) on a person sleeping in a quiet environment have been studied the most thoroughly. Typically, presentations of the sounds are widely spaced throughout a sleep period of five to seven hours. Figure 6.3.4 presents a summary of some of these observations. The dashed lines are hypothetical curves that represent the percent awakenings for a normally rested young adult male who adapted for several nights to the procedures of a quiet sleep laboratory. He has been instructed to press an easily reached button to indicate that he has awakened and has been moderately motivated to awake and respond to the noise.

While in light sleep, subjects can awake to sounds that are about 30–40 dBs above the level they can detect when conscious, alert, and attentive. While in deep sleep, subjects need the stimulus to be 50–80 dBs above the level they can detect when conscious, alert, and attentive to awaken them.

The solid lines in Figure 6.3.4 are data from questionnaire studies of persons who live near airports. The percentage of respondents who claim that flyovers wake them or keep them from falling asleep is plotted against the A-weighted sound level of a single flyover. These curves are for approximately thirty flyovers spaced over the normal sleep period of six to eight hours. The filled circles represent the percentage of sleepers that awake to a three-

**FIG. 6.3.4** Effects of brief noise on sleep. (Reprinted from J.D. Miller, 1971, U.S. Environmental Protection Agency Publication No. NTID 300.7 [Washington, DC: U.S. Government Printing Office].)

minute sound at each A-weighted sound level (dBA) or lower. This curve is based on data from 350 persons, tested in their own bedrooms. These measures were made between 2:00 and 7:00 A.M. Most of the subjects were probably roused from a light sleep.

### EFFECTS ON PERFORMANCE

When a task requires the use of auditory signals, speech or nonspeech, noise at any level sufficient to mask or interfere with the perception of these signals interferes with the performance of the task.

Where mental or motor tasks do not involve auditory signals, the effects of noise on their performance are difficult to assess. Human behavior is complicated, and discovering how different kinds of noises influence different kinds of people doing different kinds of tasks is difficult. Nonetheless, the following general conclusions have emerged. Steady noises without special meaning do not seem to interfere with human performance unless the A-weighted noise level exceeds about 90 dBs. Irregular bursts of noise (intrusive noise) are more disruptive than steady noises. Even when the A-weighted sound levels of irregular bursts are below 90 dBs, they can interfere with the performance of a task. High-frequency components of noise, above about 1000–2000 Hz, produce more interference with performance than low-frequency components of noise.

Noise does not seem to influence the overall rate of work, but high levels of noise can increase the variability of the rate of work. Noise pauses followed by compensating increases in the work rate can occur. Noise is more likely to reduce the accuracy of work than to reduce the total quantity of work. Complex tasks are more likely to be adversely influenced by noise than are simple tasks.

### ACOUSTIC PRIVACY

Without opportunity for privacy, everyone must either conform strictly to an elaborate social code or adopt highly permissive attitudes. Opportunity for privacy avoids the necessity for either extreme. In particular, without opportunity for acoustical privacy, one may experience all the effects of noise previously described and also be constrained because one's own activities can disturb others. Without acoustical privacy, sound, like a faulty telephone exchange, reaches the wrong number. The result disturbs both the sender and the receiver.

### SUBJECTIVE RESPONSES

Except when it is a heeded warning of danger, a noise which excites a fear reflex is psychologically harmful; noises which prevent rest or sleep are a detriment to health and well-being. These reactions are psychological, yet

physiological damage can result from them. Annoyance and irritation—less specific reactions—impair the quality of life.

Noise levels above the threshold of discomfort—louder than a thunderclap—are disturbing; so are any loud sounds which are not expected; so is any increase in sound level which is more rapid than a critical rate, even if it is expected. Some noises have a higher annoyance factor than others; among the most objectionable is the jet aircraft. Sound pressure data do not adequately describe these noises.

The *phon* represents loudness rather than sound pressure. It is an empirical unit; the loudness level of a noise in phons is numerically equal to the sound pressure level in decibels of a 1000 Hz tone which sounds equally loud. Thus, the phon is a subjective unit.

The *sones* is another unit of loudness using a different scale. A loudness level of 40 phons represents 1 sone, and each 10-phon increase doubles the number of sones. The change in sensation of loudness is better represented by

FIG. 6.3.5 Comparison of objective and subjective noise scales.

sones than by phons.

For the combined high frequencies and high noise levels produced by jet aircraft, other criteria have been developed; one is the unit of noisiness called the *noy*. This unit is used to express the perceived noisiness (PN) or annoyance in dBs, as PNdB. Such PNdB values can be conveniently approximated with a standard sound-level meter.

In Figure 6.3.5 the relative values for sound levels in objective and subjective units are compared; the chart is for comparison, not conversion.

These units deal with continuous noise, but fluctuating or intermittent noise is more annoying. To deal with these characteristics (for transportation noise), a procedure can calculate a “noise pollution level.” A composite noise rating also describes the noise environment of a community over twenty-four hours of the day. Like the others, it accounts for loudness and frequency characteristics, as well as fluctuations and frequency and impulsive noises, in its calculations.

One of the most disturbing elements of noise within buildings is its impairment of privacy; voices or other

noises penetrating a wall, door, or window are especially annoying. This reaction is psychological; the annoyance is in response to an intrusion, which seems impertinent.

## 6.4 NOISE MEASUREMENTS

---

---

### **Available Instruments**

Portable and precision sound-level meters, sound monitors, noise-exposure integrators, audiometers, octave-band analyzers, graphic and wide-band recorders, loudness, computers, and others.

### **Power Required**

Portable instruments are usually battery powered. Laboratory instruments or computing-type loudness meters are supplied from normal power lines with 117 volts, 60 cycle ac. Their power demand is less than 500 volt-amperes.

### **Range of Operations**

Usually from 30 to 140 dB. Usually from 20 to 20,000 Hz.

### **Cost**

Sound-level meters, from \$500 up. Frequency analyzers, from \$2000 up.

### **Partial List of Suppliers**

Ametek, Inc., Mansfield and Green Div.; B & K Instruments, Inc.; Larsen David Laboratory; Quest Technologies; H.H. Scott.

Noise measurements are usually conducted for one of three purposes:

To understand the mechanisms of noise generation so that engineering methods can be applied to control the noise  
To rate the sound field at various locations on a scale related to the physiological or psychological effects of noise on human beings

To rate the sound power output of a source, usually for future engineering calculations, that can estimate the sound pressure it produces at a given location

This section describes a few frequently used terms and units proposed for the study of sound and noise; most are quite specialized. It also describes techniques and instruments to measure noise.

## Basic Definitions and Terminology

Sound waves in air can be described in terms of the cyclic variation in pressure, in particle velocity, or in particle displacement; for a complete description, frequency and wave-form data are also required.

*Sound pressure* is the cyclic variation superimposed upon the steady or atmospheric pressure; usually it is the RMS value. An RMS value is determined by taking the square root of the arithmetic mean of the instantaneous values over one complete cycle for a sine wave, or for as many cycles of a nonsinusoidal wave form as are necessary for a reliable sample. The units of sound pressure are force per unit area—dynes per square centimeter or newtons per square meter. Particle displacement is in cen-

timeters. Most sound pressures are given in RMS values, and most sound level meters display RMS values.

To describe the range of sound pressures in a logarithmic scale is convenient, the unit of SPL is the dB, described by

$$\text{SPL} = 20 \log_{10} (P/P_{\text{ref}}) \text{ dB} \quad 6.4(1)$$

where  $P$  is measured sound pressure, and  $P_{\text{ref}}$  is the reference pressure ordinarily used. The customary reference pressure is 0.0002 dynes/cm<sup>2</sup>, or 0.0002  $\mu$  bars. (One standard atmosphere is equal to 1,013,250 microbars, so 1 microbar is nearly 1 dyne/cm<sup>2</sup>. The reference level should always be stated when sound pressure levels are given, as dB re 0.0002 dynes/cm<sup>2</sup>.)

*Sound power*—the *acoustic power* produced by a source—is described in watts. Again a logarithmic scale is used to accommodate the wide range involved, without inconveniently clumsy figures. The unit again is the dB. The PWL is expressed by

$$\text{PWL} = 10 \log_{10} (W/W_{\text{ref}}), \text{ or } 10 \log_{10} (W/10^{-12}) \text{ dB} \quad 6.4(2)$$

where  $W$  is the acoustic power in watts, and  $W_{\text{ref}}$  is the reference level which should always be stated; the reference level ordinarily used is 10<sup>-12</sup> watt. Since the power ratio 10<sup>-12</sup> can also be written as 120 dB, Equation 6.4(3) is convenient to write as:

$$\text{PWL} = 10 \log_{10} W + 120 \text{ dB re } 10^{-12} \text{ watt} \quad 6.4(3)$$

Sound pressures and sound power values are physical magnitudes, expressed in physical terms. SPLs and PWLs are ratios (the ratio of a measured value to a reference value) expressed in logarithmic terms called dBs.

Other terms and quantities used in noise control work will be defined as they are used. Sound pressures and sound powers are basic. The ear responds to sound pressure waves, and nearly all sound magnitude measurements are in terms of sound pressure. Sound power determines the total noise produced by a machine and, thus, is important in machine design.

## Frequency Sensitivity and Equal Loudness Characteristics

The ear is most sensitive in the range of frequencies between 500 and 4000 Hz, less sensitive at higher frequencies and much less sensitive at low frequencies. This range of greatest sensitivity coincides with the range for voice communication.

Through listening tests, this variation in sensitivity has been evaluated. The curves in Figure 6.4.1 present these data. These curves are commonly called *equal loudness curves*, but *equal sensation curves* describes them more accurately. They describe several of the ear's characteristics. The lowest curve represents the threshold of hearing for the healthy young ear. The dotted portions of the curves (not a part of the ISO recommendation from which these

data come) indicate the change in hearing which occurs with increasing age; they show not noise-induced presbycusis but sociocusis. These dotted curves describe a loss in hearing acuity within the intelligibility range of frequencies.

The curves also show that as the amount of energy increases, the difference in sensitivity almost disappears. The thresholds of discomfort and pain (not part of this figure) actually fall quite close to the 120 and 140 dB levels respectively.

## OBJECTIVE AND SUBJECTIVE VALUES

Sound pressure and sound power are objective values; they show physical magnitudes as measured by instruments. However, while almost anyone subjected to noise exposure beyond recognized levels experiences some hearing impairment, some psychophysiological reactions (annoyance in particular) vary with the individual. They are subjective values; they must be determined in terms of human reactions.

Loudness is a subjective magnitude. Although it depends primarily on signal intensity, or sound pressure, frequency and wave form are also important. (See Figure 6.4.1) Through listening tests, a unit of loudness level has been established; it is the *phon*. The loudness level of a sound in phons is numerically equal to that SPL in dBs of a 1000 Hz continuous sine wave sound, which sounds equally loud. For most common sounds, values in phons do not differ much from SPLs in dBs.

To classify the loudness of noises on a numerical scale, the *son* was devised as the unit of loudness. It is related to the loudness level in phons in this way: a noise of 40 phons loudness level has a loudness of 1 sone, and for each increase in level of 10 phons, the value in sones is doubled. The sone has the advantage that a loudness of 64 sones sounds about twice as loud as 32 sones; it provides a better impression of relative loudness than the dB.

Sone values are not measured directly, but they can be obtained by computation. Two general methods are accepted—one by Stevens and one by Zwicker. Their values differ slightly, but either seems satisfactory for most uses. (The Zwicker method is built into a commercial instrument; it involves separating the sound into a group of narrow-band components, then combining the magnitudes of these components mathematically.) Table 6.4.1 compares some values of sound pressure, loudness, and noisiness.

Jet airplane noise, with its broad band but predominantly high-frequency spectrum, is one of the most annoying. It is also one of the loudest continuous noises. Values in sones or phons are not adequate to describe noises of this character, and the concept of *perceived noise* has developed. Noisiness in this system is usually expressed in dBs, as PNdB. Perceived noise values, like values in sones, are not directly measurable, but are computed from measured data. For many uses, analysts can make acceptable approximations by taking measurements with a stan-

FIG. 6.4.1 Equal loudness curves. These curves display the varying sensitivity of the normal ear with both frequency and average level. The interrupted extensions at high frequencies show the typical loss in hearing acuity with age (Reprinted partially from ISO recommendation 226).

standard sound level meter, using D weighting, and adding 7 to the observed values. For jet plane noises above 90 dBA, analysts can secure useful approximate values by taking sound-level readings using A weighting, and adding 12 to the indicated value. Since not all sound-level meters have D weighting, this latter method is often used.

### WEIGHTING NETWORKS

SPL measurements are made with instruments which respond to all frequencies in the audible range; but since the

sensitivity of the ear varies with both frequency and level, the SPL does not accurately represent the ear's response. This condition is corrected by weighting characteristics in sound level meters.

Weighting networks modify the frequency response of the instrument so that its indications simulate the ear's sensitivity. One, for A weighting, gives readings representing the ear's response to sounds near the 40 dB level; another, B weighting, approximates the response of the ear at about 70 dB values, and C weighting is used for levels near 100 dB or higher. Readings taken with these weightings are

TABLE 6.4.1 COMPARISON OF NONEQUIVALENT NOISE UNITS

Loudness Level <sup>a</sup> (phons)	Description	Loudness (sones)	Sound Level (dBA)	Perceived Noise Level (PNdB)
140	Threshold of pain	1,024	140	153
125	Automobile assembly line	362	125	138
120	Jet aircraft	256	120	133
100	Diesel truck	64	100	112
80	Motor bus (50')	16	80	
60	Low conversation	4	60	
40	Quiet room	1	40	
20	Leaves rustling	0.25	20	

<sup>a</sup>Only sones and phons are rigorously related mathematically; the other values are for comparison only.

FIG. 6.4.2 Weighting curves for sound level meters (after ISO recommendation). The A, B, and C weightings are standards; the D curve is proposed for monitoring jet aircraft noise.

identified as dBA, dBB, dBC, etc; they are called sound level readings to distinguish them from SPL readings which are not modified by frequency.

Many sound level meters have a fourth or *flat* characteristic which is slightly more uniform than C weighting. It is used in frequency analysis. Still another characteristic, D weighting, is proposed for jet plane noise measurements. Figure 6.4.2 shows the response curves provided by these weighting networks.

### FREQUENCY ANALYSIS OF NOISE

The frequency characteristics of sound are important; they describe its annoyance factor as well as its potential for hearing damage. They indicate to the noise control analyst probable sources of noise and suggest means for confining them. To the mechanical or design engineer, frequency analysis can show the source of machine vibrations which produce noise and contribute to damage. Noise is often a symptom of malfunctioning, and the frequency analysis can sometimes describe the malfunction. Spectral characteristics are also useful in describing the transmission of sound through a wall or its absorption by some material.

Octave-band analyses are not difficult to make, even in the field, and are adequate for noise control work, though not for machine design. They are usually made with sets of bandpass filters attached to a sound-level meter using the flat-frequency response. The filters are designed so that

each passes all frequencies within one octave; but at the edge of the pass-band, the transmission falls off sharply. The transmission at one-half the lower band-edge frequency (or at twice the upper) is at least 30 dB below the pass-band transmission; and it is at least 50 dB below pass-band transmission at one-fourth the lower (or four times the upper) edge of the pass-band frequency.

In computing loudness from measured data, one-tenth, one-third, one-half, and full octave-band analyzers are used. In describing the noise-transmission characteristics of objects such as walls and doors and classifying noise environments for speech interference, analysts ordinarily use full octave-band analyzers. Table 6.4.2 lists the commonly used center frequencies and the frequency ranges for octave-band and one-third octave filters. Separate bandpass filter sets are often used for these analyzers; for one-tenth octave and narrower band analyzers, tunable electronic units are widely used. Narrow-band analyzers are used in studying the characteristics of machines.

### SPEECH INTERFERENCE AND NOISE CRITERIA (NC) CURVES

Interference with the intelligibility of speech is a serious problem caused by noise; it impairs comfort, efficiency, and safety. The amount of such interference depends on both frequency and level of sound; and a family of curves has been developed to describe various noise environments. These are called *NC curves* and are shown in Figure 6.4.3.

			17,936	20,000	22,421

<sup>A</sup>ISO Recommendation 266 and USAS SL6-1960 listed sets of preferred numbers which were recommended for use in acoustic design. Most filters are now designed on this basis. The tables give octave-band and one-third octave-band filter characteristics, using preferred numbers as the center frequencies from which the band-edge frequencies were computed. Older filter sets used slightly different frequencies; they are interchangeable in all ordinary work.

Each NC curve describes a set of noise conditions; the acoustic environment suitable for a need is specified with a single number. For example, a concert hall or auditorium should be NC-25 or better; a private office is NC-35. That is, octave-band SPLs measured in these areas should not exceed, at any frequency, the values specified by the appropriate NC curve.

These criteria are related to the psychological characteristics of the ear and, consequently, the shape of the curves is like the equal-sensation curves. For broad-band noise, if 7 to 9 units is subtracted from the sound level measured in dBA, the difference approximates the NC-curve rating. If the ear can detect some frequency which seems to dominate an otherwise uniform background noise, this rough criterion is not acceptable. An octave-

band analysis is needed, especially if specifications are being checked.

## Vibration and Vibration Measurement

Noise is usually accompanied by vibration; noise is caused by vibration; noise causes vibration. The physiological effects of vibration have not been studied as intensively as those of sound, but usually discomfort provides warning so that hazard is easily anticipated. However, exposure to vibration often contributes to fatigue and, thus, to loss in efficiency and to accidents. Vibration study is an important part of noise control, especially in analyzing problems.

FIG. 6.4.3 Noise criteria curves. The abscissa shows both the older bandlimit frequencies (at top) and the band-center frequencies based on the preferred-number series (at bottom). Both are still in use.

Roughly speaking, vibration becomes perceptible when its amplitude reaches about  $2 \times 10^{-3}$  millimeters at 50 Hz and seems intolerable at about  $8 \times 10^{-2}$  millimeters at 50 Hz. These estimates assume exposure for rather long periods and close contact to the vibrating surface—as riding in a vehicle. Vibration of large surfaces at these amplitudes produces high sound pressures. Individuals vary in their tolerance of vibration, but probably few people are disturbed by vibrations with accelerations less than 0.001 times that of gravity, or  $1 \text{ cm/sec}^2$ , and many can tolerate ten times that much.

Vibration can be described in terms of its frequency and either its acceleration, velocity, or amplitude as

$$a = -2\pi f v = -(2\pi f)^2 x \quad 6.4(4)$$

where  $a$  is acceleration,  $v$  velocity,  $x$  is amplitude of displacement, and  $f$  is frequency.

Vibration is measured by mechanical, optical, or electrical means (Lipták 1970) depending on conditions. The

low-frequency, large-amplitude vibrations of an elastically suspended machine might be measured with a ruler, by eye. The high-frequency, small-amplitude vibrations of a high-speed motor are best measured with an electrical instrument which is sensitive to acceleration, velocity, or displacement.

General purpose vibration meters often use a measuring element sensitive to acceleration over a range of frequencies. The instrument also shows velocity by performing one integration or displacement by performing two integrations on the acceleration signal. The integration is done electronically, within the instrument.

Vibratory force applied to an elastic membrane produces vibratory motion, thus sound pressure waves cause a window or partition to vibrate. Vibratory force applied to an elastically supported mass produces vibratory motion, as in a machine with vibration-isolating supports. In both cases, the amplitude of vibration is affected by the ratio of the frequency of the applied force—the *forcing fre-*

FIG. 6.4.4 Response of a resonant system. The response of an elastic system excited by frequencies near its undamped resonance frequency varies with both the forcing frequency and the amount of damping. Damping from 0 to 1 times critical is shown.

quency—to the natural frequency of the object. Other important parameters are the resisting force (proportional to effective mass) and the damping ratio (proportional to the amount of energy dissipated through friction). Figure 6.4.4 shows the relation between the frequency ratio and the response of the system (no units given for response in this figure).

## Measuring Noise

### BACKGROUND CORRECTIONS

Sound-measuring instruments do not distinguish between the noise of principal interest and any background noise present. Background noise corrections are needed to determine the contribution of a specific source or a group of sources.

The simplified procedure is as follows: the noise level is measured with the unknown source(s) in operation; then

with the other conditions unchanged, the unknown source is stopped and the background level measured. (If several different sources are being measured, they can be turned off in different combinations.) Analysts must evaluate the difference between the readings on an energy basis, not simply by taking numerical differences.

Table 6.4.3 provides a convenient means for adding or subtracting dB values, accurate enough for most work. Background noise corrections subtract the background from the total noise. For example, if the total noise measures 93 dB and the background noise measures 89 dB, the level for the unknown source is 90.7 dB. Using these tables, analysts can also add dB values; the values for more than one source are measured separately, then combined in pairs. Three sources, of 85, 87, and 89 dB, add to give 92 dB. In both addition and subtraction, the dB values must be obtained in the same manner, including weighting.

**TABLE 6.4.3 BACKGROUND NOISE CORRECTIONS**

<i>Subtraction of Noise Values in Decibels</i>	
<i>Total Noise Minus Background Noise (dB)</i>	<i>Correction (dB)</i>
0	∞
0.25	12.5
0.50	9.6
1.0	6.8
1.5	5.4
2.0	4.45
2.5	3.6
3.0	3.0
3.5	2.6
4.0	2.3
4.5	2.0
5.0	1.65
6.0	1.35
7.0	1.0
8.0	0.75
9.0	0.55
10.0	0.45

Procedure:

1. Measure total noise and background noise separately in dB.
2. Subtract background noise dB from total noise dB.
3. Consult table to find correction dB.
4. Subtract correction dB from total noise dB.

<i>Addition of Noise Values in Decibels</i>	
<i>Difference Between the Two Values (dB)</i>	<i>Correction (dB)</i>
0	3.0
1	2.5
2	2.0
3	2.0
4	1.5
5	1.0
6	1.0
7	1.0
8	0.5
9	0.5
10	0.0

Procedure:

1. Measure the two sources separately in dB.
2. Subtract the smaller from the larger value.
3. Consult table to find correction dB.
4. Add correction to the higher of the two values.

**INSTRUMENTS FOR MEASURING NOISE**

The basic instrument for measuring noise levels is the sound level meter, sensitive to RMS sound pressures between about 20 and 20,000 Hz. It is equipped with weighting networks, fast and slow response, an attenuator with 10–dB steps, and an indicating meter which spans 16 dBs, from –6 to +10 dB. It operates over a total range of about 30 to 140 dB sound pressure level. [Minimum specifications for general-purpose sound level meters are in the

International Electrotechnical Commission (IEC) Recommendations 123 and 177, in American National Standards Institute (ANSI) S1-4-1971, and elsewhere.]

Most sound level meters have output terminals so that accessories can be attached; these accessories include impact-noise meters, octave-band and  $\frac{1}{3}$  octave-band filter sets, graphic recorders, and the like. Self-contained analyzers are also available, with all components housed in a single unit; these often have variable width settings.

Vibration meters are like sound level meters in that they contain a sensing element, amplifier, attenuator, and output meter. They do not have weighting circuits but do have integrating circuits, so that with a single pickup acceleration, velocity and displacement can be measured. (Sometimes a vibration-measuring accessory operates with a sound level meter; it consists only of a vibration pickup, integrating circuits, and a table of conversions; the electronic circuitry in the sound level meter operates with it.) Vibration meters are usually calibrated in acceleration (cm/sec<sup>2</sup>), velocity (cm/sec), or displacement (cm) and display either peak or average values.

Figure 6.4.5 shows simplified block diagrams of typical sound level meters, vibration meters, audiometers, and noise monitors; Figure 6.4.6 shows a block diagram of the elements of a sound level meter.

Primary calibration of microphones or vibration pickups is normally done in the best equipped laboratories; most manufacturers of the instruments maintain such laboratories. Their standards are traceable to those maintained by government standards agencies (e.g., National Bureau of Standards, U.S.A.). Such calibrations are made with pistonphones, shake-tables, electrostatic actuators, and the use of reciprocity methods. Until recent years, the Rayleigh disk was widely used. Reciprocity calibrators are now easily available, and small electronic generators are widely used for field checks.

International standards and recommendations are available from the International Organization for Standardization, Geneva, Switzerland; U.S. standards are available from the U.S. ANSI, New York City.

Audiometers are basically audio-frequency oscillators, adjustable in frequency and in output level, with headsets for the subject. The subject determines the existence of the threshold. Some audiometers are more complex, having recording devices and masking noise facilities.

Since loudness is a subjective magnitude, it cannot be measured with a simple instrument. Arbitrary systems have been developed for determining loudness by instrumental measurements, using rather complex empirical criteria and techniques. A self-contained instrument is available, which analyzes the sound as it is received, breaks it up into *critical bands*—actually  $\frac{1}{3}$  octave bands—performs a number of calculations on these data, and produces a single-figure output. This equipment has been incorporated into a system for continuously monitoring impulse and continuous noise and for printing out loudness levels and occurrence

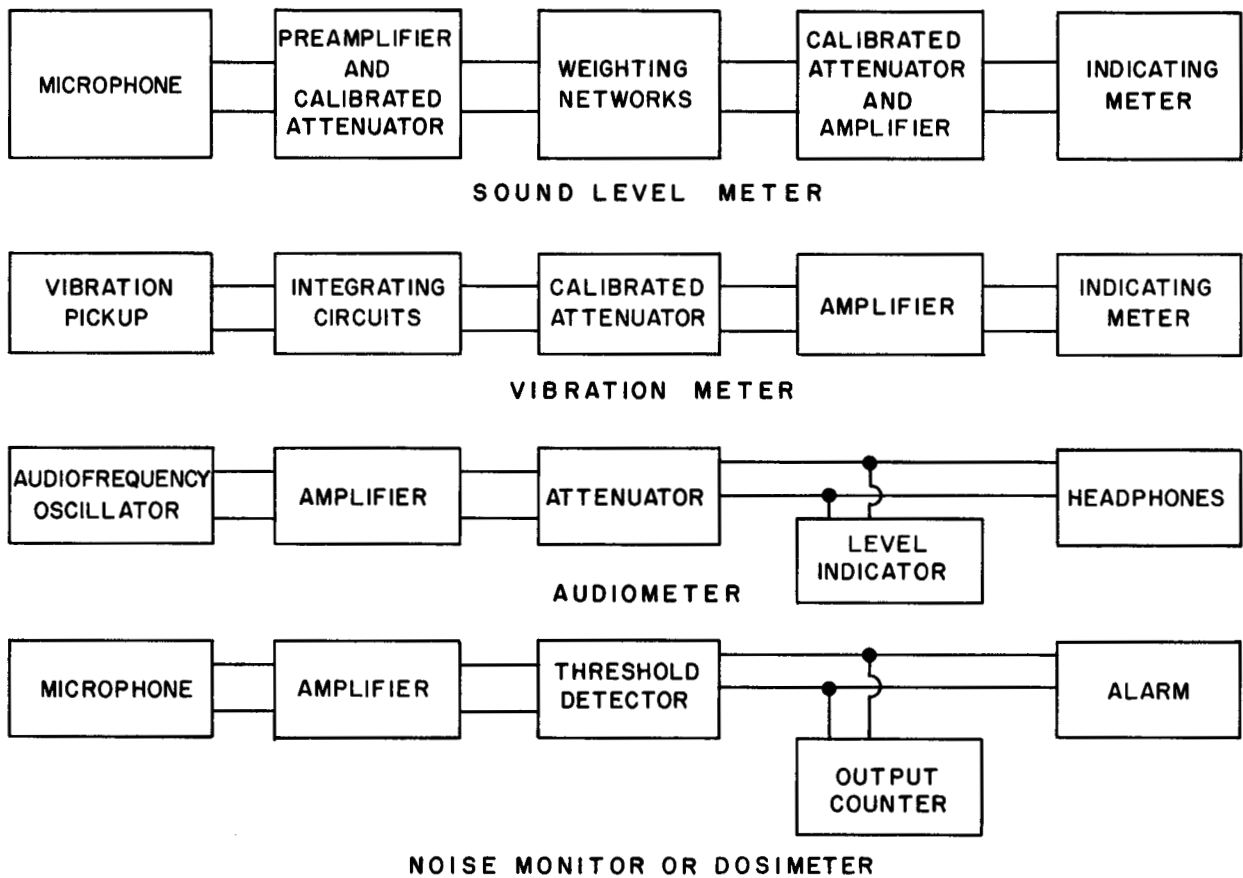

FIG. 6.4.5 Simplified block diagram of noise-measuring instruments.

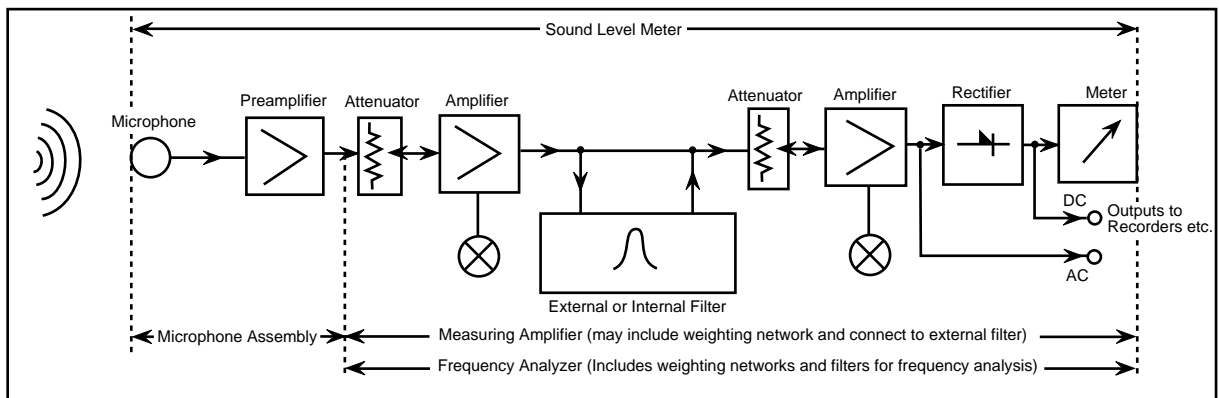

FIG. 6.4.6 Block diagram of the elements of a sound level meter.

times.

### IMPACT AND IMPULSE MAGNITUDES

The brief noise pulses (lasting only a fraction of a second) caused usually by impacts or explosions require special means of measurement. Even the fast setting of a standard sound level meter usually requires about 0.2 second to reach its deflection, and an overshoot also occurs.

Analysts can ideally measure true impulse or impact magnitudes by recording the wave form on an oscillograph for detailed analysis, and then determining frequencies and total energy as well as peak magnitudes. Most impulse noise meters are somewhat simpler.

A typical impact-noise measuring instrument can determine the peak pressure (by a sample-and-hold circuit or by a peak-reading voltmeter) and the time-average (the average voltage over a chosen period of time). The result is indicated on a pointer-type instrument, where the reading

is retained long enough to permit accurate readings. The time-average mode of operation can average over any selected period of time from 2 milliseconds to 1 second; this average provides a simple means of approximating the pulse length. The instrument should respond to rise times as short as 100 microseconds.

Analysts have devised simplified techniques for approximating peak values of impact noise based on the dynamic characteristics of the sound level meter. One method for checking at the 140 dB peak level sets the sound level meter on its C or flat weighting, fast response and the 130 dB range. If the pointer swings no higher than a 125 dB indication for impulsive noise, the peaks are probably no higher than 140 dB. This method assumes that the sound pulse is perhaps 25 to 50 milliseconds long; shorter pulses read too low; longer pulses read too high since the amount of energy in the pulse as well as the peak value affects this type of indication. The length of impact and explosive noise pulses is often increased by reflected sound; indoors, it is increased by reverberation.

## MONITORING DEVICES (NOISE DOSIMETERS)

Since noise exposure involves both duration and noise level, continuous observation is required to evaluate exposure if durations and levels vary.

Noise monitors or noise exposure meters respond only when a preset level is reached; some include several circuits with different preset values. They are available in small portable packages to be worn by a worker or in larger (and more accurate) models which are not restricted to the within-limits or exceeding-limit indication. Figure 6.4.7 shows a block diagram of a typical dosimeter that complies with the Occupational Safety and Health Administration (OSHA) criteria.

Where variations in level are wide and not easily predictable, integrating devices are used. The Occupational Safety and Health Act (OSH Act) of 1970 (and others)

halves the permissible exposure for each 5 dB increase in level above 90 dB; this computation can be made by a simple circuit.

Monitoring devices may simply record the duration of exposure above a preset level for daily examination; they may signal hazardous levels with a flashing light; for airport use, they record times of occurrence of all levels above a preset threshold and sound some alarm when another (and higher) preset limit is reached.

## FIELD MEASUREMENTS

*Field measurements* are measurements where little or no control over operating conditions is possible. *Laboratory measurements* are made in circumstances where some control is possible and conditions can at least be predicted. Usually less sophisticated equipment is used for field work; consequently, the experience and judgment of the analyst become important.

Background noise is normally present, and often it is not possible to maintain conditions while a machine under test is started and stopped. The effect of background noise should be minimized. Stationary noise sources, if small, can be approached to within a meter or so to raise the level of noise being measured relative to the background. (Questions of directivity, size of source, reflections and interferences, and other experimental problems always appear; such problems must be dealt with individually at the time they appear.) For large sources, such handling of experimental problems is seldom possible; where the effect of an entire building or a large cooling tower on a neighborhood, for example, is being studied, the ingenuity and experience of the analyst is taxed to the utmost.

Transient noises—auto horns, vehicle noises, passersby, and the like—must be avoided as far as possible. Measurements within buildings are easier in that traffic is controllable and atmospheric noises do not interfere, but the proximity of the walls introduces danger of reflections in addition to those from the analyst and his equipment.

Both the abilities and limitations of the measuring

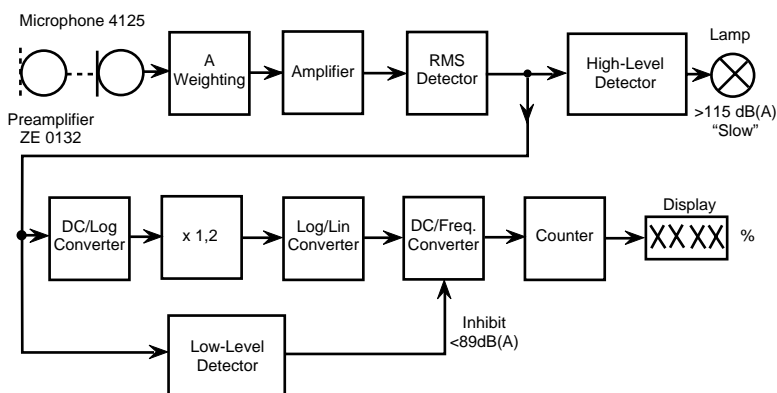

FIG. 6.4.7 Simplified block diagram of a personal noise dose meter, complying with OSHA criteria.

equipment should be known. Its condition should be checked just before use and again just afterward, including a field calibration check.

## PRACTICAL PROBLEMS

Whether indoors or out, in good conditions or bad, some problems are common to almost all noise measurements.

The convenient measurable range of sound levels extends from about 10 dB above the ambient level (which can be as low as 20 dB in good test rooms) to about 140 dB or so. Whenever measurements are made with background noise within 10 dB of the test noise level, errors tend to increase. By whatever means is convenient, the difference between the test noise level and background should be increased. Work outside these limits is possible, but not easy.

The analyst can increase the sensitivity of the measuring instrument at low levels by using a preamplifier (but with danger of introducing electrical noise) or reduce it at high levels with attenuators (but the mechanical vibration in high-noise fields can affect the operation of the instrument).

Microphones vary in their characteristics. Condenser types have wide frequency response, good sensitivity, and withstand high temperatures and high-sound levels. They are often deranged by high humidity, they require some auxiliary equipment; and their cost is rather high.

Piezoelectric microphones (made with synthetic ceramic) are excellent for general purpose use. Their stability and sensitivity are good, but their frequency response is less wide than that of condenser microphones. Their cost is relatively low. They are not usable at extremely low or extremely high temperatures.

Dynamic microphones can be used at both lower and higher temperatures than the piezoelectric and at higher humidities than the condenser types. They sometimes lose calibration over long periods of time, however, and their frequency response can vary from temperature change. Their construction employs acoustic resonating chambers, which must remain clean and dust free. None of the three types is completely nondirectional.

Frequently the acoustic power of a source is needed but is not supplied by the maker. Ideally this kind of data should be determined in a quiet room or in a free-field situation with low background noise, but practical values can often be approximated by field measurements. For outside sources, if reflecting surfaces (except the ground or pavement) are not close by and the device is the principal noise source, the following equation gives the power level:

$$PWL = SPL + 20 \log_{10} r + 0.5 - Q \text{ dB} \quad 6.4(5)$$

[See also Section 6.1 and Equation 6.1(9).] Here  $r$  is the distance in feet from the source to the sound pressure meter, and  $Q$  is a directivity factor.

The directivity factor varies from about 2 for a hard pavement to about 0.5 for absorbing grass; the sound radiated by the machine is usually somewhat directional in itself, too. Several SPL measurements should be taken to strike an average. Values obtained in this way are seldom highly accurate; usually field measurements give low values for PWL. A simpler procedure (for rough estimates) is to measure the SPL at a distance of 1 meter; the PWL value is about 15 units higher. (This procedure can be used on small sources only.) Neither of these procedures works well on extended sources such as cooling towers, large trucks, or the like, nor for distances greater than about 60 meters.

The term here called *directivity factor* is sometimes called *directional gain* or DG. It is the factor by which the power of the source should be multiplied, if its sound radiation were nondirectional, to give the measured level in the direction of measurement. The directivity factor must be determined for the location and direction in question for each measurement or machine.

Field measurements can be disturbed by wind noise. Analysts can reduce this problem by using a windscreen. Windscreens have various forms, but a common method is to surround the microphone with a skeletal spherical frame about 15 to 20 cm in diameter and stretch fine-meshed cloth over it.

At extreme distances, sound behavior becomes unpredictable; but noise control work seldom requires measurements beyond a mile or so. At high altitudes, low barometric pressure, or high humidity, the density change in the atmosphere affects calculations. For most work, these effects can be ignored.

Multiple sources are usually present, as well as multiple transmission paths; and as in other measurements, the presence of the measuring device can affect the local conditions. Interpretation in both raw and tabulated data can be a problem. Judgment, based on experience, is of the greatest importance in noise-control work.

## 6.5 NOISE ASSESSMENT AND EVALUATION

During the years after passing the OSH Act of 1970, Congress worked to define the section concerning workplace noise. Their work resulted in the promulgation of the Hearing Conservation/Noise Amendment in 1983. While OSHA regulations receive the most coverage, mining and military organizations have their own safety and health regulations. In addition, many states have regulations similar to OSHA's and occasionally more stringent. Besides workplace noise exposure, noise remains a predominant issue in communities all over the country and the world, and complaints to local officials are rising.

The amendment provides coverage for all employees exposed to a time-weighted average of 85 dBA. It outlines the following components of a hearing conservation program: (1) noise assessment, (2) hearing testing, (3) hearing protection, (4) education and training, and (5) record keeping. Workers' compensation laws established in each state may also specify noise assessment similar to OSHA's.

This section focuses on noise assessment and analysis of noise-level data in the workplace, community noise, and noise-level criteria.

### Workplace Noise

A hearing conservation program begins with determining a worker's noise exposure. It is the first step in identifying those employees who must be included in the total hearing conservation program. Several criteria suggest the need for noise assessment:

- If any area has a past record of excessive noise
- If employees complain of discomfort or temporary hearing loss
- If employees are unable to converse easily, without shouting, at a distance of 2 feet.

A dosimeter is the most important instrument in noise assessment. It determines the noise level to which employees are exposed by measuring sound over time and analyzing the information to produce a noise dose, expressed in a percentage. A noise dose,  $D$ , is defined as:

$$D = \frac{C}{T} \quad \mathbf{6.5(1)}$$

where  $D$  is the noise dose;  $C$ , actual duration of exposure in hours;  $T$ , noise exposure limit in hours. The allowable exposure time (Table G-16 of the OSHA regulations) is listed in Table 6.5.1. The employee exposure exceeds the OSHA limits if the noise dose,  $D$ , exceeds unity, or 100%.

Where the daily exposure is due to more than one noise level, the ratios for each level are added to compute the total noise dose as follows:

$$D = \frac{C_1}{T_1} + \frac{C_2}{T_2} + \dots + \frac{C_n}{T_n} \quad \mathbf{6.5(2)}$$

### NOISE DOSIMETERS

The OSHA amendment of 1983 pushed the development of noise instrumentation to higher capability levels. Noise dosimeters are programmable, data-logging, multithreshold instruments. They communicate directly with printers and personal computers. They provide information such as multithreshold doses, average sound level or LAvg, peak levels, histograms, statistical distributions, and projections.

A dosimeter is a small unit which can be attached to a belt or placed in a shirt pocket. The microphone is placed at the ear level, about 3 to 5 inches from the head, to avoid shadow error. Dosimeters must integrate all noise—continuous, variable, and impulse or impact—in the range between 80 to 130 dBs, using a 5-dB doubling or exchange rate; and they must be A weighted. (See Section 6.4)

The following definitions explain these dosimeter terms and keys:

**THRESHOLDS**—That sound level below which the instrument assumes no noise.

**TABLE 6.5.1 OSHA HEARING CONSERVATION TABLE<sup>a</sup>**

<i>A-Weighted Sound Level</i>	<i>Duration (Hours)</i>
80 dB*	32
85†	16
90‡	8
95	4
100	2
105	1
110	0.5
115	0.25
120	0.125
125§	0.063
130§	0.031

Important Levels:

\*Measuring Threshold

†Hearing Conservation Begins-50% Dose

‡Eight-Hour Criteria Level

§Minimum Upper Range

<sup>a</sup> = Table G-16a (Abbreviated)

**LTL**—Low threshold level, when set at 80 dB, measures only 80 dB and above; assumes 0s below that level. Used for OSHA hearing conservation compliance.

**HTL**—High threshold level, when set at 90 dB, measures only 90 dB and above; assumes 0s below that level. Used for OSHA engineering control compliance.

**CRITERION LEVEL**—90 dB, when measured for eight hours, reads 100% dose.

**5dB EXCHANGE RATE**—Used by OSHA; every 5 dB increase or decrease either doubles or halves the dose.

**A WEIGHTING**—Used by OSHA (and others); reads the way the human ear hears sound. Basically the low frequencies and some high are not read as loud as they acoustically are.

**LAVG**—Average sound level for the actual time measured based on other than a 3 dB exchange rate, ie. 5 dB-OSHA, 4 dB-DOD, or a 3 dB exchange rate with a threshold. Useful for short-term samples or for making projections.

**LEQ**—Average sound level for the actual time measured based on a 3 dB exchange rate and no threshold.

**TWA**—An eight-hour dB average regardless of the sample time length. For example, in a four-hour sample measurement, TWA assumes the last four hours are 0s and averages them in the overall reading, making the average dB level lower than it should be. Appropriate to use if someone works other than an eight-hour day, ie. twelve-hour shifts. TWA takes twelve hours of exposure and condenses it into eight giving the appropriate TWA for eight hours. Not appropriate to use for short samples. (Note: LAVg is always greater than TWA in samples less than eight hours. Samples of exactly eight hours result in equal LAVg and TWA, and samples longer than eight hours produce TWAs that exceed LAVg.)

**DOSE**—The accumulated exposure obtained, expressed in percent allowable over eight hours.

**SEL**—A one-second average of a noise occurrence that is any duration in length. (Used to compare several noise events with different time durations.)

The capability for multithreshold dose measurements is helpful. One threshold level is 90 dBA set by OSHA engineering regulations. A concern arises when an employee works in an environment which is always below 90 dBA but where the average sound level is in the high 80s. The dosimeter indicates this area as having no hazard (0% dosage) while the worker is within a few decibels of maximum allowable exposure (100% exposure). Having a second available threshold set at 80 dBA allows the analyst to detect marginal environments while assuring compliance with both the engineering regulation and the hearing conservation amendment. In addition, having these data available provides clues on how to attack noise problems through engineering efforts.

An analyst can determine the effect of using hearing protection devices in the workplace environment by sub-

tracting the NRR value of a device (furnished by the manufacturer) from the LAVg. Histograms, or sound-level-time history, in the printed format are quite useful. The benefits of histograms include identification of noise patterns—and significant break in patterns—during the workday. Patterns help identify sound sources which require corrective action to lower total exposure to the worker. The histogram identifies the exact time when a significant break in these patterns occurs. This information is the basis of documentation presented at compensation hearings.

## SOUND LEVEL METERS

This instrument is used to spot-check for excessive noise. When coupled with an octave-band filter, it can also be used to assess the frequency content of the noise. This information is useful for noise control.

### Integrating Sound Level Meters

Integrating sound level meters measure average dB levels and are useful for evaluating rapidly changing noise environments. They present a direct A-weighted dB (dBA) reading.

## Community Noise

A study conducted by the Department of Housing and Urban Development indicates that the number one concern among city dwellers in the United States is noise. The agencies responsible for enforcing community noise laws are the public health department, code enforcement agencies, and the police or county sheriff departments.

Before considering whether instrumentation is needed, the agency must review the local ordinance. Most ordinances include sections that address measurement requirements and techniques as well as permissible noise-level tables. These sections usually indicate indirectly the minimum instruments required to sample noise sources.

## NOISE RATING SYSTEMS

An example of the wording in the measurement techniques section of a noise ordinance might read: “The measurement must be made for a period of at least 10 minutes and any noise source that exceeds those levels set forth in Table X at least 10% of the time (L10) shall be deemed in violation of the law.” An L10 or L<sub>10</sub> is known as an *exceedance level* whereby a given dB level is exceeded 10% of the measurement period.

Other terms found in noise ordinances and their definitions follow.

**LDN OR L<sub>dn</sub> (level day night)**—A noise exposure level computed on a twenty-four-hour daily basis whereby 10 dB is added to all readings between the hours 10 P.M. (2200

hours) and 7 A.M. (0700 hours). This adjustment penalizes noise exposure levels that occur during what is considered normal sleeping hours for a community.

**LEQ OR  $L_{eq}$**  (level equivalent continuous equal energy)—That constant noise level that, over a given period of time, expends the same amount of energy as the fluctuating level over the same time period. It is expressed as follows:

$$L_{eq} = 10 \log \sum_{i=1}^{i=n} 10^{L_i/10} t_i \quad \mathbf{6.5(3)}$$

where  $n$  is the total number of samples taken,  $L$  is the noise level in dBA of the  $i$ th sample,  $t$  is the fraction of the total sample time.

$L_{dn}$  and  $L_{eq}$  are used in the U.S. Environmental Protection Agency (EPA) published noise criteria levels that it deemed necessary to health and welfare of U.S. citizens (Table 6.5.2). An  $L_{nd}$  of 45 provides a fair margin of safety. These terms appear in the Federal Housing Authority (FHA) noise standards for construction (Table 6.5.3).

**$L_{NP}$  OR  $L_{np}$**  (level noise pollution)—The sum of the A-weighted SPLs (dBA characteristics of each piece of equipment) added together using the  $L_{eq}$  equation plus 2.56 times the standard deviation of the SPL to account for annoyance due to fluctuation. Figure 6.5.1 shows the use of the  $L_{np}$  in the provisional criteria relating

the noise pollution level (NPL) to community noise level acceptability at construction site boundaries.

**TNI** (or traffic noise index)—Derived from the equation

$$TNI = L(90) + 4d - 30 \text{ dB; and } d = L(10) - L(90) \quad \mathbf{6.5(4)}$$

Some older ordinances call for octave-band analysis. These ordinances were derived from research which showed that some frequencies have a higher annoyance factor and therefore should have a lower allowable dB level. These laws are not as common since they demand a rather arduous measurement procedure and require a specialized instrument.

## INSTRUMENTATION

Generally one of the following types of instruments is indicated for community noise:

**NOISE LOGGING DOSIMETERS/ANALYZER**—Used for longer measurements, possibly twenty-four hours or more. These instruments should have the capability to measure exceedance levels and  $L_{dn}$  levels and to store all data for later printout or downloading to a personal computer.

**INTEGRATING  $L_{eq}$  SOUND LEVEL METER**—Used for measuring noise for shorter periods of time where the noise

**TABLE 6.5.2 YEARLY ENERGY AVERAGE  $L_{EQ}$  REQUISITE TO PROTECT PUBLIC HEALTH WITH ADEQUATE SAFETY MARGIN**

Measure	Indoor		To Protect	Outdoor		To Protect
	Activity Interference	Hearing Loss Consideration	Against Both Effects (b)	Activity Interference	Hearing Loss Consideration	Against Both Effects (b)
Residential with outside space and farm residences	$L_{dn}$	45	45	55	70	55
Residential with no outside space	$L_{dn}$	45	45			
Commercial	$L_{eq(2,4)}$	(a)	70(c)	(a)	70	70(c)
Inside transportation	$L_{eq(2,4)}$	(a)	(a)			
Industrial	$L_{eq(2,4)(d)}$	(a)	70(c)	(a)	70	70(c)
Hospitals	$L_{dn}$	45	45	55		55
	$L_{eq(2,4)}$				70	
Educational	$L_{eq(2,4)}$	45	45	55		55
	$L_{eq(2,4)(d)}$				70	
Recreational areas	$L_{eq(2,4)}$	(a)	70(c)	(a)	70	70(c)
Farm land and general unpopulated land	$L_{eq(2,4)}$			(a)	70	70(c)

Note: Explanation of identified level for hearing loss: The exposure period that results in hearing loss at the identified level is a period of forty years.

Code:

(a) Since different types of activities appear to be associated with different levels, identification of a maximum level for activity interference may be difficult except in those circumstances where speech communication is a critical activity.

(b) Based on lowest level.

(c) Based only on hearing loss.

(d) An  $L_{eq(8)}$  of 75 dB can be identified in these situations so long as the exposure over the remaining sixteen hours per day is low enough to result in negligible contribution to the twenty-four-hour average, that is, no greater than an  $L_{eq}$  of 60 dB.

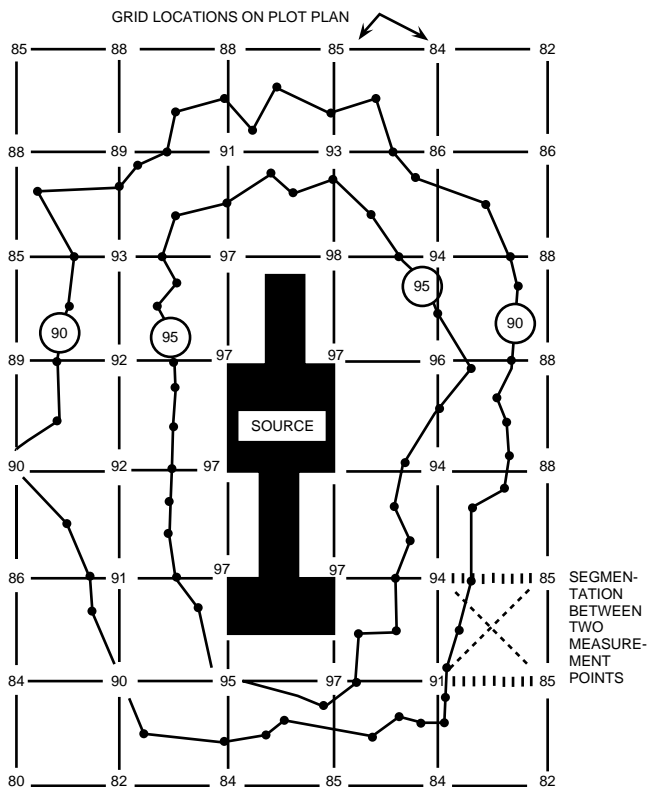

**TABLE 6.5.3 FHA NOISE STANDARDS FOR NEW CONSTRUCTION**

Land Use Category	Exterior Design Noise Level dBA <sup>a</sup>		Description of Land Use Category
	$L_{eq}$	$L_{10}$	
A	57	60	Tracts of lands in which serenity and quiet are of extraordinary significance and serve an important public need, and where the preservation of those qualities is essential if the area is to continue to serve its intended purpose. For example, such areas could include amphitheatres, particular parks or portions of parks, or open spaces, which are dedicated or recognized by appropriate local officials for activities requiring special qualities of serenity and quiet.
B	67	70	Residences, motels, hotels, public meeting rooms, schools, churches, libraries, hospitals, picnic areas, recreation areas, playgrounds, active sports areas, and parks.
C	72	75	Developed lands, properties, or activities not included in categories A and B above.
D	Unlimited	Unlimited	Undeveloped lands
E	52 (Interior)	55 (Interior)	Public meeting rooms, schools, churches, libraries, hospitals, and other such public buildings.

<sup>a</sup>Either  $L_{eq}$  or  $L_{10}$  may be used, but not both. The levels are to be based on a one-hour sample.

**FIG. 6.5.1** Provisional criteria relating NPL to community noise level acceptability. (Reprinted from U.S. Environmental Protection Agency, 1971, *Noise from construction equipment*, [Washington, D.C.: EPA], 17.)

**FIG. 6.5.2** Grid plot of noise source and surrounding areas. Isopleths of noise levels are plotted.

is variable. Additional features are the abilities to add an octave-band filter set, to output for downloading information to a printer or personal computer, and to measure exceedance levels and SEL.

**SIMPLE SOUND LEVEL METER**—A low cost alternative when a quick on-the-spot level check is all that is required. The meter should have a Max-hold feature allowing for accurate measurements of short-duration noises such as moving vehicles or impact noises.

## TRAFFIC NOISE PREDICTION

The National Cooperative Highway Research Program has developed a series of documents (NCHRP 117, NCHRP 144, and NCHRP 174) that provides design guidance to predict and control highway noise. These documents are widely used because of their simplicity and relatively high success in accurately predicting noise. The NCHRP 174 procedure is the last revision in the series. The Federal Highway Administration produced a more detailed and empirically correct version of this model in 1978.

Computer programs are available to predict noise levels generated by a proposed project. They can be used to determine the noise impact on surrounding areas. These programs (hand calculations are possible for simple cases) can determine the noise levels at distances away from the

project and for various atmospheric effects, barriers, and topographical features. Equations for these prediction methods are well documented.

## Plant Noise Survey

In addition to the objectives previously mentioned, a noise survey can be conducted to define a baseline for noise-level analysis. Planning for a noise survey includes:

- Determining the type of acoustical data and time of day measurements are to be taken
- Determining the sampling locations and the significant sound sources
- Using a map to identify significant topographical features and other structures and sound barriers
- Considering the effect of meteorological conditions, such as temperature, barometric pressure, relative humidity, and wind speed and direction on noise levels
- Mapping significant information such as residential, commercial, or industrial zones; population densities; special areas (hospitals); and areas of unique noise characteristics

Figure 6.5.2 shows a map of a region surrounding a source with lines of constant noise levels (isopleths). These isopleths illustrate the impact of a noise source on an area. From this map, a planner can determine the size of buffer zone needed to reduce the noise source impact on the community. Also, a planner can assess the environmental impact of barriers and other noise reduction techniques.

The following guidelines outline how to conduct a plant noise survey:

- Review the working area situation thoroughly; the type of sound fields, the number of people affected, and their locations.
- Determine which machine generates the most sound and find its true sound level.
- Run the survey under time variations as well as normal plant operations. Note that a change in humidity or outside interference can alter results.
- Select sound measuring devices carefully, giving particular attention to the types of microphones necessary.
- Be familiar with the sound measuring equipment before testing. Make sure it is correctly calibrated.
- Set up the measuring devices properly and have no interferences to testing conditions, if possible. Note that the microphone must be mounted on a tripod at the same height as the worker's ear.
- Make sure that all equipment aiding in measuring—the meter, recorder, and correcting apparatus—is outside the testing area.

## 6.6 NOISE CONTROL AT THE SOURCE

---

---

### Source-Path-Receiver Concept

To solve a noise problem, one must find out something about what the noise is doing, where it comes from, how it travels, and what can be done about it. A straightforward approach is to examine the problem in terms of its three basic elements; that is, sound arises from a source, travels over a path, and affects a receiver or listener.

The source can be one or any number of mechanical devices that radiate noise or vibratory energy. Such a situation occurs when several machines are operating at the same time.

The most obvious transmission path by which noise travels is a direct line-of-sight air path between the source and the listener. For example, aircraft flyover noise reaches an observer on the ground by the direct line-of-sight air path.

Noise also travels along structural paths. Noise can travel from one point to another via any one path or a combination of several paths. Noise from a washing machine operating in one apartment can be transmitted to another apartment along air passages such as open windows, doorways, corridors, or duct work. Direct physical contact of the washing machine with the floor or walls sets these building components into vibration. This vibration is transmitted structurally throughout the building causing walls in other areas to vibrate and to radiate noise.

The receiver may be, for example, a single person, or a suburban community.

The solution of a noise problem requires alteration or modification of any or all of the following three basic elements:

- Modifying the source to reduce its noise output
- Altering or controlling the transmission path and the environment to reduce the noise level reaching the listener
- Providing the receiver with personal protective equipment

Modifying the source to reduce noise output involves noise-level specifications, process substitution, machines substitution, and systems design.

### NOISE-LEVEL SPECIFICATIONS

The best way of controlling noise at its source is to buy quieter machines. Buying quieter machines is almost always more economical than trying to reduce noise by modifying the machine after purchase. Everyone profits from quieter machines: the employees' hearing is better protected, work is performed more efficiently, and the employer gains from increased production and product quality. The purchase order should specify the maximum permissible noise levels for equipment as listed in the [Table 6.6.1](#).

### PROCESS SUBSTITUTION

Substituting a quieter process, machine, or tool is another method of controlling noise. Operations such as riveting, punching, shearing, and metal-forming are often performed by impact when a slower energy application is equally effective. Welding is a quieter substitute for riveting, drilling for punching, pressing or rolling for forging, hot forming for cold forming, grinding of castings for chip-

ping, and hydraulic and pneumatic equipment for mechanical equipment.

**MACHINE SUBSTITUTION**

Noise reduction can be significant when belt drives are used instead of gears. If using gears is necessary, rotating gears should be substituted for square gears; nylon gears for metallic gears. Other recommendations for reducing noise are described in the subsection on control of noise sources by design and in Section 6.7.

**SYSTEMS DESIGN**

Besides engineering controls, noise reduction and isolation can be approached through machine mounting or by architectural means. If machines are laid out too closely, the operator may be exposed to a high dB level. However, if machines are spaced adequately apart, noise levels can be within acceptable limits. Noise can be confined within a restricted area by architectural means: building location

and arrangement, design, use of suitable building materials, and location of noise-producing and noise-sensitive areas. Sound control for ceilings in offices must also be planned at the architectural stage.

Holes should not be placed back to back immediately next to each other. Electrical boxes should be staggered, at least one stud space. A nonhardening, nonskinning, resilient caulking material should be used to seal all cutouts, such as around electrical and telephone outlets. Also, all intersections with the adjoining structure, such as under-floor and ceiling runner tracks, around the perimeter where the assembly meets the floor, ceiling, and partitions, should be sealed. Using center-of-gravity mounting whenever feasible prevents translational modes of vibration from coupling to rotational modes.

**Control of Noise Source by Design**

This section describes controlling the noise source by design including reducing impact forces, reducing speeds and pressures, reducing frictional resistance, reducing the ra-

FIG. 6.6.1 Methods of reducing impact forces to lower noise radiation.

FIG. 6.6.2 For a given mass flow, squirrel-cage fans are generally less noisy than propeller-type fans.

FIG. 6.6.3 Reducing friction of rotating and sliding parts to decrease noise radiation.

diating area, reducing noise leakage, and isolating and damping vibrating elements.

### REDUCING IMPACT FORCES

Many machines and items of equipment are designed with parts that strike forcefully against other parts, producing noise. Often, this striking action or impact is essential to the machine's function. A familiar example is the typewriter—its keys must strike the ribbon and paper to leave an inked impression. But the force of the key also produces noise as the impact falls on the ribbon, paper, and platen.

Several steps can reduce noise from impact forces. The particular remedy is determined by the nature of the machine. Not all of the following steps are practical for every machine and every impact-produced noise. However, applying even one suggested measure can often reduce the noise appreciably.

Some of the more obvious design modifications follow. Figure 6.6.1 shows the application of some of these measures.

Reduce the weight, size, or height of fall of the impacting mass.

Cushion the impact by inserting a layer of shock-absorbing material between the impacting surfaces. (For ex-

ample, insert several sheets of paper in the typewriter behind the top sheet to absorb some of the noise-producing impact of the keys.) In some situations, inserting a layer of shock-absorbing material behind each of the impacting heads or objects reduces the transmission of impact energy to other parts of the machine.

Whenever practical, one of the impact heads or surfaces should be made of nonmetallic material to reduce resonance (ringing) of the heads.

Substitute the application of a small impact force over a long time period for a large force over a short period to achieve the same result.

Smooth out the acceleration of moving parts by applying accelerating forces gradually. Avoid high, jerky acceleration or jerky motion.

Minimize overshoot, backlash, and loose play in cams, followers, gears, linkages, and other parts. To achieve this measure, reduce the operational speed of the machine, make better adjustments, or use spring-loaded restraints or guides. Machines that are well made, with parts machined to close tolerances, generally produce a minimum of impact noise.

### REDUCING SPEEDS AND PRESSURES

Reducing the speed of rotating and moving parts in machines and mechanical systems results in smoother operation and lower noise output. Likewise, reducing pressure and flow velocities in air, gas, and liquid circulation systems lessens turbulence, resulting in decreased noise radiation. The following suggestions can be incorporated in design:

Operate fans, impellers, rotors, turbines, and blowers at the lowest bladetip speeds that still meet job needs. Use large-diameter, low-speed fans rather than small-diameter, high-speed units for quiet operation. In short, maximize diameter and minimize tip speed.

All other factors being equal, centrifugal squirrel-cage type fans are less noisy than vane axial or propeller type fans.

Figure 6.6.2 shows these two types of fans.

In air ventilation systems, reducing the speed of the air flow by 50% can lower the noise output by 10 to 20

FIG. 6.6.4 Effects of static and dynamic unbalance on rotor operation.

dB, or roughly one-quarter to one-half of the original loudness. Air speeds less than 3 m/s measured at a supply or return grille produce a level of noise that usually is unnoticeable in residential or office areas. To reduce air speed in a given system operate lower motor or blower speeds, install more ventilating grilles, or increase the cross-sectional area of the existing grilles.

## REDUCING FRICTIONAL RESISTANCE

Reducing friction between rotating, sliding, or moving parts in mechanical systems frequently results in smoother operation and lower noise output. Similarly, reducing flow resistance in fluid distribution systems results in less noise radiation.

Four of the more important factors that should be checked to reduce frictional resistance in moving parts are the following (see [Figure 6.6.3](#)):

**Alignment:** Proper alignment of all rotating, moving, or contacting parts results in less noise output. Good axial and directional alignment in pulley systems, gear trains, shaft coupling, power transmission systems, and bearing and axle alignment are fundamental requirements for low noise output.

**Polish:** Highly polished and smooth surfaces between sliding, meshing, or contacting parts are required for quiet operation, particularly where bearings, gears, cams, rails, and guides are concerned.

**Balance:** Static and dynamic balancing of rotating parts reduces frictional resistance and vibration, resulting in lower noise output (see [Figure 6.6.4](#)).

**Eccentricity (out-of-roundness):** Off-centering of rotating parts such as pulleys, gears, rotors, and shaft and bearing alignment causes vibration and noise. Likewise, out-of-roundness of wheels, rollers, and gears causes uneven wear resulting in flat spots that generate vibration and noise.

The key to effective noise control in fluid systems is *streamline flow*. This fact holds true for all their systems including air flow in ducts or vacuum cleaners and water flow in plumbing systems. Streamline flow is simply smooth, nonturbulent, low-friction flow.

Two factors that determine whether flow is streamline or turbulent are the speed of the fluid and the cross-sectional area of the flow path, that is, the pipe or duct diameter. The rule of thumb for quiet operation is to use a low-speed, large-diameter system to meet a specified flow capacity requirement. However, even such a system can inadvertently generate noise if certain aerodynamic design features are overlooked or ignored. A system designed for quiet operation employs the following features (see [Figure 6.6.5](#)):

**Low fluid speed:** Low fluid speeds avoid turbulence, one of the main causes of noise.

**Smooth boundary surfaces:** Duct or pipe systems with smooth interior walls, edges, and joints generate less turbulence and noise than systems with rough or jagged walls or joints.

**Simple layout:** A well-designed duct or pipe system with a minimum of branches, turns, fittings, and connectors is less noisy than a complicated layout.

**Long-radius turns:** Changes in flow direction should be gradual and smooth. A recommendation is for turns to have a curve radius equal to about five times the pipe diameter or major cross-sectional dimension of the duct.

**Flared sections:** Flaring of intake and exhaust openings, particularly in a duct system, tends to reduce flow speeds at these locations, often with substantial reductions in noise output.

**Streamlined transition in flow path:** Changes in flow path dimensions or cross-sectional areas should be gradual and smooth with tapered or flared transition sections to avoid turbulence. A good rule of thumb is to keep the cross-sectional area of the flow path as large and uniform as possible throughout the system.

**Minimal obstacles:** The greater the number of obstacles in the flow path, the more tortuous, turbulent, and noisy the flow. All other required and functional devices in the path, such as structural supports, deflectors, and control dampers, should be as small and streamlined as possible to smooth out the flow patterns.

## REDUCING RADIATING AREA

Generally speaking, the larger the vibrating part or surface, the greater the noise output. The rule of thumb for quiet machine design is to minimize the effective radiating surface areas of the parts without impairing their operation or structural strength. This design includes making parts smaller, removing excess material, or cutting openings, slots, or perforations in the parts. For example, replacing a large, vibrating sheet-metal safety guard on a machine with a guard made of wire mesh or metal webbing might substantially reduce noise because of the reduced surface area of the part (see [Figure 6.6.6](#)).

## REDUCING NOISE LEAKAGE

In many cases, machine cabinets can be made into effective soundproof enclosures through simple design changes and the application of some sound-absorbing treatment. Adopting some of the following recommendations may lead to substantial reductions in noise output:

**Caulk all unnecessary holes or cracks, particularly at joints.**  
**Seal electrical or plumbing penetrations of the housing or cabinet with rubber gaskets or a suitable nonsetting caulk.**

**If practical, cover all other functional or required openings or ports that radiate noise with lids or shields edged with soft rubber gaskets to effect an airtight seal.**

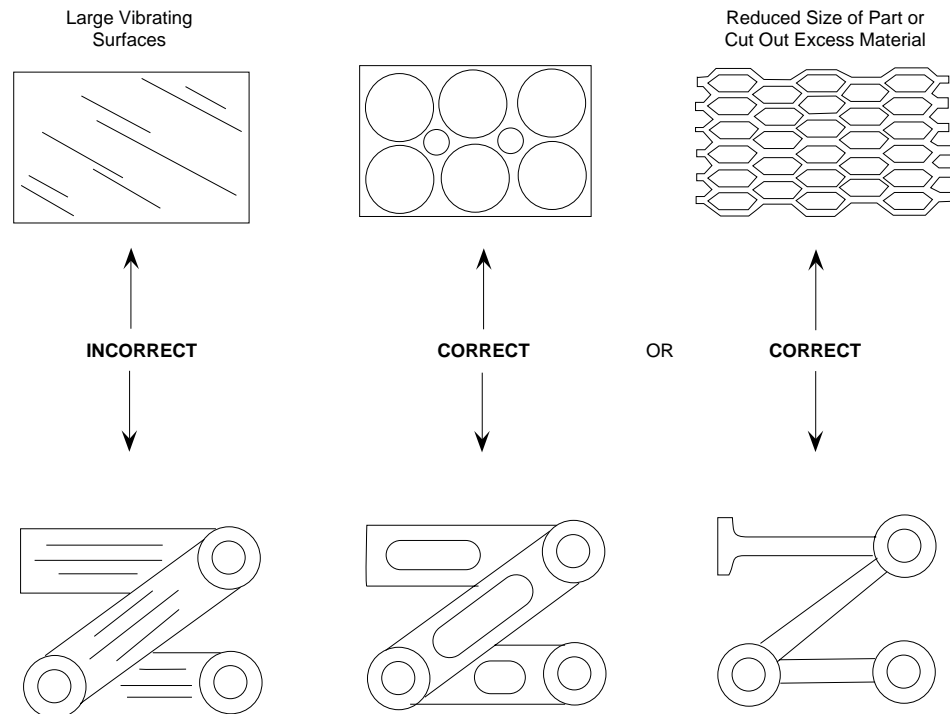

FIG. 6.6.5 Design of quiet flow systems.

Equip other openings required for exhaust, cooling, or ventilation purposes with mufflers or acoustically lined ducts.

Direct openings away from the operator and other people.

### ISOLATING AND DAMPING VIBRATING ELEMENTS

In all but the simplest machines, the vibrational energy from a specific moving part is transmitted through the machine structure, forcing other component parts and surfaces to vibrate and radiate sound—often with greater intensity than that generated by the originating source itself.

Generally, vibration problems have two parts. First, energy transmission must be prevented between the source and surfaces that radiate the energy. Second, the energy must be dissipated or attenuated somewhere in the structure. The first part of the problem is solved by *isolation*. The second part is solved by *damping*.

The most effective method of vibration isolation involves the resilient mounting of the vibrating component on the most massive and structurally rigid part of the machine. All attachments or connections to the vibrating part, in the form of pipes, conduits, and shaft couplers, must have flexible or resilient connectors or couplers. For example, pipe connections to a pump that is resiliently mounted on the structural frame of a machine should be made of resilient tubing and mounted as close to the pump

as possible. Resilient pipe supports or hangers may also be required to avoid bypassing the isolated system (see [Figures 6.6.7](#) and [6.6.8](#)).

Damping material or structures are those that have some viscous properties. They tend to bend or distort slightly, thus consuming part of the noise energy in molecular motion. The use of spring mounts on motors and laminated galvanized steel and plastic in air-conditioning ducts are examples.

When the vibrating noise source is not amenable to isolation, as in ventilation ducts, cabinet panels, and covers, then damping materials can be used to reduce the noise.

The type of material best suited for a particular vibration problem depends on several factors such as size, mass, vibrational frequency, and operational function of the vibrating structure. Generally speaking, the following guidelines should be observed in the selection and use of such materials to maximize vibration damping efficiency (see [Figure 6.6.9](#)):

Damping materials should be applied to those sections of a vibrating surface where the most flexing, bending, or motion occurs. These areas are usually the thinnest sections.

For a single layer of damping material, the stiffness and mass of the material should be comparable to that of the vibrating surface to which it is applied. Therefore, single-layer damping materials should be about two or three times as thick as the vibrating surface to which they are applied.

**FIG. 6.6.7** Isolate large radiating surfaces from vibrating parts. (Reprinted from U.S. Department of Commerce)

Sandwich materials (*laminates*) made up of metal sheets bonded to mastic (sheet metal viscoelastic composites) are more effective vibration dampers than single-layer materials; the thickness of the sheet-metal constraining layer and the viscoelastic layer should each be about one-third the thickness of the vibrating surface to which they are applied. Ducts and panels can be purchased fabricated as laminates.

### Control of Noise Source by Redress

The best way to solve noise problems is with good design of the source. However, frequently an existing source is a noise problem either because of age, abuse, or poor design. Then the problem must be redressed or corrected as it exists. The following sections identify measures for redressing or correcting the source.

**FIG. 6.6.8** Techniques to reduce the generation of airborne and structure-borne noise in machines. (Adapted from U.S. Department of Commerce)

### BALANCING ROTATING PARTS

One of the main sources of machinery noise is structural vibration caused by the rotation of poorly balanced parts, such as fans, fly wheels, pulleys, cams, and shafts. Measures used to correct this condition involve adding counterweights to the rotating unit or removing some weight from the unit. A familiar noise caused by imbalance is in the high-speed spin cycle of washing machines. The imbalance results from clothes being unevenly distributed in the tub. By redistributing the clothes, balance is achieved, and the noise ceases. This same principle of balance can be applied to furnace fans and other common sources of such noise.

### REDUCING FRICTIONAL RESISTANCE

A well-designed machine that has been poorly maintained can become a serious source of noise. General cleaning and lubrication of all rotating, sliding, or meshing parts at contact points go a long way toward fixing the problem.

### APPLYING DAMPING MATERIALS

Since a vibrating body or surface radiates noise, applying any material that reduces or restrains the vibrational motion of that body decreases its noise output. Three basic types of redress vibration damping materials are available:

- Liquid mastics, which are applied with a spray gun and harden into relatively solid materials, the most common being automobile undercoating
- Pads of rubber, felt, plastic foam, leaded vinyls, adhesive tapes, or fibrous blankets, which are glued to the vibrating surface
- Sheet metal viscoelastic laminates or composites, which are bonded to the vibrating surface

FIG. 6.6.9 Reducing vibration with damping materials.

FIG. 6.6.10 Transmission loss potential versus transmission loss realized for various opening sizes as a percent total wall area. (Reprinted from Bell, 1973, *Fundamentals of industrial noise control*, [Trumbull, CN: Harme Publications].)

### SEALING NOISE LEAKS

Small holes in an otherwise noise-tight structure can reduce the effectiveness of the noise control measures. As shown in Figure 6.6.10, if the designed transmission loss of an acoustical enclosure is 40 dB, an opening that comprises only 0.1% of the surface area reduces the effectiveness of the enclosure by 10 dB.

### PERFORMING ROUTINE MAINTENANCE

The noise of a worn muffler is familiar. Likewise, studies of automobile tire noise in relation to pavement roughness show that maintenance of the pavement surface is essential to keep noise at minimum levels. Normal road wear can yield noise increases on the order of 6 dBA.

Faulty installation and maintenance can result in ex-

cessive vibration. Equipment should be checked periodically. Gradual increases in vibration should be examined in routine maintenance; sudden increases call for action. Increased vibration in machinery can be caused by the following:

- Rotational imbalance which requires rebalancing
- Misalignment of couplings or bearings
- Eccentric journals
- Defective or damaged gears
- Bent shafts
- Mechanical looseness
- Faulty drive belts
- Rubbing parts and resonant conditions

Rapid increases in vibration can be traced to a variety of causes, such as lack of lubrication, overload, or misalign-

ment. In pumps, cavitation can erode an impeller. In fans, dirt adheres to the blades and then breaks off unevenly.

## 6.7

# NOISE CONTROL IN THE TRANSMISSION PATH

---

---

After all possible ways of controlling the noise at the source are tried, the next defense is to set up devices in the transmission path to block or reduce the flow of sound energy. This noise control can be done in several ways: (a) absorbing the sound along the path, (b) deflecting the sound in some other direction by placing a reflecting barrier in its path, or (c) containing the sound by placing the source inside a sound-insulating box or enclosure.

Selection of the most effective technique depends upon various factors, such as the size and type of source, the intensity and frequency range of the noise, and the nature and type of environment.

### Acoustical Separation

Using the absorptive capacity of the atmosphere, as well as divergence, is a simple, economical method of reducing the noise level. Air absorbs high-frequency sounds more effectively than it absorbs low-frequency sounds. However, if enough distance is available, even low-frequency sounds are absorbed appreciably.

When the distance from a point source is doubled, the sound pressure level is lowered by 6 dB. It takes about a 10 dB drop to halve the loudness. If the line source is a railroad train, the noise level drops by only 3 dB for each doubling of distance from the source. The main reason for this lower rate of attenuation is that line sources radiate sound waves that are cylindrical in shape. The surface area of such waves only increases two-fold for each doubling of distance from the source. However, when the distance

from the train becomes comparable to its length, the noise level drops at a rate of 6 dB for each subsequent doubling of distance.

Indoors, the noise level generally drops only from 3 to 5 dB for each doubling of distance in the vicinity of the source. However, further from the source, reductions of only 1 or 2 dB occur for each doubling of distance due to the reflections of sound off hard walls and ceiling surfaces.

### ABSORBENT MATERIALS

Noise, like light, bounces from one hard surface to another. In noise control work, this bouncing is called *reverberation*. If a soft, spongy material is placed on the walls, floors, and ceiling, the reflected sound is diffused and soaked up (absorbed). Sound-absorbing materials are rated either by their *Sabin absorption coefficients* ( $\alpha_{SAB}$ ) at 125, 500, 1000, 2000, and 4000 Hz or by a single number rating called the *noise reduction coefficient* (NRC).

If a unit area of open window is assumed to transmit all and reflect none of the acoustical energy that reaches it, it is assumed to be 100% absorbent. This unit area of totally absorbent surface is called a *sabin*. The absorptive properties of acoustical materials are then compared with this standard. The performance is expressed as a fraction or percentage of the sabin ( $\alpha_{SAB}$ ). The NRC is the average of the  $\alpha_{SAB}$ s at 250, 500, 1000, and 2000 Hz rounded to the nearest multiple of 0.05. The NRC has no physical meaning. It is a useful means of comparing similar materials.

FIG. 6.7.1 Various types of acoustical duct lining, baffles, and silencers.

Sound-absorbing materials such as acoustical tile, carpets, and drapes placed on ceiling, floor, or wall surfaces can reduce the noise level in most rooms by about 5 to 10 dB for high-frequency sounds, but only by 2 or 3 dB for low-frequency sounds. Unfortunately, such treatment does not protect an operator of a noisy machine who is in the direct noise field. For greatest effectiveness, sound-absorbing materials should be installed as close to the noise source as possible.

If only a small or limited amount of sound-absorbing material is available, putting it in the upper trihedral corners of the room, formed by the ceiling and two walls, is the most effective use of it in a noisy room. Due to the process of reflection, the concentration of sound is greatest in the trihedral corners of a room. Additionally, the upper corner locations also protect lightweight fragile materials from damage.

Because of their light weight and porous nature, acoustical materials are ineffectual in preventing the transmission of either airborne or structure-borne sound from one room to another. In other words, if you can hear people walking or talking in the room or apartment above, installing acoustical tile on your ceiling will not reduce the noise transmission.

## ACOUSTICAL LININGS

Lining the inside surfaces of ducts, pipe chases, or electrical channels with sound-absorbing materials can effectively reduce the noise transmitted through such passageways. In typical duct installations, noise reductions of 10 dB/m for an acoustical lining 2.5 cm thick are well within reason for high-frequency noise. A comparable degree of noise reduction for the lower frequency sounds is more difficult

to achieve because it usually requires at least a doubling of the thickness and length of the acoustical treatment. Figure 6.7.1 shows various types of duct lining baffles and silencers.

## Physical Barriers

### BARRIERS AND PANELS

Placing barriers, screens, or deflectors in the noise path is an effective way of reducing noise transmission, provided that the barriers are large enough in size and depending upon whether the noise is high-frequency or low-frequency. High-frequency noise is reduced more effectively than low-frequency noise.

The effectiveness of a barrier depends on its location, its height, and its length. Figure 6.7.2 shows that the noise can follow five different paths.

First, noise follows a direct path to receivers who can see the source well over the top of the barrier. The barrier

FIG. 6.7.2 Noise paths from a source to a receiver. (Reprinted from *National Cooperative Highway Research Program Report 174*, 1976.)

does not block their line of sight (L/S) and therefore provides no attenuation. No matter how absorptive the barrier is, it cannot pull the sound downward and absorb it.

Second, noise follows a diffracted path to receivers in the shadow zone of the barrier. The noise that passes just over the top edge of the barrier is diffracted (bent) down into the apparent shadow shown in the figure. The larger the angle of diffraction, the more the barrier attenuates the noise in this shadow zone. In other words, less energy is diffracted through large angles than through smaller angles.

Third, in the shadow zone, the noise transmitted di-

**TABLE 6.7.2 BARRIER DESIGN**

Attenuation (dB)	Complexity
5	Simple
10	Attainable
15	Very difficult
20	Nearly impossible

rectly through the barrier is significant in some cases. For example, with large angles of diffraction, the diffracted noise may be less than the transmitted noise. In this case, the transmitted noise compromises the performance of the barrier. It can be reduced with a heavier barrier. The allowable amount of transmitted noise depends on the total barrier attenuation needed.

The fourth path shown in Figure 6.7.2 is the reflected path. After reflection, noise concerns only a receiver on the opposite side of the source. For this reason, acoustical absorption on the face of the barrier can sometimes reduce this reflected noise; however, this treatment does not benefit receivers in the shadow zone.

In most practical cases, reflected noise is not important in barrier design. If the source of noise is represented by a line of noise, another short-circuit path is possible. Part of the source may be unshielded by the barrier. For example, the receiver might see the source beyond the ends of the barrier if the barrier is not long enough. This noise

from around the ends may compromise, or short-circuit, barrier attenuation. The required barrier length depends on the total net attenuation needed. When 10 to 15 dB attenuation is needed, barriers must be long. Therefore, to be effective, barriers must not only break the line of sight to the nearest section of the source, but also to the source far up and down the line.

Of these four paths, the noise diffracted over the barrier into the shadow zone represents the most important parameter from the barrier design point of view. Generally, determining barrier attenuation or barrier noise reduction involves only calculating the amount of energy diffracted into the shadow zone. The procedures presented in the barrier nomograph used to predict highway noise are based on this concept.

Another general principle of barrier noise reduction is

CORRECT

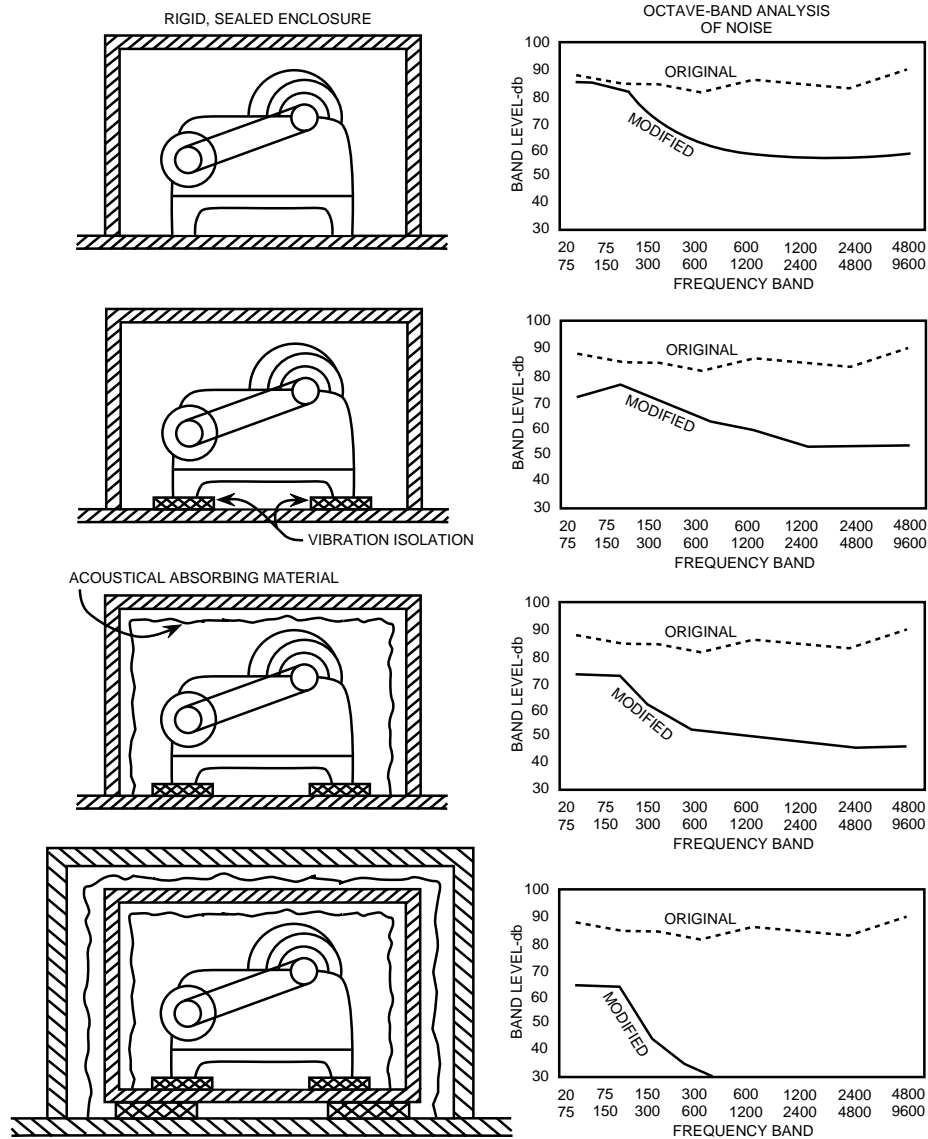

FIG. 6.7.4 Effectiveness of various noise reduction techniques. (Adapted by permission of General Radio Company.) Continued on next page

## INCORRECT

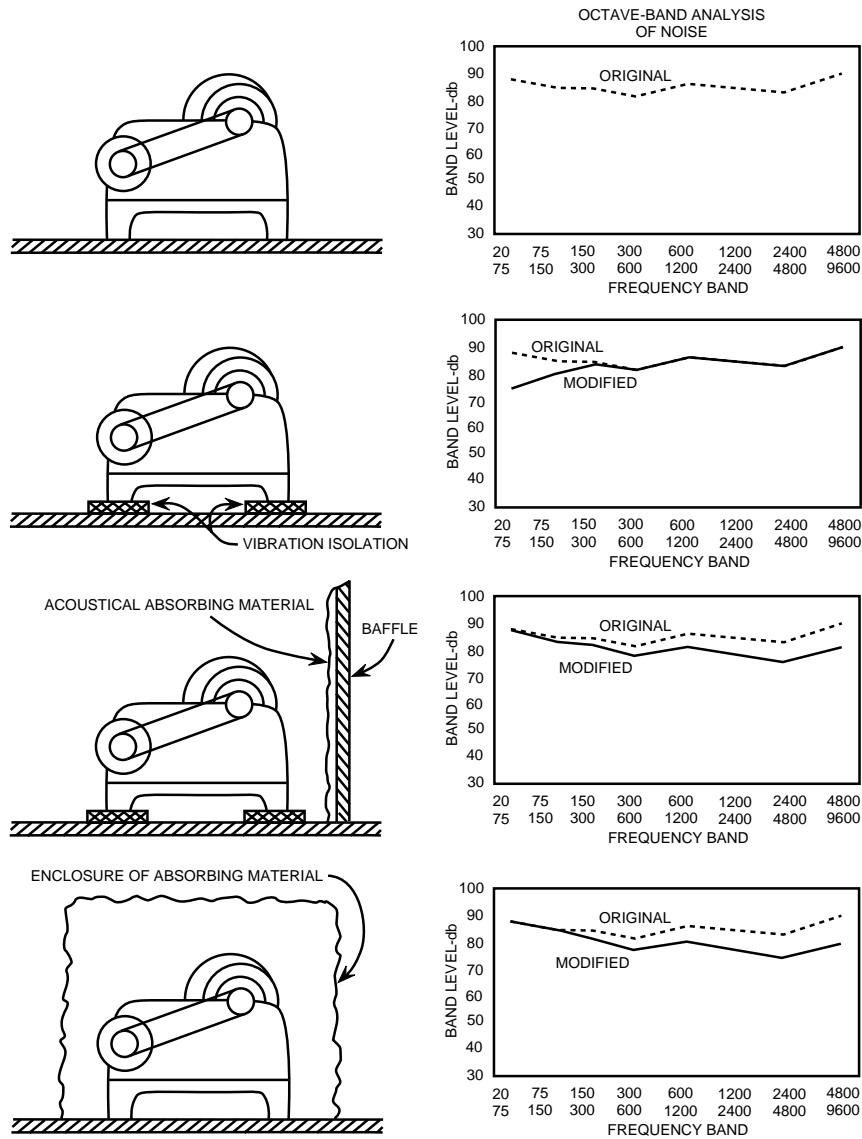

FIG. 6.7.4 Continued

the relation between noise attenuation expressed in (1) dBs, (2) energy terms, and (3) subjective loudness. Table 6.7.1 gives these relationships for line sources. As indicated in the loudness column, a barrier attenuation of 3 dB is barely discerned by the receiver. However, to attain this reduction, 50% of the acoustical energy must be removed. To cut the loudness of the source in half, a reduction of 10 dB is necessary. That is equivalent to eliminating 90% of the energy initially directed toward the receiver. As previously indicated, this drastic reduction in energy requires very long and high barriers. In summary, in barrier design, the complexity of the design increases with the need for attenuation as shown in Table 6.7.2.

The design of roadside barriers sometimes uses the barrier nomograph in reverse order. A set of typical solutions

is summarized in Table 6.7.3. The noise reduction at 152 m is less than that at 30 m because the barrier does not cast as large a shadow at a distance. The effectiveness of the barrier is reduced for trucks because of the elevated nature of the source.

### Transmission Loss

When the position of the noise source is close to the barrier, the diffracted noise is less important than the transmitted noise. If the barrier is a wall panel that is sealed at the edges, the transmitted noise is the only concern.

The ratio of the sound energy incident on one surface of a panel to the energy radiated from the opposite surface is called the *sound transmission loss* (TL). The actual

FIG. 6.7.5 Various types of flexible connectors.

energy loss is partially reflected and partially absorbed. Since TL is frequency-dependent, only a complete octave or one-third octave band curve fully describes the performance of the barrier.

## ENCLOSURES

Sometimes enclosing a noisy machine in a separate room or box is more practical and economical than quieting it by altering its design, operation, or component parts. The walls of the enclosure should be massive and airtight to contain the sound. Absorbent lining on the interior surfaces of the enclosure can reduce the reverberant buildup of noise within it. Structural contact between the noise source and the enclosure must be avoided, or the source vibration can be transmitted to the enclosure walls and thus short-circuit the isolation. For maximum effective noise control, all of the techniques illustrated in Figure 6.7.3 must be employed. Figure 6.7.4 shows the design

and effectiveness of various enclosure configurations.

## Isolators and Silencers

### VIBRATION ISOLATORS AND FLEXIBLE COUPLERS

If the noise transmission path is structure-borne in character, vibration isolators in the form of resilient mountings, flexible couplers, or structural breaks or discontinuities should be interposed between the noise source and receiver. For example, string mounts placed under a machine can prevent the floor from vibration, or an expansion joint cut along the outer edge of a floor in a mechanical equipment room can reduce the amount of vibration transmitted to the structural frame or walls of a building. These measures are shown in Figures 6.7.5 and 6.7.6; several often-used procedures, in Figure 6.7.7.

FIG. 6.7.6 Various types of vibration isolators.

FIG. 6.7.7 Isolation of machinery vibration.

*Absorptive silencer.* This silencer is the most common type and takes the form of a duct lined on the interior with a sound-absorptive material.

ABSORPTIVE SILENCER

*Reactive expansion chamber.* This type reflects sound energy back toward the source to cancel some of the oncoming sound energy.

REACTIVE EXPANSION CHAMBER

*Reactive resonator.* This type functions in approximately the same way as the reactive expansion chamber type.

REACTIVE RESONATOR

*Plenum chamber.* This device allows the sound to enter a small opening in the chamber; that sound which has not been absorbed by the chamber's acoustical lining leaves by a second small opening, generally at the opposite end of the chamber.

PLENUM CHAMBER

*Lined bend.* Sound energy flowing down a passage is forced to turn a corner, the walls of which are lined with acoustical material. The sound energy is thus forced to impinge directly on a sound-absorbing surface as it reflects its way around the corner; each successive impingement takes sound energy from the traveling wave.

LINED BEND

*Diffuser.* This device does not actually reduce noise. In effect, it prevents the generation of noise by disrupting high-velocity gas streams.

DIFFUSER

FIG. 6.7.8 Basic silencers.

## MUFFLERS AND SILENCERS

No distinction exists between mufflers and silencers. They are often used interchangeably. They are in effect acoustic filters and are used to reduce fluid flow noise. Figure 6.7.8 shows six basic types of silencers.

The devices can be classified into:

FIG. 6.7.9 Muffler.

Dissipative or absorptive silencers whose noise reduction is determined by fibrous or porous sound absorbing liners. Where hot gases are handled, the absorbent may be metal or even ceramic. These devices are good for high-frequency sounds.

Reactive silencers whose noise reduction is determined mainly by geometry. These devices are shaped to reflect or expand the sound waves with resultant self-destruction. Reactive silencers are used for low-frequency applications.

Figure 6.7.9 shows a typical muffler that is designed to attenuate sound waves with minimal back pressure. It includes a cylindrical-type unit. The outer portion of the through-pipe conduit contains a number of cavities where noise suppression occurs. A porous packing is sometimes used to increase efficiency. Airflow to the cavities is regulated by the size and number of holes from the center section. Mufflers are effective for high- and middle-frequency noise control.

## 6.8 PROTECTING THE RECEIVER

When neither reducing noise at its source nor reducing its transmission from the source to the receiver is satisfactory, the receiver must be protected. Protection is likely to be needed when conditions change frequently or when several requirements must be met at the same time.

### Work Schedules

The amount of continuous exposure to high noise levels must be limited. For hearing protection, scheduling noisy operation for short intervals of time each day over several days is preferable to a continuous eight-hour run for a day or two.

In industrial or construction operations, an intermittent work schedule benefits not only the operator of the noisy equipment but also other workers in the vicinity. If an intermittent schedule is not possible, workers should have relief time during the day. They should take their relief time at a low-noise-level location and should not trade this time for more pay, paid vacation, or an early out at the end of the day!

Inherently noisy operations, such as street repair, municipal trash collection, factory operation, and aircraft traffic, should be curtailed at night and early morning to avoid disturbing the sleep of the community.

### Equipment and Shelters

#### Ear Protection

Molded and pliable earplugs, cup-type protectors, and helmets are commercially available as hearing protectors. Such devices provide noise reductions from 15 to 35 dB (Figure 6.8.1). Earplugs are effective only if they are properly fitted by medical personnel. As shown in Figure 6.8.1, maximum protection can be obtained when both plugs and muffs are used. Only muffs with certification that stipulates the attenuation should be used.

#### Individual Enclosures or Noise Shelters

In an industrial plant, large areas where the noise level is too high for efficient work often exist. Any kind of office

FIG. 6.8.1 Sound attenuation characteristics of various types of ear protectors.

FIG. 6.8.2 Principle of the labyrinth noise shelter.

work is impractical at such noise levels, yet inplant offices are needed.

Noise shelters provide an effective solution for these problems. They may be fully enclosed rooms with separate heating and ventilating systems, which protect from dust and odors as well as noise. Plant offices are often designed and constructed this way based on the principles described in Section 6.7.

When easy access to a noise shelter is needed, the labyrinth principle can be applied. This principle is useful in isolating areas where specialized work is done (such as, inspection and final adjustment) and where both people and work move continually in and out. Figure 6.8.2 shows how this principle is constructed. Such a noise shelter can be used for the operator's station when the machine controls are within the shelter and vision is through a large window area. In such construction, the wall surrounding the sheltered area should have a high-sound-transmission loss, and double glass suitably spaced and mounted to reduce noise transmission in the window.

Noise does not enter the space because it is reflected—preferably two or more times—from surfaces covered with absorbing material. At each reflection, appreciable noise reduction occurs. The noise shelter is also lined with absorbing material to absorb what noise does enter. The per-

formance quality of such enclosures depends on their design and construction.

The labyrinth principle effectively prevents the passage of noise from one work area to another. The labyrinth principle allows free passage between work areas without the interference of closed doors.

Other kinds of individual enclosures include the cabs used on agricultural and earth-moving machines. These cabs and motor trucks provide shelter from noise as well as weather conditions. Industrial crane cabs also provide this protection since safety in their areas depends on the alertness and ability of the operator.

### Other Possibilities

When the noise within a confined area is too high to allow workers into it even with personal protection devices, the operation might be automated. An automated process is supervised from observation posts, that is, from remote-control stations where workers are adequately protected. A remote-control post receives information via a closed-circuit television, or it can be a highly insulated area within the department. Mechanical devices handle the production procedures under operator or computer control. For ex-

ample, rolling mills are controlled from soundproof cabins. The same is true of workshops for assembling and testing engines. The noise of such operations cannot normally be stifled at the source.

Noise-cancelling microphones and shielded microphones keep electrical communication operable at high-noise levels.

# Sources and Characteristics

## 7.1 NATURE OF WASTEWATER

The nature of wastewater is described by its flow and quality characteristics. In addition, wastewater discharges are classified based on whether they are from municipalities or industries. Flow rates and quality characteristics of industrial wastewater are more variable than those for municipal wastewater.

### Flow Rates

Municipal wastewater is comprised of domestic (or sanitary) wastewater, industrial wastewater, infiltration and inflow into sewer lines, and stormwater runoff. Domestic wastewater refers to wastewater discharged from residences and from commercial and institutional facilities (Metcalf and Eddy, Inc. 1991). Domestic water usage, and the resultant wastewater, is affected by climate, community size, density of development, community affluence, dependability and quality of water supply, water conservation requirements or practices, and the extent of metered services. Metcalf and Eddy, Inc. (1991) provide details on the influence of these factors. Additional factors influencing water use include the degree of industrialization, cost of water, and supply pressure (Qasim 1985). One result of the combined influence of these factors is water use fluctuations. Table 7.1.1 summarizes such fluctuations

**TABLE 7.1.1 TYPICAL FLUCTUATIONS IN WATER USE IN COMMUNITY SYSTEMS**

Water Use	Percentage of Average for Year	
	Range	Typical
Daily average in maximum month	110–140	120
Daily average in maximum week	120–170	140
Maximum day	160–220	180
Maximum hr	225–320	270 <sup>a</sup>

Source: Metcalf and Eddy, Inc., 1991, *Wastewater engineering*, 3d ed. (New York: McGraw-Hill).

Note: <sup>a</sup>1.5 × maximum day value.

(Metcalf and Eddy, Inc. 1991). About 60 to 85% of water usage becomes wastewater, with the lower percentages applicable to the semiarid region of the southwestern United States (Metcalf and Eddy, Inc. 1991).

Environmental engineers can use unit flow rate data to develop estimates for wastewater flow rates from residential areas, commercial districts, and institutional facilities. Tables 7.1.2 through 7.1.4 depict data for these use categories, respectively. Industrial wastewater flow rates vary and are a function of the type and size of industry. For estimation purposes, typical design flows from industrial areas that have little or no wet-process-type industries are 1000 to 1500 gal/acre per day (9 to 14 m<sup>3</sup>/ha · d) for light industrial developments and 1500 to 3000 gal/acre per day (14 to 28 m<sup>3</sup>/ha · d) for medium industrial developments (Metcalf and Eddy, Inc. 1991). Better estimates for industries can be developed with industry-specific information.

Wastewater volume generated in a municipality depends on the population served, the per capita contribu-

**TABLE 7.1.2 TYPICAL WASTEWATER FLOW RATES FROM RESIDENTIAL SOURCES**

Source	Unit	Flow, gal/unit · d	
		Range	Typical
Apartment:			
High-rise	Person	35–75	50
Low-rise	Person	50–80	65
Hotel	Guest	30–55	45

Rest home	Resident	50–120	85
School, day	With cafeteria, gym, and showers	Student	15–30
	With cafeteria only	Student	10–20
	Without cafeteria and gym	Student	5–17
School, boarding	Student	50–100	75

Source: Metcalf and Eddy, Inc., 1991.  
Note: 1 = gal × 3.7854.

tion, and other nondomestic sources such as industrial wastewater discharges. Environmental engineers may need to use population forecasting to project future rates of wastewater generation in the service area of a wastewater treatment plant. Some mathematical or graphical methods used to project population data to a design year include (Qasim 1985):

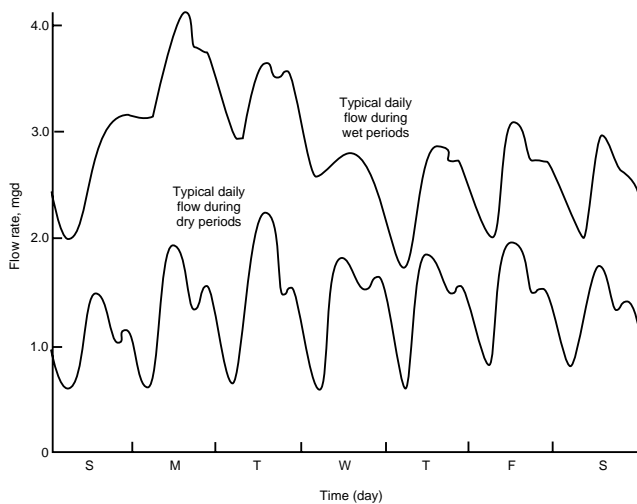

- arithmetic growth
- geometric growth

- decreasing rate of increase
- mathematical or logistic curve fitting
- graphical comparison with similar cities
- ratio method
- employment forecast
- birth cohort

Water usage exhibits daily, weekly, and seasonal patterns; and wastewater flow rates can also exhibit such patterns. [Figures 7.1.1](#) and [7.1.2](#) show typical hourly, daily,

**FIG. 7.1.1** Typical pattern of hourly variations in domestic wastewater flow rates. (Reprinted, with permission, from Metcalf and Eddy, Inc., 1991.)

and weekly wastewater flow rates, respectively (Metcalf and Eddy, Inc. 1991).

Wide variations of wastewater flow rates can occur within a municipality. For example, minimum to maximum flow rates range from 20 to 400% of the average daily rate for small communities with less than 1000 people, from 50 to 300% for communities with populations between 1000 and 10,000, and up to 200% for communities up to 100,000 in population (Water Pollution Control Federation and American Society of Civil Engineers 1977). Large municipalities have variations from 1.25 to 1.5 average flow. When storm water runoff goes into municipal sewerage systems, the maximum flow rate is often two to four times the average dry-weather flow (Water Pollution Control Federation and American Society of Civil Engineers 1977).

Flow rate information needed in designing a wastewater treatment plant includes (Metcalf and Eddy, Inc. 1991):

**AVERAGE DAILY FLOW**—The average flow rate occurring over a 24-hr period based on total annual flow rate data. Environmental engineers use average flow rate in evaluating treatment plant capacity and in developing flow rate ratios.

**MAXIMUM DAILY FLOW**—The maximum flow rate occurring over a 24-hr period based on annual operating data. The maximum daily flowrate is important in the design of facilities involving retention time, such as equalization basins and chlorine-contact tanks.

**PEAK HOURLY FLOW**—The peak sustained hourly flow rate occurring during a 24-hr period based on annual operating data. Data on peak hourly flows are needed for the design of collection and interceptor sewers, wastewater pumping stations, wastewater flowmeters, grit chambers, sedimentation tanks, chlorine-contact tanks, and conduits or channels in the treatment plant.

**MINIMUM DAILY FLOW**—The minimum flow rate that occurs over a 24-hr period based on annual operating data. Minimum flow rates are important in sizing conduits where solids deposition might occur at low flow rates.

**MINIMUM HOURLY FLOW**—The minimum sustained hourly flow rate occurring over a 24-hr period based on annual operating data. Environmental engineers need data

on the minimum hourly flow rate to determine possible process effects and size wastewater flow meters, particularly those that pace chemical-feed systems.

**SUSTAINED FLOW**—The flow rate value sustained or exceeded for a specified number of consecutive days based on annual operating data. Data on sustained flow rates may be used in sizing equalization basins and other plant hydraulic components.

## Wastewater Characteristics

Wastewater quality can be defined by physical, chemical, and biological characteristics. Physical parameters include color, odor, temperature, solids (residues), turbidity, oil, and grease. Solids can be further classified into suspended and dissolved solids (size and settleability) as well as organic (volatile) and inorganic (fixed) fractions. Chemical parameters associated with the organic content of wastewater include the biochemical oxygen demand (BOD), chemical oxygen demand (COD), total organic carbon (TOC), and total oxygen demand (TOD). BOD is a mea-

sure of the organics present in the water, determined by measuring the oxygen necessary to biostabilize the organics (the oxygen equivalent of the biodegradable organics present). Inorganic chemical parameters include salinity, hardness, pH, acidity, alkalinity, iron, manganese, chlorides, sulfates, sulfides, heavy metals (mercury, lead, chromium, copper, and zinc), nitrogen (organic, ammonia, nitrite, and nitrate), and phosphorus. Bacteriological parameters include coliforms, fecal coliforms, specific pathogens, and viruses.

Design considerations for wastewater treatment facilities are based in part on the characteristics of the wastewater; [Table 7.1.5](#) lists some key characteristics of concern.

[Table 7.1.6](#) shows the typical concentration range of various constituents in untreated domestic wastewater. Depending on the concentrations, wastewater is classified as strong, medium, or weak. [Table 7.1.7](#) shows typical mineral increases resulting from domestic water use. The types and numbers of microorganisms in untreated domestic wastewater vary widely; examples of such variations are shown in [Table 7.1.8](#).

**TABLE 7.1.6 TYPICAL COMPOSITION OF UNTREATED DOMESTIC WASTEWATER**

Contaminants	Unit	Concentration		
		Weak	Medium	Strong
Total solids (TS)	mg/l	350	720	1200
total dissolved solids (TDS)	mg/l	250	500	850
fixed	mg/l	145	300	525
volatile	mg/l	105	200	325
suspended solids (SS)	mg/l	100	220	350
fixed	mg/l	20	55	75
volatile	mg/l	80	165	275

Note: <sup>a</sup>Results for these tests are usually reported as positive or negative rather than quantified.

The TS content of wastewater can be defined as the matter that remains as residue upon evaporation at 103 to 105°C; Figure 7.1.3 shows the categories of solids in wastewater. Table 7.1.9 shows particle sizes related to different categories. Clesceri, Greenberg, and Trussell (1989) provide detailed information related to testing procedures. Figure 7.1.4 shows typical values for solids found in medium strength wastewater.

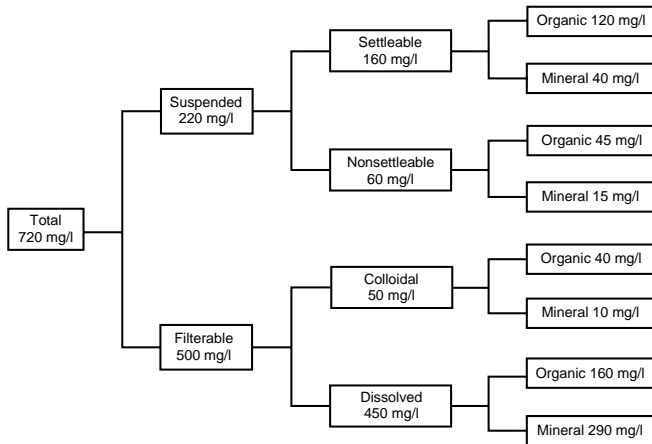

**FIG. 7.1.3** Interrelationships of wastewater solids (also called dissolved solids). (Reprinted, with permission, from Metcalf and Eddy, Inc., 1991.)

**TABLE 7.1.9 GENERAL CLASSIFICATION OF WASTEWATER SOLIDS**

Particle Classification	Particle Size, mm
Dissolved	Less than $10^{-6}$
Colloidal	$10^{-6}$ to $10^{-3}$
Suspended	Greater than $10^{-3}$
Settleable	Greater than $10^{-2}$

Source: R.A. Corbitt, 1990, Wastewater disposal, Chap. 6 in *Standard handbook of environmental engineering*, edited by R.A. Corbitt (New York: McGraw-Hill Publishing Company).

**FIG. 7.1.4** Classification of solids found in medium-strength wastewater. (Metcalf and Eddy, Inc., 1991.)

Odors in wastewater are caused by gases from decomposition or by odorous substances within the wastewater. Table 7.1.10 lists examples of odorous compounds associated with untreated wastewater.

Organic matter in wastewater can be related to oxygen demand and organic carbon measurements. Table 7.1.11 shows several measures of organic matter. BOD refers to the amount of oxygen used by a mixed population of mi-

croorganisms under aerobic conditions that stabilize organic matter in the wastewater. The 5-day BOD is primarily composed of carbonaceous oxygen demand, while the 20-day BOD includes both carbonaceous and nitrogenous oxygen demands. Figure 7.1.5 is a typical BOD curve, developed via laboratory measurements, for domestic wastewater. The following relationships and definitions are associated with Figure 7.1.5 (Qasim 1985):

$$\begin{aligned}
 \text{UOD} &= L_o + L_n \\
 y &= L_o(1 - e^{-kt}) \\
 L_{oT} &= L_o(0.02T + 0.60) \\
 K_T &= K(1.047)^{T-20}
 \end{aligned}
 \tag{7.1(1)}$$

where:

- UOD = ultimate oxygen demand, mg/l
- $L_n$  = nitrogenous oxygen demand or second stage BOD, mg/l
- $L_o$  = ultimate carbonaceous BOD, or first stage BOD at 20°C, mg/l (for domestic wastewater  $BOD_5$  is approximately equal to  $\approx L_o$ )
- $y$  = carbonaceous BOD at any time  $t$ , mg/l
- $L_{oT}$  = ultimate carbonaceous BOD at any temperature  $T^\circ\text{C}$ , mg/l
- $K$  = reaction rate constants at 20°C,  $\text{d}^{-1}$  (for domestic wastewater  $K = 0.2$  to  $0.3$  per d)
- $K_T$  = reaction rate constant to any temperature  $T^\circ\text{C}$ ,  $\text{d}^{-1}$

For medium-strength domestic wastewater, about 75% of SS and 40% of FS are classified as organic. The main groups of organic substances in wastewater include proteins (40–60%), carbohydrates (25–50%), and fats and oils (10%) (Metcalf and Eddy, Inc. 1991). Urea, a constituent of urine, is also found in wastewater along with numerous synthetic organic compounds. Synthetic compounds include surfactants, organic priority pollutants, VOCs, and agricultural pesticides.

The U.S. Environmental Protection Agency (EPA) has identified 129 priority pollutants in wastewater; these pol-

**TABLE 7.1.10 ODOROUS COMPOUNDS ASSOCIATED WITH UNTREATED WASTEWATER**

Odorous Compound	Chemical Formula	Odor, Quality
Amines	$\text{CH}_3\text{NH}_2, (\text{CH}_3)_3\text{H}$	Fishy
Ammonia	$\text{NH}_3$	Ammoniacal
Diamines	$\text{NH}_2(\text{CH}_2)_4\text{NH}_2, \text{NH}_2(\text{CH}_2)_5\text{NH}_2$	Decayed flesh
Hydrogen sulfide	$\text{H}_2\text{S}$	Rotten eggs
Mercaptans (e.g., methyl and ethyl)	$\text{CH}_3\text{SH}, \text{CH}_3(\text{CH}_2)\text{SH}$	Decayed cabbage
Mercaptans (e.g., $T =$ butyl and crotyl)	$(\text{CH}_3)_3\text{CSH}, \text{CH}_3(\text{CH}_2)_3\text{SH}$	Skunk
Organic sulfides	$(\text{CH}_3)_2\text{S}, (\text{C}_6\text{H}_5)_2\text{S}$	Rotten cabbage
Skatole	$\text{C}_9\text{H}_9\text{N}$	Fecal matter

**TABLE 7.1.11 OXYGEN DEMAND AND ORGANIC CARBON PARAMETERS**

Parameter	Description
BOD <sub>5</sub>	Biochemical or biological oxygen demand exerted in 5 days; the oxygen consumed by a waste through bacterial action; generally about 45–55% of THOD.
COD	Chemical oxygen demand. The amount of strong chemical oxidant (chromic acid) reduced by a waste; results are expressed in terms of an equivalent amount of oxygen; generally about 80% of THOD.
THOD	Theoretical oxygen demand. The amount of oxygen theoretically required to completely oxidize a compound to CO <sub>2</sub> , H <sub>2</sub> O, PO <sub>4</sub> <sup>-3</sup> , SO <sub>4</sub> <sup>-2</sup> , and NO <sub>3</sub> .
TOC	Total organic carbon; generally about 30% of THOD.
BOD <sub>L</sub>	The ultimate BOD exerted by a waste in an infinite time.
IOD	Immediate oxygen demand. The amount of oxygen consumed by a waste within 15 min (chemical oxidizers and bacteria not used).

Source: R.A. Corbitt, 1990, Wastewater disposal, Chap. 6 in *Standard handbook of environmental engineering*, edited by R.A. Corbitt (New York: McGraw-Hill Publishing Company).

lutants are subject to discharge standards. Examples of priority pollutants and their health-related concerns are listed in Table 7.1.12.

Pathogenic organisms in wastewater can be categorized as bacteria, viruses, protozoa, and helminths; Table 7.1.13 lists examples of such organisms present in raw domestic wastewater. Because of the many types of pathogenic organisms and the associated measurement difficulties, coliform organisms are frequently used as indicators of human pollution. On a daily basis, each person discharges from 100 to 400 billion coliform organisms, in addition to other kinds of bacteria (Metcalf and Eddy, Inc. 1991). In terms of the indicator concept, the presence of coliform organisms indicates that pathogenic organisms may also be present, and their absence indicates that the water is free from disease-producing organisms (Metcalf and Eddy, Inc. 1991). Total coliform and fecal coliform are often used as indicators of wastewater effluent disinfection.

The quantities of fecal coliform (FC) and fecal streptococci (FS) discharged by humans are significantly different from the quantities discharged by animals. As a result, the ratio of the FC count to the FS count can show whether the suspected contamination derives from human or animal waste. Table 7.1.14 gives example data on the ratio of FC to FS counts for humans and various animals. The FC/FS ratio for domestic animals is less than 1.0; whereas the ratio for humans is more than 4.0.

Some differences can be delineated between municipal and industrial wastewater discharges. For example, fluctuations in industrial wastewater flow rates typically exceed those for municipal wastewater. Industrial plants may not operate continuously; there may be daily, weekly, or seasonal variations in operations, reflected by flow rate variations. In addition, the number and types of contaminants in industrial wastewater can vary widely, and the concentrations can range from near zero to 100,000 mg/l

**FIG. 7.1.5** Typical BOD curve for domestic wastewater showing carbonaceous and nitrogenous oxygen demands. (Reprinted, with permission, from S.R. Qasim, 1985, *Wastewater treatment plants—Planning, design, and operation*, New York: Holt, Rinehart and Winston.)

**TABLE 7.1.12 TYPICAL WASTE COMPOUNDS PRODUCED BY COMMERCIAL, INDUSTRIAL, AND AGRICULTURAL ACTIVITIES AND CLASSIFIED AS PRIORITY POLLUTANTS**

<i>Name (Formula)</i>	<i>Use</i>	<i>Concern</i>
<b>Nonmetals</b>		
Arsenic (As)	Alloying additive for metals, especially lead and copper as shot, battery grids, cable sheaths, and boiler tubes. High purity (semiconductor) grade	Carcinogen and mutagen. <i>Long term</i> —can cause fatigue, loss of energy and dermatitis.
Selenium (Se)	Electronics, xerographic plates, TV cameras, photocells, magnetic computer cores, solar batteries, rectifiers, relays, ceramics (colorant for glass) steel and copper, rubber accelerator, catalyst, and trace element in animal feeds	<i>Long term</i> —red staining of fingers, teeth, and hair; general weakness; depression; and irritation of the nose and mouth.
<b>Metals</b>		
Barium (Ba)	Getter alloys in vacuum tubes, deoxidizer for copper, Frary's metal, lubricant for anode rotors in X-ray tubes, and spark-plug alloys	Flammable at room temperature in powder form. <i>Long term</i> —increased blood pressure and nerve block.
Cadmium (Cd)	Electrodeposited and dipped coatings on metals, bearing and low-melting alloys, brazing alloys, fire protection systems, nickel-cadmium storage batteries, power transmission wire, TV phosphors, basis of pigments used in ceramic glazes, machinery enamels, fungicide photography and lithography, selenium rectifiers, electrodes for cadmium-vapor lamps, and photoelectric cells	Flammable in powder form. Toxic by inhalation of dust or fume. A carcinogen. Soluble compounds of cadmium highly toxic. <i>Long term</i> —concentrates in the liver, kidneys, pancreas, and thyroid; hypertension suspected effect.
Chromium (Cr)	Alloying and plating element on metal and plastic substrates for corrosion resistance, chromium-containing and stainless steels, protective coating for automotive and equipment accessories, nuclear and high-temperature research and constituent of inorganic pigments	Hexavalent chromium compounds are carcinogenic and corrosive to tissue. <i>Long term</i> —skin sensitization and kidney damage.
Lead (Pb)	Storage batteries, gasoline additive, cable covering, ammunition, piping, tank linings, solder and fusible alloys, vibration damping in heavy construction, foil, babbitt, and other bearing alloys	Toxic by ingestion or inhalation of dust or fumes. <i>Long term</i> —brain and kidney damage and birth defects.
Mercury (Hg)	Amalgams, catalyst electrical apparatus, cathodes for production of chlorine and caustic soda, instruments, mercury vapor lamps, mirror coating, arc lamps, and boilers	Highly toxic by skin absorption and inhalation of fume or vapor. <i>Long term</i> —toxic to central nervous system, and can cause birth defects.
Silver (Ag)	Manufacture of silver nitrate, silver bromide, photo chemicals; lining vats and other equipment for chemical reaction vessels, water distillation, etc.; mirrors, electric conductors, silver plating electronic equipment; sterilant; water purification; surgical cements; hydration and oxidation catalyst special batteries, solar cells, reflectors for solar towers; low-temperature brazing alloys; table cutlery; jewelry; dental, medical, and scientific equipment; electrical contacts; bearing metal; magnet windings; and dental amalgams. Colloidal silver used as a nucleating agent in photography and medicine, often combined with protein	Toxic metal. <i>Long term</i> —permanent grey discoloration of skin, eyes, and mucus membranes.

**Organic Compounds**Benzene  
(C<sub>6</sub>H<sub>6</sub>)Manufacturing of ethylbenzene (for styrene monomer); dodecylbenzene (for detergents); cyclohexane (for nylon); phenol; nitrobenzene (for aniline); maleic anhydride; chlorobenzene hexachloride; benzene sulfonic acid; and as a solvent  
Intermediate in the production of styrene and as a solvent

A carcinogen. Highly toxic. Flammable, and a dangerous fire risk

Ethylbenzene  
(C<sub>6</sub>H<sub>5</sub>C<sub>2</sub>H<sub>5</sub>)

Aviation gasoline and high-octane blending stock; benzene, phenol, and caprolactam; solvent for paints and coatings, gums, resins, most oils, rubber, vinyl organosols; diluent and thinner in nitrocellulose lacquers; adhesive solvent in plastic toys and model airplanes; chemicals (benzoic acid, benzyl and bezoyl derivatives, saccharine, medicines, dyes, perfumes); source of toluenediisocyanates (polyurethane resins); explosives (TNT); toluene sulfonates (detergents); and scintillation counters

Toxic by ingestion, inhalation, and skin absorption; irritant to skin and eyes. Flammable and a dangerous fire risk  
Flammable and a dangerous fire risk. Toxic by ingestion, inhalation, and skin absorptionToluene  
(C<sub>6</sub>H<sub>5</sub>CH<sub>3</sub>)**Halogenated Compounds**Chlorobenzene  
(C<sub>6</sub>H<sub>5</sub>Cl)

Phenol, chloronitrobenzene, aniline, solvent carrier for methylene diisocyanate, solvent, pesticide intermediate, heat transfer

Moderate fire risk. Recommend avoiding inhalation and skin contact

Chloroethene  
(CH<sub>2</sub>CHCl)

Polyvinyl chloride and copolymers, organic synthesis, and adhesives for plastics

An extremely toxic and hazardous material by all avenues of exposure. A carcinogen

Dichloromethane  
(CH<sub>2</sub>Cl<sub>2</sub>)

Paint removers, solvent degreasing, plastics processing, blowing agent in foams, solvent extraction, solvent for cellulose acetate, and aerosol propellant

Toxic. A carcinogen and a narcotic

Tetrachloroethene  
(CCl<sub>2</sub>CCl<sub>2</sub>)

Dry cleaning solvent, vapor-degreasing solvent, drying agent for metals and certain other solids, vermifuge, heat transfer medium, and manufacture of fluorocarbons

Irritant to eyes and skin

**Pesticides, Herbicides, Insecticides<sup>a</sup>**Endrin  
(C<sub>12</sub>H<sub>6</sub>OCl<sub>6</sub>)

Insecticide and fumigant

Toxic by inhalation and skin absorption and a carcinogen

Lindane  
(C<sub>6</sub>H<sub>6</sub>Cl<sub>6</sub>)

Pesticide

Toxic by inhalation, ingestion, and skin absorption

Methoxychlor  
(Cl<sub>3</sub>CCH(C<sub>6</sub>H<sub>4</sub>OCH<sub>3</sub>)<sub>2</sub>)

Insecticide

Toxic material

Toxaphene  
(C<sub>10</sub>H<sub>10</sub>Cl<sub>6</sub>)

Insecticide and fumigant

Toxic by ingestion, inhalation, and skin absorption

Silvex

Herbicides and plant growth regulator

Toxic material; use restricted

(Cl<sub>3</sub>C<sub>6</sub>H<sub>2</sub>OCH(CH<sub>3</sub>)COOH)

**TABLE 7.1.13 INFECTIOUS AGENTS POTENTIALLY PRESENT IN RAW DOMESTIC WASTEWATER**

<i>Organism</i>	<i>Disease</i>	<i>Remarks</i>
<b>Bacteria</b>		
<i>Escherichia coli</i> (enteropathogenic)	Gastroenteritis	Diarrhea
<i>Legionella pneumophila</i>	Legionellosis	Acute respiratory illness
<i>Leptospira</i> (150 spp.)	Leptospirosis	Jaundice, and fever (Weil's disease)
<i>Salmonella typhi</i>	Typhoid fever	High fever, diarrhea, and ulceration of small intestine
<i>Salmonella</i> (~1700 spp.)	Salmonellosis	Food poisoning
<i>Shigella</i> (4 spp.)	Shigellosis	Bacillary dysentery
<i>Vibrio cholerae</i>	Cholera	Extremely heavy diarrhea and dehydration
<i>Yersinia enterocolitica</i>	Yersinosis	Diarrhea
<b>Viruses</b>		
Adenovirus (31 types)	Respiratory disease	
Enteroviruses (67 types, e.g., polio, echo, and Coxsackie viruses)	Gastroenteritis, heart anomalies, and meningitis	
Hepatitis A	Infectious hepatitis	Jaundice and fever
Norwalk agent	Gastroenteritis	Vomiting
Reovirus	Gastroenteritis	
Rotavirus	Gastroenteritis	
<b>Protozoa</b>		
<i>Balantidium coli</i>	Balantidiasis	Diarrhea and dysentery
<i>Cryptosporidium</i>	Cryptosporidiosis	Diarrhea
<i>Entamoeba histolytica</i>	Amebiasis (amoebic dysentery)	Prolonged diarrhea with bleeding and abscesses of the liver and small intestine
<i>Giardia lamblia</i>	Giardiasis	Mild to severe diarrhea, nausea, and indigestion
<b>Helminths<sup>a</sup></b>		
<i>Ascaris lumbricoides</i>	Ascariasis	Roundworm infestation
<i>Enterobius vericularis</i>	Enterobiasis	Pinworm
<i>Fasciola hepatica</i>	Fascioliasis	Sheep liver fluke
<i>Hymenolepis nana</i>	Hymenolepiasis	Dwarf tapeworm
<i>Taenia saginata</i>	Taeniasis	Beef tapeworm
<i>T. solium</i>	Taeniasis	Pork tapeworm
<i>Trichuris trichiura</i>	Trichuriasis	Whipworm

*Source:* Metcalf and Eddy, Inc., 1991.  
*Note:* <sup>a</sup>The helminths listed are those with a worldwide distribution.

(Nemerow and Dasgupta 1991). Some industrial wastewater contaminants are toxic; while others exhibit deoxygenation rates about five times greater than that for municipal wastewater (Nemerow and Dasgupta 1991).

### Permits and Effluent Limitations

The *Federal Water Pollution Control Act Amendments of 1972* (PL 92-500) established basic water quality goals and policies for the United States (U.S. Congress 1972). The objective of the *Clean Water Act of 1987* (also known as the *Water Quality Act of 1987*) was to restore and main-

tain the chemical, physical, and biological integrity of the nation's waters; this objective was also in the precursor laws, including PL 92-500. Three key components of the *Clean Water Act of 1987* relevant to wastewater discharges include water quality standards and planning, discharge permits, and effluent limitations.

New point sources of wastewater discharge must apply for National Pollutant Discharge Elimination System (NPDES) permits under the auspices of Section 402 of the *Clean Water Act of 1987* and its precursors back to 1972. Permits typically address pertinent effluent limitations (discharge standards) for conventional and toxic pollutants, monitoring and reporting requirements, and schedules of

**TABLE 7.1.14 ESTIMATED PER CAPITA CONTRIBUTION OF INDICATOR MICROORGANISMS FROM HUMANS AND SOME ANIMALS**

Animal	Average Indicator Density/g of Feces		Average Contribution/capita · 24h		Ratio FC/FS

Note: lb = g × 0.0022.

compliance (Miller, Taylor, and Monk 1991). Effluent limitations can be based on control technologies or required removal (treatment) efficiencies, or they can be based on achieving water quality standards. Water quality-based effluent limitations can require greater treatment levels as determined via a waste load allocation study for the relevant stream segment.

Section 402(p) of the *Clean Water Act of 1987* requires NPDES permits for storm water (runoff water) discharges associated with industrial activity, discharges from large municipal separate storm water systems (systems serving a population of 250,000 or more), and discharges from medium municipal separate storm water systems (systems serving a population of 100,000 or more, but less than 250,000). NPDES permits for storm water from industrial areas require the development of a pollution prevention plan to reduce pollution at the source (U.S. EPA 1992b). Detailed information on developing pollution prevention plans for construction activities in urban or industrial areas is also available (U.S. EPA 1992a).

## 7.2

# SOURCES AND EFFECTS OF CONTAMINANTS

---

---

### Sources of Contaminants

Contaminants in municipal wastewater are introduced as a result of water usage for domestic, commercial, or institutional purposes; water usage for product processing or cooling purposes within industries discharging liquid effluents into municipal sewerage systems; and infiltration/inflow and/or stormwater runoff. [Table 7.2.1](#) shows examples of typical physical, chemical, and biological characteristics of municipal wastewater, along with potential sources. [Table 7.2.2](#) summarizes selected sources and effects of industrial wastewater constituents.

### POINT AND NONPOINT SOURCES

Two main sources of water pollutants are point and nonpoint. Nonpoint sources are also referred to as area or diffuse sources. Nonpoint pollutants are substances introduced into receiving waters as a result of urban area, industrial area, or rural runoff; e.g., sediment and pesticides or nitrates entering surface water due to surface runoff from agricultural farms. Point sources are specific discharges from municipalities or industrial complexes; e.g., organics or metals entering surface water due to wastewater discharge from a manufacturing plant. In a surface water body, nonpoint pollution can contribute significantly to total pollutant loading, particularly with regard to nutrients and pesticides. To illustrate the relative contributions, [Figure 7.2.1](#) shows the estimated nationwide loadings of four key water pollutants.

Municipal and industrial wastewater discharges are primary contributors to point source discharges in the United States. [Table 7.2.3](#) provides quantitative information on BOD, total suspended sediments, and phosphorus discharges from municipal treatment facilities and several industrial categories.

Over the past two decades, more than \$75 billion in federal, state, and local funds were used to construct municipal sewage treatment facilities, and the private sector has spent additional billions to limit discharges of conventional pollutants (Council on Environmental Quality 1992). Between 1972 and 1988, the number of people served by municipal treatment plants with secondary treatment or better increased from 85 million to 144 million; [Figure 7.2.2](#) depicts these changes in population served. These trends suggest that further reduc-

tions in pollutant loadings from point sources will occur.

### VIOLATIONS OF WATER QUALITY STANDARDS

From a holistic perspective, a major source of wastewater discharges is associated with increases in the violations of receiving water quality standards. The 1990 National Water Quality Inventory in the United States assessed, in relation to applicable water quality standards and designated beneficial uses of the water, about one-third of the total river miles, half of the acreages of lakes, and three-quarters of the estuarine square miles. [Table 7.2.4](#) summarizes these results relative to supporting designated uses. About one-third of the three assessed water resources did not fully meet their respective designated uses (Council on Environmental Quality 1993). [Table 7.2.5](#) indicates the causes and sources of pollution for the three types of water resources.

[Figure 7.2.3](#) shows pollution sources for impaired river miles; [Figure 7.2.4](#) shows pollution in estuarine waters. While they are not the only sources of pollution, municipal and industrial wastewater discharges contribute significantly to impaired water resources.

[Table 7.2.6](#) summarizes violation rates of water quality criteria in U.S. rivers and streams from 1975–1989. FC bacteria violations are well above the rates for other constituents for each year. In addition, the percent of violations has declined for all listed parameters since 1975.

### Effects of Contaminants

The effects of pollution sources on receiving water quality are manifold and depend on the type and concentration of pollutants (Nemerow and Dasgupta, 1991). Soluble organics, as represented by high BOD waste, deplete oxygen in surface water. This results in fish kills, the growth of undesirable aquatic life, and undesirable odors. Trace quantities of certain organics cause undesirable tastes and odors, and certain organics can be biomagnified in the aquatic food chain.

SSs decrease water clarity and hinder photosynthetic processes; if solids settle and form sludge deposits, changes in benthic ecosystems result. Color, turbidity, oils, and floating materials influence water clarity and photosynthetic processes and are aesthetically undesirable.

**TABLE 7.2.1 PHYSICAL, CHEMICAL, AND BIOLOGICAL CHARACTERISTICS OF WASTEWATER AND THEIR SOURCES**

<i>Characteristic</i>	<i>Sources</i>
<b>Physical Properties</b>	
Color	Domestic and industrial wastes and natural decay of organic materials
Odor	Decomposing wastewater and industrial wastes
Solids	Domestic water supply, domestic and industrial wastes, soil erosion, and inflow/infiltration

Protists:	
Eubacteria	Domestic wastes, surface-water infiltration, and treatment plants
Archaeobacteria	Domestic wastes, surface-water infiltration, and treatment plants
Viruses	Domestic wastes

*Source: Metcalf and Eddy, Inc., 1991, Wastewater engineering, 3d ed. (New York: McGraw-Hill, Inc.).*

Excessive nitrogen and phosphorus lead to algal overgrowth with concomitant water treatment processes. Chlorides cause a salty taste in water; and in sufficient concentration, water usage must be limited. Acids, alkalies, and toxic substances can cause fish kills and create other imbalances in stream ecosystems.

Thermal discharges can also cause imbalances and reduce the stream waste assimilative capacity. Stratified flows from thermal discharges minimize normal mixing patterns in receiving streams and reservoirs. [Table 7.2.7](#)

provides an overview of certain contaminants and their impact in surface waters. [Table 7.2.8](#) summarizes the impact of certain pollutants with regard to use impairment of the water.

### ECOLOGICAL EFFECTS

The effects of pollutant discharges in municipal or industrial wastewaters can be considered from an ecological perspective. For example, Welch (1980) discusses the effects

**TABLE 7.2.2 EXAMPLES OF SOURCES AND EFFECTS OF WASTEWATER CONSTITUENTS**

<i>Component Group</i>	<i>Effects</i>	<i>Typical Sources</i>
Biooxidizables expressed as BOD <sub>5</sub>	Deoxygenation, anaerobic conditions, fish kills, odors	Large amounts of soluble carbohydrates: sugar refining, canning, distilleries, breweries, milk processing, pulping, and paper making
Primary toxicants: As, CN, Cr, Cd, Cu, F, Hg, Pb, and Zn	Fish kills, cattle poisoning, plankton kills, and accumulations in flesh of fish and mollusks	Metal cleaning, plating, and pickling; phosphate and bauxite refining; chlorine generation; battery making; and tanning
Acids and alkalines	Disruption of pH buffer systems and disordering previous ecological system	Coal-mine drainage, steel pickling, textiles, chemical manufacture, wool scouring, and laundries
Disinfectants: Cl <sub>2</sub> , H <sub>2</sub> O <sub>2</sub> , formalin, and phenol	Selective kills of microorganisms, taste, and odors	Bleaching of paper and textiles; rocketry; resin synthesis; penicillin preparation; gas, coke, and coal-tar making; and dye and chemical manufacture
Ionic forms: Fe, Ca, Mg, Mn, Cl, and SO <sub>4</sub>	Changed water characteristics: staining, hardness, salinity, and encrustations	Metallurgy, cement making, ceramics, and oil-well pumpage
Oxidizing and reducing agents: NH <sub>3</sub> , NO <sub>2</sub> <sup>-</sup> , NO <sub>3</sub> <sup>-</sup> , S <sup>-</sup> , and SO <sub>3</sub> <sup>-2</sup>	Altered chemical balances ranging from rapid oxygen depletion to overnutrition, odors, and selective microbial growths	Gas and coke making, fertilizer plants, explosive manufacture, dyeing and synthetic fiber making, wood pulping, and bleaching
Evident to sight and smell	Foaming, floating, and settleable solids; odors; anaerobic bottom deposits; oils, fats, and grease; and waterfowl and fish injuries	Detergent wastes, tanning, food and meat processing, beet sugar mills, woolen mills, poultry dressing, and petroleum refining
Pathogenic organisms: <i>B. anthracis</i> , <i>Leptospira</i> , fungi, and viruses	Infections in humans, reinfection of livestock, plant diseases from fungi-contaminated irrigation water and risks to humans slight	Abattoir wastes, wool processing, fungi growths in waste treatment works, and poultry-processing waste waters

Source: R.A. Corbitt, 1990, Wastewater disposal, Chap. 6 in *Standard handbook of environmental engineering*, edited by R.A. Corbitt (New York: McGraw-Hill Publishing Company).

of wastewater discharges on the ecological characteristics of the receiving water environment; his topics include the specific effects on phytoplankton, zooplankton, periphyton, macrophytic rooted plants, benthic macroinvertebrates, and fish.

Material and energy flow diagrams demonstrate biogeochemical cycles and system interrelationships. For example, Figure 7.2.5 shows the material and energy flow in an aquatic ecosystem. Food web (or food chain) relationships and energy flow considerations indicate the dy-

namic aspects of the biological environment. They are also used to develop qualitative and quantitative models of aquatic or terrestrial systems, useful in predicting aquatic impacts of wastewater discharges. Wetland loss or degradation from municipal or industrial wastewater discharges illustrates an ecosystem effect. Such loss or degradation also occurs as a consequence of other human activities or natural occurrences (Mannion and Bowlby 1992).

To analyze the potential effects of wastewater discharges, the engineer may consider environmental cycling

of specific pollutants. Figure 7.2.6 shows various transfer routes and processes related to pollutant movement within the hydrosphere and biosphere. Examples of specific biogeochemical cycles for one nutrient (nitrogen) and one metal (mercury) are shown in Figures 7.2.7 and 7.2.8, respectively. The information in these examples indicates that the biological environment is a dynamic system that can be stressed as a result of various wastewater discharges.

Environmental engineers can use chromium to illustrate changes within aqueous systems since it is a transition metal that exhibits various oxidation states and behavior patterns (Canter and Gloyna 1968). Trivalent chromium is generally present as a cation,  $\text{Cr}(\text{OH})^+$ , and is chemically reactive, tending to sorb on suspended materials and subsequently settle from the liquid phase. Hexavalent chromium is anionic ( $\text{CrO}_4^-$ ) and chemically unreactive,

*Source: U.S. EPA, 1992.*

*Notes: nr = not reported. In addition to the causes and sources listed, thermal modifications impair 9970 river mi. Taste and odor impairments affect 105,288 acres of lakes and reservoirs, and noxious aquatic plants impair 711,323 acres. Additional causes of pollution in estuaries are ammonia (50 sq mi), oil and grease (36 sq mi), and unknown (109 sq mi). Estimates of impairment are based on the sums of partially and not supporting designated uses in Table 7.2.4 which represent 9.5% of total U.S. river mi, 8.9% of total U.S. lake acres, and 16.7% of total U.S. estuary square mi.*

### Types

### Sources

**FIG. 7.2.3** Types and sources of pollution in rivers of the United States. Figure based on river mi monitored in 1990, which represent 9.5% of total U.S. river mi. (Reprinted from U.S. Environmental Protection Agency (EPA), 1992, *National water quality inventory: 1990*, Report to Congress, Washington, D.C.)

thus tending to remain in solution. Changes can occur in the chromium oxidation state due to stream water quality. For example, hexavalent chromium can be chemically reduced to trivalent chromium under anaerobic conditions, whereas trivalent chromium can be oxidized to hexavalent chromium under aerobic conditions. This information qualitatively predicts the impact of chromium discharges into river systems.

An additional concern is the potential reconcentration of pollutant materials (e.g., heavy metals and pesticides) into aquatic organisms and their subsequent harvesting and consumption by man. One example is the study from 1974–1990 of pesticide contaminant levels in herring gull eggs from the five Great Lakes (Council on Environmental Quality 1992). Another example is the closure of shellfish

beds due to bacterial contamination of the water and shellfish (Council on Environmental Quality 1993).

### TOXICITY EFFECTS

Depending on their constituents, some municipal or industrial wastewater discharges exhibit toxicity effects on aquatic organisms. As a result, biomonitoring can be required for effluent discharges. In biomonitoring, indicator organisms are chosen to represent all segments of the aquatic community of the water body under study (U.S. Department of Energy 1985). Five groups of organisms have traditionally been studied as indicators of water quality (U.S. Department of Energy 1985): bacteria, fish, plankton, periphyton, and macroinvertebrates. The choice of an

**FIG. 7.2.4** Types and sources of pollution in estuaries of the United States. Figure based on sq mi of estuaries monitored in 1990, which represent 16.7% of total U.S. estuaries. An estuary is a tidal body of water, formed where a river meets the sea. Estuaries, such as bays, have a measurable quantity of salt. (Reprinted from U.S. EPA 1992.)

indicator species is important in a biomonitoring study because it can affect the results of the study phase and toxicity characterization procedures.

Bacteria are indicators of fecal contamination and the presence of pathogenic organisms (U.S. Department of Energy 1985). Fish are useful in assessing water quality because in aquatic communities, they often represent the highest trophic level. If fish are lacking or exist only in small numbers, decreased water quality may be affecting the fish directly or indirectly by affecting those organisms on which the fish feed.

Plankton are good indicators of the water quality because they float passively with the currents (U.S. Department of Energy 1985). Estimating the plankton

population indicates, in part, the nutrient-supplying capability of that water body (U.S. Department of Energy 1985). Periphyton, because of their stationary or sessile existence, also indicate nutrient availability in an aquatic system; furthermore, they represent the integration of the physical and chemical conditions of water passing through their locations (U.S. Department of Energy 1985).

Benthic species are excellent indicators of water quality because they are generally restricted to the area where they are found (U.S. Department of Energy 1985). Benthic macroinvertebrates, because of their varying environmental requirements, form communities characteristic or associated with physical and chemical conditions. For example, the presence of immature insects, certain mollusks,

**TABLE 7.2.6 NATIONAL AMBIENT WATER QUALITY IN RIVERS AND STREAMS: VIOLATION RATES, 1975–1989**

Year	FC Bacteria	Dissolved Oxygen	Total Phosphorus	Total Cadmium, Dissolved	Total Lead, Dissolved

Note: Violation levels are based on U.S. EPA water quality criteria: FC bacteria—above 200 cells per 100 mi; dissolved oxygen—below 5 mg/l; total phosphorus—above 1.0 mg/l; cadmium, dissolved—above 10 µg/l; and lead, dissolved—above 50 µg/l. \* = base figure too small to meet statistical standards for reliability of derived figures.

**TABLE 7.2.7 IMPORTANT WASTEWATER CONTAMINANTS BASED ON POTENTIAL EFFECTS AND CONCERNS IN TREATMENT**

Contaminants	Reason for Importance
SS	SS can lead to the development of sludge deposits and anaerobic conditions when untreated wastewater is discharged to the aquatic environment.
Biodegradable organics	Composed principally of proteins, carbohydrates, and fats, biodegradable organics are commonly measured in terms of BOD and COD. If discharged to the environment untreated, their biological stabilization can deplete natural oxygen resources and cause septic conditions.
Pathogens	Communicable diseases can be transmitted by pathogenic organisms in wastewater.
Nutrients	Both nitrogen and phosphorus, along with carbon, are essential nutrients for growth. When discharged to the aquatic environment, these nutrients can lead to the growth of undesirable aquatic life. When discharged in excessive amounts on land, they can also lead to groundwater pollution.
Priority pollutants	These pollutants include organic and inorganic compounds selected on the basis of their known or suspected carcinogenicity, mutagenicity, teratogenicity, or high acute toxicity. Many of these compounds are found in wastewater.
Refractory organics	These organics tend to resist conventional wastewater treatment. Typical examples include surfactants, phenols, and agricultural pesticides.
Heavy metals	Heavy metals are usually added to wastewater from commercial and industrial activities and may have to be removed if the wastewater is to be reused.
Dissolved inorganics	Inorganic constituents such as calcium, sodium, and sulfate are added to the original domestic water supply as a result of water use and may have to be removed if the wastewater is to be reused.

Source: Metcalf and Eddy, Inc., 1991, *Wastewater engineering*, 3d ed. (New York: McGraw-Hill, Inc.).

and crayfish usually indicates relatively clean water; while communities of sludge worms, air breathing snails, midges, and aquatic earthworms indicate the presence of oxygen-consuming materials and deteriorating conditions.

Toxicity tests, the second category of biomonitoring, are less expensive and labor intensive than ecological surveys. Toxicity tests use indicator organisms in a controlled

situation to examine water and effluent toxicity. The toxic effects of concern are death, immobilization, serious incapacitation, reduced fecundity, or reduced growth. Toxicity tests can be used to assess acute or chronic toxicity. Acute toxicity is a severe toxic effect resulting from a brief exposure, while chronic toxicity results from prolonged exposure. Tests for acute toxicity can be conducted within

24–96 hr, and chronic tests for toxicity are conducted usually in four or more days (Clesceri, Greenberg, and Trussell 1989).

Toxicity testing can be further divided into ambient and laboratory tests. Ambient toxicity tests are conducted in situ. In such tests, indicator organisms are kept in cages within the water under study, or they are exposed to the test water in chambers at the site. The water in the latter test is renewed daily with fresh water from the study sites.

Laboratory tests are dissimilar because they are conducted offsite in a laboratory. These tests are conducted within a set of conditions such as those described in *Short-term methods for estimating the chronic toxicity of effluents and receiving waters to freshwater organisms* (U.S. EPA 1989). In such tests, the test water is fractionally diluted with synthetic water. Replicate groups of indicator species are exposed to different concentrations of a dilution series, and toxic effects are recorded for each dilution. The recorded data are then analyzed using a series of statistical tests to determine the effective or lethal concentrations. Effective and lethal concentrations are those point estimates of the toxicant concentration that cause an observable adverse effect (such as death, immobilization, serious incapacitation, reduced fecundity, or reduced growth) in a percentage of the test organisms (U.S. EPA 1989).

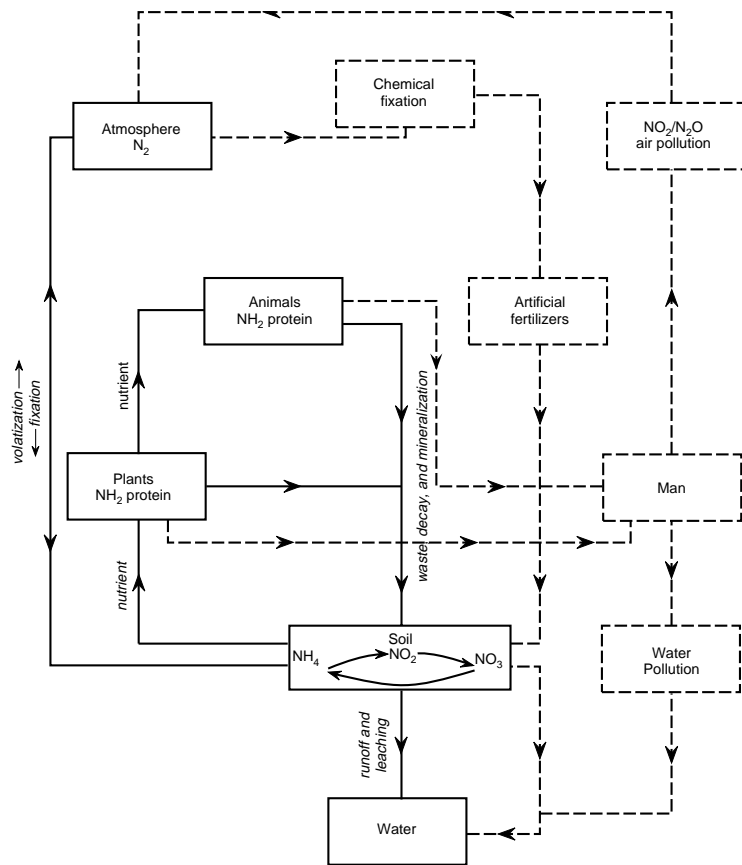

## EFFECTS OF CONTAMINANTS ON WASTEWATER TREATMENT PLANTS

As a final example of wastewater discharge effects, industrial wastewater can affect wastewater treatment plants if such wastewater is introduced into municipal sewerage systems. The pollution characteristics of industrial wastewater with definable effects on sewers and treatment plants include

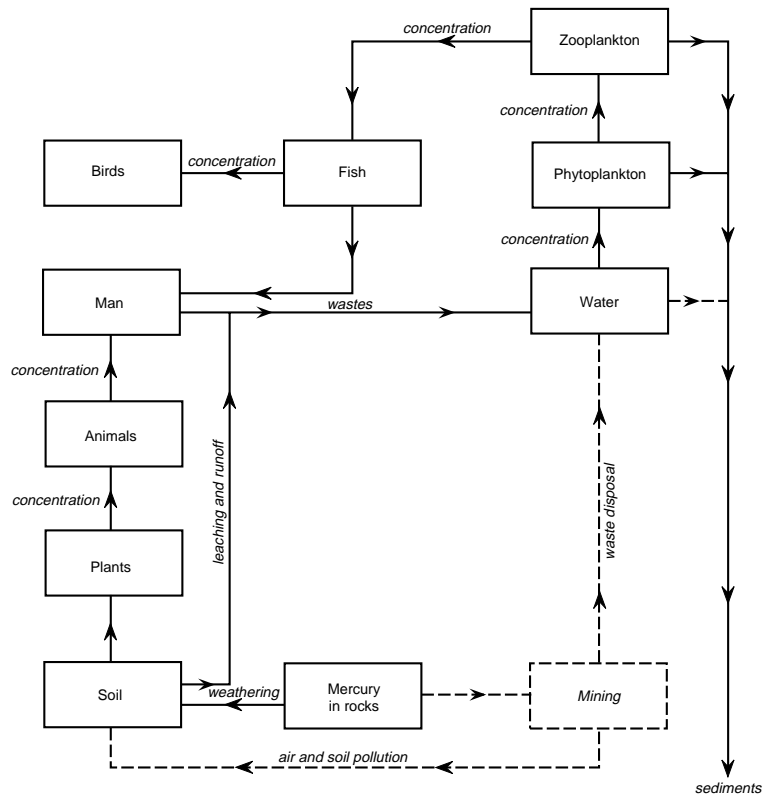

1. BOD
2. SS
3. floating and colored material
4. volume
5. other harmful constituents

Excessive BOD and volume can cause organic and hydraulic overloads, respectively. SS can create operational problems due to excess solids and sludge production. Floating and colored material are related to visible pollution. Examples of other harmful industrial wastewater constituents include (Nemerow and Dasgupta 1991):

Toxic metal ions ( $\text{Cu}^{++}$ ,  $\text{Cr}^{+6}$ ,  $\text{Zn}^{++}$ , and  $\text{Cn}^-$ ), which interfere with biological oxidation by tying up the enzymes required to oxidize organic matter  
Acids and alkalis, which can corrode pipes, pumps, and treatment units, interfere with settling, upset the bio-

## 7.3 CHARACTERIZATION OF INDUSTRIAL WASTEWATER

---

---

### Origins of Industrial Wastewater

Industrial wastewater is discharged from industries and associated processes utilizing water. Industrial water users in the United States discharge over 285 billion gal of wastewater daily (Corbitt 1990). Water is used in industrial cooling, product washing and transport, product generation, and other purposes. Although variable between industries and plants within the same industry, about two-thirds of the total wastewater generated from U.S. industries results from cooling operations (Corbitt 1990).

### WASTEWATER FROM PROCESS OPERATIONS

Water used for process operations (noncooling purposes) can become degraded as a result of introducing nutrients, suspended sediments, bacteria, oxygen-demanding matter, and toxic chemicals. The degree of pollutant (contaminant) loading is a function of the type of industry, specific unit processes, and the extent of wastewater minimization practices employed. [Table 7.3.1](#) summarizes the origin of contaminant introductions in various industries and lists some key contaminant characteristics.

Several books summarize the characteristics of wastewater from various industries; examples include Nemerow (1978) and Nemerow and Dasgupta (1991). Nemerow and Dasgupta (1991) provide information on the types

and quantities of water pollutants from major private sector categories such as the apparel, food, materials, chemical, and energy industries.

### WASTEWATER FROM PETROLEUM REFINING

As an example of industrial wastewater discharges, this section presents brief information on the pollutant discharges from petroleum refineries. The total amount of water used in a petroleum refinery is estimated to be 770 gal per barrel of crude oil (Nemerow 1978). Approximately 80 to 90% of the water is used for cooling purposes only and is not contaminated except by leaks in the lines. Process wastewaters, comprising 10 to 20% of the total, can include free and emulsified oil from leaks, spills, tank draw-off, and other sources; waste caustic, caustic sludges, and alkaline waters; acid sludges and acid waters; emulsions incident to chemical treatment; condensate waters from distillate separators and tank draw-off; tank-bottom sludges; coke from equipment tubes, towers, and other locations; acid gases; waste catalyst and filtering clays; and special chemicals from by-product chemical manufacturing.

Both conventional and toxic pollutants are found in petroleum refinery wastewater. Conventional pollutants are those that have received historical attention, while toxic pollutants relate to parameters receiving increasing atten-

**TABLE 7.3.1 SUMMARY OF THE ORIGIN AND CHARACTERISTICS OF SELECTED INDUSTRIAL WASTEWATER**

<i>Industries Producing Wastes</i>	<i>Origin of Major Wastes</i>	<i>Major Characteristics</i>
<b>Apparel</b>		
Textiles	Cooking of fibers and desizing of fabric	Highly alkaline, colored, high BOD and temperature, and high SS
Leather goods	Unhairing, soaking, deliming, and bating of hides	High total solids, hardness, salt, sulfides, chromium, pH, precipitated lime, and BOD
Laundry trades	Washing of fabrics	High turbidity, alkalinity, and organic solids
Dry cleaning	Solvent cleaning of clothes	Condensed, toxic, and organic vapors
<b>Food and Drugs</b>		
Canned goods	Trimming, culling, juicing, and blanching of fruits and vegetables	High in SS, colloidal, and dissolved organic matter
Dairy products	Dilutions of whole milk, separated milk, buttermilk, and whey	High in dissolved organic matter, mainly protein, fat, and lactose
Brewed and distilled beverages	Steeping and pressing of grain; residue from distillation of alcohol; and condensate from stillage evaporation	High in dissolved organic solids containing nitrogen and fermented starches or their products
Meat and poultry products	Stockyards; slaughtering of animals; rendering of bones and fats; residues in condensates; grease and wash water; and picking of chickens	High in dissolved and suspended organic matter, blood, other proteins, and fats
Beet sugar	Transfer, screening, and juicing waters; drainings from lime sludge; condensates after evaporator; and juice and extracted sugar	High in dissolved and suspended organic matter containing sugar and protein
Pharmaceutical products	Mycelium, spent filtrate, and wash waters	High in suspended and dissolved organic matter, including vitamins
Yeast	Residue from yeast filtration	High in solids (mainly organic) and BOD
Pickles	Lime water; brine, alum and turmeric, syrup, seeds, and pieces of cucumber	Variable pH, high SS, color, and organic matter
Coffee	Pulping and fermenting of coffee beans	High BOD and SS
Fish	Rejects from centrifuge; pressed fish, and evaporator and other wash water wastes	Very high BOD, total organic solids, and odor
Rice	Soaking, cooking, and washing of rice	High BOD, total and suspended solids (mainly starch)
Soft drinks	Bottle washing; floor and equipment cleaning; and syrup storage tank drains	High pH, suspended solids, and BOD
Bakeries	Washing and greasing of pans and floor washing	High BOD, grease, floor washing, sugars, flour, and detergents
<b>Materials</b>		
Pulp and paper	Cooking, refining, washing of fibers, and screening of paper pulp	High or low pH, color, high suspended, colloidal, and dissolved solids, and inorganic fillers
Photographic products	Spent solutions of developer and fixer	Alkaline containing various organic and inorganic reducing agents
Steel	Coking of coal, washing of blast-furnace flue gases, and pickling of steel	Low pH, acids, cyanogen, phenol, ore, coke, limestone, alkali, oils, mill scale, and fine SS
Metal-plated products	Stripping of oxides and cleaning and plating of metals	Acid, metals, toxic, low volume, and mainly mineral matter
Iron-foundry products	Wasting of used sand by hydraulic discharge	High SS, mainly sand; and some clay and coal
Oil fields and refineries	Drilling muds, salt, oil, and some natural gas; acid sludges; and miscellaneous oils from refining	High dissolved salts from field and high BOD, odor, phenol, and sulfur compounds from refinery

<i>Industries Producing Wastes</i>	<i>Origin of Major Wastes</i>	<i>Major Characteristics</i>
Petrochemicals	Contaminated water from chemical production and transportation of second generation oil compounds	High COD, TDS, metals, COD/BOD ratio, and cpds. inhibitory to biologic action
Cement	Fine and finish grinding of cement, dust leaching collection, and dust control	Heated cooling water, SS, and some inorganic salts
<b>Chemicals</b>		
Acids	Dilute wash waters and many varied dilute acids	Low pH and low organic content
Detergents	Washing and purifying soaps and detergents	High in BOD and saponified soaps
Cornstarch	Evaporator condensate or bottoms when not reused or recovered, syrup from final washes, and wastes from bottling-up process	High BOD and dissolved organic matter; mainly starch and related material
Explosives	Washing trinitrotoluene (TNT) and guncotton for purification and washing and pickling of cartridges	TNT, colored, acid, odorous, and containing organic acids and alcohol from powder and cotton, metals, acid, oils, and soaps
Pesticides	Washing and purification products such as 2,4-D and dichlorodiphenyl trichloroethane (DDT)	High organic matter, benzenering structure, toxic to bacteria and fish, and acid
Phosphate and phosphorus	Washing, screening, floating rock, and condenser bleedoff from phosphate reduction plant	Clays, slimes and tall oils, low pH, high SS, phosphorus, silica, and fluoride
Plastic and resins	Unit operations from polymer preparation and use and spills and equipment washdowns	Acids, caustic, and dissolved organic matter such as phenols and formaldehyde
Fertilizer	Chemical reactions of basic elements and spills, cooling waters, washing of products, and boiler blowdowns	Sulfuric, phosphorous, and nitric acids; mineral elements, P, S, N, K, Al, NH <sub>3</sub> , and NO <sub>3</sub> ; Fl; and some SS
Toxic chemicals	Leaks, accidental spills, and refining of chemicals	Various toxic dissolved elements and compounds such as Hg and polychlorinated biphenyls (PCBs)
Mortuary	Body fluids, washwaters, and spills	Blood salt, formaldehydes, high BOD, and infectious diseases
Hospital and Research Laboratories	Washing, sterilizing of facilities, used solutions, and spills	Bacteria and various chemicals and radioactive materials
Chloralkali wastes	Electrolytic cells and making chlorine and caustic soda	Mercury and dissolved metals
Organic chemicals	Various chemical productive processes	Varied types of organic chemicals
<b>Energy</b>		
Steam power	Cooling water, boiler blow-down, and coal drainage	Hot, high volume, and high inorganic and dissolved solids
Scrubber power plant wastes	Scrubbing of gaseous combustion products by liquid water	Particulates, SO <sub>2</sub> , impure absorbents or NH <sub>3</sub> and NaOH
Coal processing	Cleaning and classification of coal and leaching of sulfur strata with water	High SS (mainly coal), low pH, high H <sub>2</sub> SO <sub>4</sub> , and FeSO <sub>4</sub>

**TABLE 7.3.2 SUBCATEGORIES OF THE PETROLEUM REFINING INDUSTRY REFLECTING SIGNIFICANT DIFFERENCES IN WASTEWATER CHARACTERISTICS**

---

Topping: Topping and catalytic reforming whether the facility includes any other process in addition to topping and catalytic process. This subcategory is not applicable to facilities that include thermal processes (e.g., coking and visbreaking) or catalytic cracking.

Cracking: Topping and cracking, whether the facility includes any processes in addition to topping and cracking, unless specified in one of the following subcategories listed.

Petrochemical: Topping, cracking, and petrochemical operations, whether the facility includes any process in addition to topping, cracking, and petrochemical operations<sup>a</sup>, except lube oil manufacturing operations.

Lube: Topping, cracking, and lube oil manufacturing processes, whether the facility includes any process in addition to topping, cracking, and lube oil manufacturing processes, except petrochemical operations.<sup>a</sup>

Integrated: Topping, cracking, lube oil manufacturing processes, and petrochemical operations, whether the facility includes any processes in addition to topping, cracking, lube oil manufacturing processes, and petrochemical operations.<sup>a</sup>

Notes: <sup>a</sup>The term petrochemical operations means the production of second generation petrochemicals (i.e., alcohols, ketones, cumene, and styrene) or first generation petrochemical and isomerization products (i.e., benzene/toluene/xylene [BTX], olefins, and cyclohexane) when 15% or more of refinery production is as first generation petrochemicals and isomerization products.

---

tion due to their potential environmental toxicity (U.S. EPA 1980). Five refinery subcategories, based on throughputs and process capacities, delineate information on wastewater characteristics as defined in Table 7.3.2. Table 7.3.3 presents ranges and median loadings in raw wastewater of conventional pollutants for the petroleum refining industry subcategories. Raw wastewater is the effluent from the oil separator, which is an integral part of refinery process operations for product and raw material recovery prior to wastewater treatment. Table 7.3.4 lists the toxic pollutants that have been measured in wastewater generated at petroleum refineries; no concentration data are included.

## Wastewater Discharge Standards

The flow rates and quality characteristics of wastewater within and between types of industries vary widely. Therefore, wastewater discharge standards are related to industry type. For example, Table 7.3.5 summarizes the effluent limitations based on best practicable treatment (BPT) for point sources associated with the cracking subcategory of petroleum refining.

Effluent limitations can be technology-based or water quality-based, with the former considering BPT, best available technology economically achievable (BAT), best conventional pollutant control technology (BCT), or new source performance standards (NSPSs). BPT emphasizes end-of-pipe controls and reflects the average of the best for the industry category; it deals primarily with conventional pollutants such as BOD, oil and grease, solids, pH, and some metals. BAT can include pollution prevention through process control and end-of-pipe technology; it deals primarily with toxics such as organics and heavy metals. BCT is used with BAT. NSPSs are based on the best available demonstrated control technology (BADCT); it is typically similar to BAT with BCT.

Water quality-based effluent limitations can require greater levels of treatment as dictated by a waste load allocation scheme based on the total maximum daily load for the stream segment. Adjustment factors for the effluent limitations, which account for facility size and specific processes, are in the regulations (40 *CFR* Chap. 1, part 419). Effluent limitation information is also available for BAT, BCT, and NSPS for the cracking subcategory and for BPT, BAT, BCT, and NSPS for the topping subcategory, petrochemical subcategory, lube subcategory, and integrated subcategory (40 *CFR* Chap. 1, part 419)

Effluent discharge standards have been developed for wastewater from many industry types. This section does not address multiple types of industries; however, as an illustration of variability, Table 7.3.6 lists the water quality parameters for fourteen types of industries (Corbitt 1990). As the table shows the parameters are industry-specific.
