Preface

The disorder that we now know as autism was first formally described in 1943 by the Austrian born child psychiatrist, Leo Kanner, in his seminal paper "Autistic Disturbances of Affective Contact" (1943). For the next 20 years or more, "infantile autism" was considered to be a rare disorder affecting fewer than 5 in 10,000 individuals (Lotter, 1966). However, over the last 20 years, autism has come into the awareness of individuals from all walks of life and most of the world's countries. Kanner's autism has come to represent the classic form of a spectrum of disorders that are often conceived of as having core deficits in social functioning, communication, and repetitive behaviors; taken together these are now typically referred to as autism spectrum disorders (ASDs). Current estimates of the prevalence of autism spectrum disorders is on the order of 1 in 100 children (Rice, 2009), more frequent than many other childhood disorders that are often considered common, such as juvenile diabetes and childhood cancer.

One measure of the increased interest in autism research can be seen in the number of times Kanner's paper has been referenced in the peer reviewed scientific press. Overall, the paper has been cited nearly 2,300 times since its publication[1]. But, from 1945 until 1954, the paper was only cited 34 times. As illustrated in Figure 1, citations for the paper remained at a relatively low level until the 1990s, when there was a substantial increase in the rate at which this classic paper was referenced, paralleling an increase in biomedically based autism research.

There are many reasons for what could be considered a modern renaissance in autism research. Much of the credit for the increased research is due to the dedicated advocacy efforts of parents of children with autism throughout the world. One early example of this was Bernard Rimland, PhD,

a psychologist and father of a son with autism. His influential book, *Infantile Autism: The Syndrome and Its Implications for a Neural Theory of Behavior* (which had a forward by Leo Kanner), published in 1964, dismissed the myth that early psychodynamic influences—the "refrigerator mother"—caused autism. In short, Rimland reasoned that if many of the comorbid conditions of autism, such as epilepsy, were due to neural dysfunction, so should be the core features of autism. In retrospect, the chilling influence of psychoanalytic theory on biomedical research into autism's etiology could be considered remarkable, given that in his original paper, Kanner clearly saw autism as a biological, likely genetically mediated disorder in many cases.

Initially, advocacy groups such as the Autism Society of America were founded to advocate for research and more effective treatments of individuals with autism, but they did not focus their efforts on direct support of medical researchers. This organization shared a common mission with the National Autistic Society (a name adopted in 1975, when the original Autistic Children's Aid Society of North London, founded in 1962, was expanded to serve all of the United Kingdom). Autism first received widespread public attention through the Barry Levinson film *Rainman*. Dustin Hoffman, who portrayed a young man with autism and wanted his depiction of the disorder to be as accurate as possible, modeled his performance after an unusual autistic savant. The Oscar-winning best picture portrayed many of the social and communicative impairments of autism and particularly highlighted the circumscribed interests and the desire for routine and sameness in the environment.

Major impetus for the expansion of autism research was the founding in the mid-1990s of two parent advocacy organizations, the National Alliance for Autism Research (NAAR) and Cure Autism Now (CAN) that promoted not only the awareness of autism spectrum disorders, but also the need for research into the biological bases of autism. With the merger

---

1 These numbers are based on information from the Institute for Scientific Information (ISI) Web of Knowledge^sm. Numbers reflect times the paper is cited in peer-reviewed journals and does not include references in books or the popular press.
Citations in each year

Figure 1 Citations of Kanner 1943. The graph displays the number of times the seminal paper by Kanner (1943) was referenced in the peer-reviewed scientific press from the time of publication to the end of 2009. Various events in the evolution of autism advocacy are indicated on the chart and are described in the text.

of these fund-raising and advocacy groups into Autism Speaks in 2005, a highly effective engine for worldwide autism research has been developed that has greatly expanded the scope and intensity of all levels of research concerning autism spectrum disorders. More recently, the Simons Foundation, which is focused primarily on genetic and neurobiological investigations, has also had a significant impact on funding of basic science research in autism. A 2009 study by Singh et al. found that the number of autism research grants funded in the U.S. from 1997 to 2006 increased 15% each year, with the majority of grants focused on genetics and neuroscience. This is a significant trend, but it must be acknowledged that it started from a very low baseline. At the beginning of this period, the total spending by the National Institutes of Health directed specifically at autism was estimated to be only about $6M dollars. Further, if one considers that estimates of disease costs indicate that the actual economic impact in the United States is $35 billion per year (Gantz, 2007), such an increase was clearly warranted. So, in many ways the rapid growth in funding for autism research is considered by many in the advocacy and research communities as necessary to make up for what could reasonably be framed as decades of neglect.

Fortunately, in addition to basic science funding, trends toward increased support in the areas of translational and clinical research have emerged in recent years, suggesting a transition from basic research to applied research that seeks to deliver real-world improvements for persons with autism. By 2008 the United States was spending over $222 million on autism research with 35% of the funding coming from private foundations. Given this brief history, it is not surprising that

the field of autism research is moving rapidly forward and that knowledge about autism spectrum disorders is greatly increasing. In 2000, Medline listed 441 articles with the search terms "autism" or "autism spectrum disorders," whereas in 2009 the same terms identified 1,522 articles! Thus, from our perspective, the time was right to bring together summaries of as much of this new knowledge as possible into one volume—hence the genesis of this book. One now has the sense that this increase in research funding has finally created a critical mass of researchers from many different disciplines in the field, enabling true advances in understanding and treatment of autism. Here, the role of research advocacy groups in creating the proper permissive environment for the growth of the field via increasing governmental spending and by direct philanthropy cannot be overstated. Many of the advances described in this volume are a direct result of these efforts.

There are currently many excellent books that deal with various aspects of autism spectrum disorders. The guiding vision for this book was a core emphasis on ASD as a biological condition, so as to frame autism first and foremost from a biomedical perspective. We wished to provide a broad perspective on our current understanding of ASD, ranging from basic science to clinical symptomatology, to best clinical practices and social policy. We sought out leading authorities with diverse viewpoints and expertise, ranging from bench scientists to practitioners to parents and advocates. We encouraged authors to offer their own perspectives on the key themes guiding their field of study or interest, and provided commentary on the chapters from additional authors. Our goal was to paint the landscape of autism science and practice

from a biomedical perspective, including what is currently known and where the field is heading.

Many books have provided detailed information and descriptions of the behavioral features and development of individuals with ASD. Although such information is also included in this book, we encouraged authors focusing primarily on behavior to consider biological constructs, such as how our current understanding of brain plasticity informs theories of behavioral development and intervention, and the role of pharmacological or other biological modulators of brain plasticity in facilitating conventional behavioral therapies in autism. Other authors considered how probes of brain function such as functional magnetic resonance imaging or magnetoencephalography may ultimately be sensitive readouts of the efficacy of behavior therapy.

Many of the most exciting recent advances have resulted from collaborative and interdisciplinary efforts at understanding autism. It is this realization that initially prompted the undertaking of this book project and provided a second guiding principle, namely that topics should be inclusive of all levels of research that will now or in the future affect research on ASD. Thus, every effort has been made to include topics that range from basic discovery of genetic and environmental risk factors to translational studies involving animal models to best practices in the fields of diagnosis, behavioral intervention, and medicine. Our hope is that those readers whose backgrounds are in the basic sciences will gain a better appreciation of challenges inherent in translating discoveries into clinical practice. Conversely, we hope that those readers whose primary interest is in clinical practice will learn how the basic sciences are pointing toward new directions for treatment and diagnosis that are derived from an increased understanding of the biology of ASD. Thus, this book is intended as much for the clinician, who is occupied primarily with diagnosis and treatment of individuals with autism, as for scientists who are studying selected biological features of autism spectrum disorders. Since the book is comprehensive in scope, we hope that it will be valuable to a wide audience, ranging from students who are entering the field of autism research, to advanced scientists who may be moving into the investigation of autism from some other area of research, to interested caregivers and educators. For most chapters, the authors have provided an introductory list of key points that summarize the most important ideas in their chapters, as well as future directions and challenges and suggested readings at the end, so as to provide a broad perspective on each topic.

A final guiding principle of the book is that the content will evolve over time. Currently, the book's 81 chapters are organized into several sections, with initial chapters discussing the history and phenomenology of autism spectrum disorders followed by deeper analyses of the core features of autism spectrum disorders. The book then moves to important comorbid psychiatric and medical conditions associated with autism and several chapters discussing different aspects of the broader autism phenotype. The next section delves into the neurobiological facets of autism spectrum disorders including what is known about brain chemistry, electrophysiology, imaging, and neuropathology, followed by a section on etiological factors. Here, recent findings in genetics and genomics based on many diverse approaches and models are presented; the emerging role of environmental factors is also covered. These etiological findings provide a solid foundation for translation into animal models, which we expect to play a rapidly expanding role in the biomedical research in ASD. Thus, this section is followed by a number of contributions on experimental animal models in species ranging from zebrafish to primates, as well as contributions on theoretical models of autism. These include primarily biologically based theories, those rooted in cognitive neuroscience, and those that bridge both areas. The penultimate section of the book is directed at treatment, which is the target that we all hope our research will influence. These chapters include several on a variety of behavioral and psychosocial interventions and summaries of current and future medical interventions including complementary and alternative medicine. We conclude with a number of chapters on "best practices" in diagnosis and treatment, as well as policy statements and perspectives related to the future of autism research and advocacy. Given the rapid pace of autism research, we fully expect that the content and complexion of the next edition of this book will be very different from the current one.

We thank the many contributors to this volume and the staff at Oxford University Press for their help in bringing it to fruition. We also want to express our gratitude to the parents and other family members, as well as many individuals with ASD themselves, who have fought hard for the resources that made much of the work discussed in this book possible. Their courage, tenacity, and dedication are an inspiration. We hope that this book adds impetus to continuing autism research efforts that ultimately improve the lives of persons with autism spectrum disorders and their families.

Foreword

When our grandson Christian was diagnosed with autism in 2004 we were shocked. As a family involved with producing and developing some of our nation's most up-to-the-minute media, we were incredibly surprised and dismayed that we knew so little about the disorder. We were even more stunned to learn that the physicians and scientists to whom we reached out for help had very little information about autism. Like so many families around the United States we were left with more questions than answers. It was this quest for knowledge that became the catalyst in creating Autism Speaks.

Since the founding of Autism Speaks, we have moved closer to unlocking the mysteries of this often misunderstood disorder. The year 2010 marks the fifth anniversary of Autism Speaks, and we are proud that the past five years have seen accelerated scientific progress and a better understanding about autism. We have committed over $160 million dollars to autism scientific research, and we are aggressively examining a number of determinants, including genetic and environmental risk factors, biological systems and pathways, accompanying conditions, and most importantly, how to provide the best care possible for children and families.

Autism Spectrum Disorders provides a scholarly, yet accessible summary of the state of autism science, best practices, policy, legislation, and future directions. From language development, sleep disorders, and genetics to environmental toxicants, neuroscience, and early intensive interventions, this book delivers many of the answers that families like ours have been seeking. *Autism Spectrum Disorders* also exposes the knowledge gaps and unmet needs that our families continue to face every day.

What is clear now is that more has to be done for the autism community. Today, Autism Speaks is on the frontlines fighting for autism insurance reform. Until very recently, most families who received an autism diagnosis were denied insurance coverage for autism services—and for a disorder affecting one percent of children in the United States, this kind of treatment by insurance companies is not only negligent, it is outright discriminatory. Autism Speaks has been lobbying lawmakers around the clock, and at the time of this writing, 23 states have passed autism insurance laws, while an additional 25 have bills in progress. President Obama has made health care a priority. As part of this focus, he has allocated 85 million dollars in stimulus funds to autism research through the Recovery Act and is supporting language to end discrimination against autism in all insurance plans. Additionally, the Combating Autism Act, which was passed in 2006, authorizes nearly one billion dollars in expenditures over 5 years beginning in 2007, to combat autism spectrum disorders, Asperger's syndrome, Rett syndrome, childhood disintegrative disorder, and PDD-NOS through screening, education, early intervention, prompt referrals for treatment and services, and research.

On September 22, 2009, Autism Speaks hosted its second annual World Focus on Autism in New York City. There we announced our "Decade for Autism" challenge, a global call to action for international leaders and stakeholders to raise a combined $100 million dollars in their countries over the next 10 years for autism research, awareness, and service development. Our greatest wish is that 5 years from now—only halfway through the "Decade for Autism"—many of the questions raised here in this book will have been answered, and many of the pressing needs of the autism community will have been addressed. This book, hopefully, will inspire the scientific and professional community to continue with a sense of urgency in their efforts to find answers and use those answers to discover ways to effectively treat and prevent autism.

Autism Spectrum Disorders

This page intentionally left blank

Introduction ⊞ Isabelle Rapin

Autism Turns 65: A Neurologist's Bird's Eye View

Asking a neurologist to write the introduction to a book on the autism spectrum disorders (autism for short in this chapter) seems unexceptional in 2008 because it is now taken for granted that autism is the behavioral consequence of any one of a multitude of developmental disorders of the immature brain. Not so when I was in training in the 1950s. What has brought about such a profound change in perspective? This introduction highlights a few of the changes I have witnessed over a half-century, including ideas about causation, prevalence, language subtypes, epilepsy and language regression, sensorimotor symptoms, neuropathology/imaging, genetics, and intervention. Whereas this book provides in depth discussion of each of these issues and others, this limited bird's eye view makes no apology for the myopia of a single person's perspective.

⊞
Biology vs. Refrigerator Parents

As far as disorders of complex human behaviors are concerned, the first half of the twentieth century saw the ascendancy of the Freudian hypothesis that attributed to early psychic traumas even such a life-long disorder as schizophrenia, despite its fluctuating, deteriorating course. Kanner was an Austrian-born, Berlin-educated child psychiatrist who spent much of his professional life at the Harriet Lane Children's Hospital of Johns Hopkins Medical School in Baltimore. His astute and comprehensive 1943 description of autism in 11 children (Kanner, 1943) remains valid to this day. He characterized their disorder as "an inborn autistic disturbance of affective contact," yet emphasized their parents' lack of warmth. By 1954 he had compiled his observations on 100 children (Kanner, 1954) and expressed the view that highly educated mothers' (and fathers') parenting inadequacies were largely responsible for their children's autism. He must have swung back to the hypothesis of innateness because, according to his

biographer Sanua (Sanua, 1990), at the 1969 national convention of parents of children with autism, Kanner said: "Herewith, I officially acquit you people as parents." His writings continued to reflect ambivalence, however, as in the 1979 edition of his textbook, *Child Psychiatry*, he still states, according to Sanua, that childhood schizophrenia—a term routinely used for autism until the 1970s, although allegedly not by Kanner—was more strongly correlated with parental attitudes than with genetic or metabolic factors. Predictably, the widely publicized views of this father of American child psychiatry and professor at a prestigious medical school were promptly disseminated and almost universally adopted in this country and abroad.

Because of the tenor of the times and lack of ostensible evidence for a neurologic basis for autism and other developmental disorders, 30 years were to go by before enough evidence had accumulated to refute the inadequate parenting theory of autism. The 1952 discovery of chlorpromazine's dramatic effectiveness in schizophrenia opened the door to an avalanche of new evidence regarding the role of neurotransmitters, neuromodulators, and neuropeptides in synaptic transmission. Their discrete distributions in the brain, together with progress in neuroendocrinology, ushered in the era of biologic psychiatry. The contemporaneous birth in the 1970s of neuroscience and expansion of the field of neuropsychology, coupled with the explosion of new technologies for studying the living brain, finally led to neurobiology's eclipsing Freudian psychiatry and theories of refrigerator mothers.

Two factors pushed the neurobiologic view of autism to the forefront and, perhaps prematurely, denied any causal relevance of deleterious early life experiences. The first factor was the 1964 congenital rubella epidemic which left in its wake a number of children with autism. Stella Chess, a child psychiatrist who worked at Bellevue Hospital in New York City, evaluated many of these children (Chess et al., 1971). They reinforced her long-standing opinion of autism as a disorder

of the brain. The second factor was the realization that some third of the children with autism developed epilepsy (Deykin & MacMahon, 1979), to which I will come back later. Richard Schain, a child neurologist at the University of California in Los Angeles, had made the earlier seminal observation that about one-third of children with autism have elevated levels of serotonin in their platelets, but this report was overlooked until research on neurotransmitters progressed sufficiently (Schain & Freedman, 1961).

The late Bernard Rimland, a psychologist whose son has autism and is artistically gifted, wrote the first book defending the biologic basis of autism: *Infantile Autism: The Syndrome and Its Implications for a Neural Theory of Behavior* (Rimland, 1964). He was also the first and most influential parent advocate and achieved tremendous influence, which persists to this day. He collected thousands of questionnaires filled out by parents of children with autism from around the globe, a treasure trove of data waiting to be mined comprehensively. Rimland disseminated promptly and widely any new information with potential therapeutic implications, without waiting for empirical support. I assume he did so because of his burning desire to make sure parents had access to the newest potentially useful information, but this has resulted in the uncritical worldwide adoption of some unproven diets, other interventions, and theories about the causation of autism.

Mary Coleman, a child neurologist, atypically chose to limit her Washington DC practice to autism. Equally convinced that autism had a neurobiologic basis, she evaluated each child extensively for this possibility. Together with Christopher Gillberg, a child psychiatrist from Göteborg, Sweden, trained in pediatrics and epidemiology, she published *The Biology of the Autistic Syndromes* in 1985 (Coleman & Gillberg, 1985). Its 2000 third edition (Gillberg & Coleman, 2000) details not only clinical and epidemiologic evidence and management issues but also lists many of the rare genetic conditions occasionally associated with autism. The first 1987 edition of the encyclopedic *Autism and Other Developmental Disorders: A Handbook*, edited by the late Donald Cohen and colleagues (Cohen et al., 1987), is also in its third edition (Volkmar et al., 2005) and getting thicker with each iteration.

I particularly want to draw attention to the French child psychiatrist and electrophysiologist Gilbert LeLord of Tours, who started biologic studies of autism in the early 1970s (LeLord et al., 1973), because he and his colleagues have been bucking the mainstream of French psychiatry which, to this day, is strongly invested in psychoanalysis. LeLord eventually attracted a large cadre of collaborators whose many lines of quality research parallel autism studies in Anglo-Saxon, Scandinavian, and other countries. With the active help of parent-advocates, the Tours group organized a day school to educate children with autism, described in their 1995 book *Infantile Autism: Exchange and Development Therapy*, which particularly emphasizes social skills training (Barthélémy et al., 1995).

Controversies Regarding Prevalence and Classification

Information on the prevalence of autism has changed dramatically over the past half-century. At first only classic Kanner-type children, whom the DSM and ICD systems label Autistic Disorder, were counted, and their prevalence was quoted as ~1/2,500 children (e.g., Lotter, 1966; Ritvo et al., 1989). Lorna Wing, a London child psychiatrist, was among early clinicians to recognize the wide spectrum of severity of the social and other impairments of autism and the triad of behavioral domains affected (Wing & Gould, 1979). The psychologist Uta Frith's translation into English of Asperger's 1944 paper (Frith, 1991) contributed to awareness and acceptance of more mildly affected individuals as belonging on the autism spectrum, which helped swell the statistics. Wing (Wing & Potter, 2002) and others (e.g., Fombonne, 2003) attribute the recent so-called epidemic of autism, i.e., 1/110, largely to such changes in diagnostic criteria. I acknowledge up front that I have contributed to the "epidemic" in New York, as my threshold for an autism spectrum diagnosis dropped dramatically over the years. For example, I recently reviewed the chart of an 18-year-old musician about to enter college whose high functioning autism diagnosis was instantly obvious to me from his father's description over the phone. In the early nineties I had diagnosed this same child, then 4 years old, as having a "severe developmental language disorder with serious behavioral problems."

A factor strongly contributing to the increase in prevalence is availability, for the past 20 years or so, of standardized autism-focused diagnostic and screening instruments like the Childhood Autism Rating Scale (CARS) (Schopler et al., 1986); an autism-focused history, the Autistic Diagnostic Interview (ADI) (Le Couteur et al., 1989); the age-stratified Autistic Diagnostic Observation Schedule (ADOS) (Lord et al., 1989); and the Checklist for Autism in Toddlers (CHAT) (Baron-Cohen et al., 2000), to name some of the more widely applied tests. A consequence of their use in the clinic, not just for the selection of research subjects, is that a diagnosis of autism spectrum disorder became applicable to hitherto ignored individuals at both the very severe and mild ends of the spectrum. Still another factor is that many parents, at least in the United States, now push for an autism diagnosis because it brings with it access to more intensive services than a diagnosis of other developmental disorders. Their hope is that, through early intervention, their child may eventually be included in mainstream education. There is no exclusionary criterion for a diagnosis of autism. Use of standardized diagnostic instruments therefore resulted in many children with rare disorders who already carried a medical diagnosis being newly counted among those with autism, inasmuch as they fulfilled the behavioral diagnostic triad of autism, namely impaired sociability and communication, and a narrow perseverative behavioral repertoire. *Secondary autism* is the term widely used today for the minority—estimated at less than

20%—of children on the autism spectrum with an identifiable etiology (Rutter et al., 1994), be it genetic or unequivocally environmental, like congenital rubella.

Primary autism, the only group counted in early studies, encompasses the great majority of cases of autism without a known cause or associated somatic deficit, a fraction expected to shrink with advancing etiologic research. Individuals currently diagnosed with Asperger's syndrome and high functioning autistic disorder (HFA), and those with Pervasive Developmental Disorder Not-Otherwise-Specified (PDD-NOS), i.e., more mildly affected individuals, some without cognitive impairment, were not counted in early epidemiologic studies. The "autistic traits" of these individuals would not have made the diagnostic cut. It remains controversial how to classify persons with epilepsy or with other behavioral problems warranting an additional DSM/ICD psychiatric diagnosis. For example, should autism with attention deficit disorder with hyperactivity (ADHD) (Landgren et al., 1996) or bipolar disorder (Rzhetsky et al., 2007) be classified as primary autism with comorbidity or as secondary autism?

The bottom line is that because autism is a behaviorally, i.e., dimensionally defined, diagnosis, its classification is based on agreed-upon cut-off criteria along a behavioral continuum, not on dichotomous biologically based criteria. For all these reasons, prevalence figures are and will continue to remain approximate and disputed. Regardless of the reasons for its cause, the prevalence of autism spectrum diagnoses has risen dramatically over the past several decades.

Language Disorders, Language Regression, and Epilepsy in Autism

I will not attempt to cover here the vast neuropsychologic and electrophysiologic advances of recent decades, nor will I focus on the core deficits in sociability and joint attention. My colleagues and I did carry out exhaustive evaluations of anamnestic, neurologic, neuropsychologic, language, play, and behavioral dimensions in preschool children with autism compared to cognitively matched developmentally impaired controls who did not have autism (Rapin, 1996a). The child neuropsychologist Deborah Fein and her students have published a number of studies of these same children followed at school age, (e.g., Fein et al., 1999; Stevens et al., 2000). Here, I confine myself to studies of language to which I have personally contributed.

Language Disorder Subtypes in Autism

Delayed or absent language, together with impaired conversational use of language (pragmatics) constitute the second criterion for an autism diagnosis. Impoverished imaginative play is also a component of this criterion. I was fortunate to work with the late Doris A. Allen, a developmental psycholinguist with a background in education, psychology, and speech

pathology. She directed the Therapeutic Nursery of the Einstein Division of Child Psychiatry, which, before she took it over in the mid-seventies, was still run by a psychoanalyst. Dr. Allen turned it around by addressing children's communication deficiencies, social and play deficits. A parent or other caretaker had to accompany the child to school every day because one of her focuses was to teach "in the trenches" more effective skills for managing the child's difficult behaviors (Allen & Mendelson, 2000).

Pooling our skills, Doris Allen and I developed an observational classification of developmental language disorders suitable for clinicians' use in their offices (Allen et al., 1988; Rapin, 1996b). We discovered that the subtypes of language disorders in unselected consecutive young children with autism evaluated clinically overlap those of children with developmental language disorders who do not have autism, except for major differences in subtype prevalence (Allen & Rapin, 1992; Tuchman et al., 1991a). Besides their signature pragmatic deficits, young children on the autism spectrum, verbal or not, all have comprehension deficits for conversational speech, whereas a sizable proportion of language disordered children without autism do not. We were struck that, in both groups, epilepsy is strongly linked to verbal auditory agnosia (VAA), the most severe subtype of receptive/expressive disorder for speech sound processing (phonology) (Tuchman et al., 1991b). VAA is characterized by dysfunction in auditory cortex, which jeopardizes the acquisition of verbal comprehension and expression at the language-learning age.

Until very recently (Kjelgaard & Tager-Flusberg, 2001; Tager-Flusberg & Joseph, 2003), studies of language in autism focused mainly on its impaired pragmatics (conversational use), a correlate of autism's social impairment, and on abnormal features like echolalia, pronominal reversal, perseverative questioning, and aberrant vocabulary and prosody. The accepted tenet was that phonology (speech sound production) and grammar (syntax and morphologic markers), although often delayed, were unaffected in autism. When children started to speak, often after a considerable delay, they did so competently and thus did not have "structural" language disorders. Our clinical observations in unselected preschoolers, together with a recent study at school age using formal tests, indicate that this is not true of some third of children (Rapin et al., 2009). It is the case that the intellectually deficient children on the autism spectrum are those who are most likely to have impaired expressive and receptive language. Yet, blaming global cognitive deficit for impaired expressive phonology and grammar and for an impoverished vocabulary begs the question of the neurologic basis of the deficient language. Having similar subtypes of language disorder in no way implies that autism and developmental language disorder are on a continuum or share a common etiology. It does suggest that they have in common dysfunction in a corresponding language network, although not necessarily in the same node of that network.

In more than three quarters of typically developing children and adults, even in the majority of those who are left-handed,

it is well known that language depends strongly on the function of the left superior temporal (Wernicke's) and inferior frontal (Broca's) cortices and on the pathways that interconnect them (Galaburda et al., 1990). On average these areas are typically asymmetric, larger on the left than the right. Classically, lesions affecting Wernicke's area in adults compromise comprehension of the meaning of language (semantics) but not the production of phonology or syntax, and lesions affecting Broca's area interfere with language expression, specifically with phonology and syntax. Morphometric studies showed similarly reversed asymmetry, compared to normally developing controls, in a sample of children with autism and with developmental language disorders without autism (Herbert et al., 2002; Herbert et al., 2005), findings that support parallel involvement of language networks in both disorders. In an independent sample, De Fossé and colleagues (De Fossé et al., 2004) detected reversed asymmetry of frontal language cortex in children with developmental language disorders and among those with autism, only in those whose expressive phonology and grammar were impaired on formal testing; asymmetry was not reversed in those who did not fulfill criteria for this subtype of language disorder. The study provides further evidence for the existence of more than a single subtype of language disorder in autism.

Epilepsy and Language/Autistic Regression

We noted earlier that the occurrence of epilepsy (defined as at least two unprovoked seizures) in some one third of children with autism by adolescence provided critical evidence against the psychogenic etiology of autism (Deykin & MacMahon, 1979; Olsson et al., 1988; Tuchman et al., 1991b; Volkmar & Nelson, 1990). Earlier evidence indicated that infantile spasms (West syndrome), one of the malignant epileptic encephalopathies of infancy, may leave autism in its wake (Taft & Cohen, 1971); in other words, infantile spasms (or the encephalopathy responsible for the spasms) may damage permanently selective pathways required for sociability, communication, and behavioral flexibility. Despite recent intensive work, it remains controversial whether in these children autism and epilepsy arise from a common underlying molecular mechanism, or whether in some cases it is the seizures that, by damaging certain critical networks, are responsible for the autism and the intellectual impairment likely to accompany it (Tuchman et al., 2009). Parents' reports of regression of language and sociability around 15 to 30 months were greeted at first with skepticism. My doubting an identical story told to me by scores of mothers would have been foolish, especially when Japanese mothers gave identical reports (Kurita, 1985). The reality of regression finally received empirical corroboration when home videos documented language/autistic regression in some third of toddlers (Werner & Dawson, 2005). Its cause remains frustratingly elusive, however.

One possibility we and others explored was that covert epilepsy might be responsible for autistic regression. This hypothesis was based on awareness of the rare but dramatic language regression without autism well documented in older children in the context of epilepsy or of an epileptiform EEG without clinical seizures (acquired epileptic aphasia— Landau-Kleffner syndrome). A brief questionnaire brought out that language regression in children under age 3 is highly predictive of autism, whereas in older children it more often signals clinical or subclinical epilepsy (Shinnar et al., 2001). Overnight EEGs are more likely to reveal epileptiform activity, and seizures are more prevalent in older children with language regression than in the younger children, who are at much higher risk for autism (McVicar et al., 2005). Language regression per se is not a strong predictor of epilepsy in autism (Tuchman & Rapin, 1997). Thus, these studies indicate that the pathophysiologies of language regression in autism and in Landau-Kleffner syndrome differ and that epilepsy, be it overt or subclinical, seems to play a minor role in the language regression of autism.

Sensorimotor Deficits

As long as autism was considered a psychogenic disorder, sensorimotor symptoms were largely ignored, despite parents' concerns about them and despite articulate adults' descriptions of their own atypical sensory experiences (Grandin, 1995). Information regarding the sensory and motor symptoms of autism is sparse, yet they are targets of many expensive therapeutic attempts to influence them, with little empirical evidence of efficacy (Baranek, 2002).

Neurologic explanations are being sought for the frequent and puzzling co-occurrence in the same individual of hyper- and hyposensitivity to sound and visual, somatosensory, and other less well studied sensory inputs (Rapin, 2006). A notable change over the past decade is that researchers have started to think of the autistic brain as different rather than damaged and have started to investigate the brain basis of enhanced perception and talent of some individuals with autism (Mottron et al., 2006; Samson et al., 2006). This change was prompted, in part, by early studies of savants, most of whom had autism and all of whom had severe impairments outside their extraordinary talents (Obler & Fein, 1988; Treffert, 2005).

The main motor symptoms in autism are stereotypies, difficulty imitating and mastering complex motor tasks, persistent toe walking, and "hypotonia" (Akshoomoff et al., 2007). Parents view stereotypies, purposeless rhythmic, repetitive movements, as particularly troublesome because they are stigmatizing (Goldman et al., 2009). Stereotypies are widely regarded as enjoyable bad habits to be squashed, rather than as temporarily suppressible movement disorders in some ways akin to tics (Berthier et al., 2003; Rapin, 2001). Despite a large animal literature (Saka et al., 2004), little is known about the neurologic basis of stereotypies in humans.

Why is it that some individuals with autism do not imitate, are clumsy, and have trouble learning the sequence of movements required to tie their shoes or write (Fuentes et al., 2009)?

Rather than signaling lack of motivation, these inadequacies may signal inadequate procedural learning and inefficient cerebellar-basal ganglia-parietal circuitry (Mahone et al., 2006; Mostofsky et al., 2000). A characteristic of many children with autism is their impaired imitation of movements, for which lack of attention to the task does not seem to provide a convincing explanation (Vivanti et al., 2008). In a study of sensorimotor function comparing children with autism to children without autism but with either developmental language disorders or low IQ, we were unable to determine reliably whether failure to carry out motor tasks was due to inability to perform or impaired motivation (Mandelbaum et al., 2006). Functional neuroimaging suggests that poor imitation may reflect absent or dysfunctional mirror neurons, which play a crucial role in imitation (Iacoboni & Mazziotta, 2007; Rizzolatti & Craighero, 2004; Rogers, 2007).

A frequent motor characteristic of autism is toe-walking (Ming et al., 2007). No one knows why so many children with autism toe-walk in the absence of spasticity, bony or soft tissue structural abnormality.

Physical therapists regularly comment on "hypotonia," by which they mean increased joint mobility without weakness. Neurologists gave a score for hypotonia to a quarter of preschoolers with autism, but also, among those without autism, to a third of those with low IQ and 13% of those with language disorders (Rapin, 1996c). In the absence of a standardized metric for "hypotonia" in young children, the significance of these observations, their specificity and functional importance are undetermined. The literature is replete with reports of "hypotonia" in a large variety of children with chromosome anomalies and other developmental syndromes, but its basis is essentially never specified. It remains to be seen whether "hypotonia" in autism, when real, is a consequence of cerebellar or proprioceptive impairment, conceivably muscle mitochondrial dysfunction, or whether in some children cytogenetic or micro DNA rearrangements may have implicated a gene for collagen or elastin. In any case, in view of physical and occupational therapists' huge expenditures of effort to improve "hypotonia," this is a symptom that cries for much more rigorous definition and metric, longitudinal assessment of its functional significance, and specification of its almost certainly disparate causes.

Neuropathologic/Imaging Evidence

Autism had no known neuropathology until 20 years ago when Margaret Bauman, a child neurologist, and Thomas Kemper, a neuropathologist and anatomist, both from Boston, described subtle stunting of the soma and dendrites of some limbic neurons and, surprisingly, no neocortical pathology (Bauman & Kemper, 1985). Their report of a reduced number of Purkinje and granular cells in the cerebellum was a clap of thunder. This unexpected finding, amplified in subsequent papers (Bauman & Kemper, 2003), opened the door to a flood of morphometric studies of the cerebellum and to reconsideration of its role not only in autism but in other complex human behaviors like language, attention, and affect, to name but a few (Schmahmann, 2004). Kemper & Bauman also noted subtle differences in specific brain nuclei of children and adults (Kemper & Bauman, 2002), suggesting the possibility of an ongoing process in some individuals. The aberrant early growth curve of the brain in autism (Courchesne et al., 2007) bolsters this contention.

As technologies for neuroimaging advanced, a more detailed understanding of the anatomy and function of the autistic brain began to emerge. Recent computer-assisted morphologic studies of the neocortex revealed increased numbers of narrower neuronal minicolumns (Casanova, 2006). These may account for enlargement of the radiate white matter fibers that interconnect neocortical areas described in some of the children we had studied behaviorally (Herbert et al., 2004). Overconnectivity of some cortical circuitry, underconnectivity of others involving subcortical relays such as the basal ganglia, amygdala and other limbic areas, and the cerebellum are at the forefront of current investigations (Geschwind & Levitt, 2007; Minshew & Williams, 2007). Studies range from behavioral to morphometric and functional imaging, and from electrophysiology down to the level of the synapse (Zoghbi, 2003) and of neurotransmitters like dopamine, glutamate, and others (Yip et al., 2007).

Subtle neuronal migration defects were observed in a handful of severely affected individuals (Bailey et al., 1998), and an unsuspected variant of neuroaxonal dystrophy in two others (Weidenheim et al., 2001), not to mention the variety of other findings in individuals with defined etiologies like tuberous sclerosis (Asano et al., 2001), or fragile X, in which dendritic spines are thin and immature-looking (Hagerman et al., 2005). Signs suggesting inflammation (Vargas et al., 2005) point to neuroimmunologic abnormalities, long suspected but not demonstrated in children with a history of regression (Ashwood et al., 2006; Cabanlit et al., 2007; Wills et al., 2007). The National Alliance for Autism Research (NAAR), a parent-initiated group now part of Autism Speaks, supports the Autism Tissue Program (Pickett, 2001), which has raised awareness of the urgent need for continued tissue donation from affected individuals and nonaffected controls. Tissue enables investigators around the world to carry out studies of the cellular and molecular biology of autism that are impossible without this precious resource.

Genetics and Epigenetics

Awareness that genetics might be an important player in autism grew in the 1970s and '80s following early reports of strong concordance of autism in identical twins (Folstein & Rutter, 1977; Steffenburg et al., 1986). Genetic studies gained momentum in the mid-nineties after a parent advocacy group, Cure Autism Now (CAN), also currently part of Autism Speaks, sponsored the systematic collection of detailed family

and personal histories and DNA from families with more than one rigorously diagnosed affected member. The resultant Autism Genetic Resource Exchange (AGRE) has enrolled many hundreds of families across the country and some abroad (Geschwind et al., 2001; Ylisaukko-oja et al., 2006). The NIH and Autism Speaks now support this extraordinarily valuable resource. I learned when I first came to Einstein 50 years ago the power of interdisciplinary coalitions of basic scientists working hand-in-hand with clinicians to elucidate the pathophysiology of obscure neurogenetic diseases, several of which generated novel biologic insights (Goldfischer et al., 1973; Purpura & Suzuki, 1976). This same multidisciplinary approach, yoked with spectacular technologic advances following the 2001 completion of the human genome project, has uncovered unexpected complexities of autism genetics (O'Roak & State, 2008). Single mutations with strong effects seem to be the exception in "primary" autism, judging from the small proportion of families with a typical Mendelian or mitochondrial pattern of inheritance. Multigenetic influence is likely in view of relatively weak linkages of the many newly discovered genes to "primary" autism and of the high prevalence of unaffected family members with lesser developmental deficits (Dawson et al., 2007). Stunningly rapid progress in genetics makes it a challenge to keep clinicians up-to-date; two Einstein medical students, whose knowledge of genetics was much fresher than mine, attempted to do so for pediatricians a few years ago (Muhle et al., 2004), and Roberto Tuchman and I more recently for neurologists (Rapin & Tuchman, 2008). The public needs to be reminded again and again that the brain, not genes, causes or explains behavior (Abrahams, B. S. and Geschwind, D. H., 2010). Any one gene is likely to accumulate many different mutations in different families, resulting in potentially different phenotypes. The role of genes in autism will not be understood until it becomes clear what protein each codes for and what roles the protein plays in the brain and its different cell types.

Hitherto unsuspected complexities in the inheritance of autism have important implications for genetic counseling. Prenatal diagnosis is not in the cards now and unlikely to become so, except for families with identified cytogenetic, Mendelian, or mitochondrial traits. Most cases of autism are sporadic, that is, neither parent carries a mutation identified in their child. An as yet unknown proportion of de novo mutations arise either in the gonad of one of the noncarrier parents or possibly in the early embryo. Such couples are at minimal risk of having another affected child, but that child's descendents, especially males, will be at high risk of inheriting the trait (Zhao et al., 2007). Some of these new traits are micro DNA deletions, duplications, or other rearrangements (Weiss et al., 2008), which may affect not only coding but also noncoding regulatory parts of one or more genes.

Postmitotic epigenetic effects, some of them environmentally mediated, may have direct biologic consequences or influence brain development indirectly. I witnessed an extreme example of a presumed epigenetic effect that caused a gross anatomic difference in a set of monozygotic twin girls with Joubert syndrome. One of the twins had autism and was very intellectually impaired, with a major motor handicap and much more severe cerebellar malformation than her sister (Raynes et al., 1999). Others have reported presumed epigenetic influences in phenotypically discordant monozygotic twins with tuberous sclerosis and autism (Humphrey et al., 2004). Epigenetic influences may be major or subtle. I cannot discount several parents who reported convincingly an abrupt autistic regression in their children following a stressful life event like a separation, a move, or a brief hospitalization that another child would have weathered without lasting consequence. Kurita and colleagues heard similar stories from several Japanese mothers (Kurita et al., 1992). These rare occurrences suggest the synergistic effect of a stressor in an individual vulnerable because of an inherent (genetic?) predisposition.

There is evidence to suggest that at least some autistic symptoms may reflect functional rather than structural changes in the brain. We (Rapin, 1996d) and others reported that children's behavior may improve when they have a fever, an effect that can persist for several days following defervescence (Curran et al., 2007). A provocative suggestion is that dysfunction of the locus coeruleus-noradrenergic system may account for these observations, with obvious potential implications for intervention (Mehler, 2008, Mehhler & Purpura, 2009).

A very recent realization is that the number of noncoding RNAs increases exponentially from lower organisms to man, in the face of fairly similar numbers of protein coding genes. These RNAs provide a plausible explanation for increasing brain complexity, as many are specific to the brain and especially active during its development (Mattick & Mehler, 2008; Mehler, 2008). Epigenetics, that is postmitotic control of gene expression, plays a crucial and very specific role in neuronal and neural network development and function. MicroRNAs can turn on and off messenger RNAs and noncoding RNAs, which control entire neural networks transiently or permanently. They are highly sensitive to environmental influences and therefore are potent epigenetic modulators of genetic developmental programs in response to random life events (Mehler & Mattick, 2007; Persico & Bourgeron, 2006). They may thus provide a partial explanation for the puzzling clinical observations of sudden language/autistic regression. By the same token they might play a role in the brain plasticity that underlies the behavioral amelioration that often results from intensive early education and competent parenting (Dawson, 2008; Helt et al., 2008).

Intervention: Psychopharmacology and Education

From my perspective, progress in the psychopharmacology of autism has been disappointing despite growing understanding of neurotransmitters and neuromodulators. Risperidone is the

only FDA medication approved specifically for autism, and, at that, only for irritability and aggression (McCracken et al., 2002; Scahill et al., 2007). Yet it is prescribed extensively off-label in small doses in attempts to control stereotypies and other undesirable behaviors. It is known to affect both serotonin and dopamine receptors and has largely supplanted the dopamine blockers that were prescribed in the fifties and sixties. Stimulants, anticonvulsants, specific serotonin reuptake inhibitors, and many other psychotropic drugs are widely prescribed to help modify specific behaviors, but their very multiplicity indicates that none is a magic bullet (Mintz et al., 2006). I am impressed with potentially undesirable—especially long-term—side effects such as abnormal involuntary movements in susceptible children treated with dopamine reuptake inhibitors, and weight gain precipitated by risperidone. I believe that medications should be limited to specific behavioral indications, mostly in more severely affected children.

Without doubt the major revolution in the management of autism is early intervention and education. Ivar Lovaas's report (Lovaas, 1987) that intensive systematic operant conditioning had ameliorated the outcome of 9 of 19 preschoolers to the point of their becoming educable in regular classrooms was the second thunderclap in the field. The improvement was lasting, since 4 years after the training, 8 of the 9 were described as indistinguishable from their normally developing peers (McEachin et al., 1993). This impressive success was recently replicated in another small cohort (Sallows & Graupner, 2005) and no doubt in others. Up to the development of this strategy, prognosis for improvement in children with autistic disorder was dismal, professionals' attitudes defeatist, and intervention was viewed as largely futile. The news of an effective treatment that raised IQs and suppressed bad behaviors in some children spread like wildfire. The Lovaas Applied Behavior Analysis (ABA) approach has become dominant, at least for preschoolers, with the caveat that it works best in children with a reasonable intellect and that it is not a "cure" but can make some previously unreachable children available to less rigid educational approaches. The field of applied behavior analysis has developed dramatically over the years, spawning a number of less rigid early intervention curricula that incorporate naturalistic and developmental approaches to formal operant conditioning. Two of the most widely accepted are those of Eric Schopler (Schopler & Olley, 1982), which emphasizes structured teaching, and of Stanley Greenspan (Greenspan, 1992), based on child-centered play-based methods. Today's eclectic programs may borrow features from the three programs and others (Schreibman & Ingersoll, 2005). They tend to focus on pivotal social behaviors such as motivation, self-initiated interaction, responsiveness to cues, and others shown to enhance learning of language and other skills (Koegel et al., 2001). For example, adding to an ABA-based preschool program 30 minutes per day for 6 weeks of training in either joint attention or symbolic play yielded additional gains in language and sociability that were sustained for a year (Kasari et al., 2008).

The program I am most familiar with is a preschool for higher functioning children on the spectrum that focuses on teaching sociability and communication to the child and on training of parents to achieve control of their child's difficult behaviors (Mendelson et al., 2007). Most recently, two of my colleagues have published a curriculum (Dunn, 2005) and practical guidance for teachers of children able to be educated in regular classes (Fein & Dunn, 2007).

It is now clear that intervention is most likely to be effective in very early childhood, when development is fastest and the brain most plastic. Prospective study of the younger siblings of probands is currently providing the opportunity to compare affected and nonaffected infants from birth (Landa & Garrett-Mayer, 2006; Zwaigenbaum et al., 2005). The goal is to identify the earliest signs of autism so that intervention can start forthwith. Diagnosis of an autism spectrum disorder before age 3 years entitles children in the United States to intensive early intervention under the umbrella of federally mandated state-delivered agencies. After age 3 years children fall under the jurisdiction of local school districts, which may provide as much as full day, 11 months/year, specialized education and therapies. This educational revolution has turned around the management of children on the autism spectrum but is straining the resources of educators and parents. Many parents insist on every possible therapy in school and pay out of pocket for touted unconventional, unproven interventions they read about on the Internet (Levy & Hyman, 2005).

At this time in developed countries, many intensive interventions are recommended from toddlerhood to young adulthood. Desperate parents, anxious for their children not to miss out on any potentially helpful intervention, are often eager to try pharmacotherapy and, sadly, alternative and expensive treatments of dubious effectiveness. What is still glaringly missing is empirical evaluation of these disparate medical and educational approaches. Equally inadequate are programs for adults who may need ongoing more or less intensive support in their every day lives. Worse of all is the inequality of what can be provided for the rich and vocal and for the poor, especially in developing countries. It is urgent that effective interventions that parents can provide at home be devised, evaluated, and exported to needy children both here and abroad. There is no way teachers and therapists can do it all.

Summary and Conclusion

Autism has come full circle in a half-century, from an obscure "psychiatric disease" to the symptom of a partially understood deviance in brain development influenced by both genetics and the environment. I highlighted what I believe to be the main reasons for dramatic changes in its prevalence. I emphasized our complete lack of understanding of what triggers language/autistic regression and provided evidence against epilepsy as a major player in its occurrence. I presented my

view of subtypes of language disorders in autism, pointing out that, besides their universally and persistently impaired use of language (pragmatics), some children have undisputable deficits at the level of receptive and expressive phonology and grammar. I did not discuss the potential role of inflammatory/immunologic factors in autism and, particularly, in regression. I only acknowledged major advances in electrophysiology, functional imaging, and neuropsychology. I mentioned anatomic and pathologic evidence suggesting that, at least in some individuals, autism might be an ongoing developmental process and stressed the dire need for more tissue for research. I pointed out that the study of sensorimotor deficits has been neglected for too long, a fertile area for neurologic study. I stressed that major progress in modern genetics applied to autism has yet to have a major impact on our understanding its cause or our ability to provide genetic counseling to most families. Finally, I stated that I considered advances in pharmacologic intervention disappointing, in contrast to my much more optimistic appraisal of progress in education, especially in toddlers who are being diagnosed at ever earlier ages. I hope that the detailed chapters of this book show my views to be overly pessimistic, but these do represent those of a clinician evaluating real children and attempting to inform their parents.

I choose to emphasize here the pressing need for empirical evidence to help weed out some of the many expensive and conflicting recommendations for evaluation and management. Providing all of these in the clinic and the school is breaking the bank, without proof of which are cost-effective. I did not spell out the many frankly exploitative panaceas touted to parents by word of mouth or on the Internet. I do not doubt the effectiveness of early, intensive, specialized education for many of the children, but there is a need for evidence-based research on the efficacy of the many expensive mainstream therapies they receive. Education, even though it does not "repair" the brain, can improve many symptoms and enable some high functioning adults to take an independent place in society. They demand, legitimately, to be considered somewhat different, but not "sick" (Chamak, 2008). In large part because of better education, even though some individuals will require long-term help, nowadays only the most severely affected will spend their days in idleness in institutions. That is real progress. And who would have predicted early on that autism would help advance basic neuroscience and education and that some individuals with autism would be recognized as able to make contributions to society that individuals without autism cannot make?

Autism Spectrum Disorders: Looking Backward and Looking Forward

⠿ Points of Interest

- Meaning of association with raised paternal age.
- Meaning of copy number variations.
- Nature of nongenetic causal influences.
- Nature of genetic liability at the molecular level.
- Transition from the broader phenotype to a handicapping disorder.

⠿ Introduction

It is now well over half a century since Kanner (1943) first postulated the syndrome of autism. He provided a remarkably incisive, detailed description and conceptual outline that has stood the test of time in almost all respects. Nevertheless, there have been huge changes in the understanding of autistic spectrum disorders (ASD), and research findings have clarified a range of crucial questions while, at the same time, presenting many further challenges. This chapter starts with a succinct summary of some of the main research accomplishments to date, then proceeds to outline a range of challenges that remain. Throughout, there is an emphasis on research findings and research challenges that have potentially important clinical implications.

⠿ Clinical Findings

The story starts with the validation of the differentiation between autism and a range of other child psychiatric disorders. This was shown by the distinctiveness of the clinical pattern, after matching groups for mental age, together with the finding that these differences persisted over time and were accompanied by a distinctive cognitive profile (Rutter, Greenfeld, & Lockyer, 1967; Lockyer & Rutter, 1969; Lockyer & Rutter, 1970). For a while, autism was regarded as an infantile psychosis, but numerous differences between autism and schizophrenia indicated that it was a mistake to see autism as an early manifestation of schizophrenia (Kolvin, 1971; Rimland, 1964; Rutter, 1972). Equally, although many individuals with autism also showed an intellectual disability, autism differed from general intellectual disability in numerous ways, including sex ratio, cognitive patterns, social class distribution, head circumference, and neuropathological findings (Rutter & Schopler, 1987).

Although Kanner had postulated that autism had a "constitutional" origin, he had not specified a neurodevelopmental origin as such. This was first demonstrated decisively by the finding that individuals with autism, who had shown no discernible neurological abnormality in early childhood, nevertheless showed a markedly increased rate of epileptic seizures in adolescence or early adult life (Rutter, 1970). More recent research (Bolton et al., in press) has shown that, in the majority of cases, seizures began after age 10 years. Epilepsy in the proband was not associated with an increased risk of epilepsy in relatives, but it was associated with the broader phenotype in other family members. Follow-up studies identified low IQ and a lack of language by age 5 as the key predictors of outcome (Eisenberg, 1956; Kanner, 1973; Howlin, Goode, Hutton, & Rutter, 2004).

Once the diagnostic criteria for autism became clarified, it became both possible and necessary to develop reliable and valid interview and observation measures. A range of assessment methods were developed but, over time, the autism diagnostic interview (Lord, Rutter, & Le Couteur, 1994; Rutter, Le Couteur, & Lord, 2003) and the autism diagnostic observation schedule (Lord et al., 1989; Lord, Rutter, DiLavore, & Le Couteur, 2001) came to be accepted as the best diagnostic methods available. Initially, most clinicians had assumed that children with autism were untestable by quantified

psychometric approaches, and it was important that both the follow-up studies and detailed experimental studies showed that this was not the case (Lockyer & Rutter, 1969; Hermelin & O'Connor, 1970). To the contrary, given appropriate skilled testing, most individuals with autism are testable and moreover the psychometric findings proved stable over time.

As the concept of autism changed from a psychogenic variety of early-onset schizophrenia to an early-onset neurodevelopmental disorder, methods of treatment switched in parallel to developmentally oriented behavioral methods. It became clear from comparative studies that structure and focus in special education were the key features (Schopler, Brehm, Kinsbourne, & Reichler, 1971; Rutter & Bartak, 1973), and psychological methods of treatment that involved developmental and behavioral principles and partnership with parents were developed (Schopler & Reichler, 1971; Howlin et al., 1987; Marcus, Kunce, & Schopler, 2005). Moreover, systematic studies showed that these methods of intervention brought worthwhile benefits (National Research Council, 2001; Howlin, 1998).

As concepts of autism changed, attention turned to the possibility of genetic influences on the liability to autism. Initially, most commentators had dismissed the possibility on the grounds that the base-rate of autism in siblings was so low—estimated at ~2% in the 1960s. The key question, however, was whether the rate of autism in families exceeded the base rate in the general population. Expressed in this way, it became clear that there was a huge increase in relative risk of the order of 20- to 100-fold (Bolton et al., 1994). Moreover, twin studies showed that the familial loading was strongly genetically influenced (Bailey et al., 1995). Most psychiatric geneticists in the 1970s tended to think of genetic influences in relation to Mendelian transmission of an entirely determinative kind. The first systematic twin study (Folstein & Rutter, 1977a, 1977b) was important in demonstrating that the genetic liability extended beyond the traditional diagnosis to include a broader phenotype (Le Couteur et al., 1996). This provided a key indication of the necessity to broaden the concept of autism.

The altered concept of autism as a neurodevelopmental disorder meant that attention came to be paid to the possibility that some cases might arise on the basis of a medical condition of some kind. Gillberg (1992) claimed that this applied to as many as 37% of cases, but an overall review of the evidence suggested that the proportion was probably nearer 10% (Rutter, Bailey, Bolton, & Le Couteur, 1994). Nevertheless, 10% was sufficiently high to mean that the clinical assessment of individuals with autism had to include a proper assessment of possible associated medical conditions. The evidence was strongest in the case of the association with tuberous sclerosis (Smalley, 1998) and, to a lesser extent, the Fragile X anomaly (Bailey et al., 1993), but it included a mixed bag of other medical conditions and it was also found that the 5–10% rate of chromosome anomalies (albeit not diagnostically specific) seemed to be substantially increased above base population levels. The use of Wood's light to pick up cases of tuberous

sclerosis became routine, as did the use of DNA methods to identify Fragile X. Although the meaning of chromosome anomalies was not clear, it also became standard practice to karyotype individuals. Interestingly, in his first report Kanner (an astute clinician) had noted the enlarged head size found in a substantial minority of individuals with autism. More recently, his findings have been amply confirmed initially by head circumference measurement (Fombonne, Rogé, Claverie, Courty, & Frémolle, 1999; Woodhouse et al., 1996), then later by structural brain imaging findings. During the last decade or so, systematic research has also been highly informative in showing that the enlarged brain size is not evident at birth but develops during the 1- to 3-year age period then tends to stabilize and not increase further (Courchesne, Carper, & Akshoomoff, 2003; Redcay & Courchesne, 2005). It seems highly likely that, although the mechanisms remain ill-understood, this is a neural feature that differentiates autism from other neurodevelopmental conditions.

A key breakthrough with respect to cognitive patterns came with Hermelin and O'Connor's (1970) demonstration of a basic mentalizing defect. This led the way to identification in the mid-1980s of an impaired Theory of Mind (ToM) associated with the majority of cases of autism (Baron-Cohen, Leslie, & Frith, 1985). Attention came to be focused on the possible role of specific cognitive deficits as the basis for the social abnormalities of autism (Rutter, 1983, 1987). The ToM finding has been amply confirmed as applying to the great majority of individuals with autism, although some 20% pass standard ToM tests (Frith, 2003a; Happé, 2003). One problem with the Theory of Mind notion, however, is that the social deficits repeatedly found in autism are evident long before ToM, at least as established in relation to standard tests, becomes apparent in normal children. This led the way to a study of key social cognitive deficits (especially joint attention) evident before the development of ToM (Mundy & Sigman, 1989; Sigman et al., 1999; Mundy & Burnette, 2005). In his initial case report, Kanner had argued that individuals with autism had a basically normal level of general intelligence. That has not proved to be the case, but what has become clearer is that savant skills (usually involving mathematics or memory, as evident in calendrical calculation or the ability to draw in detail from memory or similarly play a piece of music heard only once), or unusual specific cognitive skills (meaning skills—often on visuospatial or memory tests—that are both above the individual's own overall cognitive level and above general population norms) are common in autism—applying to some 1 in 4 autistic individuals (Howlin, Goode, Hutton, & Rutter, 2009). Moreover, systematic experimental studies have shown that these skills are real and not just peculiar tricks (Hermelin, 2001). Accordingly, explanations of autism need to account for both intellectual impairment and also marked intellectual skills (see also Happé & Frith, 2010).

About the same time as Kanner's first report, there was a report by Asperger (1944) of a somewhat similar syndrome. His account does not compare with Kanner's in terms of incisiveness, but it highlighted that autistic-like patterns could and

did develop in individuals who lacked the global language delay that, at least up until that point, had been viewed as a necessary characteristic of autism. Although there were a number of reports of autistic psychopathy in the European literature in the years that followed (see van Krevelen, 1963), the diagnostic concept only became established after a key report by Lorna Wing (1981) and a publication of the English translation of Asperger's paper (Frith, 1991). Numerous epidemiological and clinical studies since then have amply confirmed the reality of this pattern, although views differ on the distinctiveness of the syndrome as different from autism in intellectually high functioning individuals (Klin, McPartland, & Volkmar, 2005; Szatmari et al., 2009). Nevertheless, whatever the answer to that query may prove to be, the descriptions played an important role in the acceptance of a broader spectrum of autism disorders. The extension upward into syndromes in the individuals of normal levels of overall intelligence was paralleled by the earlier demonstration by Wing and Gould (1979), of the extension downward to individuals with profound intellectual disability.

Numerous reports over the years had indicated that a substantial minority (25–33%) showed a pronounced developmental regression usually occurring at the end of the second year of life (Rutter, 2005a, 2008). Surprisingly, these reports gave rise to remarkably little in the way of systematic research, but home videos (Werner & Dawson, 2005) and, more recently, follow-up of siblings of individuals with autism (Bryson et al., 2007) have confirmed the reality of the pattern of regression. Moreover, it seems that this pattern may be particularly distinctive in autism, regression in other neurodevelopmental disorders being much less common (Baird et al., 2008; Pickles et al., 2009).

In 1966, there was a key discovery of a hitherto unrecognized syndrome involving characteristic loss of purposive hand movements—usually in the second year of life—and accompanied by a range of social and behavioral abnormalities (Rett, 1966). At first, it received little recognition, and its general acceptance was only established some years later by a key report by Hagberg, Aicardi, Dias, and Ramos (1983). Subsequently, it was found that in the great majority of cases, the disorder was due to a pathological mutation on the X chromosome (Amir et al., 1999). Although, for convenience, Rett syndrome was placed within ASD, it is clinically quite different with respect to diagnostic features, and particularly course and etiology (Rutter, 2005b). It occurs almost exclusively in females (contrasting with the male preponderance in ASD), there is deceleration of head growth in the early years (the opposite of the patterns in ASD), there is a loss of purposive hand movements (not found in ASD), and there is a later deterioration in motor function (Van Acker, Loncola, & Van Acker, 2005).

Although the claim that autism was a psychogenic disorder associated with poor parenting had long since become discredited (not because it was decisively disproven, but because of a lack of supporting evidence coupled with growing evidence for the importance of genetically influenced neurodevelopmental impairment), findings have shown that an autistic-like pattern develops in a substantial minority of individuals subjected to profound institutional deprivation (Rutter et al., 1999, 2007). It is similar to autism with respect to impaired social reciprocity and awareness of social context, as well as in the presence of abnormal preoccupations and circumscribed interests. It differs, however, in the greater presence of social approach and communicative flexibility, and especially in the marked diminution in autistic features as the individuals grow older (see also Rutter & Sonuga-Barke, 2010). The precise meaning of this pattern in relation to etiology remains unclear, but circumstantial evidence suggests that profound perceptual deprivation, arising from environmental conditions, may give rise to a similar pattern that is more ordinarily associated with autism. The same may apply to the autistic-like patterns found in some congenitally blind children (Hobson, Lee, & Brown, 1999).

Research Accomplishments Reflecting Technological Innovations

Dawson and her colleagues (Dawson, Finley, Phillips, & Galpert, 1985; Dawson, 1994) pioneered the EEG use of evoked event-related potentials to examine brain functioning in autism. The technique remains a useful one (Nelson & Luciana, 1998), especially as current studies focus on the earliest patterns of brain function in infants and toddlers at risk for autism. To date, however, the two technologies that have been most informative with respect to autism have been structural and functional brain imaging (Frith, 2003b) and molecular genetics (Bacchelli & Maestrini, 2006; Freitag, 2007). The former have been consistent in showing that autism is not due to a localized brain abnormality. The findings have also shown that the increased head size reflects an increased brain size (Redcay & Courchesne, 2005). Although the details are not yet entirely clear, it is generally accepted that the imaging data indicate that autism is associated with some form of abnormal neural connectivity. The functional imaging findings have also been instructive in showing that individuals with autism solve cognitive tasks using areas of the brain that differ from those used by typically developing individuals (Frith & Frith, 2008). Neurochemical findings have been, on the whole, rather uninformative, apart from the fact that it has been consistently found that blood serotonin levels are raised in a substantial minority of individuals with autism (although this does not show diagnostic specificity; Anderson & Hoshino, 2005). Molecular genetic evidence has pointed to several chromosomal regions likely to contain susceptibility genes. On the other hand, it has proved quite frustrating that specific genes underlying multifactorial autism have not, as yet, been identified. The most recent findings, bringing together several large-scale data sets, have shown the likely importance of copy number variations—meaning submicroscopic deletions and duplications (Persico & Bourgeron, 2006; Sebat et al., 2007; Autism Genome Project Consortium, 2007; Weiss et al., 2008).

Overview of Research Accomplishments

Looking back on the successful research strategies, it is evident that good use has been made of longitudinal studies with appropriate comparison groups, that the observation of the unexpected has been crucial, that the development of systematic standardized measures has greatly improved comparability across studies, and that knowledge on psychological processes associated with autism have greatly benefited from parallel studies in typically developing children. Quantitative genetics have been decisive in showing that the heritability of liability to autism is very high—probably in the region of 90%. Creative experimental strategies have been crucial in delineating the cognitive features associated with autism and structural and functional imaging has been invaluable in demonstrating the neural concomitants of these cognitive features. Molecular genetic strategies are likely to be highly informative, and there is replicated evidence of likely chromosomal regions that may be expected to contain susceptibility genes, but the identification of these genes remains a challenge for the future.

Some Inconclusive Research

There is no convincing evidence that the basic deficits associated with autism are regularly relieved by any form of psychotropic medication (Scahill & Martin, 2005). That is a striking negative finding because pharmacological interventions have proved of value in almost all other psychiatric disorders. Equally, there is no convincing evidence of any neurochemical abnormality specifically associated with autism (Anderson & Hoshino, 2005) and no convincing evidence of particular EEG patterns that are specifically associated with autism (Minshew, Sweeney, Baumann, & Webb, 2005). There are leads pointing to possible immune abnormalities associated with autism, but the evidence to date is inconclusive (Medical Research Council MRC, 2001; Pardo, Vargas, & Zimmerman, 2005). Finally, there is no convincing evidence that the benefits of psychological intervention are contingent on either very early or very intensive application. Authoritative reviews (National Research Council, 2001) have suggested that very early intensive intervention may be particularly effective, but it has to be said that the evidence in support is relatively scanty. On the other hand, there is growing evidence that comprehensive early behavioral treatments result in substantial worthwhile developmental gains (Rogers & Vismara, 2008). The uncertainties concern both the claims that these gains only occur with highly intensive, very early treatment, and the claims of full recovery.

Animal models have proved immensely informative in medicine because of their value in testing causal mechanisms (Hernandez & Blazer, 2005; Weatherall, 2006). They allow systematic study of the temporal sequence of events, and by the removal and add-back of hypothesized mediators (at the genetic, protein, physiological, behavioral, or social environment level), strong leverage on causal questions is possible. Of course, these are crucially dependent on the validity of the animal model—a particularly difficult challenge in the case of autism (Crawley, 2007). Mentalizing skills and language features cannot be assessed in rodents. Nevertheless, ingenious ways of measuring social interaction and communication in mice have been developed. Once one or more susceptibility genes have been identified, the possibilities could be transformed if a genetically modified mouse could be created, as was done in the case of Rett syndrome.

Two main varieties of model have been employed. First, there are those that focus on embryological origins—such as Rodier, Ingram, Tisdale, Nelson, and Romano's (1996) use of valproate to mimic the supposed prenatal effects of thalidomide on liability to autism. The thalidomide evidence is not very convincing (because it focuses on cranial nerve lesions that are not characteristic of autism), and the supposed validation through reproduction of cerebellar abnormalities (Ingram, Peckham, Tisdale, & Rodier, 2000) has the limitation of using a disputed human finding (see Bailey, Phillips, & Rutter, 1996). Second, targeted gene mutations may be used to examine gene effects—as has been done very successfully in the case of Rett syndrome (Guy, Hendrich, Holmes, Martin, & Bird, 2001; Shahbazian et al., 2002). Oxytocin knockout mice were found to display deficits in social recognition and social memory, but not in social approach (Crawley et al., 2007), leaving the parallel with autism somewhat uncertain. Cross-fostering can be used as an additional research tactic to check whether social differences between genetic strains might be an artifact of the rearing environment (Yang, Zhodzishsky, & Crawley, 2007). Because of the difficulties in the modeling of key features of autism in mice, the potential of mouse models is difficult to evaluate, but it would seem to be an avenue worth further exploration. Primates are closer to humans. Study of amygdala lesions in developing and mature macaque monkeys was informative in showing that it was unlikely that the amygdala has a fundamental role in the core social impairments found in autism, although it did play a role in fear responses that could be relevant (Prather et al., 2001; Bauman, Lavenex, Mason, Capitanio, & Amaral, 2004; Amaral & Corbett, 2003).

Some Misleading Research Claims

There have been many misleading therapeutic claims. These are too numerous to list but they include; fenfluramine (McDougle, 1997), secretin (Scahill & Martin, 2005), and holding therapy (Howlin, 1998). Of course, it is inevitable that some promising interventions may not prove their worth, but what is regrettable is that some of these claims have been in high-impact journals and accompanied by extremely uncritical statements from leading scientists. There is also the

misleading claim that facilitated communication reveals normal functioning in autistic individuals. Early studies led to the claim that autism was caused by urinary polypeptide abnormalities, but when the research was undertaken with experimenters blinded to the diagnosis of the contributors of the samples it could not confirm the findings (Le Couteur, Trygstad, Evered, Gillberg, & Rutter, 1988). In recent times, there was the claim that MMR (Measles, Mumps, & Rubella vaccine) had led to a massive epidemic of autism. Although the claim was based on a very weak study, it too was published in a high-impact journal (Wakefield et al., 1998). Subsequent epidemiological research has been consistently negative with respect to the claim that MMR has led to a rise in the rate of autism (see Honda, Shimizu, & Rutter, 2005; Rutter, 2005) and well-conducted studies have also shown that the measles virus in tissues claims were mistaken (Baird et al., 2008; Hornig et al., 2008; D'Souza, Fombonne, & Ward, 2006; Afzal et al., 2006).

Earlier, there was a claim that at least one quarter of cases of autism were caused by the Fragile X anomaly (Gillberg & Wahlström, 1985), whereas better studies subsequently showed that the true proportion was probably below 5% (Bailey et al., 1993). Another early claim was that autism was due to perceptual inconstancy (Ornitz & Ritvo, 1968), or to vestibular dysfunction (Ornitz, 1978). This claim was based on comparisons that did not take account of mental age (see Yule, 1978, on the need to control for mental age), and the findings have not stood the test of rigorous testing. The same applies to claims regarding overselectivity (Lovaas & Schreibman, 1971), which proved to be a function of mental age (Schover & Newsom, 1976; Lovaas, Koegel, & Schreibman, 1979).

Looking Ahead: Remaining Puzzles and Challenges

Inevitably, as with any field of inquiry, numerous research challenges remain. Here, attention is primarily drawn to those that are likely to have important clinical implications. It is appropriate to start with three well-demonstrated clinical features that, nevertheless, remain very poorly understood. First, there is the question of what is the meaning of the regression that occurs in ASD (see Rutter, 2008). What brain mechanisms underlie its occurrence, and how often is it found in other developmental disorders of language? Recent evidence (Baird et al., 2008; Pickles et al., 2009) indicates that a developmental regression is particularly characteristic of autism and is much less frequent with other developmental language disorders. Finding from multiplex families suggest that there is no familial influence on regression other than that which concerns autism itself (Parr et al., in press). The likelihood is that it reflects a developmental change in the neural mechanisms underlying language related skills, rather than any extrinsic environmental influence, but what are those neural mechanisms?

What is the meaning of the savant skills in autism (Howlin et al., 2009), what brain mechanisms underlie their recurrence, and how often are they found in other neurodevelopmental disorders? With respect to both regression and savant skills, there is a need to question what leads to their occurrence and also to question whether it is a categorical feature or rather a dimensional characteristic that may be found in greater or lesser degrees. What is the meaning of epilepsy in autism? What brain mechanisms underlie its occurrence, and why is the peak age of onset in late adolescence (Minshew et al., 2005; Bolton et al., in press) rather than in early childhood, which is what is usually found in both the general population and in individuals with intellectual disability?

It is well established that there is a broader phenotype of autism, meaning a qualitatively similar pattern of social communicative and developmental impairments that is similar to that found in autism "proper," but that differs in not being associated with either intellectual disability or epilepsy (Bailey et al., 1995). Questions remain on how this is best identified and quantified (but see Dawson et al., 2007). What happens to individuals with a broader phenotype as they grow older? What mechanisms are involved in the transition of the broader phenotype to the more obviously handicapping disorder? Does this simply reflect a higher "dose" of the genetic liability or is there some kind of "two hit" mechanism, in which some other factor (either intrinsic or extrinsic) is implicated?

What are the origins of the intellectual disability found in so many individuals with autism? Some researchers who have focused on higher functioning individuals have tended to dismiss the issue on the grounds that it is simply some independent impairment having a different origin. This seems rather unlikely, given both the strength of the association and the fact that, within monozygotic twin pairs, one may show intellectual disability and the other not (Le Couteur et al., 1996). Moreover, experimental cognitive studies have shown substantial overlap in the pattern of impairments found in individuals with autism who are and who are not intellectually disabled.

Traditionally, autism has been conceptualized as a meaningful syndrome, but recently that concept has been challenged by claims that the individual components of autism may not only be more separate than appreciated, but also that they may reflect different genetic influences (Ronald, Happé, & Plomin, 2005). The question is a reasonable one, but it has to be said that the evidence in support of the claim is somewhat contradictory and inconclusive. What is needed (and not yet available) is evidence on the general prevalence of the different components of autism, individually measured in a way that does not necessitate the diagnostic concept. The key question then is to what extent the three main domains of impairment in autism co-occur.

A rather different question is why autism differs from most other psychiatric disorders in showing no substantial response to neuroleptics? There are minor benefits with respect to individual behavioral features, but the evidence to date is that

there is no substantial effect on the basic features of autism. Does that mean that research has focused on the wrong neuroleptics or does it mean that the abnormalities should not be conceptualized in neurotransmitter terms but, rather, in terms of some other underlying mechanism, such as immunological abnormalities (Pardo, Vargas, & Zimmerman, 2005)? The supporting evidence on immune features is weak and inconclusive, but it constitutes a possibility worth investigating more thoroughly.

A recent well conducted study showed a quite strong association between high paternal age and an increased risk of ASD (Reichenberg et al., 2007). Two other studies (Cantor, Yoon, Furr, & Lajonchere, 2007; Croen, Najjar, Fireman, & Grether, 2007) have shown something similar, so it may be that this is a reasonably robust finding. Nonetheless, further replication is desirable and the question remains on what this association means. Why is the association mostly with paternal age rather than maternal age (although there is some evidence in support of both associations)? If confirmed, does the association mean that the nongenetic factor in autism should be conceptualized in terms of stochastic (random) developmental perturbations, rather than the influence of some specific environmental factor?

A somewhat similar question has to be posed with respect to the association with copy number variations (CNV) and with a high rate of chromosome abnormalities. The evidence to date suggests that it may not be the effect of a specific CNV (but see Eichler & Zimmerman, 2008; Weiss et al., 2008, with regard to CNVs on chromosome 16 and ASD unassociated with regression), or a specific chromosomal anomaly (apart from the association with interstitial duplications on chromosome 15 that are of maternal origin). Rather, the basic questions concern why individuals with ASD are much more likely than other people to have a chromosomal anomaly or microdeletions and microduplications, the nature of the biological consequences of CNV (Cook & Scherer, 2008), and the meaning of the indication that CNVs may be associated with schizophrenia as well as with autism (International Schizophrenia Consortium, 2008).

What mechanisms underlie the male preponderance in ASD? Baron-Cohen (2002) has argued that autism constitutes an extreme of "maleness," but that ignores the important finding that a male preponderance is common with most, but not all, early neurodevelopmental disorders (Rutter, Caspi, & Moffitt, 2003). Although there might be mechanisms that are specifically associated with each neurodevelopmental disorder, it seems likely that there will be some commonality underlying the male preponderance. What mechanism might this reflect? Might it reflect some influence on gene expression, for example?

It is already noted that major intellectual disability is a very important prognostic factor for poor outcome in autism, but what is surprising from the systematic long-term follow-up studies, is that a substantial proportion of individuals of normal intelligence nevertheless also have a poor adult outcome (Howlin et al., 2004). Why is this the case? Does it reflect some aspect of the underlying neural abnormality, or does it reflect inadequate interventions in childhood, or does it reflect inadequate services in adult life? Satisfactory answers to these questions have yet to be obtained.

The genetic evidence suggests that autism is usually a multifactorial disorder—meaning that multiple genetic influences and multiple environmental factors are likely to be implicated (Rutter, 2005b). But what are the nongenetic contributory causes of autism, and what mechanisms might be involved? Attention has rightly shifted from the unlikely hypothesis that poor parenting is responsible, to the more likely expectation that some prenatal or early postnatal factor might be implicated. Large-scale prospective studies beginning during pregnancy, and involving good biological measures, are clearly indicated (Magnus et al., 2006; Rønningen et al., 2006; Stoltenberg et al., 2010). Insofar as there are prenatal or early postnatal environmental causal effects, do they operate through toxicological, allergic, or immunological mechanisms? So far, it is unclear what the answers may be, but we must take seriously the possibility that there are important environmental features that play a role in the etiology of autism. Their elucidation is likely to be facilitated by gains in our understanding of genetic vulnerability (Geschwind & Levitt, 2007).

What is the neuropathology of autism (Amaral, Schumann, & Nordahl, 2008; Bailey et al., 1998; Bauman & Kemper, 2005)? There is abundant evidence that some form of neural underpinning is likely to be implicated in autism, but what is it? Evidence to date suggests that, ordinarily, prenatal abnormalities are likely to be responsible, but the evidence base is decidedly slim. Moreover, the postmortem studies are constrained by the fact that most deaths occur in individuals who have severe intellectual disability and epilepsy as well as autism. The question remains as to how far the neuropathological findings in this group generalize to the broader range of ASD. It is undoubtedly good that brain-banks are being established in the United States and Europe, but the findings so far are not providing definitive answers. On the other hand, the integration with imaging studies may constitute an important way forward (Munson et al., 2006; Schumann & Amaral, 2006; Courchesne et al., 2007; Kennedy & Courchesne, 2008).

What neural processes underlie the increase in brain size in the early preschool years? Prospective high-risk sibling studies with appropriate measures would help, but it is also essential that studies using animal models take on board the need to examine this key feature of the ASD phenotype. The experience with Rett syndrome, again, shows that this can be achieved (Guy et al., 2001). Moreover, the Rett example shows that, against expectation, the brain changes may be potentially reversible (Guy, Gan, Selfridge, Cobb, & Bird, 2007).

Claims have been made that dietary factors play a role in either the genesis of autism or the severity of impairments of autism. It has to be said that the evidence is, so far, rather unconvincing, but nevertheless it would be premature to rule out the possibility that dietary factors may play a role. For example, they seemed rather unlikely to be operative in ADHD, but good studies have indicated that they do play a role in a minority of cases (McCann et al., 2007). Although it seems

unlikely that dietary factors play a primary role in the etiology of autism, they could constitute a contributory factor, and the possibility should be investigated. If they are shown to be operative, the further question arises as to what mechanisms might be involved.

A somewhat different question is what can be achieved through psychological interventions? There is good evidence in terms of their efficacy in reducing impairments and improving outcome. Nevertheless, it remains uncertain as to what extent efficacy depends on their early application at high intensity (Helt et al., 2008). Claims have been made that it does, but empirical evidence is thin. An important new randomized controlled trial of early intensive behavioral intervention (Dawson et al., 2009) showed there was a significant increase in IQ (albeit of modest size) in the treated group and not in controls. However, what this means is uncertain because there was no increase in social functioning as measured by the Vineland scale after 12 months. Also, the results showed there is no effect of the treatment on core features of autism assessed by the autism diagnostic observation schedule. Consequently, the study certainly does not support the Lovaas claims (Lovaas, 1987; McEachin, Smith, & Lovaas, 1993) about the huge benefits of early treatment leading to recovery.

What is also very new is the introduction of methods of treatment focussed on improving parental sensitivity and responsiveness. The randomized controlled trial undertaken by Green and his colleagues (2010) provides an excellent model of how RCTs should be undertaken. The findings were encouraging in showing substantial significant positive changes in parental sensitivity/responsivity, but disappointing in that there was only a very small improvement (relative to the control group) in the children's autistic features.

Moreover, we need to go on to ask what mechanisms mediate the observed efficacy. Also, do the children, apparently relieved of their major autistic handicaps, show a normalization of the social/cognitive deficits (Howlin, 2005)? The early reports from McEachin et al. (1993) reported that normalization was achieved in nearly half the cases, but subsequent studies have indicated that the benefits may be much more modest (Howard, Sparkman, Cohen, Green, & Stanislaw, 2005; Cohen, Amerine-Dickens, & Smith, 2006; Magiati, Charman, & Howlin, 2007). Also, follow-up studies of groups not receiving intensive interventions have shown that a few individuals with autism in the early preschool years, and a rather larger proportion with ASDs other than autism, cease to show autism by middle childhood. Do the findings indicate uncertainty over diagnosis at, say, 2 years, or has there been a true remission? Either way, the findings mean that caution should be exercised over therapeutic claims (Lord et al., 2006; Sutera et al., 2007).

What early psychological abnormalities precede the onset of the overt clinical manifestations? What is their meaning in terms of the abnormal psychology involved in autism and what is the meaning of the abnormal interconnectivity as found in imaging studies? How can the observations be translated into meaningful neural mechanisms? The empirical findings are persuasive, but it remains quite unclear what they mean in terms of what is going on in the brain. What are the brain mechanisms involved in compensatory processes? Up to now the greatest emphasis has been placed on impairments but, equally, it is clear that an important minority of individuals make remarkable progress. What is different about them and their experiences? We need to focus on protective mechanisms as well as on risk mechanisms. One of the interesting basic science findings concerns the identification of mirror neurons—meaning neurons that respond both to an individual's movements and to the observation of similar movements in another individual (Rizzolatti & Craighero, 2004). Clearly there is the potential that an abnormality in such mirror neurons might underly autism (see Dapretto, Lee, & Caplan, 2005), but do they actually underlie autism? How might that be tested in a rigorous systematic fashion? Fan, Decety, Yang, Liu, & Cheng (2010) used *mu* suppression on the EEG as an index of mirror neuron activity with findings casting doubt on the causal influence of mirror neurons in autism.? Also, if they are causal, the question remains as to why the psychological abnormalities are not manifest earlier than seems to be the case.

With respect to the genetic influences on liability to autism, a host of different questions arise. Are different genes involved in each of the key domains of autistic symptomatology? Will progress on identified genes require a focus on subgroups such as shown by language impairment (Alarcón, Yonan, Gilliam, Cantor, & Geshwind, 2005; Alarcón et al., 2008), insistence on sameness (Shao et al., 2003), or macrocephaly (Sacco et al., 2007)? Also, does the genetic liability vary between males and females? Will studies of gene expression help in establishing connections between genetic risk and specific brain structures (Alarcón et al., 2008; Nishimura et al., 2007)? Does the genetic liability operate dimensionally or categorically? What genetic factors and nongenetic factors operate in the transition from the broader phenotype to autism? What is the role of stochastic variation and developmental perturbations? Are these more relevant in sporadic cases of ASD than in familial cases (Sebat et al., 2007)? Also, are the relevant genes ones that code for proteins, or are they noncoding genes that influence genetic expression? To what extent is gene-environment interaction involved (see D'Amelio et al., 2005, for a suggestion of genetic vulnerability to organophosphates as used in pesticides)? To what extent is the genetic liability for autism shared with other neurodevelopmental disorders.

In recent years, evidence has emerged that a tiny minority of cases of autism are associated with single-gene pathological mutations (Persico & Bourgeron, 2006). The key question is whether the findings on these rare variants can be extrapolated to the broader range of multifactorial ASDs. On the one hand, it is clear that there are well-established examples in which rare Mendelian variants do seem to reflect the same pathophysiology as the much more common multifactorial disorders—as in the case of Alzheimer's disease. On the other hand, there are contrary examples (see below). In short, it would be wrong to dismiss the evidence derived from rare Mendelian variants but,

equally, it would be wrong to assume that the findings extrapolate to the more frequent multifactorial varieties of ASD.

The problem is that many monogenic disorders can occasionally give rise to a clinical phenotype that is very much like ASD. The Fragile X anomaly, Down syndrome, and tuberous sclerosis all illustrate this point. In each case, the pathophysiology (insofar as it is known) seems not to mimic that seen in autism. The tubers of tuberous sclerosis are not found in ASD, and neither is the microcephaly of Down syndrome. Although it has been argued that the findings on correction of the Fragile X syndrome in mice has implications for autism (Dölen et al., 2007), that seems dubious. Why then should one suppose that the single-gene mutations (such as the X-linked neuroligins, SHANK-3 or neurexin) that are associated with ASD in a tiny handful of cases might involve mechanisms that could generalize more widely? The possible answer is that they affect neural processes (such as synaptic function and circadian rhythm or developmental disconnection) that might be applicable (Durand et al., 2007; Bourgeron, 2007; Geschwind & Levitt, 2007; Jamain et al., 2008). In addition, attention needs to be paid to the connection between neuronal activity and gene expression (Flavell & Greenberg, 2008). Research into the neural underpinnings of autism needs to be informed by an understanding of normal brain function. The fact that each of these genes seems to be associated with a wider range of phenotypes than just ASD is not necessarily an objection. Genes do not code for *DSM-IV* or *ICD-10* diagnostic categories! Nevertheless, unless the neural abnormalities can be shown to be specifically associated with ASD there must be doubts over the meaning of the finding.

Somewhat similar challenges arise with respect to CNV. Undoubtedly, they constitute an important new focus for genetic studies. On the other hand, for the most part, because the de novo mutations appear to apply to phenotypes that are quite varied (on the limited basis of the published data), it is unclear whether they will be informative on what may be specific for ASD. It remains uncertain what proportion of cases they account for, but it certainly seems to be a small proportion and, insofar as they are de novo mutations, they do not account for the familiality of ASD. What is clear is that such CNVs are much more common in a mixed range of neurodevelopmental disorders than they are in the general population. That raises the question about what it is that has brought about this increased proportion of CNV. Might this, for example, be a function of raised parental age in increasing the rate of developmental anomalies or perturbations—the parallel is the well-established association between maternal age and Down syndrome?

Some General Messages on Research Challenges

Clearly, there are a variety of specifics that warrant systematic attention, but here there is concentration only on general messages. First, it would appear that a greater focus is needed on neglected clinical issues. The examples of regression, savant skills, and epilepsy stand out in that connection.

Second, there is a need to use epidemiological methods in a more hypothesis-testing fashion. Two rather different examples may be provided. First, large-scale prospective epidemiological studies are required to look at the possibility that prenatal and early postnatal environmental risk factors are involved in etiology. Second, epidemiological research is needed to examine the possibility that autism does not constitute a meaningful, cohesive syndrome but rather three disparate domains of malfunction that happen to have been brought together as a result of prevailing diagnostic concepts.

Third, there is a need to increase the more searching creative use of the technologies such as imaging or molecular genetics. There is no doubt that these technologies provide powerful research tools, but progress will not come in throwing a technological bag of tricks at the problem. Rather, the technologies need to be used in hypothesis-testing fashion to examine competing alternative hypotheses.

Fourth, why is it taking so long to identify susceptibility genes for ASD? Larger and larger samples are unlikely to provide a sufficient solution, and it will be essential to use innovative strategies to focus on possibly meaningful subgroups, or possible interplay with stochastic variations, and on possible gene by environment interactions (see Dodge & Rutter, in press, for a fuller discussion). In addition, there may be value in focusing on the minority of cases of ASD born to children from consanguineous partnerships (Walsh et al., 2008).

Finally, funding agencies need to recognize that research advances usually derive from creative research that reflects often iconoclastic approaches born out of new ways of looking at old problems.

Diagnosis of Autism Spectrum Disorders

Points of Interest

- History of autism and ASD classification.
- Current criteria for and presentation of pervasive developmental disorders.
- Potential revisions to ASD criteria and classification framework.
- Participant characteristics that affect diagnosis.
- Instruments and methods for assessing ASD.
- Diagnostic issues often overlooked in research.

Introduction

Since its original description by Leo Kanner in 1943, autism has come to be recognized as a neurodevelopmental disorder that manifests in infancy or early childhood and encompasses both delays and deviance in a "triad" of behavioral domains (Wing & Gould, 1979): reciprocal social interaction, communication, and restricted and repetitive behaviors and interests. Autism is thought to be the cornerstone of a spectrum of disorders, commonly referred to as autism spectrum disorders (ASD) or pervasive developmental disorders (PDD). This spectrum includes Asperger's syndrome (AS), and Pervasive Developmental Disorder-Not Otherwise Specified (PDD-NOS, or atypical autism), as well as two very rare disorders, Rett's disorder and Childhood Disintegrative Disorder (CDD).

Studies of monozygotic twin concordance for autism, and of families in which parents have multiple affected children, have established that risk for ASD is influenced by genetic factors (Morrow et al., 2008; Constantino & Todd, 2008). A "broader phenotype" of social impairments in family

members of individuals with ASD continues to generate interest as a potential window into the genetic transmission of these disorders (Dawson et al., 2007). Though associations have been shown between increased rates of ASD and genetic, chromosomal, and/or brain abnormalities, no biological marker adequately accounts for a significant minority of cases with reasonable specificity. Therefore diagnosis is currently based on behavioral phenotype alone.

In this chapter, we provide an overview of the history of autism and ASD classification, including criteria for and presentation of each of the PDDs, participant characteristics that affect diagnosis, instruments and methods for assessing ASD, innovative uses for the diagnostic measures, and diagnostic issues often overlooked in research.

Epidemiology and Diagnosis

Whereas autism was previously thought to occur in approximately 4 children out of 10,000 based on epidemiological studies published in the 1960s, the autism spectrum currently is thought to have a combined prevalence rate of 50–60 out of 10,000 school-age children (Chakrabarti & Fombonne, 2005; CDC, 2007). Refinements to diagnostic criteria, addressed later in this chapter, surely have impacted these prevalence rates (D. Bishop, Whitehouse, Watt, & Line, 2008). Growing ASD prevalence and awareness of the disorders in turn demand greater research attention to the boundaries of and within this spectrum. Indeed, one of the primary issues in ASD diagnosis today is a debate about the clinical and biological validity of distinct categorical disorders within the spectrum (see below).

ASD is more prevalent among males, with an approximate gender ratio of 4:1. There seems to be a higher proportion of severe cognitive impairment in females with ASD than in

males (Fombonne, 2005a). It is speculated that gender may be differently associated with various etiological subtypes in ASD (Miles et al., 2005). Though we may come to see subgroups with different ASD severity levels and cognitive ranges in which sex ratios differ from that in the overall population, at this point there is no specific profile of ASD impairments that distinguishes girls from boys (except for greater female prevalence in Rett's disorder).

Factors such as race, ethnicity, and socioeconomic class are not thought to influence presentation of ASD. We mention them here, however, because they have been associated with age of first diagnosis, and with over- or underdiagnosis of ASD, depending on the specific group. Kanner noted that the parents of his sample were well educated and high achieving, leading to a notion that autism was more prevalent among the higher socioeconomic classes. Later, more rigorous studies of SES and ASD found that autism crosses social class (Schopler, Andrews, & Strupp, 1980; Wing, 1980). However, early diagnosis of children with lower SES is often impeded by less sensitive referral sources, limited access to specialized clinics, and the cost of a diagnostic evaluation. Accurate diagnosis for a complicated case of ASD may span a couple of years and require thousands of dollars (Shattuck & Grosse, 2007). One study found that children from poor or near-poor families receive an initial diagnosis up to 11 months later than children from wealthier families (Mandell, Novak, & Zubritsky, 2005). Age of identification was significantly higher for African American and Latino children than for white children in another study in which the entire sample had low SES (Mandell, Listerud, & Levy, 2002), although this was not replicated in two more recent studies (Mandell et al., 2005; Wiggins, Baio, & Rice, 2006). In 2009 Mandell and his research team examined age of diagnosis by race and other factors in over 76,000 Medicaid-enrolled children with new diagnoses of an ASD. They found that African American children were diagnosed with an ASD at a mean age of 70.8 months, compared to the overall sample mean of 68.4, whereas Latino and Asian children tended to receive diagnoses at younger ages than did children in other ethnic groups, including Caucasian children (Mandell, Morales, et al., 2009). The author postulates that the findings might be due to the amelioration of ethnicity-related disparities in impoverished samples, or perhaps a phenomenon in which the most severely impaired children within some ethnic groups are the only ones to be identified in early childhood, decreasing the observed age of diagnosis for a particular group. Indeed, another study by the same team found that black and Hispanic children were less likely to have a documented ASD than were white children (Mandell, Wiggins, et al., 2009). Research is currently being done to determine the influence of cultural factors in observing and reporting autism behaviors, as well as differences in ASD prevalence across racial/ethnic groups (Mandell, Wiggins, et al., 2009; Bhasin & Schendel, 2007; Overton, Fielding, & Garcia de Alba, 2007; Schieve, Rice, & Boyle, 2006).

Diagnostic Classification

In 1943, Kanner used the term "infantile autism" to describe 11 children who exhibited limited interest in and impaired social response to others from infancy onward (Kanner, 1943). These children were either nonverbal or had impaired communication, as well as behavioral rigidity. Virtually simultaneously, Hans Asperger described a similar group of male children (Asperger, 1944), but the fact that Kanner published in English and Asperger in German barred the comparison of these findings. For decades, most mental health professionals continued to think of children with this behavioral profile as having "childhood schizophrenia" (Tidmarsh & Volkmar, 2003), until the work of Rutter and Kolvin in the 1970s distinguished the two conditions in terms of clinical characteristics and outcome (Rutter, 1970, 1972; Kolvin, 1971). Whereas childhood schizophrenia was characterized by disordered personality, thought, and mood and blunted affect, usually with normal intelligence and an onset after 11 years of age, "infantile autism" was noted from infancy or shortly after in children with a range of intellectual functioning, and was marked by speech delay, ritualistic behaviors, and deficits in social relationships and imaginative play.

In 1980, the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition (DSM-III; APA, 1980), first included "infantile autism" under a new diagnostic category of Pervasive Developmental Disorder, partly in recognition of Wing's "triad of impairments" often associated with intellectual disabilities (Wing & Gould, 1979). With the 1987 revisions, DSM-III-R changed the diagnostic label to "autistic disorder." Also, "Not Otherwise Specified" categories were added to this version of the DSM, thereby creating PDD-NOS. The World Health Organization's *International Statistical Classification of Diseases and Related Health Problems*, 10th Revision (ICD-10; WHO, 1990), which included Rett's disorder and CDD in the Pervasive Developmental Disorder category, came into widespread use in 1994. The DSM-IV was published in the same year (APA, 1994), and had PDD criteria revised to correspond to ICD-10 criteria for these disorders.

The DSM-IV PDD classifications and a brief overview of their criteria are presented below (see also Tidmarsh & Volkmar, 2003). Because ICD-10 categories and criteria are so similar to DSM-IV classification, the former system will not be reviewed in depth here. ICD-10 includes more subtypes of PDD than does DSM-IV. Nonetheless, the similarity between these systems has already had a profound impact by enabling international merging of datasets and comparison of research findings (e.g. International Molecular Genetic Study of Autism, Gong et al., 2008; Autism Genome Project et al., 2007).

Autistic Disorder

In the DSM-IV, autistic disorder is diagnosed when six symptoms are present across the three domains of qualitative

impairment in social interaction, communication, and restricted repetitive and stereotyped patterns of behavior, interests, and activities. At least two of the symptoms must be from the social domain, with at least one symptom present from each of the other two domains. Social, language, or play abnormalities or delays must be present before the age of 3, and Rett's disorder and CDD must first be ruled out before assigning a diagnosis of autistic disorder.

Impairment in social reciprocity is believed to be the central defining characteristic of autism (Williams White, Koenig, & Scahill, 2007; Carter, Davis, Klin, & Volkmar, 2005). Difficulties in social interaction present in various ways within and across individuals, such as a toddler who does not direct eye contact or a changed facial expression to her parent when something startles her, but looks up briefly in the direction of the noise and continues playing, an adolescent who interjects abruptly during a group conversation to bring up his own interest in videogames, or an adult who makes no response to another's comment about having a terrible day.

Delay, impairment in, or absence of communication strategies is also characteristic of autism. These difficulties are evident in both verbal (e.g., late onset of phrase speech, pronoun reversal, stereotyped speech) and nonverbal (e.g., minimal use of gestures) aspects of communication. Recent factor analyses of standardized diagnostic measures, the Autism Diagnostic Observation Schedule (ADOS; Lord et al., 2000) and the Autism Diagnostic Interview–Revised (ADI-R; Lord, Rutter, & LeCouteur, 1994), have shown that social and communication domain items from these measures load onto a single factor (Gotham et al., 2008; Georgiades et al., 2007; Lecavalier et al., 2006), and therefore it is possible that these two symptoms domains will be merged in DSM-V criteria for autistic disorder.

Restricted, repetitive behaviors and interests (RRBs) comprise the third domain of autism symptomatology. These include repetitive motor mannerisms (e.g., hand flapping), unusual sensory interests (e.g., squinting one's eyes to peer at a wind-up toy), and restricted or unusual topics of interest (e.g., collecting ticket stubs, learning and reciting everything there is to know about the Roman emperor Nero). Based on recent analyses of the factor structure and developmental course of behaviors in the RRB domain, some researchers have suggested that this third domain of behavior be split into two separate categories: "repetitive sensory motor behaviors," which include motor mannerisms, sensory interests, and repetitive use of objects, and "insistence on sameness behaviors," such as compulsions and rituals and overreliance on routines (Cuccaro et al., 2003; Bishop, Richler, & Lord, 2006; Richler, Bishop, Kleinke, & Lord, 2007).

Asperger's Syndrome (AS)

Like autism, AS is also marked by social impairment and restricted interests and behaviors. Development of speech is not delayed in AS, but communication abnormalities are often present, including flat intonation, pedantic speech (e.g., "Could

I trouble you to answer some questions with regard to this new development?"), and diminished conversational reciprocity, often associated with restricted topics of interest. According to DSM-IV, autistic disorder must be ruled out before a diagnosis of AS can be made. When this rule is observed, the prevalence of AS is very low, making it difficult to gather samples large enough to study potential differences between this disorder and high functioning autism (HFA; or autism without intellectual disability) (see Szatmari, 2000). The DSM-IV rule-out criterion is therefore often ignored, with many clinical and research facilities each tending to use their own AS criteria.

Earlier studies suggested that children with AS differed from those with HFA with regard to impoverished motor skills (Gillberg, 1989) and profiles of discrepantly high verbal IQ (Volkmar et al., 1994). However, the lack of standardization of diagnosis has made these findings difficult to corroborate (Klin, Paul, Schultz, & Volkmar, 2005), and a number of more recent reviews have found little evidence of distinction between AS and HFA (Macintosh & Dissanayake, 2004; Frith, 2004; see also Howlin, 2003). For example, Bennett, Szatmari, and colleagues (2008) found that grouping 6- to 8-year-olds by the presence or absence of structural language impairment (deficits in grammar or syntax) explained more variance in outcome through ages 15–17 on an array of dimensions, including adaptive behavior and scores on the Autism Behavior Checklist (Krug, Arick, & Almond, 1980), than did grouping the sample by clinical diagnoses of AS and HFA. Similarly, Cuccaro and colleagues (2007) found no differences in repetitive behaviors between individuals with diagnoses of AS versus HFA. Based on widespread disagreement in the field about how to diagnose AS, as well as lack of evidence of differences between AS and HFA, there are likely to be significant changes in how AS is conceptualized in future DSM and ICD editions.

Pervasive Developmental Disorder, Not-Otherwise-Specified (PDD-NOS)

PDD-NOS diagnoses are assigned to children who do not meet onset criteria for autistic disorder or whose pattern of impairments falls short of the required number of symptoms in each domain. An individual with PDD-NOS may have symptoms meeting criteria in the social and one other domain, but exhibit no symptoms in the remaining domain, or alternatively, he/she may have a subthreshold number of symptoms in all three domains. Because this category does not have specific criteria of its own, it is often used as a "catch-all" diagnosis for individuals with a spectrum disorder difficult to specify, or for young children to whom professionals do not yet feel comfortable giving an autism diagnosis (Walker et al., 2004; Lord et al., 2006). In a study of interrater diagnostic reliability using three expert raters, the agreement for PDD-NOS (versus autism or AS) was not better than chance (Mahoney et al., 1998). Walker and colleagues (2004) suggested that the reliability and utility of the category may be improved by creating a separate designation for individuals with significant social

and communication impairment without restricted, repetitive behaviors (RRBs). However, other studies have indicated that most individuals with PDD-NOS *do* have RRBs (Matson, Dempsey, LoVullo, & Wilkins, 2008; Bishop et al., 2006), so this revised definition would only account for a very small proportion of PDD-NOS cases.

PDD-NOS and AS may have dimensional differences from autism in some cases, but their utility as distinct, reliable categorical disorders will depend on evidence of their specific value in determining etiology and treatment (Volkmar & Lord, 2007). For future DSM and ICD versions, it will be important to examine whether PDD-NOS should remain a "catch-all" diagnosis or whether the population currently identified with this label could be divided into more definable subtypes, with the "NOS" label used less frequently for cases that fall short of meeting criteria for any PDD subtype.

Rett's Disorder

This rare disorder appears primarily in girls. Development in infancy is not obviously abnormal initially, but soon head growth slows and fine and gross motor skills may be lost. The loss may include language skills and social interest as well. Social interaction usually improves by late childhood or adolescence, though severe mental retardation and motor impairment are persistent. Rett's Disorder is characterized by stereotypical motor behaviors, most prominently hand-wringing, and breathing abnormalities, such as breathholding or hyperventilation; seizure activity is common. Mutations to X-linked gene MECP2 account for most cases (Amir et al., 1999).

Because Rett syndrome is associated with a identifiable genetic mutation, it has been argued that it should not be considered within the autism spectrum. However, more recently, as various genetic associations become apparent within this spectrum, the proposal has been made to give an ASD diagnosis on the basis of behavioral characteristics regardless of genetic findings, with genetic or chromosomal abnormalities coded on a separate axis. Thus, children with other identified disorders (e.g., genetic syndromes, fetal alcohol spectrum disorders) could receive an additional diagnosis of ASD if they meet behavioral criteria for social and communication impairments.

Childhood Disintegrative Disorder

Also rare, with prevalence estimated at 2 cases per 100,000 children (Fombonne, 2005b), CDD is differentiated from autism by a marked regression between 2 and 10 years of age following normal development in at least the first two years of life. In CDD, skills are lost in two or more of the following areas: language, social interaction, motor skills, play, or adaptive behavior. Though regression occurs in other ASDs as well (approximately 20–33% of children on the autism spectrum develop some single words in infancy and then lose them, usually between the ages of 18 and 24 months; even more children "lose" other social or communication skills; Luyster et al., 2005),

in non-CDD regression, the developed speech is often very limited (i.e., 3–10 single words) and only present for a few weeks or months. Additionally, while loss of eye contact or other signs of social interest and engagement or play skills are often reported in children with autism, regressions in autism, unlike CDD regressions, are less frequently accompanied by losses in adaptive or motor skills.

It once seemed likely that CDD was etiologically distinct from autism. However researchers have recently questioned whether this disorder represents an arbitrary distinction from autism on the basis of the timing of the regression, the level of the child's skills before the regression, and the type of skills lost. Studies about the validity of CDD as a distinct disorder have suggested that CDD may be accompanied by higher rates of epilepsy, increased fearfulness, and lower intellectual functioning (or less discrepancy between verbal and nonverbal IQ) than is seen in autism (Kurita, Osada, & Miyake, 2004; Malhotra & Gupta, 2002; Volkmar & Rutter, 1995). At this time, it remains unclear whether CDD represents extremes on all three dimensions of autism-like regression (e.g., lateness of regression, strength of prior skills, and amount of skills affected by the regression) or a unique disorder.

Factors That Affect the Presentation of ASD

ASDs are heterogeneous disorders, and individuals with these diagnoses can look quite different from each other. A nonverbal 16-year-old who avoids eye contact and spins in circles might share a diagnosis of autism with a hyperactive, verbally fluent 4-year-old who seeks out others to talk at length about his interest in maps and state capitals. Because ASDs are developmental disorders, they both influence and are influenced by developmental levels of the individual (such as language level, "mental age," and chronological age). Thus, diagnosticians must be familiar with the range of factors that can affect the presentation of ASD across individuals. Furthermore, although autism spectrum disorders are considered some of the most reliably diagnosable psychiatric disorders of childhood (Volkmar & Lord, 2007), current classification systems may be most useful in the diagnosis of somewhat verbal, school-age children with mild-to-moderate intellectual disability. Special considerations must be taken, therefore, when assessing individuals on the "extremes" of the spectrum: very young children and adults; individuals with severe intellectual disability and those with average to above-average intelligence; and individuals with very limited or very strong verbal skills.

Chronological Age

As with any developmental disorder, chronological age has a significant impact on the way in which ASD symptoms manifest. Individuals behave differently at different phases in development, and these changes affect the presentation of their symptoms, as well as the contexts in which they should be

evaluated. Most individuals with ASD continue to exhibit social and communication difficulties and restricted or repetitive behaviors across the lifespan, but the particular nature of these symptoms is likely to change dramatically with age.

In recent years, a great deal of attention has been given to identifying symptoms of ASD in very young children. Early identification of autism has been emphasized in clinical research and practice due to the reported benefits of early intervention. Current research suggests that autism can be diagnosed reliably by age 2 and nonautism ASD by age 3 (Turner, Stone, Pozdol, & Coonrod, 2006; Chawarska, Klin, Paul, & Volkmar, 2006). Some first signs in infants that are associated with later ASD diagnoses include failure to respond to one's name, poor eye contact, and an array of unusual reactions to sensory properties of objects (Dawson et al., 2004; Baranek, 1999). Although the field continues to make gains in the area of early assessment and diagnosis (see Chapter 5 in this volume), many professionals are still not well versed in the range of social and communication abilities exhibited by typically developing infants and toddlers. Knowledge of chronological age expectations in normal development is therefore essential for all professionals working with this population (see Bishop, Luyster, Richler, & Lord, 2008).

Unlike infants and toddlers, adolescents and adults with ASD have received relatively little attention in the recent literature, particularly with regard to assessment and diagnosis. Adolescents and adults with ASD often exhibit greater social interest than younger children, but have exaggerated, stilted, or otherwise abnormal means of interacting, including poor social reciprocity and difficulty sustaining interactions. Across many studies, the use of communicative speech increases from childhood to adulthood, but aspects of communication remain impaired in ASD into adulthood, particularly those related to social functioning, such as gestures, perseveration, or overly literal interpretation of language (Seltzer, Shattuck, & Abbeduto, 2004). Based on a more limited body of research, the presence of RRBs seems to be relatively stable into adulthood, though the particular manifestation of these behaviors may change, for example, shifting from a toddler who seeks out only toys that have buttons, to an adolescent conversing about her restricted interest in constellations (Seltzer et al., 2004).

As a result of rising prevalence estimates and increased public awareness of ASD, more and more adults are presenting for initial evaluations with concerns about ASD. However, because ASD is normally diagnosed during childhood, most empirically derived assessment tools were designed for and validated on samples of children with ASD. Future research will need to dedicate more attention to developing best practice guidelines for assessment and diagnosis of adults with suspected ASD.

Mental Retardation

Intellectual disability was once thought to be present in most autism cases, but findings from more recently recruited samples estimate that 29–60% of children with autism fall in the normal range of nonverbal IQ (Fombonne, 2005a; Tidmarsh & Volkmar, 2003). Although there is a great deal of variability in developmental trajectories and outcomes for children with ASD, nonverbal IQ has been found to be one of the best prognostic indicators (Thurm, Lord, & Lee, 2007; Venter, Lord, & Schopler, 1992). Consequently, information about a child's cognitive abilities is important in programming and planning for the future.

Because skill expectations are different for children at different developmental levels, knowledge about a child's cognitive abilities is necessary in order to accurately assess his/her social and communication skills. We would not expect, for example, the same level of social sophistication from a 14-year-old with mild intellectual disability as we would if his cognitive abilities were in the average range. Thus, as mentioned previously, it is essential that clinicians familiarize themselves with typical social behaviors for individuals at different developmental stages, taking into account both chronological and mental age. This is necessary in order to "separate" the behaviors related to ASD from those related to intellectual disability. Studies comparing children with ASD to children with nonspectrum developmental delays (e.g., Down syndrome, intellectual disability of unknown etiology), have provided essential information about behaviors that are more or less specific to ASD, and have shown that even children with significant delays (without ASD) exhibit social competencies, such as joint attention skills, that many children with ASD do not (Dawson et al., 2004; Bishop, Gahagan, & Lord, 2007).

It is more difficult to make diagnostic differentiations in children with profound levels of intellectual disability. These individuals are very likely to meet criteria for ASD because their general level of functioning falls below a preschool level. In these cases, it may not be possible to differentiate individuals with profound mental retardation in whom the ASD is "primary" from those in whom the intellectual disability is the central cause of their difficulties. Furthermore, as discussed below, diagnostic instruments for ASD do not have the same psychometric properties when applied to populations of individuals with very severe cognitive disabilities.

Language

As is the case with nonverbal skills, language abilities vary widely among children and adults with ASD. Whereas many or most children with autism were once expected to be nonverbal or minimally verbal, these rates have changed dramatically with the recognition of milder cases, as well as greater access to early language intervention. In one study of children with relatively severe ASD, about 40% of school-age children had complex fluent speech by age 9, and the proportion of completely nonverbal children was less than 15% (Lord et al., 2006), indicating that previous estimates of 50% of children with ASD being nonverbal are no longer valid.

Assessing social difficulties and communication impairments across a range of language levels from nonverbal to

fluent requires expertise in various instruments (as discussed later) but also an understanding of the *range* of behaviors associated with the autism spectrum. It is important to recognize that individuals with more limited language abilities who do not have ASD still employ nonverbal forms of communication, such as gestures and eye contact, to initiate social interactions. Therefore, understanding the numerous ways in which humans communicate and what is expected for individuals at different developmental stages is required in order to be able to distinguish ASD from other disorders.

Comorbid Disorders

Comorbidity of ASD with other psychiatric disorders occurs frequently and may have great impact on the already heterogeneous presentation of these disorders. Some of the most common comorbid disorders include anxiety, depression, hyperactivity, attention problems, obsessive-compulsive features, oppositional-defiant disorder, tics, and epilepsy. Tuberous sclerosis and Fragile X account for a relatively small proportion of ASD cases (though conversely, a significant proportion of children with these disorders have autism or ASD) (Lord & Spence, 2006; see also Chapter 46, this volume). Schizophrenia has also been reported to co-occur with ASD, though infrequently. Adults with ASD may sometimes receive a schizophrenia diagnosis because of social isolation, flat affect, speaking their thoughts aloud, and/or endorsing the idea of "hearing voices" based on a literal interpretation, e.g., someone was speaking in the next room and could be heard despite not being immediately present (Fitzgerald, 1999).

Physical disabilities, such as blindness, deafness, or conditions that impair or prohibit motor coordination, also impact ASD presentation and diagnosis. These disabilities can affect social development; they also can render irrelevant certain behaviors that influence diagnosis, e.g., eye contact in blind children, or response to name in deaf children. These conditions may also prevent a referred individual's participation in standard forms of assessment (e.g., a child with cerebral palsy who cannot construct block designs for cognitive testing).

Many of these disorders have social implications, and some of them are associated with specific kinds of repetitive behaviors, especially motor mannerisms, which can make diagnosis of ASD and comorbid disorders challenging. Comorbidity is more the rule than the exception in assessment today, due to high rates of co-occurring conditions within individuals on the autism spectrum (Sterling, Dawson, & Estes, 2008; Matson & Nebel-Schwalm, 2007).

While ASDs are commonly thought to be life-long disorders, there has been a great deal of recent interest and research on "optimal outcome" children—those who come to function in the normal range of cognitive, adaptive, and social skills, and thus no longer qualify for an ASD diagnosis. Though the accuracy and standardization of assessment and diagnosis may play a role in the observation of this phenomenon, a subtype of children on the spectrum who "recover" would likely be associated with and influenced by many of the factors described in this section—such as strong initial language and cognitive abilities and younger chronological age at identification (Helt et al., 2008).

Assessment of ASD

Diagnostic assessment of ASD is carried out by a number of professionals, e.g., physicians, psychologists, and educators. The type of professional or service system making the diagnosis will often affect how that diagnosis will be used to obtain services: distinct labels from different professionals are usually needed for eligibility of insurance or governmental funding, educational placement, or treatment planning (Shattuck & Grosse, 2007). Regardless of the assessment venue or the qualifications of the evaluator, it is vital that all professionals undertaking ASD assessment have clinical experience, skill, and familiarity with individuals with ASD and related disorders. Diagnosticians should be aware of best practices in the field and utilize standardized instruments. At the same time, clinical judgment has been found to contribute to the stability of ASD diagnosis beyond the classification from common standardized measures (Lord et al., 2006). Thus, even when required training has been completed for use of a particular diagnostic measure, a background of clinical experience with individuals with ASD is integral to competent diagnostic practice. Frequent, active contact with individuals with ASD led to excellent interrater reliability for clinical diagnosis in DSM-IV field trials, compared to fair reliability in less experienced professionals (Volkmar et al., 1994). Beginning professionals must have access to adequate supervision, and "experts" must maintain a high rate of ongoing clinical involvement with the ASD population.

Components of a Diagnostic Assessment

Before proceeding with a behavioral assessment for ASD, appropriate steps should be taken to ensure that the referred individual is physically healthy. These may include a physical exam to take growth measurements and rule out medical disorders that might obscure the presentation of ASD, as well as hearing, speech, and language assessments. In some cases, additional neurological or genetic testing may be indicated (see the American Academy of Pediatrics Council on Children with Disabilities guidelines for autism evaluation, Johnson et al., 2007).

A multidisciplinary assessment for ASD should include a caregiver-based developmental history that addresses milestones and noted abnormalities in the individual's earliest years. A pregnancy and birth history should be taken, as well as an overview of the referred individual's general health, including sleeping and eating behaviors, and a family history documenting relatives with ASD, genetic conditions, and mental health issues. Teachers or daycare providers can also assist in providing additional information about the individual's behavior.

In addition to obtaining information from parents and teachers about an individual's behavior, a diagnostic assessment should always include a direct observation of the referred individual. The child or adult with ASD should be seen personally by the diagnostician, and ideally, the observation should include the administration of a semistructured observational measure to assess the presence of symptoms associated with ASD (see below). The direct assessment should also include cognitive and language testing, as verbal and non-verbal abilities directly affect how symptoms of ASD manifest. Furthermore, a home or school visit may be useful for directly observing behavior problems or peer relationships that occur outside of the clinic setting.

When evaluating adolescents and adults who have the cognitive and language abilities to report on their own symptoms, it may also be appropriate to incorporate self-report measures into the diagnostic assessment. Standardized self-report questionnaires such as the Autism Spectrum Quotient (AQ: Baron-Cohen, Wheelwright, Skinner, Martin, & Clubley, 2001—see below) have been developed to obtain symptom reports directly from the referred individual. These instruments hold promise as a means of gaining a better understanding about the perspectives and internal experiences of individuals with ASD. However, given that lack of insight is one of the features of ASD, further work is required to understand the extent to which adolescents and adults with ASD are capable of providing valid reports about their own strengths and difficulties (see Bishop & Seltzer, submitted).

Following the assessment, diagnostic feedback should be provided to the parents or referred adult both in person and in a written report. The family should be provided with information about ASD, and the clinician may wish to discuss coping skills and support resources with the family (Lord & McGee, 2001). If the primary clinician is not a psychiatrist, parents should have the option of requesting a psychiatric consult to discuss the patient's medication needs, if any.

Because of the time, expertise, number of professionals, waiting lists, and costs, multidisciplinary assessments may not be a reality for all families with children with ASD, nor is it necessary in all contexts (e.g., confirming a previous diagnosis for research inclusion). However, clinicians should attempt to review information from as many of the above-mentioned sources as possible when making a clinical diagnosis of ASD. Communication between professionals from various disciplines promotes accurate and efficient diagnosis.

Differential Diagnosis

Many psychiatric disorders impact social communication, thus differential diagnosis of ASD can be complicated. Some of the most common non-ASD diagnoses given to children referred for ASD evaluations are language disorders, such as receptive-expressive language disorder or pragmatic language impairment, attention-deficit/hyperactivity disorder (ADHD), and intellectual disability. In each case, social and communication impairments should be assessed relative to the individual's

developmental level (Volkmar & Lord, 2007). Other diagnoses that referred children may have received in error include right hemisphere learning problems, hearing disabilities, obsessive compulsive disorder (OCD), schizoid personality disorder, attachment disorder, selective mutism, and Landau-Kleffner syndrome (characterized by language loss and seizure onset; Landau & Kleffner, 1998). While some differential diagnoses are more likely to be ruled out before an ASD diagnosis is made (e.g., schizoid personality disorder or selective mutism), others may warrant consideration as comorbid disorders (e.g., language disorders or intellectual disability).

Diagnostic Measures

Diagnosis of ASD has benefited from the development of standardized measures. This review will touch on the clinical utility and psychometric properties of a few questionnaires, interviews, and observational measures that have historical importance or current relevance in ASD diagnosis. See Lord and Corsello (2005) for a more detailed review of ASD diagnostic instruments.

Though measures vary in their purpose and convenience (thus clinical diagnosticians and research projects employ a range of the measures described below, as well as others), a number of instruments have come to be included in an internationally recognized "best practice" diagnostic assessment for ASD. These include the parent/caregiver interview, the Autism Diagnostic Interview-Revised (ADI-R; Lord et al., 1994), and the standardized clinical observation, the Autism Diagnostic Observation Schedule (ADOS; Lord et al., 2000), as well as the Social Communication Questionnaire (SCQ; Rutter, Bailey, & Lord, 2003) and the Social Responsiveness Scale (SRS; Constantino, 2002). The ADI-R and ADOS exist in 20 authorized translations worldwide, the SCQ in 17, and the SRS in 18. Due in part to the widespread use of these instruments, research findings can be more easily compared and samples collapsed across data collection sites.

Despite the strong predictive validity of some of the assessment tools described below, an individual's diagnosis of ASD should never depend on the diagnostic classification of a single measure or combination of measures. Be it for access to early intervention, educational services, or inclusion in a research sample, the ability of an experienced clinician is required to integrate information from standardized diagnostic instruments and other sources into a clinical diagnosis.

Questionnaires

Questionnaires offer the advantage of being able to collect a large amount of information in a relatively short amount of time. As part of a diagnostic assessment, questionnaires can also be useful for gathering information from multiple informants, such as teachers, daycare workers, or, in the case of adult clients, supervisors, siblings, or spouses. A number

of questionnaires have been designed to assess behaviors characteristic of ASD. Whereas earlier questionnaires relied on general and vague descriptions of behavior, such as "social interest" or "emotional connection," more recently developed instruments inquire about specific, empirically identified symptoms of ASD that are intended to differentiate children with ASD from those who are typically developing or who have nonspectrum disorders. Nevertheless, even recently developed questionnaires have limitations, including reliance on the report of "lay observers" (e.g., parents), as well as inter-reporter differences in the way that questions are interpreted. Thus, whereas these tools can be useful for quickly gauging the types of behaviors that a child exhibits in different settings, questionnaires used as part of a diagnostic assessment should be combined with information from a parent interview and child observation.

Questionnaires developed to assist in the diagnosis of ASD include the Autism Behavior Checklist (ABC; Krug, Almond, & Arick, 1993), the Gilliam Autism Rating Scale (GARS; Gilliam, 1995), the Social Communication Questionnaire (SCQ; Rutter, Bailey, & Lord, 2003), and the Autism Spectrum Screening Questionnaire (ASSQ: Ehlers, Gillberg, & Wing, 1999). The ABC may be filled out by parents or teachers and inquires about behaviors related to sensory interests, body and object use, language and social interaction, and self-help. Based on findings that the instrument does not always adequately distinguish between individuals with autism and those with nonspectrum disorders (Volkmar et al., 1988, Eaves, Campbell, & Chambers, 2000), the ABC may be more appropriate for documenting change in response to treatment or education, rather than as a diagnostic measure (Lord & Corsello, 2005). Similarly, the GARS, which is also a parent-rated questionnaire intended to indicate autism likelihood, has been shown to underidentify children as having autism (sensitivity = .48) (South et al., 2002), suggesting that it should not be used as a primary diagnostic tool. The SCQ is a parent checklist based on questions from the Autism Diagnostic Interview (see below). Though the SCQ works relatively well for identifying children with ASD in certain populations (especially when used together with the Autism Diagnostic Observation Schedule—see below), cut-offs may need to be adjusted for younger children (see Corsello et al., 2007). The ASSQ is another brief symptom checklist for use in a clinical setting. It is specifically intended to identify characteristics of Asperger's syndrome and high functioning autism, and thus is not appropriate for use with the full range of individuals referred for ASD diagnostic assessment.

Questionnaires that have been designed as continuous measures of ASD symptoms or traits include the Social Responsiveness Scale (SRS; Constantino, 2002) and the Autism Spectrum Quotient (AQ: Baron-Cohen, Wheelwright, Skinner, Martin, & Clubley, 2001). The SRS is a parent- or teacher-rated questionnaire that consists of 65 items assessing communication, social interaction, and repetitive and stereotyped behaviors and interests. When parent and teacher ratings are combined, the measure has excellent specificity for indicating the presence of ASD

(.96) versus other disorders, but sensitivity is relatively low (.75) (Constantino et al., 2007). When only a parent rating is used, specificity is still good (.84), though sensitivity is less clear (Constantino et al., 2007). In its current format, the SRS is only validated for children between the ages of 4 and 18 years, though an adult research version of the instrument is currently being developed (see Constantino & Todd, 2005). For adults with suspected ASD, the Autism Spectrum Quotient (AQ) is available as a continuous measure of ASD traits. The AQ is a self-report measure for adults with average or above average intelligence. Adapted versions of the instrument have been validated for use with adolescents (Baron-Cohen, Hoekstra, Knickmeyer, & Wheelwright, 2006) and children aged 4–11 (Auyeung, Baron-Cohen, Wheelwright, & Allison, 2008) with suspected ASD. Parent-report versions of the AQ are also available to supplement the self-report forms (see Baron-Cohen et al., 2001; Baron-Cohen et al., 2006).

Interviews

Like questionnaires, diagnostic interviews collect information from informants about an individual's behaviors. An advantage of the interview format is that the interviewer has some control over the way in which questions are interpreted, because clarification can be provided when necessary. Semistructured interviews that are scored by the interviewer are also advantageous, because, as opposed to more subjective interpretations of behavior (e.g., a parent rating a behavior as normal/abnormal, mild/severe), scores are derived from a trained interviewer's objective assessment of a behavioral description. On the other hand, interviews are often lengthy and thus time-consuming. Furthermore, unlike questionnaires, which can be mailed and completed anywhere, interviews require face-to-face contact between an informant and a trained examiner.

The Autism Diagnostic Interview-Revised (ADI-R; Lord et al., 1994) is a standardized, semistructured parent interview that is administered by a trained clinician in approximately 2–3 hours. Diagnostic algorithms, which yield a classification of "autism" or "nonspectrum," are overinclusive for individuals with nonverbal mental ages below 18 months and those with severe to profound intellectual disability (Lord, Storoschuk, Rutter, & Pickles, 1993; Nordin & Gillberg, 1998). However, the measure has good to excellent predictive validity for most other developmental groups, especially when used in combination with the Autism Diagnostic Observation Schedule (see Risi et al., 2006). Although some researchers have used ADI-R scores to measure severity of autism symptoms and improvement over time, the ADI-R was developed with the goal of distinguishing individuals with ASD from those without ASD. Thus, more research is required to determine the extent to which higher scores on the ADI-R correspond to "more severe" autism, as well as whether current scores can be used to track changes over time.

The Diagnostic Interview for Social and Communication Disorders (DISCO; Wing, Leekam, Libby, Gould, & Larcombe,

2002) is another semistructured, standardized interview used in ASD assessment. It is primarily intended to assist in clinical assessment of an individual rather than to yield a categorical diagnosis, although diagnostic algorithms for research use have been created (Leekam, Libby, Wing, Gould, & Taylor, 2002). Unlike the ADI-R, the DISCO assesses a number of non-ASD-specific behaviors, including maladaptive behaviors and those related to daily living skills.

Observational Measures

Observation by a trained clinician is a critical component of any ASD diagnostic evaluation, and a diagnosis should never be made without first directly observing and interacting with a referred individual. Use of a standardized observation instrument is also recommended, because the observational period can be structured to specifically elicit behaviors associated with an ASD diagnosis. For example, in the absence of any particular demands, an individual who is allowed to talk at length about a particular topic may appear socially skilled, but as soon as he is encouraged to talk about something outside of his interests, his difficulties with conversation and social reciprocity will become more apparent. Thus, employing some type of semistructured observation measure is preferable to simply watching an individual referred for ASD.

The Childhood Autism Rating Scale (CARS; Schopler, Reichler, & Renner, 1986) is one of the most widely used autism diagnostic scales. Originally designed to be scored based on an examiner's observations, the CARS is often used now as a general rating of all information available (e.g., scores may be derived from parent report, as well as from direct observation). Created before the current diagnostic classification systems, it is likely that the CARS overidentifies certain children (e.g., young nonspectrum children with intellectual disability) as having autism, while underestimating the difficulties of high-functioning children with ASD (see Lord & Corsello, 2005; Van Bourgondien, Marcus, & Schopler, 1992). Consequently, whereas it may be useful in some cases as a screening measure or a summary coding of all clinical information, care should be taken in using the CARS as the only observation measure in a diagnostic assessment.

The Autism Diagnostic Observation Schedule (ADOS; Lord et al., 2000) is a semistructured, standardized observation of children and adults referred for ASD. Like the ADI-R, its companion measure, the ADOS was created by operationalizing DSM-IV criteria for autism. Both original and revised diagnostic algorithms (see Gotham, Risi, Pickles, & Lord, 2007) show strong predictive validity, with the revised set of algorithms showing better specificity in lower-functioning populations. Because of its strong discriminant validity, the ADOS is widely used in international clinical and research efforts. It is useful in standardizing clinical observation, but must be considered in conjunction with a developmental history and clinical judgment of an experienced clinician.

With the recent interest in early diagnosis of ASD, several observational measures have been developed for use in very young children at risk for ASD and other communication disorders. The Communication and Symbolic Behavior Scales (CSBS; Wetherby & Prizant, 2002) evaluates communication and symbolic abilities in babies and toddlers and can be useful in identifying children who may require further evaluation. The Screening Tool for Autism in Toddlers (STAT: Stone, Coonrod, & Ousley, 2000) is an interactive screening measure for children between 24 and 35 months. The STAT has been shown to distinguish 2-year-old children with autism from those with nonspectrum developmental delays, but it is less good at picking up children with milder ASD symptoms (e.g., children with PDD-NOS). More recently, the Autism Observation Scale for Infants (AOSI: Bryson, Zwaigenbaum, McDermott, Rombough, & Brian, 2004) was developed to identify very young children (6 to 18 months) who may be at risk for ASD. Finally, the ADOS has been adapted for use with children aged 12 to 30 months; see Luyster et al., 2009, for description and psychometric analysis of this new toddler module.

Though direct observation is a crucial component of ASD diagnostic assessment, children and adults do not always behave as they normally would when they are "under the microscope," being observed by professionals in an unfamiliar setting. Furthermore, it is not always possible to observe an individual's full range of strengths and difficulties within a relatively short clinical observation period. Questionnaires and interviews provide information about behaviors that occur across various settings outside of a clinical context. As such, all three sources of information (questionnaires, interviews, and observations) are valuable components of a thorough ASD assessment.

Complementary Assessment Measures

In addition to ASD-specific diagnostic instruments, measures of cognitive, adaptive, and language abilities should be included in an ASD diagnostic evaluation. Individuals with ASD often have significantly discrepant verbal and performance IQ scores, so cognitive tests that yield separate verbal and nonverbal IQ scores should be selected. When working with individuals with less sophisticated language abilities, tests with lower language demands, such as the Mullen Scales of Early Learning (Mullen, 1995) and the Differential Ability Scales (DAS; Elliot, 1990), are sometimes preferable to tests that rely more on verbal instructions (e.g., the Wechsler Intelligence Scale for Children; Wechsler, 2003). Adaptive functioning is most commonly assessed with a parent interview, such as the Vineland Adaptive Behavior Scales, 2nd edition (Vineland-II; Sparrow, Cicchetti, & Balla, 2005), which yields separate normalized scores and age equivalents in the domains of communication, daily living skills, socialization, and motor skills. Language testing is also an important component of an ASD assessment. Tests should be selected such that receptive and expressive language skills are evaluated separately (see Paul, 2007).

Supplementary assessment tools may be indicated depending on the particular behavioral profile, or on the intervention, educational, or vocational needs of an individual referred for diagnostic assessment. Measures might be drawn from other areas of psychopathology to assess for comorbidities or to evaluate particular aspects of learning or achievement. For example, the Child Behavior Checklist (CBCL) is a parent/caregiver questionnaire that results in a total score, an Internalizing and Externalizing Scale score, and Syndrome and DSM Oriented Scales, one of which is a Pervasive Developmental Disorder Problems scale (Achenbach & Rescorla, 2000). The CBCL is not intended to be diagnostic, but can be used to identify a range of behavioral issues (ASD-specific and otherwise) to target for intervention. The Repetitive Behavior Scale–Revised (RBS-R; Bodfish, Symons, Parker, & Lewis, 2000) evaluates a range of repetitive behaviors seen in individuals with ASD and other developmental disorders and may be useful both for diagnostic purposes and for tracking changes in these behaviors over time. Other questionnaires that can be used to assess problematic behaviors in ASD include the Aberrant Behavior Checklist (Aman & Singh, 1994) and the Nisonger Child Behavior Rating Form (Tasse, Aman, Hammer, & Rojahn, 1996). The PDD Behavior Inventory (PDD-BI: Cohen, Schmidt-Lackner, Romanczyk, & Sudhalter, 2003) includes questions about adaptive and maladaptive behaviors, and is designed to evaluate responsiveness to intervention in children with ASD. For educational or vocational planning for individuals with ASD, the Psychoeducational Profile, 3rd edition (PEP-3; Schopler, Lansing, Reichler, & Marcus, 2004) and the Adolescent and Adult Psychoeducational Profile (AAPEP; Mesibov, Schopler, & Carson, 1989) may be used.

Though this list is far from exhaustive, we have attempted to review some of the more widely used instruments in ASD assessment. Evaluators should always keep in mind that certain accommodations may be necessary in order to obtain valid assessments of individuals with ASD, such as supplementing verbal directions with visual supports (e.g., schedules or reward systems), or using tests outside of the standard age range (e.g., administering a preschool language test to an older child with limited verbal abilities).

Looking Ahead

The field has made great strides in designing and validating instruments for use in ASD assessment and diagnosis, as well as in revising diagnostic criteria to be more inclusive of individuals across the full autism spectrum. However, there are many challenges that lie ahead in terms of further refining classification criteria and diagnostic instruments to meet current needs. As mentioned previously, more research is needed in the area of assessment methods for very young and/or very cognitively impaired individuals, and for adults across the range of abilities. It will be necessary to examine how well current diagnostic standards, which are largely based on observations of school-age children with ASD, apply to very young or older individuals. Do the same symptoms continue to be diagnostically relevant as individuals grow older, or should core symptoms of the disorder be defined relative to a person's developmental stage?

Some researchers have proposed shifting from a categorical approach in ASD diagnosis toward a more dimensional framework. Continuous measures of social and communication difficulties could be used to describe a child's level of social impairment/competence across different domains. Since many childhood disorders are characterized by social difficulties, this would aid in identifying areas of strength and difficulty in children with various disorders (including ASD), which could then be used to guide intervention efforts for these children.

Another advantage of thinking dimensionally about ASD symptoms rather than relying primarily on categorical distinctions is that we may be able to develop more meaningful measures of severity. There is currently no well-defined benchmark for "average autism," so it is difficult to classify children as mild or severe, especially since a child may have very severe symptoms in one domain of behavior and relatively mild symptoms in another. Quantitative approaches to measuring symptoms across domains could improve our ability to describe different developmental trajectories and responses to treatment, which would in turn further efforts to identify subgroups of children with ASD and to isolate endophenotypes that may map onto specific genetic or neurobiological findings.

Conclusions

Standardized diagnostic criteria and "best practice" assessment measures have been associated with more comparable research findings and the ability to reliably describe younger and milder cases of autism spectrum disorders. Current research is underway to explore the relationship between participant characteristics such as gender, ethnicity, cognitive and language abilities, and comorbid disorders with specific ASD symptoms and severity. Further advancements in ASD diagnostic practices are needed to identify subtypes for neurobiological, genetic, and treatment research, as well as to define boundaries or dimensional gradations within the spectrum for clinical and research use.

Challenges and Future Directions

- Achieving consistent early identification practices across geographic regions and within socioeconomic and ethnic groups
- Revising international classification criteria to reflect data on symptom specificity and presentation

- Identifying symptom profiles in historically overlooked populations, such as individuals with severe intellectual disability and adults with ASD
- Measuring autism severity as a means to subtype groups within the spectrum

Asperger's Syndrome: From Asperger to Modern Day

☷

Points of Interest

- The DSM-IV and ICD-10 definitions of Asperger's syndrome reflect an unhelpful compromise based on seminal, historical descriptions but limited evidence or operationalization, which collectively render these definitions virtually irrelevant.
- The lack of consensual definitions has given rise to a wide range of usages of the term that reflect popularity among investigators and in the community rather than replicable, empirical findings; this state of affairs renders the literature on external validity uninterpretable.
- Forthcoming updates of DSM-IV and ICD-10 will take place in suboptimal conditions of evidence, while the stakes for clinical practice and advocacy could not be higher given the increasingly larger numbers of individuals diagnosed and the proliferation of support agencies coalescing around the term to provide sorely needed services.
- Knowledge advancements of developmental factors mediating outcome, discovered through prospective and longitudinal studies, are likely to elucidate the utility of empirically derived categorical subtypes of the autism spectrum disorders.

☷

Introduction

Asperger's syndrome (AS) is one of the pervasive developmental disorders (PDD)—a group of neurodevelopmental conditions of early onset characterized by impairments in social interaction and communication, and by restricted interest and behaviors. The prototypical PDD is autism. Unlike autism, however, AS is marked by a lack of any clinically significant delay in spoken or receptive language, cognitive development, self-help skills, or curiosity about the environment.

Over 60 years after its initial description, the nosologic validity of AS relative to autism without intellectual disabilities (or higher functioning autism; HFA) and relative to the residual PDD category or Pervasive Developmental Disorder Not-Otherwise-Specified (PDD-NOS), is still questionable. A large number of studies seeking to test its external validity on the basis of genetic, neurobiological, neurostructure and neurofunction, neuropsychological, treatment, and outcome research have yielded conflicted data (Klin, McPartland, et al., 2005). This research, however, is difficult to interpret because of fundamental ambiguities inherent in the formal definitions of the syndrome (i.e., definitions provided by the *Diagnostic and Statistical Manual* published by the American Psychiatric Association; DSM-IV-TR, APA, 2000; and by the *International Classification of Diseases* published by the World Health Organization; ICD-10, WHO, 1992). This state of affairs has meant assignment of the diagnosis to participants in clinical and experimental research cannot be easily standardized for compliance with a consensual approach. This, in turn, makes comparison of results across studies virtually impossible.

A failure in formal definitions to yield distinguishable diagnostic groups has led to a multitude of usages of the term AS in research, clinical practice, and advocacy. Some definitions single out one variable defined rather simplistically as delays in the acquisition of single words or phrase speech, dichotomizing diagnostic assignment into autism and AS on the basis of presence or absence of this criterion, respectively. Others consider all individuals with autism spectrum disorders (ASD) with preserved intellectual skills as having AS. Others consider AS a diagnosis encompassing individuals who have milder symptoms or whose social presentation is marked by some difficulties without necessarily leading to functional impairment. In the research literature,

a "conservative" approach has been to list autism with preserved intellectual skills, or HFA, and AS as equivalent terms, in this way circumventing the need to define either one. This is typically done despite the rule in formal nosology—the "precedence rule," according to which if an individual meets criteria for autism he or she should not receive a diagnosis of AS.

While the validity status of AS has generated a controversial and not very productive debate, the clinical and real-life challenges faced by the vast majority of individuals with this condition are an incontrovertible reality regardless of which diagnostic construct is assigned to them. In fact, the formalization of AS in official diagnostic manuals in the 1990s has led to a great explosion in public awareness of "higher functioning" individuals with ASD. As a result, a large number of support and advocacy groups and organizations were formed around the world coalescing around the term AS. Thousands of individuals who were until then almost invisible to their surrounding communities—in many ways, struggling within the hidden environments of family and self-support only—were now "discovered" by the educational and mental health structures capable of fostering their growth. With this new awareness came also fascination by the media, with both good and detrimental results. The portrayal of individuals with AS as eccentric intellectuals—"the geek syndrome"—introduced stereotyped views that sensationalized intellectual prodigies while ignoring the majority's life struggles. Juxtaposed to this media portrayal came the advocacy for stopping the "medicalization" of the term "AS," defining it instead as a "style of learning," something to be contrasted to "neurotypical" learning, rather than a psychiatric diagnosis intended to entitle the person to comprehensive treatments, appropriate educational programs, and community supports. While achieving political correctness and a semblance of integration, this movement also diluted the term, making it even harder for advocates to secure sorely needed services without which these individuals are unlikely to fulfill the promise of independent, self-supporting, and productive adult lives.

Against this clinical, research, and cultural backdrop, the future nosologic status of AS continues to be discussed, now with greater urgency given the forthcoming update of formal classification systems (i.e., DSM-V), and the uncertainty as to whether or not the term will be included within the PDDs. This chapter provides an overview of the historical and research background of AS leading to current debates, the changing nature of this discussion given the transformative changes in autism research in general in the past decade, the unchanging nature of these individuals' needs whether or not the term survives new updates in psychiatric classification, and suggestions for a future more likely to clarify old questions while raising new and more scientifically helpful ones. This future should avoid past sterile debates and focus more intensively on the developmental nature of this and related disorders of social and communicative functioning. To anchor this discussion in clinical realities, an overview of clinical features, treatment, and support services is also provided.

History and Nosology of Asperger's Syndrome (AS)

Although AS was accorded formal diagnostic status only in the 1990s (in DSM-IV; APA, 1994; and in ICD-10; WHO, 1992), the original description appeared in 1944 (Asperger, 1944), only one year after Kanner's seminal account of autism (Kanner, 1943). The first influential description of Asperger's work appeared in English only in 1981 (Wing, 1981), the year after Hans Asperger's death. But it was only in the 1990s, and particularly after the publication of DSM-IV and ICD-10, that his work became better known. Since then, however, the clinical and research literature making use of the term AS has grown exponentially. To exemplify this growth, publications including AS in their title in PsychINFO grew from a handful before 1981, to maybe a few more than 10 between 1981 and 1990, to 140 between 1991 and 2000, to 452 in since 2001. The numbers since 1991 still represent only about 10% of the number of publications including the word "autism" in their title. Since 2001, the use of the term "autism spectrum disorder" (ASD) has also been growing exponentially. From fewer than 10 titles during the 1990s, there have been close to 260 titles since 2001. And the term is now commonly used in grant applications and large research meetings, particularly as more and more investigators in a whole range of disciplines from molecular genetics to social policy are baffled by the heterogeneity of autism related disorders. It is possible that the increasingly more popular term ASD will gradually replace the term AS in future clinical and research work.

Hans Asperger's Original Construct

In 1944 Hans Asperger, an Austrian pediatrician with interest in special education, described four children who had difficult integrating socially into groups (Asperger, 1944). These 4 children were 6 to 11 years of age, and all appeared to have intact if not gifted intellectual functioning. This text was translated in 1991 by Uta Frith, who also added some background on his professional training and clinical practice (Frith, 1991). Unaware of Kanner's publication (1943), Asperger termed the condition he described *Autistischen Psychopathen im Kindesalter*, or autistic psychopathy in childhood, echoing Bleuler's (1916) use of the term "autism" in schizophrenia to signify extreme egocentrism. He contrasted this condition from schizophrenia, however, by emphasizing the stable and enduring nature of the social impairments and by voicing the optimist view that unlike in schizophrenia, his patients were able to eventually develop some relationships. His term is probably better translated into today's psychiatric nomenclature as a stable personality disorder marked by social isolation. His use of the term "autism" marked his belief that difficulties in socialization represented the defining feature of the condition.

The four children had come to Asperger's attention, to some extent, because of school failure and behavioral problems displayed in social situations, including aggression, noncompliance, and negativism. He did not consider these to be willful transgressions of social mores but reflections of a true inability to understand others, particularly their non-verbal signals and communications. He described a marked reduction in the quantity and diversity of facial expressions and in the use of gesture, and profound difficulties in understanding nonverbal cues conveyed by others. They were verbose, and their own spontaneous communications were marked by correct formal language structures but highly idiosyncratic form. There were frequent circumstantial utterances (e.g., failing to distinguish information about the world from their own autobiographical narration); speech typically involved long-winded and incoherent verbal sequences failing to convey a clear message or thought (e.g., tangential speech triggered by a series of nonmeaningful associations); and conversation was profoundly one-sided (e.g., failing to demarcate changes of topic or to introduce new materials, thus leading to other people's confusion). The children also displayed unusual and highly circumscribed interests which absorbed their attention and learning, often appeared to preclude the acquisition of practical and self-help skills, and dominated the content of their communications with others. Their emotional presentation was marked by poor empathy, the tendency to intellectualize feelings, and a profound lack of intuitive understanding of other people's affective experiences and intentions. They were also motorically clumsy, unable to participate in group sports, and often lagged in the acquisition of motor coordination skills such as riding a bike or producing good penmanship.

Other important features of Asperger's description included his belief that the condition could not be recognized in early childhood because speech, language and intellectual curiosity in the environment appeared intact in the first few years of life. Also, he thought that there was a clear familial nature to his syndrome, as similar traits in parents or close relatives could be found in almost every case. Almost always, both affected individuals and vulnerable family members were male.

With the exception of one brief communication that appeared in the year before his death (Asperger, 1979), Asperger's work was published in German, and remained largely unknown in the English-speaking world until Wing's publication in the 1981. In contrast, Leo Kanner's (1943) description of 11 children with "autistic disturbances of affective contact," whom he had begun to see in the 1930s, was published in English by someone who was the founding figure of child psychiatry in the United States, and became an instant classic. Although both men's native language was German, World War II and the lack of academic communication across languages signified that neither had knowledge of the other's work, at least not in the 1940s and 1950s. And yet, there were clear commonalities in the syndromes they described. Their patients had profound difficulties in social interaction, affect, and communication, and displayed unusual and idiosyncratic patterns of interest. The main differences related to Asperger's observation that his patients' speech and language acquisition as well as intellectual functioning were less commonly delayed, motor deficits were more likely, onset was later in childhood, and all of his initial cases occurred in boys. More importantly, however, there were significant differences in terms of aspects and severity of symptomatology in the areas of social-emotional functioning, communication and cognitive skills, motor mannerisms, and circumscribed interests. In retrospect, however, some of these differences appear to have been a function of the presentation of the specific children initially described by Kanner and Asperger rather than some fundamental markers denoting two fully independent syndromes. Kanner's patients included preschoolers, were less verbal, and some were considerably more cognitively disabled. Asperger's patients were primarily school-age children, and were highly verbal and cognitively intact if not gifted. Consequently, Kanner's initial description became associated with the "classically" cognitively impaired or "lower functioning" child with autism, whereas Asperger's initial description became associated with the more cognitively able and highly verbal older child with ASD.

That the nature of patients originally described by Kanner and Asperger was a more important factor in accounting for differences separating the two accounts is clear in some of the work appearing subsequently. For example, Robinson and Vitale (1954) described three cases of children aged 8 to 11 years who showed a pattern of circumscribed interests reminiscent of Asperger's patients. The children were interested in developmentally precocious topics such as chemistry, nuclear fission, transportation systems, astronomy, and electricity, among others. They talked about these topics incessantly in one-sided conversations with peers and adults. They were socially isolated, had little adherence to social niceties, and their play revolved almost exclusively around their interests. Kanner (1954) was the invited discussant of this paper. The descriptions reminded him of "infantile autism" (the term that had by then become the common clinical construct used to denote autism). But he felt that these children were less socially withdrawn and more affectively engaged with others than the children he had described in previous years. Still they lacked friends and did not participate in group activities. As the paper focused on circumscribed interests, Kanner suggested that the various topics dominated the lives of these children, monopolizing their learning and interfering with their ability to engage others in reciprocal relationships. And because these interests were so unusual, consisting of collections of facts rather than conceptual inquiries or hobbies; they could not be shared with others and could not easily become a springboard for vocational learning. It is of interest, therefore, that Kanner's incisive clinical observations greatly resembled those of Asperger when he was called to describe children similar to those Asperger encountered in his original case studies.

An equivalent example in Asperger's writings—the description of "lower functioning" children—cannot be found in the English literature, but it may be available in his

considerable body of work from 1944 to the time of his death. But one important difference set Asperger's and Kanner's accounts apart, and to some extent influenced their power to generate research. While Asperger's frame of reference was special education on the one hand—his patients were not willful transgressors of rules but children who could not process social information—and the prevailing concept of schizophrenia on the other hand—his patients had a stable, longstanding personality structure marked by social disabilities—Kanner's frame of reference was deeply developmental. Influenced by the work of Arnold Gesell, a developmentalist at the Yale Child Study Center, Kanner described autism as a congenital disorder partially because of his appreciation of the fact that his children failed to display social communication, learning, and play skills that were effortlessly acquired by much younger, typically developing children. While Asperger's description was primarily clinical in nature, Kanner ventured into learning structures (e.g., difficulty in integrating information in learning) and other observations (e.g., macrocephaly) that generated a wide array of cognitive and other hypotheses that are still very much relevant to this day. It was probably not a coincidence that 2 years after Kanner's description of autism, Scheerer and colleagues (1945) published an exquisite set of neuropsychological experiments involving one of Kanner's patients, which foreshadowed much of cognitive research that began to appear only in the 1970s and 1980s.

Evolving Conceptualization of as in the 1980s

Although historically Kanner's and Asperger's clinical syndromes appeared more complementary than mutually exclusive, the introduction of Asperger's work to English-based psychiatry was inherently tied to the question of whether the diagnostic constructs they described were "the same or different." To some extent, this introduction was first made by Van Krevelen (1963), who made a deliberate attempt to distinguish the concept of "autistic psychopathy" from Kanner's autism (Van Krevelen, 1971) and concluded that they were sharply different. His discussion clearly separated onset patterns, social and communicative functions, and intellectual and language abilities that are characteristic of lower functioning children with ASD from those that are more characteristic of higher functioning children. Kanner never discussed this distinction, whereas Asperger appeared to support it later in life (Asperger, 1979; Hippler & Klicpera, 2003).

As noted, awareness of Asperger's syndrome did not increase until Lorna Wing's (1981) influential case series was published. She described 34 individuals, aged 5 to 35 years, of whom 19 had a clinical presentation similar to that described by Asperger, whereas the remaining sample had a current presentation similar to the syndrome but onset patterns and early history were different. Concerned that the term "psychopathy" might connote sociopathic behavior (rather than the intended personality disorder), and hoping to ground the condition in developmental terms (thus ensuring that no

support to the position blaming autism on parents could be derived from this work), Wing chose the eponymous "Asperger's Syndrome" instead of "autistic psychopathy." She summarized Asperger's original text and proposed some modifications for the syndrome on the basis of her case studies. Although Asperger thought that the condition was unrecognizable prior to age 3 years, Wing suggested that several difficulties were present in the first 2 years of life, including problems in socialization, speech, and communication; pronounced narrow interests and restricted behaviors; and restrictive imaginative play. She also suggested that AS could be found in girls and in individuals with mild intellectual disabilities.

While Wing's publication set in motion a great surge of interest in AS, it also blurred the distinctions made by Van Krevelen, essentially bringing Asperger's construct within the triad of impairments involving social, communication, and imaginative symptoms (Wing, 1986). There was palpable progress made in fostering awareness of the challenges of higher functioning individuals, but also an unexpected consolidation of the "same or different" preoccupation in the field, which Wing subsequently thought of as a major and unjustified distraction (Wing, 2000). And yet the two decades that followed Wing's initial publication on AS were primarily characterized by such attempts at separating autism from AS. Several definitions were derived from her account on the basis of the experience of influential clinical investigators (Gillberg & Gillberg, 1989; Szatmari et al., 1989; Tantam, 1988), yielding results that fell on either side of the "same or different" question. The use of different definitions yielded, not surprisingly, different groups for comparison (Klin, Pauls, et al., 2005). This undermined any attempt to interpret this literature, and failed to shed light on developmental mechanisms of interest that might account for differential outcomes, and which could be proven diagnostically meaningful (Klin, McPartland, et al., 2005).

Formalization of AS as a Diagnostic Category in DSM-IV and ICD-10

As noted, AS was not officially recognized until the 10th edition of the *International Classification of Diseases* (ICD-10; WHO, 1992) and the 4th edition of the *Diagnostic and Statistical Manual* (DSM-IV; APA, 1994). The coordinated and simultaneous inclusion in both systems followed limited evidence provided by a large, joint field trial that revealed that AS could be differentiated from autism unaccompanied by intellectual disabilities or higher functioning autism (HFA) on the basis of some limited data (Volkmar et al., 1994). This work was prompted by the recognition that autism is a clinically heterogeneous disorder and that the characterization of subtypes of PDD or ASD might help behavioral and biological research by allowing the identification of clinically more homogeneous groups (Bailey et al., 1998; Rutter, 1999; Volkmar et al., 1997). An awareness of the large number of individuals with serious social disability who did not meet

strict criteria for autism was a further concern. For some disorders like Rett's syndrome (Amir et al., 1999), this approach facilitated neurobiological research.

This hope, however, was not realized in the subtyping of the more commonly found PDDs, namely autism, AS, and PDD-NOS. To begin with, there was some ambivalence about the inclusion of AS as a "new" category, impacting on the final definition adopted in DSM-IV and ICD-10, which has proven highly problematic in many respects. Limitations of the adopted formal definition of AS were pointed out almost immediately (Miller & Ozonoff, 1997). It has since been criticized as overly narrow (Eisenmajer et al., 1996; Szatmari et al., 1995), rendering the diagnostic assignment of AS improbable or even "virtually impossible" (Mayes et al., 2001; Miller & Ozonoff, 2000). Equally concerning, criteria were modified by investigators for a given study, or were disregarded altogether in favor of the investigator's own criteria (see Klin, McPartland, et al., 2005 for a discussion). Studies attempting to compare different diagnostic schemes (e.g., Ghaziuddin et al., 1992; Leekam et al., 2000; Klin, Pauls, et al., 2005; Kopra et al., 2008; Woodbury-Smith et al., 2005) invariably revealed, not surprisingly, discordance in case assignment among the various schemes adopted.

The DSM-IV Definition of AS

The DSM-IV approach to the definition of AS was to adopt the triad of symptom clusters used for the definition of autism, namely qualitative impairments in social interaction and communication, and restricted repetitive and stereotyped patterns of behavior. And while the text accompanying the definition of AS in the text revision of DSM-IV (DSM-IV-TR; APA, 2000) was modified, the formal criteria for the diagnosis were not (as these cannot be changed but in a new edition of the manual). In DSM-IV, symptom requirements in the social and restrictive behaviors cluster are identical for AS and autism (or Autistic Disorder). In contrast to autism, there are no symptom requirements in the communication cluster, despite the fact that communication difficulties are universally reported in AS (Paul, in press). In essence, therefore, DSM-IV makes a distinction between autism and AS solely on the basis of the onset criteria. In autism, any concerns prior to the age of 3 years involving social interaction, social communication, or symbolic/imaginative play are sufficient for the criteria to be met. In contrast, any concern involving cognitive development (during childhood), self-help skills, or more broadly defined adaptive behavior (other than social interaction but including social communication) would rule out the diagnosis of AS. The overinclusive nature of onset criteria for autism and overexclusive nature of onset criteria for AS (and any ambiguities left in the definition, e.g., how to distinguish social interaction from social communication) are resolved in terms of the "precedence rule," according to which if an individual meets criteria for autism, he or she cannot be assigned the diagnosis of AS (Volkmar & Klin, 2000). Moreover, the clinical literature is replete with cases

who defy this classification on the basis of a mixture of developmental features such as early language delays, or early cognitive delays (consistent with autism), and maybe adolescent presentation with no deficits in formal language skills or learning (more consistent with AS).

The impracticality of this scheme led to attempts at systematic modification, which, however, have not been followed up in subsequent research. They did, however, highlight pros and cons of possible alternatives for the current DSM-IV scheme. One influential approach has been to divide children with an early-emerging social disability but apparently normative cognitive development in terms of whether or not there were single words by age 2 years, and phrase speech (typically defined as non-echolalic 3-word combinations used meaningfully for communication) by the age of 3 years (i.e., AS is assigned if a child meets these criteria, and autism is assigned if the child does not (e.g., Gilchrist et al., 2001; Szatmari, 1995; 2000). Although this approach allows for important research on developmental paths and outcome, it greatly narrows the potential lines of distinction between autism and AS in that other aspects of onset as well as any unique features in the child's current presentation are disregarded (Volkmar & Klin, 2000). In essence, given that individuals with HFA may not present with speech delays as defined, there is a potential for the resultant samples (of individuals with HFA and AS) to overlap considerably in terms of other symptomatology, thus increasing the potential for type II errors (i.e., not finding differences) in such studies. Other practical concerns include the fact that many individuals with AS are not diagnosed as young children (McConachie et al., 2005; Mandell et al., 2005) and some are even diagnosed in adulthood (in fact, more frequently now than before), making the attainment of reliable and valid, as well as detailed developmental history quite challenging.

An additional factor contributing to the weakening of the AS construct is the fact that the benchmark diagnostic instruments in ASD—the *Autism Diagnostic Interview–Revised* or ADI-R; reference; and the *Autism Diagnostic Observation Schedule* or ADOS; reference—which are keyed in to DSM-IV criteria and are virtually universally required in research of ASD, do not include any of the PDD subtypes, limiting the resulting classification to Autism (or Autistic Disorder), ASD (often equated with PDD-NOS), and non-ASD. While it is clear that AS never achieved sufficient validity to be included in the instruments, the instruments were never adjusted by any investigators to attempt a better operationalization of the construct.

The result of these enduring nosologic quandaries has been a virtual abandonment of DSM-IV criteria and rules for the diagnostic assignment of AS. And yet, the construct survives nevertheless, having acquired what can be termed as "usage validity." As noted, the vast majority of clinical and research publications equate AS with autism without intellectual disabilities, or expand its meaning to encompass borderland expressions of ASD. Invariably, however, the term is used for school-age children, adolescents, and adults but not for young children, negating, therefore, its neurodevelopmental nature

(and curiously perpetuating Asperger's original assertion that the condition cannot be identified in the first years of life).

Subtyping of the Autism Spectrum Disorders and the Diagnostic Status of AS

The need for subtyping of the autism spectrum disorders (ASD) is based on several different challenges in clinical practice and research. The ASDs are early-emerging neurodevelopmental disorders that impact on most domains of social and communicative functioning, with associated impact on cognitive and adaptive functioning. They are vastly heterogeneous in genotype and phenotype, which in turn likely reflects multiple etiologies and pathogenetic courses (Volkmar et al., 2004). These multiple levels of variability are often viewed as one of the greatest obstacles blocking the advancement of research on causes and treatments of these disorders. The advancement of meaningful clinical subtypes could yield more homogeneous samples, with the hope that these in turn could translate into advances in research on etiology, treatment specificity, and outcome optimization.

As noted, the separation between AS and autism was thought to provide a starting point for reducing heterogeneity, thus empowering research. However, the tentative inclusion of AS in DSM-IV and ICD-10 was not followed by research substantiating clear-cut distinctions in regard to traditional external validators such as etiology, developmental course, learning profiles, differential treatment response, or differential outcome (see Klin, McPartland, et al., 2005 for a review). Much of the validation work was thought to be confounded by the lack of a common nosologic framework and by circular reasoning, when validating factors were not clearly independent of the defining diagnostic criteria used to assign participants to different groups in the first place (Frith, 2004). This frustration intensified the use of the term "ASD," which blurs the categorical boundaries among the most common PDDs—autism, AS, and PDD-NOS—into a hypothesized continuum of affectedness (Wing, 1986; Wing & Gould, 1979). The term "spectrum" implies that a number of meaningful dimensions could generate the full range of syndrome expression (not unlike, for example, the spectrum of light) (Klin, 2009). These dimensions, if validated, could be considered as factors mediating the relationship between etiology(ies) and behavioral expressions. Several of such dimensions—also called "endophenotypes"—have been proposed at multiple levels of causation, from gene(s) and gene combinations, neuroanatomic abnormalities and disease processes, to onset patterns, neurocognitive abnormalities, combinations of symptom clusters, and levels of developmental skills such as language and intellectual endowment (e.g., Dawson et al., 2002; DiCicco-Bloom et al., 2006).

These endophenotypes, however, are still a work in progress, but collectively, this work further reinforces the need for subtyping research. And yet, discussions of subtyping of the PDDs typically focus primarily on the creation of categorical subdivisions of ASDs, their validation, and utility (Volkmar & Klin, 2005; Volkmar et al., 2009). There is a ubiquitous expectation that subtyping solutions in one domain of research or clinical practice should necessarily apply to other domains of clinical science (Klin, 2009). And yet, there is no reason to assume that factors underlying classification for one purpose should necessarily apply in the case of other purposes. For example, classification for clinical management and decisions on eligibility for educational services should be inclusive, reflecting the consensus that programming for persons with ASD should be determined on the basis of individualized profiles of strengths and deficits, and not on basis of the person's specific PDD diagnosis (NRC, 2001). In contrast, classification for the purpose of brain research should focus on the mechanism of interest in a given study. For example, several studies have suggested accelerated brain growth in the infancy period of children with ASD (e.g., Courschene et al., 2001). The full potential of this finding depends to some extent on quantified evaluation of the behavioral correlates of accelerated brain growth, including, for example, a specific timetable for onset and course of the atypical patterns of brain growth (Hazlett et al., 2005).

In this light, defining the purposes and expectations for diagnostic subtyping is critical (Klin, 2009; Volkmar et al., 2009). While current data available do not support validation of the PDD subcategory of AS (Frith, 2004; Klin et al., 2005b; Witwer & Lecavalier, 2008), they do not necessarily refute the premise that meaningful onset patterns may in fact delineate meaningful clinical entities. They only refute the simplistic notion that poorly defined and poorly operationalized behavioral statements are a sufficient basis to create distinguishable and meaningful diagnostic constructs, particularly if these are dependent on ascertainment of onset patterns carried out for individuals who are already adolescents or adults. While it is important not to perseverate on the seminal descriptions of 15 children made by two influential clinicians over 60 years ago (Kanner, 1943; Asperger, 1944) with the hope that research "by exegesis" might solve our current nosologic quandary, it is equally important not to prematurely foreclose the possibility that the vastly heterogeneous social disabilities encompassed by the term "ASD" cannot gain from better, developmental cognitive science research on mechanisms of socialization and their unfolding during the first years of a child's life (Johnson, 2001). For example, following from the experience-expectant model of child development (Johnson & Karmiloff-Smith, 2004) in which the genetically determined schedule of neural maturation matches the timing of adaptive tasks, disruptions of socialization processes occurring at different times are likely to result in different outcomes (Jones & Klin, 2009). Similarly, different outcomes are likely to result from a wide range of permutations of intact and impaired mechanisms of social cognition. What might be the consequences of these developmental processes to eventual outcomes, including any meaningful clusters of symptoms and abilities in individuals with ASD, is not known at present.

The potential contribution of developmental cognitive neuroscience is typically left unexplored in nosology research, which tends to go back to the classic clinical descriptions. For example, while Kanner emphasized the congenital nature of autism (Kanner, 1943), Asperger emphasized the later onset of the condition he described (1944). This incidental point of departure in the two accounts subsequently led to the hypothesis that presence or absence of speech delays could lead to meaningfully different clinical entities. This scenario should be considered hopelessly simplistic given current knowledge of developmental psychopathology and development cognitive science. The ASDs are quintessential neurodevelopmental disorders. By all accounts, diagnosis of vulnerabilities consistent with this diagnosis can be made within the first 2 or 3 years of life (Chawarska et al., 2007) if not earlier (e.g., Klin et al., 2004). It would be naïve to disregard the fact that variability in developmental profiles early in life might not have consequences for phenotypic variability later in life.

Two parallel sets of advancements bode well for this field: First, our knowledge of normative processes in child development has increased dramatically in the past 10 years, although autism research has been slow in fully assimilating new investigative paradigms, technologies, and concepts (Klin et al., 2008). Second, the advent of prospective studies of large cohorts of genetically at-risk infants, a proportion of whom will develop autism, carries the promise of shedding light on this critical period of pathogenesis hitherto confined to knowledge based on retrospective accounts or less-than-ideal methods of infancy research (Zwaigenbaum et al., 2007). As knowledge accrues from these efforts, it is very likely that a great deal of what we know about ASD will have to updated if not fully modified.

In this light, the future of nosologic research on AS needs to rely on these advancements if the field is to move forward beyond the sterile debates as to whether autism and AS represent "same or different" diagnostic entities. Clearly, several of the validation problems briefly described above could only be systematically tackled if there were some agreement as to a set of criteria, comprehensively detailed and uniformly utilized according to standardized ascertainment procedures. But at the root of this problem is the fact that the all-important onset criteria have been, universally, ascertained retrospectively, often many years after the person's early childhood. It is possible that the advent of prospective studies will answer some of these questions more productively. For example, meaningful differential patters of onset or developmental mechanisms can be used as independent variables, whereas diagnostic assignment later on in life can be analyzed as dependent variables, thus exploring the full range of meaningful diagnostic outcomes associated with clusters of well-quantified, early symptoms or developmental profiles (e.g., language, communication, social cognition). This effort might yield systematic mapping of developmental factors on trajectories and eventual outcomes, thus avoiding circular reification of definitions, and moving instead to a developmentally based and empirically derived nosology of the higher functioning ASDs (Klin, 2009).

Such studies are underway, and there is some hope that they will be available prior to DSM-V, the next update of the formal diagnostic system used in the United States and several other countries. In their absence, a new round of arbitrary decisions impacting on the definition of AS is likely, maybe yielding to the concept of "usage validity" (i.e., the most popular patterns of use), or, more likely, removing the construct in favor of a more encompassing construct such as ASD.

Diagnosis and Clinical Features

The diagnosis of AS requires the demonstration of qualitative impairments in social interaction and restricted patterns of interest, criteria that are identical to autism. In contrast to autism, there are no criteria in the cluster of language and communication symptoms, and onset criteria differ in that there should be no clinically significant delay in language acquisition, cognitive, and self-help skills. These symptoms result in significant impairment in social and occupational functioning (APA, 2000).

Social and Communication Functioning

In some contrast to the social presentation in autism, individuals with AS find themselves socially isolated but are not usually withdrawn in the presence of other people, typically approaching others but in an inappropriate or eccentric fashion. For example, they may engage the interlocutor, usually an adult, but also same-age peers, in one-sided conversation characterized by long-winded, pedantic speech about a favorite and often unusual and narrow topic. They may express interest in friendships and in meeting people, but their wishes are invariably thwarted by their awkward approaches and insensitivity to the other person's feelings, intentions, and nonliteral and implied communications (e.g., signs of boredom, haste to leave, and need for privacy). They may also react inappropriately to or fail to interpret the valence of the context of the affective interaction, often conveying insensitivity, formality, or general disregard for the other person's emotional expressions. They may be able to describe correctly, in cognitive and often formalistic fashion, other people's emotions, expected intentions, and social conventions; however, they are unable to act on this knowledge in an intuitive and spontaneous fashion, thus losing the tempo of the interaction. Their poor intuition and lack of spontaneous adaptation are accompanied by marked reliance on formalistic rules of behavior and rigid social conventions. This presentation is largely responsible for the impression of social naïveté and behavioral rigidity that is so forcefully conveyed by these individuals.

Circumscribed Interests

Individuals with AS typically amass a large amount of factual information about a topic in an intense fashion (Klin,

Danovitch, et al., 2007). The actual topic may change from time to time, but often dominates the content of social exchange. Frequently the entire family may be immersed in the subject for long periods of time. This behavior is peculiar in the sense that oftentimes extraordinary amounts of information are learned about very circumscribed, and occasionally unusual topics (e.g., snakes, names of stars, TV guides, deep fat fryers, weather information, sports statistics, personal information on politicians or celebrities) without a genuine understanding of the broader phenomena involved. This symptom may not always be easily recognized in childhood because strong interests in certain topics, such as dinosaurs or fashionable fictional characters, are ubiquitous. In younger and older children with AS, however, special interests typically interfere with learning in general because they absorb so much of the person's attention and motivation, and also interfere with the person's ability to engage in more reciprocal forms of conversation with others.

Speech, Language, and Communication

Although significant abnormalities of speech and formal language skills are not typical of individuals with AS, there are at least three aspects of their communication patterns that are of clinical interest (Klin, McPartland, et al., 2005; Paul, in press). First, speech may be marked by poor prosody, although inflection and intonation may not be as rigid and monotonic as in autism. There is often a constricted range of intonation patterns that is used with little regard to the communicative function of the utterance (e.g., assertions of fact, humorous remarks). Rate of speech may be unusual (e.g., too fast) or may lack in fluency (e.g., jerky speech), and often there is poor modulation of volume (e.g., voice is too loud despite physical proximity to conversational partner). The latter feature may be particularly noticeable in the context of a lack of adjustment to the given social setting (e.g., social contact occurring in a library or at a funeral). These various oddities can be extremely stigmatizing given low tolerance for these oddities among members of the general community.

A second important communication pattern of interest relates to the fact that speech may often be tangential and circumstantial, conveying a sense of looseness of associations and incoherence. Even though in a very small number of cases this symptom may be an indicator of a possible thought disorder, the lack of contingency in speech is more typically a result of the one-sided, egocentric conversational style (e.g., unrelenting monologues about the names, codes, and attributes of innumerable TV stations in a country); failure to provide the background for comments and to clearly demarcate changes in topic of conversation; and failure to suppress vocal output accompanying internal thoughts.

A third noticeable symptom relates to a communication style that is often characterized by marked verbosity. The child or adult may talk incessantly, usually about a favorite subject, often in complete disregard to the listener's interest, engagement, or attempt to interject a comment or change the subject of conversation. Despite such forceful monologues, the individual with AS may never come to a point or conclusion. And attempts by the interlocutor to elaborate on issues of content or logic, or to shift the conversation to related topics, are often unsuccessful.

Motor Difficulties

Although Asperger noticed pronounced "motoric clumsiness" in his patients, attempts to use this symptom as a point of differentiation between the diagnosis of AS (where motoric dysfunction is contrasted with preserved intellectual skills) and the diagnosis of autism (where presumably motor skills are at a higher or at least commensurate level with intellectual skills) have yielded conflicted results. Comparisons of individuals with AS and autism at similar cognitive levels have generally suggested that motor deficits are displayed by individuals with both syndromes (Smith, 2000). Patterns of acquisition of motor skills, or potential developmental factors underlying possible differences in motoric functioning later in life have not been systematically studied.

Practically, however, individuals with AS may have a history of delayed acquisition of motor skills, such as pedaling a bike, catching a ball, opening jars, and climbing outdoor play equipment. They are often visibly awkward and poorly coordinated and may exhibit stilted or bouncy gait patterns and odd posture.

Comorbid Features

The most common disorders co-occurring with AS are depression and anxiety. Estimates of comorbid anxiety and/or depression in individuals with AS are as high as 65 percent, and some researchers have suggested that these elevated rates represent a distinction between AS and higher functioning autism (HFA) (Ellis et al., 1994; Fujikawa et al., 1987; Ghaziuddin, 2002; Ghaziuddin et al., 1998; Green et al., 2000; Howlin & Goode, 1998). Other data suggest, however, that individuals with AS and HFA are equally at increased risk for problems with anxiety and depression, with no differences between the groups (Kim et al., 2000). Anxiety in AS has been observed to stem from several sources. Concern about possible violations of rigid routines or rituals can be anxiety-provoking for individuals with AS. They frequently rely on particular schedule or methods of completing daily activities that, when violated, result in significant upset. Conversely, when placed in a context in which no clear schedule or set of expectations is known, anxiety may result. Also, devoid of an intuitive sense of other people's intentions and unspoken rules of social engagement, and yet often painfully aware of previous experiences of social failure, there may be great anticipatory anxiety relative to social encounters, the outcomes of which are perceived as situations these individuals have little control over.

Equally common to anxiety and typically appearing in early adolescence, depressive symptoms represent the result of the unique pairing of social desire in the absence of

social intuition or skill. Chronically frustrated by their repeated experiences of failure to engage others and form friendships or romantic relationships, individuals with AS often become despondent, negativistic, and bitter, or even clinically depressed, which may require treatment, including psychopharmacological treatment.

Several other comorbid conditions have been reported. Hyperactivity and inattention are common among children with AS (Eisenmajer et al., 1996; Schatz et al., 2002), and many children with the disorder are often initially misdiagnosed with attention-deficit/hyperactivity disorder as mental health providers or educational professionals fail to appreciate the neurodevelopmental nature of their social and communication difficulties. Some studies have associated AS with Tourette's syndrome (Kerbeshian & Burd, 1986; Littlejohns et al., 1990; Marriage et al., 1993, obsessive-compulsive disorder (Thomsen, 1994), and psychotic conditions (Gillberg, 1985). Some studies have investigated the notion that the combination of preserved intellectual and linguistic capacities with limited empathy and social understanding might predispose individuals with AS to violent or criminal behavior (Everall & Le Couteur, 1990; Scragg & Shah, 1994), but this hypothesis is unsupported by other studies (Ghaziuddin et al., 1991). Nevertheless, these individuals' lack of "common sense," reduced intuition, and extreme "gullibility" at times leads to unintentional transgressions of rules that may have legal consequences which can be grave. For example, the combination of extreme social isolation and technical competencies in operating computers often result in unlimited, typically unsupervised Internet use with the attending perils that this medium poses to naïve users. Serious crimes can be committed through naïve, reckless, or otherwise unguided or unsupervised use of the Internet, including crimes for which there are mandatory sentences (e.g., downloading of illegal images).

Course and Prognosis

There are no systematic long-term follow-up studies of children with AS as of this writing, partially because of nosologic issues. Many children are able to attend regular education classes with additional support services, although these children are especially vulnerable to being seen as eccentric and being teased or victimized; others require special education services, usually not because of academic deficits but because of their social and behavioral difficulties. Asperger's initial description predicted a positive outcome for many of his patients, who were often able to use their special talents for the purpose of obtaining employment and leading self-supporting lives. His observation of similar traits in family members (e.g., fathers, grandfathers) may also have made him more optimistic about the ultimate outcome. Although his account was tempered somewhat over time, Asperger continued to believe that a more positive outcome was a central criterion differentiating individuals with his syndrome from those with Kanner's autism. Although some

clinicians have informally concurred with this statement, particularly in regard to gainful employment, independence, and establishing a family, no studies using consensual definitions of the condition have to date addressed long-term outcome in longitudinal follow-ups. Clearly, since cognitive and language levels are probably the most important factors in predicting outcome (Howlin, 2005), the perception of differences between individuals with autism and those with AS relative to prognosis in adulthood might be confounded by perceptions of the definitions of these conditions (i.e., AS being associated with higher level of cognitive and language skills).

Medical and Neurobiological Factors

Several reports of medical abnormalities associated with AS have appeared, but, due to nosological issues and the preponderance of case reports and or small studies, no factors have been reliably associated with AS across studies. Wing (1981) reported high frequency of perinatal problems (nearly half of her original sample) among individuals with AS. Other reports have associated AS with medical conditions, including aminoaciduria (Miles & Capelle, 1987) and ligamentous laxity (Tantam et al., 1990). A case series by Gillberg (1989) reported high frequencies of medical anomalies common to both AS and autism, but these results have not been consistently replicated (Rutter et al., 1994). Epilepsy occurs more frequently in individuals with ASD than in the general population (Tuchman & Rapin, 2002), and this increased rate has been detected in case series investigating individuals with AS (Cederlund & Gillberg, 2004). Anomalies have also been detected in eye movements and visual scanning in individuals with ASDs (Sweeney et al., 2004), particularly in natural viewing of social scenes (Klin et al., 2002) but these findings have not yet been shown to distinguish AS from other ASDs. Neurochemical studies of autism spectrum disorders have produced inconsistent results. The most robust finding is elevated blood serotonin levels, but other studies have reported atypicalities in peptide excretion, neuroendocrine/HPA function, amino acid levels, uric acid excretion, and central cholinergic and gabaergic receptors. Some of these findings have been seriously challenged in more recent studies (Cass et al., 2008). At any rate, none of these findings seems to apply differentially to AS versus other ASDs (Anderson & Hoshino, 2005).

In recent years extensive neuroimaging research has been conducted to investigate structural anomalies in the brains of individuals with AS. However, no clear common pathology has emerged in individuals with AS, both with respect to typical individuals and in terms of differentiation among other ASDs. Berthier and colleagues (Berthier et al., 1990) reported MRI results indicating left frontal macrogyria and bilateral opercular polymicrogyria in patients with AS. Other studies have reported gray tissue anomalies (McAlonan et al., 2002), left temporal lobe damage (Jones & Kerwin, 1990), left occipital hypoperfusion (Ozbayrak et al., 1991), and dysmorphology

superior to the ascending ramus of the Sylvian fissure proximal to the intersection of the middle frontal gyrus and the precentral sulcus (Volkmar et al., 1996). The most robust neuroanatomical findings (applying to ASDs in general) are of rapid brain growth in early childhood leading to increased brain volume that normalizes in mid-childhood, and reduced size of the corpus callosum (Minshew et al., 2005) although once again, there have been no claims that such findings differentiate AS from other ASD subtypes.

Functional imaging has also provided information about ASDs, though, as is the case for structural findings, minimal evidence exists to indicate reliable differences among AS and other ASDs. FMRI and event-related potential studies of hemodynamic and electrophysiological brain responses have detected abnormalities in brain activity associated with face-processing mechanisms in inferotemporal cortex (Dawson et al., 2005; Schultz, 2005), and some of these anomalies have been specifically replicated in adults (but not children) with AS (O'Connor et al., 2005). Single Photon Emission Computed Tomography (SPECT) imaging has suggested abnormal right-hemisphere functioning in AS (McKelvey et al., 1995), which is consistent with the hypothesis that neuropsychological profiles of individuals with AS, but not of those with autism, are marked by strengths and deficits consistent with a nonverbal learning disability (Klin et al., 1995; Rourke et al., 1989). Other research has found dysfunction in brain regions subserving social cognition (anterior cingulate cortex, prefrontal cortex, temporoparietal junction, amygdala, and periamygdaloid cortex; Schultz & Robins, 2005). An emerging body of research suggests problems with functional connectivity among separate brain regions in ASDs (Just et al., 2004) and, specifically, in AS (Welchew et al., 2005). Though brain imaging technologies have shed some light on the pathobiology of ASDs, current research fails to present a clear picture of the specific neurobiological underpinnings of AS or factors that distinguish it from other PDD subtypes.

Genetics

Asperger's (1944) original description of the disorder noted common symptoms in family members, especially fathers, and empirical research since that time has supported this observation. Overall, ASDs are among the most heritable of psychiatric conditions, although genetic etiology and pattern of heritability is still poorly understood (Rutter, 2005). Many case reports have reported AS, ASD, or autistic-like traits in family members, particularly among fathers (Bowman, 1988; DeLong & Dwyer, 1988; Ghaziuddin, 2005; Gillberg et al., 1992; Gillberg & Cederlund, 2005; Volkmar et al., 1996; Wolff & McGuire, 1995), and recurrence rate in siblings of children with an ASD is considerably higher than the population base rate (Rutter, 2005). Some family history studies have also indicated associations with other psychiatric disorders including depression, schizophrenia, and schizoid personality disorders (Ghaziuddin et al., 1993). Klin and colleagues (Klin, Pauls, et al., 2005) reported rates of ASDs or the broader autism

phenotype in parents and grandparents of probands with AS that were triple the rate found for the same relatives of probands with HFA (17% vs. 5%). Though this finding suggests AS may have an even stronger genetic component than autism, the preponderance of research suggests shared genetic mechanisms common to all ASDs (Frith, 2004; Rutter, 2005). Though no clear genetic etiology has been established for the majority of ASDs in general, or AS in particular, a subgroup of individuals have identifiable genetic abnormalities (perhaps 10%) which include translocations, balanced translocations, and de novo translocations (chromosomes 1, 5, 11, 13, 14, 15, 17; Cederlund & Gillberg, 2004; Anneren et al., 1995; Tentler et al., 2001; 2003), autosomal fragile site (Saliba & Griffiths, 1990), Fragile X syndrome (Bartolucci & Szatmari, 1987), and 21p+ (Cederlund & Gillberg, 2004), among others. As in other areas of medical, neurobiological, and genetic research, however, none of these findings have been claimed to differentiate individuals with AS from those with other PDD subtypes.

Treatment

As in autism, treatment of AS is essentially supportive and symptomatic and, to a great extent, overlaps with the treatment guidelines applicable to individuals with autism unaccompanied by mental retardation, or higher functioning autism (HFA) (Attwood, 2006; Klin & Volkmar, 2000; Ozonoff et al., 2002; Powers & Poland, 2002). One initial difficulty encountered by families is proving eligibility for services. As these children are often very verbal and many of them do well academically, educational authorities might judge that the deficits—primarily social and communicative—are not within the scope of educational intervention. In fact, these two aspects should be the core of any educational intervention and curriculum for individuals with this condition.

In regard to learning strategies, skills, concepts, appropriate procedures, cognitive strategies, and behavioral norms may be more effectively taught in an explicit and rote fashion, using a parts-to-whole verbal instruction approach, in which the verbal steps are in the correct sequence for the behavior to be effective. Additional guidelines should be derived from the individual's neuropsychological profile of assets and deficits. Typically, however, individuals with AS have very poor organizational skills, which are more globally described as executive function deficits. They require specific and explicit help with planning ahead, breaking down problems into accomplishable components, executing them in a stepwise fashion while keeping in mind the overall goal of the activity, among many other challenges.

The acquisition of self-sufficiency skills in all areas of adaptive functioning should be a priority (Klin, Saulnier, et al., 2007; Saulnier & Klin, 2007). There should be a concerted effort to prepare children for independent, self-supporting life. Areas of proficiency in adulthood should include personal hygiene, grooming, and management of clothing; awareness of and

capable management of health issues; an operationalized view of what is private and what can be displayed or otherwise be spoken in public; sexuality; home management, including budgeting, purchasing, cooking, cleaning, and disposing of unnecessary items; budgeting, paying bills, and complying with financial and personal duties such as maintaining financial records and paying taxes; knowledge of how to deal with authority, including police, how to behave in situations of emergency, how to manage telemarketers, how to avoid falling prey to offers that are "too good to be true," critical knowledge of perils associated with Internet use, management of "junk" electronic and paper mail, among many others critical aspects of real life.

The tendency of individuals with AS to rely on rigid rules and routines can be used to foster positive habits and enhance the person's quality of life and that of family members. Specific problem-solving strategies, usually following a verbal algorithm, may be taught for handling the requirements of frequently occurring, troublesome situations (e.g., involving novelty, intense social demands, or frustration). Training is usually necessary for recognizing situations as troublesome and for selecting the best available learned strategy to use in such situations. Social and communication skills are best taught by a communication specialist with an interest in pragmatics in speech in the context of both individual and small-group therapy. Communication skills training should include appropriate nonverbal behavior (e.g., the use of gaze for social interaction, monitoring and patterning of voice inflection, verbal decoding of nonverbal behaviors of others, social awareness, perspective taking skills, and correct interpretation of ambiguous communications such as nonliteral language.

Often adults with AS fail to meet entry requirements for jobs in their area of training (e.g., college degree) or fail to maintain a job because of their poor interview skills, social disabilities, eccentricities, or anxiety attacks. It is important, therefore, that they be trained for and placed in jobs for which they are not neuropsychologically impaired and in which they will enjoy a certain degree of support and shelter. Therefore, it is preferable that the job not involve intensive social demands, time pressure, or the need to quickly improvise or generate solutions to novel situations.

The available experience with self-support groups suggests that individuals with AS enjoy the opportunity to meet others with similar problems and may develop relationships around an activity or subject of shared interest. Special interests may be use as a way of creating social opportunities through hobby groups. Supportive psychotherapy, as well as pharmacological interventions, may be helpful in dealing with feelings of despondency, frustration, and anxiety, although a more direct, problem-solving focus is thought to be more beneficial than an insight-oriented approach. Recently, the use of especially adapted forms of cognitive behavioral therapy has been shown to be effective and beneficial, particularly in regard to, but not limited to, anxiety symptoms.

Conclusions

The inclusion of the term "Asperger's syndrome" (AS) as one of the pervasive developmental disorders in the DSM-IV and ICD-10 has decisively contributed to greater awareness of individuals with autism spectrum disorders with preserved cognitive and language functioning. This in turn has generally translated into greater availability of services and supports to persons who previously had to fend for themselves in their daily challenges with only the support of their families and often with the disservice of misconceptions of the origins of their behavioral difficulties. In this light, the term "Asperger's syndrome" has certainly had a beneficial impact on the community of individuals with autism spectrum disorders and their families (Wing, 2000).

In contrast to this positive outcome, research on the external validity of the construct relative to other PDD subtypes has been undermined by the lack of operationalized and consensual definitions of the condition, the virtual irrelevance of the DSM-IV and ICD-10 formal definitions, and the rather arbitrary way in which the term has been used in clinical investigations. As researched in the past, this issue is not likely to be clarified in the future without radical changes. The forthcoming update of formal nosology presents an opportunity for such changes, but there is little definitive evidence to base decisions on. The alternatives available are not appealing: (1) to maintain the tentative status of AS within formal PDD nosology and, in so doing, to possibly perpetuate for yet another decade the current situation; or (2) to remove the term from formal PDD nosology and, in so doing, to leave the community without a term previously used as a coalescing force for advocacy.

At present, an empirically based decision is rather difficult because while AS has not been shown to differ from other PDD subtypes on a whole array of important variables, it has not been shown to be the same either because research on this issue has been uninterpretable. While one can state that the onus should be on disproving the nil hypothesis (i.e., that AS is meaningfully different from related PDD subtypes), the construct of Asperger's syndrome has taken a life of its own with many real-life consequences as alluded to before. A possible solution for this quandary will not help nosology in the short term, but it can rephrase the question in a way that valuable insights may eventually follow. This solution involves deriving the more far-reaching implications of the fact that autism spectrum disorders (ASD) are the quintessential neurodevelopmental disorders, and that a great many aspects of interest in investigations and clinical practice should be conceptualized in light of developmental psychopathology processes (Klin et al., 2003). Thus fully quantifying key aspects of developmental skills and symptomatology in infants and toddlers with ASD and then following these children longitudinally while casting the search for meaningful categorical subtypes as dependent, outcome variables might free this

debate from some sterile, past discussions. We still do not know what are important mediators of outcome beyond the obvious notion that IQ and language matter. In other words, we still do not know what are the dimensions that generate the spectrum of autism conditions beginning in early infancy.

Two parallel sets of advancements bode well for this field: first, our knowledge of normative processes in child development has increased dramatically since the early 1990s, although autism research has been slow in fully assimilating new investigative paradigms, technologies, and concepts (Volkmar et al., 2004). Second, the advent of prospective studies of large cohorts of genetically at-risk infants, a proportion of which will develop autism, carries the promise of shedding light on this critical period of pathogenesis. Until recently, our knowledge of this period of development was confined to retrospective accounts or less-than-ideal methods of infancy research (Zwaigenbaum et al., 2007). As knowledge accrues from these efforts, it is very likely that a great deal of what we know about ASD will have to be reappraised and updated, if not fully modified.

In regard to nosology and classification of ASD, prospective work singling out relevant patterns of onset and examining the range of associated symptomatic expressions over time is likely to systematize the search for empirically defined subtypes. This should allow for an examination of their utility in terms of response to treatment and outcomes. This process has begun with the identification of earlier- and later-onset autism (Landa et al., 2007), and possibly the existence of regressive subtypes (Lord et al., 2004; Siperstein & Volkmar, 2004; Werner & Dawson, 2005). It is possible, however, that these distinctions are still too crude, and are going to be remediated only by more detailed and quantified analyses of infancy data than those performed to date (Jones & Klin, 2009).

As new genes or genetic anomalies are found to be associated with ASD, some have argued for an etiology-based nosology as a viable approach to reduce the marked heterogeneity of phenotypic expressions of this family of conditions: there would be many "autisms," each corresponding to a "disease process." However, genotypic variability seems to be as baffling as phenotypic variability, if not more. For example, although more and more susceptibility loci are being identified, each is thought to account for only a small number of overall cases (e.g., Weiss et al., 2008). Likewise, de novo mutations may play a causal role in a relatively large percentage (~ 10%) of individuals with autism who do not have an affected first-degree family relative (e.g., Zhao et al., 2007). Other disorders, such as Rett syndrome, in which the genetic mutation has been identified nevertheless retain the clinical diagnosis based on clinical features, recognizing that not all cases that fit the clinical diagnosis have the underlying mutation and that the clinical diagnosis has utility in terms of describing clinical course and prognosis.

Given the multiplicity of possible causes, it is in fact surprising that ASD are identified, reliably, as a fairly unitary, though variable, syndrome (Jones & Klin, 2009). Beginning

with Kanner's original description, consensus on core diagnostic features has remained relatively stable. Autism-specific diagnostic instruments have strong sensitivity and specificity by age 2 years, and among experienced clinicians, agreement in diagnostic assignment is typically high (Klin et al., 2000; Lord & Corsello, 2005). These factors highlight homogeneity of basic features despite the wide range of genomic causes and varying outcomes.

But the interclinician reliability for the assignment of an ASD diagnosis is high relative to the differentiation of children with ASD vs. non-ASD. This is not so for the differentiation of ASD subtypes (i.e., autism, AS, and PDD-NOS). Thus it seems that the balance is tilted toward the adoption of the all-encompassing ASD construct, a disregard of the other subtypes, with the addition of maybe a dimensional qualifier such as level of cognitive or language functioning. This might be a palatable, interim solution until the subtyping enterprise can be more solidly derived from prospective, longitudinal research of early-emerging developmental pathways leading to social communication disabilities.

Challenges and Future Directions

- Prospective, longitudinal studies of well-characterized infants and toddlers with ASD identifying meaningful and quantified outcomes as dependent variables is likely to yield empirically derived subtyping schemes for the pervasive developmental disorders;
- In the absence of well-operationalized and consensually accepted definitions of AS, research on its external validity in the future is likely to fail. This will perpetuate the current unsatisfactory situation, which includes a complete disregard of the DSM-IV definition and the adoption of a whole array of other definitions in clinical research. The decision of whether or not to include AS in the forthcoming DSM-V will be made under less than optimal conditions and yet it is likely to have a far-reaching impact on the community; and
- "AS" is a term around which many affected individuals, their families, and advocacy agencies coalesce to advance factors beneficial to this community. In case AS is excluded from DSM-V, it will be critically important to minimize the deleterious impact of this decision on the entitlements of the individuals with this condition, or on their advocates' power to increase public awareness of their needs and challenges.

Regression and Other Patterns of Onset

Points of Interest

- Dichotomous classification of onset (early onset, regression) is insufficient to describe the many ways that symptoms of autism emerge in early development.
- Parent report methods for measuring regression may not be reliable.
- Prospective investigations of high risk samples suggest that regression may be much more common in children with autism than previously thought.
- Symptoms of autism appear to emerge slowly during the first year of life. Behavioral signs of autism are not present at or shortly after birth in most children, as Kanner once suggested.

Introduction

The onset of autism is usually described as occurring in one of two patterns. In one onset prototype, children show abnormalities in social and communicative development in the first 12 months of life. The most common initial symptom recognized by parents is delayed speech development (De Giacomo & Fombonne, 1998), but a growing body of literature suggests that social and nonverbal communicative delays predate the language abnormalities that typically lead to diagnosis. Behaviors that discriminate between young children with autism, developmental delays, and typical development are orienting to name, looking at the faces of others, joint attention, affect sharing, and imitation (Baranek, 1999; Osterling & Dawson, 1994; Stone et al., 1994, 1999; Werner, Dawson, Osterling, & Dinno, 2000; Wetherby et al., 2004). A few studies suggest that symptoms can be detected before the first birthday in some children (Baranek, 1999; Werner et al., 2000), but these

very early differences appear to be nonspecific (e.g., sleeping, eating, temperament patterns) and do not differentiate children with developmental delays from those with autism (Werner et al., 2005). Group differences are more reliably present and consistently found across studies in the second year of life (Palomo et al., 2006). This so-called early onset pattern is thought to occur in the majority of individuals with autism.

In the second pattern of onset, regressive autism, children appear to be developing typically for the first year or two of life. Between the first and second birthday, they lose skills that they had previously acquired, accompanied by the onset of autistic symptoms. The earliest literature on autism made no mention of this onset pattern. Kanner (1943), for example, did not report any loss of previously acquired skills in the 11 cases he described initially. The phenomenon was first reported in the 1970s by researchers in Japan (as cited in Kobayashi & Murata, 1998) and further described in the following decade (Hoshino et al., 1987; Kurita, 1985; Volkmar & Cohen, 1989).

Domains of Loss

The developmental areas most affected by regression are communication and social abilities. Much less frequently, adaptive and motor losses are reported (Davidovitch et al., 2000; Ozonoff et al., 2005; Siperstein & Volkmar, 2004). Several studies have found loss of language skills to be the most common type of regression reported by parents (Goldberg et al., 2003; Siperstein & Volkmar, 2004), possibly because speech is so eagerly awaited and salient to parents. Regression typically also involves loss of social interest and behaviors. As described by Rogers and DiLalla (1990), "the onset of their children's symptoms began with a change in or loss of the child's previous apparently normal social behavior. A loss of interest in others, the loss of eye contact, increasing isolation, the loss of interpersonal initiative including normal play were

among the behaviors that the parents reported" (p. 866). Almost all parents who reported loss of words also described loss of social skills (Goldberg et al., 2003; Lord et al., 2004). Ozonoff and colleagues (2005) found loss of eye contact to be the most frequently reported change in social behavior, with 90% of parents of children with regression reporting such a loss. The second most frequently lost social behavior was a loss of social interest, which was reported in 61% of children with regressive autism (Ozonoff et al., 2005).

Timing of Loss

Regression is most often observed between the first and second birthday, with mean or median ages of regression reported across different samples between 16 and 20 months (Goldberg et al., 2003; Kurita, 1985; Ozonoff et al., 2005; Shinnar et al., 2001). In a large epidemiological sample, parents of children with regression first became concerned about development at a mean age of 19.8 months (Fombonne & Chakrabarti, 2001), which is consistent with the smaller studies.

Prevalence of Regression

Fombonne and Chakrabarti (2001) reviewed six early studies that reported regression rates in the range of 22% to 50%. Similar rates have been found in other studies. Rogers and DiLalla (1990) and Tuchman and Rapin (1997) reported approximately 30% of their samples displayed a loss of skills. Kurita (1985) reported that 37% of his sample showed speech loss. In these and other similar studies, which do not use epidemiological or community-based samples, sample sizes are typically small and cases may be ascertained in a manner that is biased toward greater severity (e.g., through clinics or hospitals). Samples from epidemiological studies provide better estimates of prevalence. In one such study, Taylor et al. (2002) reported a 25% rate of developmental regression in a large cohort of children with autism born between 1979 and 1998 in London. Another epidemiological study undertaken in California found that 34.7% of 277 children with autism had histories of regression (Byrd et al., 2002). Thus, both epidemiological and individual sample studies indicate that regression in autism occurs in a substantial minority of cases and is not a rare form of onset.

Later Outcomes

Several studies have compared the later outcomes of children with regression to those of their peers with early onset autism, with varying results. Hoshino et al. (1987) reported more severe speech and behavioral problems, as well as lower adaptive levels, in children with regression. Rogers and DiLalla (1990) found that children with regression had significantly lower IQs than those who did not lose speech. However, Short and Schopler (1988) found no statistically significant differences in IQ between early onset and regression cases, and one early study actually found a better prognosis for children who

had experienced a regression (Harper & Williams, 1975). In most studies, the results have been mixed. Richler et al. (2006) reported on a large (n = 351) multisite sample (mean age 9 years) and found that children with regressive autism displayed significantly lower social reciprocity and verbal IQ than children with autism without regression, but found no differences on twelve other measures of intelligence, autism severity, and adaptive skills. Other studies (Brown & Prelock, 1995; Kobayashi & Murata, 1998; Meilleur & Fombonne, 2009; Wiggins, Rice, & Baio, 2009) have reported similarly mixed results, with some skills lower in children who regressed, but other skills no different from children with early onset autism. These studies assessed outcome at a variety of ages and many were based on small samples. A recent study examined two different cohorts of children with autism (ages 6–9 years and 16–19 years at data collection) from a large community-based sample, comparing functioning in children with and without regression. No differences were found between the onset groups in autism severity, intellectual function, or social, communicative, and adaptive outcomes. Similarly, no significant differences were found between the onset groups in any of the potential etiological factors examined, such as rate of seizures, MMR vaccination history, gastrointestinal symptoms, prenatal or neonatal risk factors, and family history (Heung, 2008). Similar findings of virtually no group differences between children with and without regression on a range of outcome measures have been reported by others (e.g., Hansen et al., 2008; Werner, Dawson, Munson, & Osterling, 2005). Hansen et al.'s investigation examined a large sample and had excellent statistical power to detect group differences, but nevertheless found very few. Thus, while some earlier studies suggested otherwise, large-scale investigations, some of which followed children for years after onset, indicate that regression histories are not necessarily associated with poorer developmental outcomes.

Potential Etiologies of Regression

The mechanisms underlying autistic regression (or for that matter, early onset autism) are unknown. Accelerated rates of head growth have been reported in several studies of young children with autism, suggesting that processes of synaptic growth and pruning may go awry and lead to autism. However, no differences in head circumference trajectories were found between children with signs of autism early in life and those with regression in one recent study (Webb et al., 2007); head growth was accelerated in both groups.

The possibility that seizures or other electrophysiological disruptions contribute to regression has also been suggested (Mantovani, 2000), in part due to the apparent reversibility of "autistic-like" features with anticonvulsant treatment found in a small subset of individuals with another regressive condition, Landau-Kleffner syndrome (Deonna, Ziegler, Maeder, Ansermet, & Roulet, 1995; Nass, Gross, Wisoff, & Devinsky, 1999; Neville et al., 1997). Kobayashi and Murata (1998) found epilepsy to be twice as frequent in children with a history of regression than in children without such a history

(31% versus 15%). Hoshino et al. (1987) also found a higher incidence of epileptic seizures and febrile convulsions in children who had experienced regression (23% versus 5%). However, this finding is not universal. Among their sample of children on the autism spectrum, Tuchman and Rapin (1997) found no difference in the frequency of reported epilepsy between children with autistic regression and those without (12% and 11%, respectively). Similarly, Shinnar et al. (2001) found that regression was actually more common in children with autism without seizures. Neither Hansen et al. (2008), Baird et al. (2008), or Heung (2008) found differences in rates of epilepsy between regression and no regression groups.

Past research has occasionally suggested that psychosocial stressors might trigger regression in a vulnerable child. Kurita (1985) found that events such as the birth of siblings, parental discord, and change of residence were occasionally reported just before the regression. Rutter (1985) noted, however, that the specific life events that have been associated with developmental regression are relatively minor and common to many children, questioning their causal association. Clearly, the majority of children who experience such stressors do not suffer from regression.

Immunizations

Wakefield et al. (1998) linked autism to MMR vaccination in their study of 12 autistic children with gastrointestinal (GI) symptoms such as chronic constipation, pain, bloating, and esophageal reflux. The GI symptoms reportedly began around the same time that the children's autistic symptoms appeared. Endoscopy revealed lymphonodular hyperplasia and macroscopic evidence of colitis. These findings led Wakefield and his colleagues to hypothesize that the children's regressive autism was induced by the MMR vaccinations through a series of events involving mucosal damage, increased permeability of the intestines, and gastrointestinal absorption of toxic neuropeptides, causing central nervous system dysfunction and behavioral regression (Hansen & Ozonoff, 2003).

Wakefield et al.'s (1998) paper was later retracted by 10 of the study's 13 authors (Murch et al., 2004), in part due to the paucity of epidemiological evidence supporting the theory (e.g., Dales, Hammer, & Smith, 2001; Farrington, Miller, & Taylor, 2001; Kaye, del Mar Melero-Montes, & Jick, 2001; Taylor et al., 2002; Uchiyama, Kurosawa, & Inaba, 2007). For example, Taylor et al. (1999) found no evidence of changes in incidence or age at diagnosis associated with the introduction of the MMR vaccine in the United Kingdom in 1988. A later study by this group (Taylor et al., 2002) compared three groups of children: (1) children who received the MMR vaccine before their parents became concerned about their development, (2) children who received the vaccine after such concern, and (3) children who had not received the vaccine at all. Findings showed no significant differences in incidence of regression between these three groups.

In addition to the lack of epidemiological evidence for MMR influence, there is also little support in the literature for

a specific regressive phenotype of autism that Wakefield (1998) termed "autistic enterocolitis." One large study found more GI symptoms in children with regression than those without regression (Richler et al., 2006), but this has not been reported in several other empirical studies. Fombonne and Chakrabarti (2001) analyzed one epidemiological sample and two clinical samples of children (total N = 262) and found no association between developmental regression and GI symptoms; only 2.1% of the samples experienced both problems, and this rate did not exceed chance expectations. In addition, this study compared children who were exposed to the MMR immunization with those who were not exposed and found no difference in the reported rates of regression between the two groups. These authors also found no evidence that children with regressive autism have symptom or severity profiles that are different from children with early onset autism (Fombonne & Chakrabarti, 2001). Similar lack of association between GI problems and regression has been reported by several other groups (Baird et al., 2008; Hansen et al., 2008; Heung, 2008; Taylor et al., 2002).

Concerns about MMR extended to other combinations of vaccines, to the increasing number of vaccines, and then to potentially toxic components of vaccines. One such component that attracted much attention was thimerosal, a mercury-containing preservative found in vaccines. James and colleagues (2004) found that, compared to controls, some children with autism have a severe deficiency of glutathione, which is required for heavy metal detoxification and excretion. Contrary to this hypothesis, however, increases (rather than decreases) in the incidence of autism following discontinuation of thimerosal-containing vaccines have been reported in Denmark (Madsen et al., 2003) and California (Schechter & Grether, 2008). Andrews et al. (2004) found no relationship between vaccine doses (and thus, levels of thimerosal exposure) and subsequent neurodevelopmental disorders including autism. Some have suggested that symptoms of autism are similar to those of mercury poisoning (e.g., Bernard et al., 2001; Blaxill, Redwood, & Bernard, 2004), but this was refuted by Nelson and Bauman (2003) who found no link between either the clinical manifestations or the neuropathology of autism and mercury poisoning. Thus, there is no direct support for the hypothesis that immunizations contribute to autism and/or developmental regression. Recently, research is focusing on whether certain medical conditions that can be associated with autism, such as mitochondrial disorders, may increase vulnerability to adverse effects of vaccines (Poling, 2006; Weissman et al., 2008).

Genetics

It has been suggested that autism with regression may represent a different genetic subtype. One study (Xi et al., 2007) examined a group of 31 boys with autism and speech loss for mutations in MeCP2, the gene that causes Rett syndrome, another condition involving developmental regression. Only one sequence variant was found, leading the authors to

conclude that mutations in the coding region of the MeCP2 gene are not common causes of regression in autism.

Both Schellenberg et al. (2006) and Molloy et al. (2005) conducted linkage analyses in large cohorts of siblings with autism and found different linkage signals for pairs with and without regression, suggesting a possible genetic susceptibility to the regressive form of onset. The association found by Molloy et al.'s group was not replicated in the International Molecular Genetic Study of Autism Consortium (IMGSAC) cohort of affected siblings (Parr et al., 2006), however. The methods of the two studies differed in that the Molloy et al. study examined only siblings concordant for regression (n = 34 pairs), while the IMGSAC study included all pairs in which at least one sibling had experienced language loss (n = 58), of which only 12 were concordant for regression. Therefore, these linkage findings require further investigation and replication. The low rate of concordance for regression (20.7%) in the IMGSAC sample is, in and of itself, an important finding, suggesting that the regression phenotype is likely to be etiologically heterogeneous and multifactorial.

The liability to autism includes not only the full autism syndrome but also qualitatively similar but milder deficits (e.g., shyness, intense interests, speech delays, or other communication difficulties). This subclinical set of social and language differences seen in nonautistic relatives of individuals with autism is called the broader autism phenotype (BAP) and is found in 12 to 50% of relatives of those with autism (Lainhart et al., 2002). The BAP is considered an index of genetic vulnerability to autism (Piven, 2001).

Lainhart et al. (2002) compared the BAP in relatives of children with early onset and regressive autism. In a sample of 88 children, they found that parents of children with and without regression showed similar rates of the BAP (27.8% versus 32.9%, p = 0.33). Both groups had significantly higher rates of the BAP when compared to parents of children without autism (3.6%; p ≤ 0.01). The authors argued that these findings suggest that environmental factors are unlikely to be the sole cause of regressive autism. That is, if regressive autism were caused solely by nongenetic factors, such as immunizations, one would instead expect to find similar rates of the BAP in relatives of children with regressive autism and the general population, both of which would be significantly lower than relatives of children with early onset autism (Lainhart et al., 2002).

Case Studies of Onset Types

We end this section with two case studies that illustrate the traditionally defined patterns of onset described so far in this chapter. These case descriptions were reconstructed from both parent responses on the Autism Diagnostic Interview–Revised (ADI-R; Lord et al., 1994; Rutter et al., 2003) and family videos collected as part of an IRB-approved home movie study (Ozonoff et al., 2008). Unique to these case studies, family home movies were systematically analyzed by coders unaware of the child's diagnosis or the purposes of the study, trained to

reliability on an objective coding system (Werner & Dawson, 2005). Coded data was divided into four developmental periods, each 4 months long. To account for differences in the amount of footage available in each period, raw duration and frequency scores were converted to proportion and rate scores, respectively. Means for each period were calculated and graphs of the developmental trajectories are presented in Figure 4-1. The rates of key social-communicative behaviors are thus objectively quantified during the window of development when autism symptoms emerge, illustrating the two prototypical patterns of onset described in this chapter. Informed consent was obtained from parents prior to participation in the research project, as well as prior to the writing of these descriptions (which use pseudonyms and disguise identifying characteristics).

Case 1: Isaac, Early Onset Autism

Isaac was the product of a full-term pregnancy with no reported complications. His medical history is unremarkable. He is the first child born to parents with no family history of autism. He has two younger sisters who are typically developing.

Birth to 5 months: On the ADI-R, Isaac's parents reported that they had concerns about his development "from birth, coming home from the hospital" and said that they had noticed "no eye contact around two weeks." Corroborating these reports, family home video taken at three months of age shows Isaac fixating on the ceiling fan while his grandfather attempts to engage him in a social game. Although his grandfather's face is animated and just a few inches away, Isaac never looks at him. By three months of age, his parents had already become concerned specifically about the possibility that their son had autism, although they had little experience or knowledge of the condition.

6 to 10 months: During this time, Isaac continued to ignore the social approaches of others and demonstrated multiple unusual visual and repetitive behaviors. At 10 months he is observed on video repetitively flipping and rolling a marker across the floor. Coding of home videos shows that Isaac rarely oriented to his name, vocalized, or smiled at others during this period. He also shows an elevated level of unusual visual behavior, such as prolonged staring at objects (see Figure 4-1).

11 to 15 months: In home video from this period, Isaac continues to be socially isolated. At 12 months, he can be observed on camera failing to respond to his mother's repeated attempts to engage him in a game of peek-a-boo. Instead, his attention remains focused on a large hairbrush that he is spinning on the tiled bathroom floor. At 11 months of age, his parents refer him to the first author for an autism diagnostic evaluation. He is diagnosed with Autistic Disorder at 13 months.

16 to 20 months: During this period, Isaac begins receiving intensive early behavioral intervention and speech therapy. Home video footage at this time shows Isaac repeatedly pushing a button on a musical toy and putting his face up close to the blinking lights that accompany the song. At 16 months, he fails to make eye contact or respond to his
Figure 4–1. Developmental trajectories of key behaviors coded from home video.

father's verbal prompts when they are looking through a picture book together.

21 to 24 months: Footage from just prior to his second birthday shows Isaac repetitively waving a flashlight on the

ceiling and examining it from the corner of his eyes. Coded data from this period show that he rarely responded to his name, smiled at others, or vocalized. He continued to meet full criteria for Autistic Disorder when retested as part of a research study at 24 months of age.

Case 2: Kyle, Autistic Regression

Kyle is the only child of parents with no family history of autism. He was born at full term; no complications were experienced during pregnancy, labor, or delivery. His medical history in the first year and a half of life revealed nothing significant. Onset of GI problems around 18 months of age was reported.

0 to 5 months: Parent report and observation of family home videos from this time period indicate that Kyle was socially well engaged, displaying frequent reciprocal smiles and babbling often. At 5 months, for example, he is seen on video playing peek-a-boo with his mother, laughing, and babbling reciprocally to continue the game.

6 to 10 months: Kyle continues to demonstrate high rates of warm positive affect, eye contact, and vocalizations throughout this period (see Figure 4-1). At 9 months he is observed on video imitating his mother blowing raspberries, laughing, and taking turns in this social game.

11 to 15 months: Both by parent report and as observed on home video, Kyle's behavior becomes more variable, particularly toward the end of this period. Home video at 11 months captures several word approximations ("nye-nye," "hi," "yeah"), bright smiles toward others, and immediate orientation when his name is called. Between 13 and 15 months he begins to appear more interested in objects than people, displays less positive affect, and demonstrates a few repetitive behaviors, but these concerning behaviors are interspersed with some typical social interactions, moments of excellent eye contact, and clearly directed smiles on home video. For example, at 13 months Kyle is filmed pushing plastic balls around the edge of a table as he circles it multiple times. Although his mother is sitting a few feet away, he does not approach her or look in her direction, even when accidentally backing into her, but later turns to his father, who is filming, and gives a broad smile. Similarly, at 15 months, Kyle is seen running back and forth across the living room, flapping his hands and sporadically squealing in a high-pitched manner as he approaches people and smiles. Kyle's parents reported on the ADI-R that they began to have concerns about Kyle's development at 15 months, when he "lost interaction and connectedness and began to withdraw socially."

16 to 20 months: During this period, Kyle's symptoms become much more pronounced on video and by parent report. At 20 months he is observed making repeated stereotyped vocalizations and failing to orient to his mother, who is just a few feet away. While playing outside, he is seen flapping his hands and sifting repetitively through a pile of rocks.

He ignores others when they call or approach him. No word-like vocalizations are coded on video.

21 to 24 months: Home movies taken just before his second birthday show Kyle playing with a string of beads, repeatedly setting them on the edge of a table and closely watching as they slide over the side. He does not respond to the social overtures of others in any video clips. Kyle was diagnosed with Autistic Disorder at 27 months of age.

Problems with Traditional Views of Onset

Despite the prototypicality of these two case descriptions, as well as the progress that has been made in the last half century in describing the regression phenotype, a number of difficulties with traditionally held views about onset have become evident with time. One problem is that definitions of regression and methods of describing onset differ across studies and newer research has shown that results can be quite influenced by these measurement differences. A second issue is that recent research has not always upheld previous views or clinical intuitions about the central features of and differences between onset types. Finally, prospective studies provide new data that do not fully support the findings of onset investigations that used retrospective methods (parent recall or home video analysis). Therefore, we may need to revise current conceptualizations of how the symptoms of autism emerge in the first years of life. It is to these topics that we move in the following sections.

Definition and Measurement Issues

Until relatively recently, when prospective studies that follow children from infancy through the window of autism susceptibility have been conducted, the only methodologies to investigate the early autism phenotype and onset patterns were retrospective. One method is the analysis of home movies of children later diagnosed with autism spectrum disorders. While this reduces potential reporting biases of parent interviews, home movie methodology suffers from several biases (Palomo et al., 2006). There is tremendous variability across families in the amount, content, and quality of footage of early development that is captured on video. Many families do not tape their children early in life, so home movie studies are not representative of all children with autism. Many families turn off video cameras when children are not behaving as expected or in a positive manner. Finally, home movie analysis is a very time-intensive method of collecting information about early development that is not practical for routine research use. Thus, most studies of the early autism phenotype (and clinical practice) have employed parent report, a more efficient method of collecting early history. However, parent report can be biased by knowledge of the child's eventual diagnosis, poor recall, or lack of sensitivity to developmental differences. Retrospective reports are subject to problems of memory and interpretation (Finney, 1981; Robbins, 1963) and need to

be used with caution when examining hypotheses that demand precision in estimating event dates and frequencies (Henry, Moffitt, Caspi, Langley, & Silva, 1994). When people are asked to recall particular episodes, they often report them as having occurred more recently than they did, an error called "forward telescoping" (Loftus & Marburger, 1983). This phenomenon has been described specifically in investigations using parent report to study autism onset (Lord et al., 2004). Thus, it is critical to understand the degree of accuracy in parent reports of regression, particularly since other methods (e.g., video analysis) are labor intensive and require expert training.

One widely used instrument that collects detailed parent recollections of early development is the ADI-R, a "gold standard" research interview used in diagnosis (Lord et al., 1994; Rutter et al., 2003). This instrument has a section of 18 questions that collect detailed information about potential losses, including specific skills lost, duration of losses, and potential factors associated with the losses. It first asks about language losses (question 11, "Were you ever concerned that [your child] might have lost language skills during the first years of life?"). If the parent responds in the affirmative, the interviewer then probes for the number of words lost, how they were used prior to the loss, the duration of establishment of the skill, and the duration of loss of the skill. To meet ADI-R criteria for loss of language, at least five words must have been used spontaneously, meaningfully, and communicatively for at least three months before being lost for at least three months. If there are losses indicated by the parent that do not meet these criteria (e.g., words lost that fail to meet the quantity or duration criteria or other communicative losses, like loss of babbling or gesture use), they can be recorded on the form, but the child does not meet ADI-R criteria for word loss. There is no consensus in the field yet as to how to handle parent-reported losses that are subthreshold. Parents can give very convincing descriptions of 4 word losses or of losses of 5+ words that had not consistently been in the child's vocabulary for the three months required to meet ADI-R criteria. In most studies, these children would not be included in a language regression group.

A later ADI-R item asks parents about losses in other domains (question 20, "Has there ever been a period when [your child] seemed to get markedly worse or dropped further behind in his/her development?"). If the parent indicates yes, then possible losses in motor, self-help, play, and social abilities are probed, in that order. If the parent does not endorse other losses, no querying is done nor examples given. This may lead to underendorsement of losses, particularly in the social domain. In our experience, parents do not as readily regard social behaviors as acquired skills or specific developmental achievements that can be lost. However, when examples are provided, such as asking whether the child got markedly worse in their eye contact or lost interest in interacting with them, parents occasionally recognize this pattern and change their report.

The vast majority of children losing language also lose behaviors indicative of social interest and engagement, such as

direct gaze and response to name (Goldberg et al., 2003; Lord, Shulman, & DiLavore, 2004; Ozonoff et al., 2005), but the converse is not always true. Some children show marked changes only in social development and do not lose spoken language. While it is very uncommon for children to retain acquired speech when experiencing a clear loss of social interest and engagement, many children have not acquired language at the time of the regression and therefore have no language to lose (Goldberg et al., 2003; Kurita, 1985; Ozonoff et al., 2005). Hansen et al. (2008) found that only 18% of a large (n = 138) sample of children with regression lost language skills alone, while 46% exhibited social losses alone, and 36% had losses in both language and social behaviors. Goldberg et al. (2003) found similar rates in a smaller sample, with language losses reported to occur about 2 months after losses of direct gaze, orientation to name, and social exchanges.

There is debate about whether definitions of regression should require loss of language and how children who only lose social milestones should be classified. Early studies tended to characterize regression as speech loss (Brown & Prelock, 1995; Kurita, 1985; Rogers & DiLalla, 1990) without including loss of social milestones as part of the criteria. Requiring the loss of language excludes from the regression group children who only experience social losses without substantial language loss. In many studies, such children were placed into the no-regression or early onset group (Kurita, 1985; Lainhart et al., 2002). However, recent studies suggest that there are very few differences between children who lose both words and social skills and those who experience losses in social milestones alone (Lord et al., 2004; Luyster et al., 2005). In a multisite study of children with ASD, Luyster et al. (2005) compared 125 children with word loss to 38 children with nonword loss (regression in areas other than language). They found no differences between the two regression groups. Children with word loss and nonword loss regression lost the same skills, including prespeech behaviors, games, and routines, and phrase comprehension, with almost exactly the same frequency (Luyster et al., 2005). Therefore, more recent studies have expanded definitions of regression to include losses in domains other than language (Davidovitch et al., 2000; Fombonne & Chakrabarti, 2001; Kobayashi & Murata, 1998).

Not surprisingly, the prevalence of regression is dependent on the definitions used. When a narrower definition that required language loss was used, only 15% of a large epidemiological sample of children with ASD met criteria for regression, whereas when losses in either language or social behaviors was used to classify onset patterns, 41% were found to have experienced losses (Hansen et al., 2008). Thus, requiring loss of language appears to significantly underestimate the frequency of developmental regression.

There is one published study that reports the test-retest reliability of parent report of regression. Richler et al. (2006) reported data from the multisite Collaborative Programs of Excellence in Autism (CPEA) sample (n = 351). The ADI-R was used initially to determine study eligibility and then later a detailed interview about regression was conducted by telephone. The time lag between administration of these two instruments was not specified in the study, but ranged from several months to several years. Conflicting information about word loss on the ADI-R and regression interview was apparent for 18.9% of the sample, with 12.3% reporting no loss on the ADI-R, but loss on the phone interview and 6.6% demonstrating the opposite pattern.

In unpublished data from our lab, we administered the same instrument (ADI-R) on two occasions, an average of 2 years apart. Four of 34 parents (11.8%) reported conflicting information on the ADI-R at times 1 and 2, with two feeling that their child had not regressed when asked at a mean age of 34.4 months but reporting a definite regression when asked again at a mean age of 57.4 months, and two displaying the opposite pattern (regression reported at time 1 but denied at time 2). This study also examined concurrent reliability of report of regression using two different parent report instruments. We used both the ADI-R and the Early Development Questionnaire (EDQ), a measure that asks 45 questions about social and communication development in the first 18 months of life, as well as 25 detailed questions about regression. We found that 7 of 40 parents of children with autism (17.5%) gave inconsistent information about regression across the two measures. In all cases, report on the ADI-R indicated no losses (either definite reports of no regression, 7.5%, or losses that fell short of the criteria, 10%), while report on the EDQ suggested some regression. Similarly, another investigation conducted at the M.I.N.D. Institute, the Childhood Autism Risk from Genetics and Environment (CHARGE) study (Hansen et al., 2008), found that 23 of 245 parents (9.4%) from a largely independent sample gave inconsistent information about regression on these two measures.

When reports of onset are inconsistent, it is quite difficult to determine which is accurate. Two home movie studies (Goldberg, Thorsen, Osann, & Spence, 2008; Werner & Dawson, 2005) have compared parent report with videotape footage and shown that parent report is generally valid, but poorer for reports of social than word loss and for reports of regression than no regression. Specifically, the Goldberg et al. study found 85% concordance between parental reports and independent video coders' ratings of loss or no loss of spoken language, but only 49% concordance between parent and home video coders' reports of social losses. Parents were more consistent when reporting no loss than when reporting loss across both language and social domains (Goldberg et al., 2008). Thus, neither parent report nor home video analysis can be considered a gold standard method of documenting whether a child displayed early signs of autism or experienced a regression in skills and the respective limitations of each method need to be recognized by researchers.

As we end this section, we provide a few recommendations that may improve the quality of future data acquisition using parent report, the more feasible of the retrospective methods currently in use. First, interviewers need to be well trained to ask questions fully (with appropriate probes) without being too leading. They should realize that parents not only may

have difficulty recalling specific behaviors and their exact timing, but also may not define or conceptualize behaviors in the same way as interviewers. Examples and queries are permitted on the ADI-R, a semistructured interview that encourages examiners to ask additional questions until they are certain that the parents have understood the behavior being measured and have given a valid response. Parents often do not ask for clarification of questions and it is the interviewer's job to anticipate when this is necessary. Parents may misinterpret failures to progress as regression and this is an additional difficulty that examiners need to be aware of during their queries. It is not uncommon for an initial positive response to questions about regression to change to a negative report of losses after further probing, when it becomes clear that although the child failed to gain anticipated new skills, he did not experience any actual losses of acquired skills. This kind of querying needs to be balanced by the recognition that subtle losses of skills are indeed possible.

Evidence for Other Patterns of Loss

A second problem with current definitions of onset is that dichotomous categorical conceptualizations do not capture all the different ways that autism can emerge. The traditional view of regression has been that development is typical prior to the loss of skills. For example, Rogers and DiLalla (1990) reported that parents of children with later onset autism "were emphatic about the normalcy of their children's behavior in the first year of life. The onset of their children's symptoms began with a change in or a loss of the child's previous apparently normal social behavior" (p. 866). Data from recent studies, however, have raised doubt regarding the universality of typical development prior to regression. Ozonoff et al. (2005) identified a subset of children who presented abnormalities prior to regression. Of 31 children with regression, 45% were reported by parents to have displayed social and communication delays prior to the onset of the losses. This subset of children were reported by their parents to have never displayed several typical early-developing social behaviors, such as joint attention, showing, and social games (Ozonoff et al., 2005). Kurita (1985) also described a subset of children who showed signs of abnormalities prior to regression. Of the 97 autistic children with speech loss in his study, 78.3% showed some developmental abnormalities before the onset of the speech loss, including lack of stranger anxiety and limited social responsiveness (Kurita, 1985). Goldberg et al. (2003) reported that over two thirds of their sample with regression were already delayed in their language acquisition prior to the loss of skills. Similarly, Heung (2008) found that two thirds of subjects with regression had some indication of delayed language or social development prior to the onset of their regression. These studies and others (Meilleur & Fombonne, 2009; Richler et al., 2006; Wiggins et al., 2009) suggest that mixed onset features, with evidence of both early delays and later losses, are quite common.

Further evidence that traditional onset classifications are insufficient comes from the CHARGE study, a large epidemiological investigation of genetic and environmental risks for autism. Using an independent measure of regression, the EDQ (described above), Hansen and colleagues (2008) demonstrated that even children whose parents reported no evidence of regression on the ADI-R occasionally reported subtle losses of specific skills on the EDQ. Figure 4-2 displays the distribution of scores on the EDQ as a function of onset subtype. This finding is consistent with another report that some children whose parents reported no losses indicative of regression on the ADI-R nevertheless demonstrated subtle loss of skills on home video (Werner & Dawson, 2005).

Some parents report neither early signs of autism nor later regression. For example, in one sample, less than a third of parents of children who did not experience a regression reported concerns before the first birthday and, in fewer than half, were these concerns specifically social or autistic-like in nature (De Giacomo & Fombonne, 1998). In another sample, approximately one third of parents identified only nonspecific temperament or physiological patterns (e.g., irritability, passivity, eating or sleeping problems) before the first birthday "which evolved into typical autistic features like stereotypical behavior, aloneness, and a lack of eye contact in the second year of life" (Rogers & DiLalla, 1990, p. 866). In our own data, we have found that many parents who do not report a regression also report several intact early social behaviors. For example, 35% stated that their child often looked at others during social interactions in the first 18 months of life, 50% smiled back when others smiled at them, and 28% enjoyed interactive games such as peek-a-boo (Ozonoff et al., 2005).

Collectively, these findings suggest that there is an additional pattern of symptom emergence that is characterized by intact early social development and/or nonspecific abnormalities that are followed by a failure to progress and gain new skills as expected. It has been hypothesized that this pattern may be due to failures to use intact early dyadic social reciprocity skills to support the typical maturational processes of speech acquisition, intentional communication, and triadic
Figure 4–2. Number of skills lost in children with and without regression. Data from Hansen, R. L., Ozonoff, S., Krakowiak, P., Angkustsiri, K., Jones, C., Deprey, L. J., et al. (2008). Regression in autism: Prevalence and associated factors in the CHARGE study. *Ambulatory Pediatrics, 8*(1), 25–31.

social interactions (Chawarska et al., 2007). In such cases, the intact early behaviors fade away because they are not reinforced by the natural predisposition to seek and communicate with others. What might seem like a loss of skills is simply a failure to progress and transform the basic skills into their more developmentally advanced versions. Klin et al. (2004) used the term "pseudo-regression" to describe this pattern and it has also been referred to as "developmental stagnation" (Siperstein & Volkmar, 2004) and "developmental plateau" (Hansen et al., 2008; Kalb, Law, Landa, & Law, 2010). Little empirical research has been conducted on this pattern, and little is known about whether it differs from other onset patterns in phenotypic features unrelated to symptom emergence. A recent study suggests that the plateau onset pattern may be associated with better adaptive outcomes (Jones & Campbell, 2010).

Data from two large population-based studies at the M.I.N.D. Institute reinforce the notion of additional onset patterns beyond the traditionally defined categories. Byrd et al. (2002) recruited a random sample of children with autism from California's Regional Centers, which provide services for persons with developmental disabilities. Two cohorts were studied, one born in 1983–1985 and the other in 1993–1995. The CHARGE study, described above, is a large epidemiological sample also recruited from the Regional Center system, with the birth cohort extending from 1998 to 2004. The ADI-R was employed in both studies. Not only does it ask about regression, as described above, but also it asks about "onset as perceived with hindsight" (Question 4). Examining the intersection of these questions is informative to onset typology. Traditional definitions of onset suggest that most or all children without regression displayed symptoms early in life, while most or all with regression had typical early development. Thus, there should be very few, if any, subjects in the shaded diagonals of Tables 4-1 and 4-2. As is evident, however, almost half of both samples fell in these cells.

In summary, recent research suggests that there may be several different patterns of symptom emergence. Whether these are best characterized as additional onset types or conceptualized in some other way is not yet clear. We will return to this topic after finishing this section with insights from recent prospective studies of autism onset.

Onset as Measured in Prospective Investigations

Prospective investigations are a very helpful method of studying onset, because they reduce errors due to parental recall and biases introduced by selective home videotaping, as well as provide the opportunity to test specific hypotheses through experimental methods. In the past decade, several research groups have instigated prospective investigations that study children at higher risk for autism because they have one or more siblings with the condition. Several infant sibling studies have now been published and thus far all have failed to find differences before the first birthday (at 4, 6, and 9 month visits of

Table 4–1.
Data from Byrd et al., 2002

| | Loss of Skills (ADI-R Q 11 or 25) | |
	No	Yes
Symptoms before 1st birthday (ADI-R Q 4)	Early Onset N = 82 28.7%	Mixed N = 34 11.9%
Symptoms after 1st birthday (ADI-R Q 4)	Plateau N = 96 33.6%	Regression N = 74 25.9%

the respective studies) between children who are later diagnosed with autism and those who develop typically (Landa & Garrett-Mayer, 2006; Nadig et al., 2007; Zwaigenbaum et al., 2005; see also Yirmiya & Ozonoff, 2007 for a summary of this work). Bryson and colleagues (2007), in a consecutive case series of infant siblings followed prospectively from 6 months of age, describe several children whose symptoms are not present at their 6 and 12 month visits, but emerge slowly during the second year of life. Not a single child who developed autism (n = 9) displayed marked limitations in social reciprocity at 6 months. All nine infants were described as interested in social interactions, responsive to others, demonstrating sustained eye contact and social smiles. Most of the children did not experience an explicit loss of previously acquired skills that would meet established definitions of regression either. Two prospective case studies (Dawson et al., 2000; Klin et al., 2004) report on children who were noted to be symptomatic by the first birthday, but who presented with mostly intact social behavior at 6 months and did not experience a clear regression as symptoms began to emerge.

Table 4–2.
Data from Hansen et al., 2008

| | Loss of Skills (ADI-R Q 11 or 25) | |
	No	Yes
Symptoms before 1st birthday (ADI-R Q 4)	Early Onset N = 123 35%	Mixed N = 58 17%
Symptoms after 1st birthday (ADI-R Q 4)	Plateau N = 94 27%	Regression N = 76 22%

Notes: n = 351. Hansen, R. L., Ozonoff, S., Krakowiak, P., Angkustsiri, K., Jones, C., Deprey, L. J., et al. (2008). Regression in autism: Prevalence and associated factors in the CHARGE study. *Ambulatory Pediatrics, 8*(1), 25–31.

Data from the UC Davis Infant Sibling study (Ozonoff et al., 2010) are consistent with this published research. We followed 90 infants with older siblings with autism from birth through age 3. At each visit, they were administered the Mullen Scales of Early Learning, among other measures, and parents completed detailed questionnaires eliciting concerns about development and presence of autism symptoms. After each visit, the examiner made summary ratings of the infant's eye contact, social reciprocity, spontaneous engagement, initiatives, shared affect, and vocalizations. Interactions between the examiner and infant were also recorded and coded later by research staff unaware of the infant's group membership or outcome. The first 13 infants to be diagnosed with autism are included in Table 4-3, which depicts a reconstruction of the onset of developmental concerns and autism symptoms in these children.

Data used to rate onset of concerns included, at all ages, Mullen scores, parent concerns elicited at the end of each session, and examiner summary ratings of social engagement. At 18 months and up, scores on the Autism Diagnostic Observation Schedule (Lord et al., 2000), Social Communication Questionnaire (Rutter et al., 2003), and Modified-Checklist for Autism in Toddlers (Robins et al., 2001) were used as well. Table 4-3 demonstrates the rarity of children with developmental concerns at 6 months and the gradual emergence of concerns over time. Four of the five infants seen at 6 months were in the average range on all developmental tests, had no concerns raised by parents, and were rated as typical in social engagement by experienced examiners unaware of group status. The fifth infant (Child 5 in Table 4-3) scored low on motor testing, and both parents and examiners expressed concern about motor development, but social, communicative, and cognitive development were all in the average range. At 12 months, concerns had been raised about 5 of 11 children seen at this age, but over half the group continued to present relatively normally to both examiners and parents and to score in the average range on standardized testing. By 18 months, however, concerns had been raised about all children with eventual autism/ASD outcomes and 3 were formally diagnosed.

On the ADI-R, none of these 13 children was rated as having significant regression in development by their parents. Two parents noted loss of individual skills: loss of eye contact between 12 and 18 months in Child 6 and loss of gestures and language comprehension between 18 and 24 months in Child 11. Concerns had already been raised about the development of both children prior to these losses (see Table 4-3). No parents reported that their child had acquired and then lost language.

The scarcity of children with symptoms before 12 months, combined with the lack of parent-reported regression, was initially unexpected but is consistent with the results of retrospective studies reported in the previous section. To further examine the validity of this phenomenon, we used growth curve analyses to examine developmental trajectories of examiner summary ratings of social engagement. Analyses revealed a significant group by time effect ($F_{3, 49.38} = 9.71$, $p < .001$). As seen in Figure 4-3, the interaction effect was due to a significant decline in social engagement over time in the autism/ASD group. Post hoc tests revealed no group differences at 6 months. At 12 months, the autism/ASD group scored significantly lower than a group with no family history of autism (Low-Risk Typical group; Beta = .604, $t = 2.44$, $p < .05$).

Table 4–3.
Onset of concerns and age of diagnosis in infants with autism/ASD outcomes

Child	6 Months	12 Months	18 Months	24 Months	36 Months
1	No concerns	No concerns	Concerns	Diagnosed	Diagnosed
2	No concerns	No concerns	Concerns	Diagnosed	Diagnosed
3	No concerns	Concerns	Concerns	Diagnosed	Diagnosed
4	No concerns	Concerns	Diagnosed	Diagnosed	Diagnosed
5	Concerns	Concerns	Diagnosed	Diagnosed	Diagnosed
6		Concerns	Concerns	Concerns	Diagnosed
7		Concerns	Diagnosed	Diagnosed	Diagnosed
8		No concerns	Concerns	Concerns	Diagnosed
9		No concerns	Concerns	Concerns	Diagnosed
10		No concerns	Concerns	Diagnosed	Diagnosed
11		No concerns	Concerns	Concerns	Diagnosed
12			Concerns	Diagnosed	Diagnosed
13			Concerns	Concerns	Diagnosed

Notes: Data from the UC Davis Infant Sibling Study (Ozonoff et al., 2010). Blank entries indicate the child was not seen at that visit.
Figure 4–3. Developmental trajectories of social engagement ratings.

Figure 4–4. Frequency of eye contact with the examiner coded during the session.

By 24 months and later, the autism/ASD group had significantly lower scores than a Speech Delay group, a group with a positive family history of autism but who was developing typically (High Risk Typical group), and the Low Risk Typical group (Beta = .814, t = 3.22, p < .01). Coded data of the frequency of eye contact, vocalizations, and shared affect during the lab visit were highly consistent with the picture revealed by the examiner summary ratings, indicating again intact skills during the first year of life, followed by diminishing rates of social and communicative behaviors over time. See Figure 4-4. Similar declining trajectories in the onset of autism in infant siblings have also been reported by other research teams (Dawson, Munson, Webb, Nalty, Abbott, & Toth, 2007; Landa, Holman, & Garrett-Mayer, 2007).

Thus, infant sibling studies are consistent with retrospective studies in finding that for many, perhaps most, children with autism symptoms emerge gradually over the first 18 months or so of life.

Summary

The research literature reviewed in this chapter suggests that onset of autism is a gradual process that involves both diminishment of certain key social behaviors and failure to progress in other more advanced social-communicative processes over time. Autism appears to *emerge* over the first year and a half of life and is not present in most cases from shortly after birth, as once suggested by Kanner (1943).

Data from both retrospective and prospective studies are consistent in finding that two-category onset classification systems do not fit the empirical data well. There is evidence that the traditionally defined categories of early onset and regressive autism are overly narrow prototypes that may not in fact be very common. There is ample evidence of other ways in which symptoms emerge that are not captured by these prototypes. One possibility is that we need to expand the number of categories used to describe onset. For example, perhaps there are four rather than two categories of onset, adding a plateau and a mixed group. We suggest another possibility, however. We hypothesize that symptom emergence may better be considered as a continuum. The two extremes of this continuum are anchored by the traditionally defined, prototypical early onset and regressive cases, such as those of Isaac and Kyle described above, but many intermediate phenotypes containing mixed features and varying degrees of early deficits, subtle diminishments, failures to progress, and frank losses are also possible. We propose that variable combinations and timings of these processes across children lead to symptoms exceeding the threshold for diagnosis at different points in the first 24 months for different children, as also suggested by Landa et al. (2007).

A second insight from the body of research summarized in this chapter is that regression may be much more common than initially thought. If defined narrowly, in the traditional manner (requiring loss of language, as in the ADI-R criteria), regression is relatively rare. If defined more broadly, to include diminishment in social engagement, regression may be the rule rather than the exception. However, losses are subtle, are usually preceded by some early concerns, and are followed by failures to progress in other areas, rather than characterized by typical development followed by catastrophic losses, as traditionally defined. Others have suggested that many, even most, children with autism undergo some regression during the course of symptom onset (Dawson et al., 2007). Along these lines, we propose that symptom emergence may better be conceptualized as a continuum characterized by the amount and timing of regression. In this conceptualization, at one end of the continuum lie children who display loss of social interest so early that the regression is difficult to see and symptoms

appear to have always been present. At the other end of the continuum lie children who experience losses of social interest and communication skills so late that the regression appears quite dramatic.

Conclusions

Thus, it is clear that existing definitions of onset patterns will need to undergo further development as new data emerges from future studies. Investigations using prospective samples may be especially fruitful because they will be less affected by potential videotaping, reporting, and recall biases inherent in retrospective studies. Further research clarifying whether onset is better conceptualized categorically (dichotomously) or dimensionally is urgently needed for etiologic studies, which have been hindered already by the tremendous heterogeneity of the autism phenotype. Finally, future research should strive to find early processing or biological markers that may predict who will develop autism prior to the onset of behavioral symptoms. It is possible that infants who are behaviorally asymptomatic at 6 and 12 months may show differences in lower-level underlying processes that can impact later development. For example, differences in visual attention, such as prolonged visual fixations (Landry & Bryson, 2004), might lead to joint attention deficits or behavioral rigidity a few months later. Deficits in the dorsal stream visual pathway, which is specialized for quick processing of global, low spatial-frequency information, could create a cascade of functional differences in brain regions downstream. Recently, McCleery et al. (2007) found high luminance contrast sensitivity in a subgroup of younger siblings of children with autism on a task measuring the integrity of the magnocellular visual pathway (part of the dorsal stream). Two of the infants developed autism, leading the authors to speculate that early abnormalities in the magnocellular pathway might be a risk marker for autism. Thus, research on lower level processes that may signal an affected child prior to the onset of behavioral signs could permit interventions to be applied that might significantly lessen disability or perhaps even prevent the disorder from developing.

Finally, this body of work has clinical implications for screening, diagnosis, and intervention. Universal screening has been recommended by the American Academy of Pediatrics at 18 and 24 months (Johnson et al., 2007), but many have hoped that identification even earlier than this might be possible. The research reviewed here suggests that identification of autism prior to the first birthday will be a major challenge and may not possible in many children. In fact, for the large group of infants whose autism emerges through diminishment in skills, they may be showing few or no behavioral signs of the disorder at the first birthday. Therefore, screening twice, at both 18 and 24 months, is essential, as many children will be missed at the earlier time point. Given the gradual and protracted course of symptom emergence, we urge professionals to consider referring children for

intervention at the point that there is a suspicion of autism and not wait for a definitive diagnosis. Finally, development of treatments appropriate for infants and young toddlers is an urgent priority.

Challenges and Future Directions

- Studies of larger, community-ascertained samples at high risk for autism must be conducted, ideally with enrollment during pregnancy or shortly after birth, prior to the emergence of developmental concerns that may bias subject inclusion and study results
- Identification of risk markers prior to the onset of behavioral signs of autism
- Development of diagnostic criteria appropriate for infants and toddlers
- Development of screening guidelines that incorporate results of recent research on infants at risk for autism
- Development of treatments appropriate for infants and toddlers

Screening, Risk, and Early Identification of Autism Spectrum Disorders

⁙

Points of Interest

- Retrospective studies and prospective studies of high-risk infants indicate that ASD symptoms are often apparent by 12 months of age, and include atypicalities in social and communication development, play interests, and regulation of attention, emotions, and functions essential to physical well-being, such as eating and sleeping.
- Recent screening data suggest that both the Modified–Checklist for Autism in Toddlers (M-CHAT) and the Infant Toddler Checklist (ITC) have the potential to efficiently identify very young children with ASD, including some that may not be flagged by parental concerns or surveillance by community physicians.
- Future evaluation of ASD screening should adopt a broader health systems perspective in order to more fully gauge the potential impacts of screening, and to gain further support among health care providers and policy-makers.

⁙

Introduction

The clinical heterogeneity and varying patterns of onset of the autism spectrum disorders (ASD) as discussed by Lord, and by Ozonoff in this volume, highlight the complex challenges associated with developing a comprehensive early detection strategy. However, it is essential to develop effective approaches to identify and diagnose children with ASD early in life. ASD is one of the most prevalent forms of developmental disability, occurring in approximately 1 in 150 children (Bertrand et al., 2001; Chakrabarti & Fombonne, 2001; Yeargin-Allsopp et al., 2003; Fombonne, Zakarian, Bennett, Meng, & McLean-Heywood, 2006; Scott, Baron-Cohen, Bolton, & Brayne, 2002;

see Fombonne in this volume for a detailed review). Earlier diagnosis creates opportunities for children with ASD to benefit more fully from intervention (e.g., Harris & Handleman, 2000). Gains through early intervention can reduce the burden-of-suffering and enhance the quality of life for affected children and their families, and may ultimately reduce the considerable family and societal costs related to ASD across the lifespan (Jacobson & Mulick, 2000; Jarbrink & Knapp, 2001). Earlier diagnosis also allows parents to be better informed about recurrence risk to later-born children, and better able to monitor for early signs of autism (Zwaigenbaum et al., 2005) and other related concerns (Bailey, Palferman, Heavey, & Le, 1998; Dawson et al., 2002). Overall, the frequency, burden of suffering, long-term cumulative costs, and efficacy of early intervention provide a strong rationale for efforts aimed at earlier identification and diagnosis of ASD.

There is considerable evidence to suggest that autism and other ASDs could be diagnosed at an earlier age than is the current norm. Although there are published reports of ASD diagnoses being established as early as 14–15 months (Chawarska, Klin, Paul, & Volkmar, 2007; Landa, Holman, & Garrett-Mayer, 2007), a recent report by the Centers for Disease Control and Prevention (Autism and Developmental Disabilities Monitoring Network, 2007) indicated that the median age of ASD diagnosis across 14 U.S. states ranged from 49 to 66 months. Howlin and Moore in their survey of 1300 families in the UK, found that these parents typically became concerned around 18 months of age, and sought out medical attention by age 2 (Howlin & Moore, 1997). Often parents were offered reassurances without recognition of the seriousness of their concerns, followed eventually by a referral for a more specialized assessment, and then, further delays: many children were seen by at least 3 different consultants before receiving a diagnosis of autism. The experience of parents in North America has been similar (Mandell, Novak, & Zubritsky, 2005; Siegel, Pliner, Eschler, & Elliott, 1988). Studies in both the UK and North America have suggested that the delays in

diagnosis experienced by families of children with Asperger's syndrome are more extreme (Howlin & Asgharian, 1999; Mandell et al., 2005). Consistent with the survey by Howlin and Moore (Howlin & Moore, 1997), several studies have found that 80–90% of parents of children with ASD recall developmental concerns dating back to the first two years of life (De Giacomo A. & Fombonne, 1998; Ohta, Nagai, Hara, & Sasaki, 1987; Rogers & DiLalla, 1990; Gillberg et al., 1990). Analyses of home videos also demonstrate that many children with autism show signs of impairment long before they are diagnosed (Adrien et al., 1992; Osterling & Dawson, 1994; Osterling, Dawson, & Munson, 2002; Werner, Dawson, Osterling, & Dinno, 2000). Prospective studies of high-risk infants ascertained by a positive family history (older sibling with ASD; discussed in detail below) have also identified behavioral profiles specific to ASD as early as 12–18 months (Zwaigenbaum et al., 2005; Landa et al., 2007; Brian et al., 2008). Clearly, there are opportunities to accelerate the process that occurs between the initial emergence of ASD symptoms and confirmation of diagnosis. Fortunately, there have been advances in the development of measures and service models aimed at early detection of ASD that could facilitate earlier diagnosis, lessen the burden on families, and improve opportunities for children to benefit from intervention.

To highlight advances in early identification of ASD and priorities for future research, this chapter will focus on current knowledge about early signs, strengths and limitations of current screening options, and implications for early diagnosis.

Early Signs of ASD

ASD screening measures draw heavily from the literature on parents' retrospective descriptions of early concerns, as well as data from analyses of early home videos. Concerns involving delayed speech and language development (and/or lack of responsiveness, e.g., when the child's name is called) are among the most common (De Giacomo & Fombonne, 1998; Coonrod & Stone, 2004). Other recollections include atypical reactivity (from passive and underreactive to irritable and difficult to console, with features of both extremes in some children) and disruption in the social-communicative, play, sensory, and motor domains of development (Hoshino et al., 1987; Tuchman & Rapin, 1997). Concerns may also be expressed about medical or regulatory functions such as sleeping and eating (Young, Brewer, & Pattison, 2003). In 20–50% of children with ASD, parents retrospectively describe a pattern of regression involving loss of speech and/or social-emotional connectedness during the second year of life, most often around 18 months of age (see Chapter 4 in this volume for a detailed review) (Young et al., 2003; Baranek, 1999; Adrien et al., 1991; Dawson et al., 2004; Rutter & Lord, 1987). Analysis of early home videos also suggests that many children later diagnosed with ASD show signs of atypical development

by their first birthday or shortly afterward (Gray & Tonge, 2001). Social-communicative findings from home videos include atypical patterns of social orienting, joint attention (i.e., sharing attention with others), imitation, and affect regulation, as well as reduced use of gestures (Osterling & Dawson, 1994; Maestro et al., 2001; Maestro et al., 2002; Volkmar, Chawarska, & Klin, 2005; Yirmiya, Gamliel, Shaked, & Sigman, 2007). Infants later diagnosed with ASD show decreased variety and appropriateness of object-oriented play compared to infants later diagnosed with mental retardation (Baranek et al., 2005).

Emerging data from prospective studies of infants with an older sibling with ASD also show that behavioral risk indicators can be identified early in life (Zwaigenbaum et al., 2007). These "infant siblings" have an increased risk of developing ASD, estimated at 5–8% (Ritvo et al., 1989; Sumi, Taniai, Miyachi, & Tanemura, 2006), or roughly 20-fold higher than the risk in the general population (Rice et al., 2007). Complementing this approach is research aimed at identifying features that differentiate ASDs from other developmental disorders and from typical development among 12- to 24-month-olds who have failed a screen for communication deficits (Wetherby et al., 2004; Wetherby, Watt, Morgan, & Shumway, 2007). In both types of studies, participants are assessed systematically early in development, and then evaluated for ASD at 24–36 months, when reliable diagnoses are more possible. To date, findings from prospective research are highly consistent with risk markers identified in retrospective studies. Impairments and/or delays associated with ASD are observed by 12–18 months in one or more of the following domains: (1) *Social-communication*: atypicalities in eye gaze, orienting to name, social smiling, and social interest and affect, with reduced expression of positive emotion (Zwaigenbaum et al., 2005; Landa et al., 2007; Bryson et al., 2007; Wetherby et al., 2004); (2) *Language*: delays in babbling (especially back-and-forth social babbling), verbal comprehension and expression, and in gesturing (Mitchell et al., 2006; Landa et al., 2007; Bryson et al., 2007; Wetherby et al., 2004; Brian et al., 2008); (3) *Play*: delays in the development of motor imitation (Zwaigenbaum et al., 2005) and functional use of toys (Landa et al., 2007; Wetherby et al., 2004), as well as unusually repetitive actions with toys and other objects (Zwaigenbaum et al., 2005; Bryson et al., 2007; Wetherby et al., 2004; Ozonoff et al., 2008); (4) *Visual*: atypicalities in visual tracking and fixation, and prolonged visual examination of toys and other objects (Zwaigenbaum et al., 2005; Bryson et al., 2007; Loh et al., 2007; Wetherby et al., 2004; Ozonoff et al., 2008); (5) *Motor*: delayed fine and gross motor skills (Landa et al., 2007; Iverson & Wozniak, 2007) and atypical motor mannerisms (Loh et al., 2007; Wetherby et al., 2004).

Overall, there is convergent evidence from both retrospective and prospective studies that ASD symptoms emerge, in the vast majority of cases, in the first two years of life, affecting multiple domains of development, including social, communication, and repetitive interests/behaviors (the so-called "autistic triad") as well as regulation of attention, behavioral

reactivity, motor activity, and in some children, regulatory behavior such as eating and sleeping (for review, see Zwaigenbaum et al., 2009). However, the application of knowledge regarding behavioral signs of ASD toward the important goals of early detection and diagnosis is a complex process. Clearly, a systematic population health strategy is required to effectively identify children with these early signs, and then to ensure that these children receive specialized diagnostic assessments and intervention services in a timely manner. Continuing education efforts aimed at physicians and other health/developmental service providers working with young children have been an important part of this strategy (First Signs Inc., 2009; see www.firstsigns.org). However, there is growing consensus that formal ASD screening, integrated into a broader framework of developmental surveillance, is needed for meaningful progress toward lowering the average age of diagnosis (see Johnson & Myers, 2007; Greenspan et al., 2008 for detailed discussion). The next section outlines recommended practice models aimed at surveillance and screening for ASD, and describes currently available ASD screening tools in detail.

Surveillance and Screening for ASD

Surveillance and screening are different but complementary processes aimed at detecting individuals at increased risk of a disorder for further assessment, with the goal of reducing or preventing subsequent disability through earlier initiation of intervention. *Surveillance* consists of an ongoing and multifaceted evaluative process that includes inquiry about parents' concerns and observations of the child, and is aimed at obtaining an overall picture of the child's developmental health over time (Dworkin, 1989). Decisions regarding the need for further evaluation are made based on clinical judgment. *Screening* involves administering and scoring a specific instrument (i.e., parent questionnaire, observational tool, or a combination) to identify at-risk individuals in need of further assessment. Developmental surveillance can also include the administration of standardized tools, but with the aim of gathering additional information to help inform clinical decisions, rather than using scoring cut-points as a basis for referral.

The following terms are used to describe the measurement properties of screening tools; i.e., classification accuracy. "Sensitivity" refers to the proportion of children with ASD who are correctly identified as "high-risk" by a screen; a child with ASD who is not identified by the screen is considered to be a "false negative." "Specificity" is the proportion of children who do not have ASD who are correctly classified by the screen (a child who does not have ASD yet fails the screen is considered to be a "false positive"). Children with and without ASD who are correctly classified by the screen can be considered to be "true positives" and "true negatives," respectively. Thus, the "case positive rate" of a screen, relevant to allocating resource needed for follow-up assessments, is the total number of "true positives" and "false positives." Positive predictive value (PPV)

is the likelihood of having the diagnosis, given a positive screen. Negative predictive value (NPV) is the likelihood of not having the diagnosis, given a negative screen. Notably PPV and NPV vary with the base rate of ASD in the group being screened. For a screening test of given sensitivity and specificity, the PPV will be higher when disorder is more prevalent within the population, and lower when the disorder is rarer. Sensitivity and specificity are often considered to be intrinsic properties of a screening test; however there is evidence that these parameters can vary, based on the severity of symptoms in the group being screened. For example, children with severe symptoms are more likely to be correctly identified than those with milder or more equivocal symptoms. In general, the properties of the screening instrument should be evaluated in populations similar to those in which they are to be implemented, and one should be cautious about extrapolating from one context to another, particularly if there are differences in base rates and/or symptom severity (for more detailed discussion, see Sackett, Haynes, Guyatt, & Tugwell, 1991).

Over the past decade, several professional groups, including the American Academy of Neurology (Filipek et al., 2000), the American Academy of Child and Adolescent Psychiatry (Volkmar, Cook, Jr., Pomeroy, Realmuto, & Tanguay, 1999), and the American Academy of Pediatrics (Johnson & Myers, 2007; AAP Committee on Children with Disabilities, 2001) have issued practice parameters focused on the early identification and diagnosis of children with ASD. The way in which screening is incorporated varies somewhat among these statements. The AAP and other groups initially recommended an approach that combines developmental surveillance with ASD-specific screening: screening is targeted to children who are flagged due to concerns regarding language development or other early signs of ASD, or due to a positive family history or other known biological risk factor. This approach is considered *second-stage* or targeted screening, in that the screen is targeted to children who have been identified as being at increased risk. In contrast, subsequent practice parameters from Johnson, Myers, and the AAP Counsel on Children with Disabilities (Johnson & Myers, 2007) recommend developmental surveillance and monitoring for ASD-related concerns as well as ASD screening for *all* children at ages 18 and 24 months regardless of concerns; that is, *first-stage*, or universal screening.

First-stage screening has the potential advantage of higher sensitivity but also potential disadvantages in terms of resource demands to support screening and necessary follow-up of children who are flagged by the screen, particularly those who do not truly have ASD (i.e., false positives). Second-stage screening also presents challenges. To be effective, general developmental surveillance must identify children with ASD for further assessment. However, there is evidence that general screeners miss some children flagged by ASD-specific screens (Pinto-Martin et al., 2008). Recent reports also indicate that first-level ASD screening identifies children with the diagnosis who are not detected by experienced clinicians through routine surveillance (Wetherby, Brosnan-Maddox, Peace, & Newton,

2008; Robins, 2008). To date, first- and second-level screening approaches have not been directly compared.

The next section will provide a review of instruments that have been evaluated as first- or second-level screens and have published psychometric information about the accuracy of detecting children with ASD in children younger than 36 months of age. Recognizing that decisions about implementing ASD screening requires more than a consideration of sensitivity and specificity, a more general evaluation framework focused on clinically meaningful endpoints and overall impacts on the health system will also be discussed.

Review of Available Screening Tools

Checklist for Autism in Toddlers (CHAT)

Much of the recent progress in ASD screening can be traced back to conceptual and methodological contributions from the Checklist for Autism in Toddlers by Baron-Cohen and colleagues (Baron-Cohen, Allen, & Gillberg, 1992; Baron-Cohen et al., 1996; Baron-Cohen et al., 2000). This work was the first to show that some children with ASD could be identified via a screening questionnaire as early as 18 months of age (Baron-Cohen et al., 1992). The CHAT is also the only ASD-screening tool that has been assessed in a true population sample with comprehensive follow-up to identify children who were initially misclassified.

Initially, 41 infant siblings of children with ASD and 50 low-risk control children were assessed with the CHAT at 18 months, and subsequently evaluated at age 3½ years, blind to group status and CHAT scoring. Four children, all in the sibling group, were diagnosed with autism, each of whom at 18 months had failed 3 key CHAT items: gaze monitoring, protodeclarative pointing (i.e., pointing to show), and pretend play (Baron-Cohen et al., 1992). The CHAT was then expanded to 5 key items: the original 3 based on direct observation, plus parents' reports for pointing to show and pretend play. The screen was then administered by home visitors (mainly nurses) to a population-based sample (N = 16,235) of 18-month-olds, and again at 20 months to children who had failed any item. Children with severe developmental delays (including motor impairments) were excluded at the discretion of the home visitor. Diagnostic assessments (including the Autism Diagnostic Interview–Revised; ADI-R) were completed within 2 months on the 12 children who failed all 5 key CHAT items, on 22 of 44 children who passed "gaze monitoring" but failed at least one other key item (termed "developmental delay" risk group), and on 16 of the remaining 16,179 children (termed "normal") who passed all key items. *Ten of 12 children failing all key items were diagnosed with autism, compared to none of the 38 children in the two contrast groups.* The authors did not calculate sensitivity and specificity from these data, and rightly so, given that these estimates would be biased by lack of diagnostic information on half of the "developmental delay" risk

group and almost the entire "normal" group at this stage. Sensitivity would be overestimated, to the extent that some children in the untested group may have received a diagnosis of autism if they'd received the same follow-up evaluation as the screen-positive group. As well, specificity would be underestimated by excluding from the denominator the large number of children who passed the screen and truly did not have autism. However, sensitivity and specificity estimates have been reported for other measures (e.g., the M-CHAT; see below) despite lack of diagnostic assessment of toddlers who screen negative. For comparison, the sensitivity of the CHAT at 18 months would be calculated as 100% (all 10 children diagnosed with autism at 20 months had failed the screen) and the specificity as 95% (only 2 of 40 children who were not diagnosed at this stage failed the screen).

Cox et al. (1999) reported a 2-year follow-up of the sample of children assessed at 20 months. Of the 10 children initially diagnosed with autism, each had the diagnosis confirmed at age 42 months (although for one child, the diagnosis was changed to PDD). Of the 40 children who were not diagnosed at 20 months, 9 received a diagnosis at age 42 months (7 with PDD, and 2 with Asperger's syndrome, all from the "developmental delay" risk group). In other words, both the CHAT *and* a comprehensive assessment by an expert clinician failed to identify an autism spectrum disorder at 20 months in almost half of the children who were diagnosed at 42 months. The "developmental delay" criteria were redefined as "medium-risk criteria" for autism in the 6-year follow-up paper (Baird et al., 2000), with the original cutoff of all 5 key items failed redefined as "high-risk criteria."

Additional children with ASDs were identified by surveillance methods at 42 months. The original sample of 16,235 was rescreened using a "Checklist for Referral" by a health practitioner or by a questionnaire mailed to parents (Baird et al., 2000). Based on this checklist, 22 children in addition to those in the subsample reported by Cox et al. (1999) were identified as possibly having ASD (Baird et al., 2000); these children were each seen for a diagnostic assessment. In total, the research team identified 24 children with autism at 42 months out of the original sample screened at 18 months (Charman et al., 2001). Of these 24 children, only 10 were considered to have failed the CHAT at 18 months using the original ("high-risk") criteria (sensitivity = 41.7%), whereas 19 of 24 children with ASD at 42 months met threshold for "medium-" or "high-risk" criteria on the 18-month CHAT (sensitivity = 79.2%). Case ascertainment at 6-year follow-up was even more comprehensive. The investigators mailed a second screening questionnaire to parents of children in the original sample (of which 47.8% were completed and returned), and reviewed case records of children diagnosed with ASD at regional centers and special education needs registers to identify members of the original sample (Baird et al., 2000). Children identified by these procedures were assessed, with diagnoses confirmed by consensus best-estimate review of case records, cognitive and language testing, and the ADI-R. In all, 50 children with autism and 44 children with other

ASDs were identified, a total of 94 children with ASD. Sensitivity and specificity of the CHAT were estimated for autism and for "all PDDs" (equivalent to ASD) for both high- and medium-risk criteria. Based on the original criteria (i.e., all 5 key items failed on two occasions), sensitivity of the CHAT at 18 months for a later diagnosis of autism is only 18% (9 of 50), although the positive predictive value is high (75%). The sensitivity for other forms of PDD is only 2.3% (1 of 44), for an overall sensitivity for ASD of 11.7%. Using less stringent criteria (failing "medium-risk" criteria on a single occasion) increases sensitivity for autism to 38% (19 of 50), but positive predictive value drops to 4.7% (19 of 407). Similarly, the sensitivity of these less stringent criteria for ASD as a whole at 6-year follow-up is 35.1% (33 of 94 cases correctly identified), with a positive predictive value of 8.1% (33 of 407).

Baird and colleagues (2000) suggested that the low sensitivity of the CHAT may be due to dichotomous scoring of critical items (i.e., ever vs. never), which would miss children that rarely, as opposed to never, demonstrate targeted skills. Requiring that skills be absent based on both observation *and* parent report may also be overly stringent. The authors acknowledged that the low sensitivity of the CHAT limits its utility as a stand-alone screener.

Although the CHAT was developed for first-stage screening, a subsequent study assessed its sensitivity and specificity in a clinically referred sample. Scambler, Rogers, and Wehner (2001) evaluated the CHAT in 26 children with established diagnoses of autism and in 18 children with other developmental delays, including 6 with Down syndrome. Participants ranged in age from 2 to 3 years (mean = 33 months). The purpose of the study was to assess whether expanding the "medium-risk" CHAT screening criteria to include children who fail protodeclarative pointing *or* pretend play (rather than just those who fail protodeclarative pointing) would improve overall classification rate. The original "medium-risk" criteria correctly identified 17 of 26 children with autism (sensitivity = 65%), whereas the modified criteria identified 22 (sensitivity = 85%), without any change in false positive rate (no child with a diagnosis of developmental delay failed the CHAT by either criteria). Two-year follow-up of the sample indicated that improved classification by the modified criteria was maintained (Scambler, Hepburn, & Rogers, 2006). Although these data are encouraging, findings from a convenience sample of children with established diagnoses will not necessarily generalize to a community screening context. In particular, there may have been a selection bias toward children with more straightforward clinical presentations. Assessing agreement between screening and diagnostic measures in a cross-sectional study is very different from using a screening tool to predict future diagnoses in a longitudinal study. Ultimately, research with the CHAT (Baird et al., 2000; Baron-Cohen et al., 1996; Cox et al., 1999) illustrates how estimates of the sensitivity and specificity may be influenced by several factors other than characteristics of the test or criteria used to establish risk status, including sampling strategy, age at screening, duration of follow-up, and case detection methods.

Nevertheless, Scambler et al.'s (2001; 2006) findings suggest that using broader screening thresholds and targeting older toddlers (i.e., 2 years rather than 18 months) may yield higher sensitivity while retaining high levels of specificity.

Subsequent modifications to the CHAT have successfully used these strategies, most notably, the Modified Checklist for Autism in Toddlers (Robins, Fein, Barton, & Green, 2001), discussed below. In addition, Baron-Cohen and colleagues have developed the Quantitative–Checklist for Autism in Toddlers (Q-CHAT; Allison et al., 2008). In contrast to the CHAT, the Q-CHAT is limited to parent-report, items are scored on a 5-point Likert scale (rather than "ever" vs. "never"), and cover a broader range of ASD symptoms. Preliminary Q-CHAT data from 160 preschool children with ASD (including 41 younger than 36 months) and 2360 low-risk 18- to 24-month-olds indicate large group differences in total score, although no specific screening cutoffs have yet been established (Allison et al., 2008).

Modified Checklist for Autism in Toddlers (M-CHAT)

The M-CHAT, developed by Fein and colleagues (Robins et al., 2001), differs from the CHAT in two main ways. The M-CHAT covers a broader range of developmental domains, including sensory and motor abnormalities, imitation, and response to name, and is administered as a parent-completed questionnaire, with no observational component. It includes two questions covering critical CHAT items (pointing to show and pretending, but not gaze monitoring). The M-CHAT was initially assessed in 24 month-olds, although it has since been reported in toddlers aged 16 to 30 months.

Robins et al. (2001) evaluated the M-CHAT in toddlers being seen for routine checkups with their community physician (n = 1122 from 98 selected practices) and in toddlers referred to early intervention programs due to language delays or other developmental concerns (n = 171). Parents were contacted if: (1) at least 3 of 23 items were endorsed, (2) 2 of 6 critical items were endorsed (see below), or (3) the clinician noted concerns. Critical items were selected by a discriminant function analysis (DFA) of the first 600 participants, and included pointing to indicate interest, responding to name, showing interest in other children, bringing objects to show, looking where someone points, and imitating. In total, telephone interviews were conducted with parents of 132 toddlers, and 58 positive screens were confirmed. Subsequent ASD diagnoses were assigned by clinical judgment, using a semistructured DSM-IV-based interview and the Childhood Autism Rating Scale (CARS), as well as standardized assessments of language, cognitive, and adaptive skills. A total of 39 children were diagnosed with ASD, at a mean age of 27.6 months, including 3 of 1122 who were referred at well-child visits (i.e., first-level screening) and 36 of 171 from early intervention services (i.e., a second-level screening context). Children who did not meet M-CHAT criteria or who were "OK on phone interview" did not receive further assessment. The sensitivity

and specificity of the M-CHAT for ASD, using 3 of 23 items as the screening cutoff, was initially estimated to be 97% and 95% respectively, and using the criteria of 2 of the 6 critical items, 95% and 98% respectively. However, *these estimates assume that there were no cases of ASD among the children who were not seen for clinical assessment*, i.e., no cases among the 1235 "screen negative" children, including 74 who were flagged by the questionnaire but whose risk status was not confirmed during the phone interview. A follow-up study by (Kleinman et al., 2008) included 1416 toddlers drawn from the original sample and a second replication sample, each recruited from both low- and high-risk settings (i.e., from community physicians and early intervention services). Participants were rescreened using the M-CHAT, 2 years after the initial screen (follow-up rate = 57%; mean age = 58 month), and were assessed for ASD if screen positive on the parent questionnaire and telephone interview. Seven children with ASD were identified either by rescreening or by clinical referral after the initial screen, although it was not reported whether these cases came from the original or replication samples.

Despite these follow-up data, the sensitivity and specificity of the M-CHAT *cannot* truly be estimated in the initial cohort (Robins et al., 2001) because toddlers below the screening cutoff received no further evaluation. With this constraint, the proportion of toddlers diagnosed with ASD who exceeded the M-CHAT cutoff simply reflects whether the procedures for selecting participants for clinical assessment were followed consistently. For example, there was one child who received a diagnosis but had 2 (rather than 3 or more) positive items; presumably this child was one of the first 600 participants assessed prior to the change in cutoff criteria, or else had 2 of the 6 critical items. Because the sampling frame for the M-CHAT was not geographically defined, even for the low-risk sample, surveillance for subsequent ASD diagnoses in screen negative toddlers depended on individual follow-up rather than review of community-wide medical and/or educational records.

However, the positive predictive value (PPV) of the M-CHAT *can* be accurately estimated, as this relies on diagnostic information from the screen positive group only. Both the case positive rate and PPV are relevant to resource planning, as these parameters describe the expected proportion of toddlers who will require further assessment, and within this group, the expected rate of ASD. In the M-CHAT replication study by Kleinman et al. (2008), 189 of 3309 of the low-risk sample were screen positive (case positive rate = 5.7%), of whom 19 were diagnosed with ASD (PPV = 0.11). It would be difficult to justify comprehensive, ASD-specific assessments for 5.7% of all toddlers in the community, particularly when only about 1 in 10 are expected to result in an ASD diagnosis. In contrast, when the questionnaire is followed up by the structured telephone (or in-person) interview clarifying parents' responses on endorsed items, the case positive rate drops to 31 of 3309 (<1%), and the PPV increases accordingly (19 of 31, or 0.65). This approach essentially combines first- and second-stage screening. First, at-risk toddlers are identified

from the general community using the questionnaire, and then the number of potential referrals is reduced by further screening using the follow-up interview, reducing costs and potentially improving feasibility. With further recruitment to a total of 6776 screened toddlers, Fein and colleagues (Pandey et al., 2008) has reported the positive predictive value of the M-CHAT by age (16–23 months versus 24 months and older) and risk group: 0.28 for younger, low-risk infants; 0.61 for older, low-risk infants; 0.79 for younger, high-risk infants; and 0.74 for older, high-risk infants. As in Robins et al.'s (2001) original report, more cases of ASD were found among the high-risk group (155 of 726; 21.3%) than the low-risk group (29 of 6050; 0.5%), but the false positive rate even among the low-risk group was relatively low, particularly in toddlers 24 months or older. Moreover, over 90% of screen positive children in both the older and younger high-risk groups and the older low-risk group, and 72% of the younger low-risk group, had atypical development when other diagnoses (e.g., language delay, global developmental delay, as well as ASD) were considered. In an independent sample of 14- to 27-month-old low-risk toddlers assessed in community pediatricians' offices, Robins (2008) reported that 466 of 4797 (9.7%) met screening criteria on the M-CHAT questionnaire. Of 362 toddlers from the group whose parents participated, 61 (1.3% of the total sample) screened positive on the follow-up interview. Of 41 toddlers from this group who were subsequently seen for diagnostic evaluation, 21 were diagnosed with ASD, an additional 17 were diagnosed with other developmental delays/disorders, and 3 were typically developing. Thus, of the toddlers who were assessed, 57% were diagnosed with ASD (21 cases, or 0.4% of the total sample of screened toddlers), and of the nondiagnosed children 17 of 20 (85%) had other developmental delays. Only 4 of 21 toddlers with ASD were clinically flagged by their pediatricians, whereas no toddlers with ASD were identified by their pediatricians who weren't also identified by the M-CHAT questionnaire and interview (Robins, 2008).

Overall, the M-CHAT shows considerable promise as a combined first- and second-stage screen for ASD. Recent studies (Kleinman et al., 2008; Pandey et al., 2008; Robins, 2008) have addressed some of the limitations of the M-CHAT evaluation (Charman et al., 2001). First, a follow-up study consisting of rescreening the original screened cohort of toddlers has been initiated (Kleinman et al., 2008), although a more comprehensive follow-up of screen-negative toddlers is still needed. Second, whereas the screening properties of the M-CHAT were first described in a combined sample from low- and high-risk settings, both Pandey et al. (2008) and Robins (2008) have reported data specific to low-risk settings in a large number of toddlers (combined sample size over 10,000). Third, in these recent reports, the follow-up procedures are described more explicitly, and evidence is provided that the screen positive rate drops substantially when questionnaire responses are clarified by the interview (e.g., from 9.7% to 1.3% in Robins, 2008). Finally, recognizing that sensitivity and specificity estimates are uncertain without

follow-up of screen negative toddlers, psychometric assessment of the M-CHAT has shifted to positive predictive value. Pandey et al. (2008) and Robins (2008) reported that over 50% of screen positive children seen for assessment were diagnosed with ASD, and in the latter study, most were not independently flagged by their community pediatrician as being at increased risk. With a case positive rate of around 1%, the M-CHAT appears to identify a substantial number of toddlers with ASD who might not otherwise be flagged at an early age, without generating excessive burden on diagnostic services.

Infant Toddler Checklist (ITC)

The Infant–Toddler Checklist (Wetherby et al., 2004) is a component of the Communication and Symbolic Behavior Scales Developmental Profile (CSBS DP), developed by Wetherby and Prizant (2002). In contrast to ASD-specific measures such as the CHAT and M-CHAT, the ITC is designed to be a broadband screener for communication delays. This parent-completed questionnaire includes 24 items focused on social communication milestones that are rated on a 3- to 5-point scale, and an open-ended question about current concerns regarding the child's development. A unique strength of the ITC is that it has been standardized in a normative sample of over 2000 children, and thus in addition to screening cutoffs, results can be reported as standard scores for infants and toddlers aged 6 to 24 months (Wetherby & Prizant, 2002).

Wetherby et al. (2004) reported a study of 3021 children aged 12–24 months recruited from selected childcare and health care agencies. An additional 5 children under 24 months with known developmental delay (DD) also participated. Children scoring below the 10th percentile on the ITC (n = 377), a random sample of children scoring above this cutoff (n = 230), and the 5 children with known delays were invited for further assessment using an observational component of the CSBS-DP, the "Behavioral Sample." Assessments were completed in 490 children, excluding 122 who were lost to follow-up. Children scoring below the 10th percentile on the Behavioral Sample, a random sample scoring above this cutoff (n's not reported separately), as well as the 5 children with known DD were invited for additional cognitive and language assessment, which was completed in 298 children (i.e., 147 were lost to follow-up). Finally, children with communication delays (based on the Behavioral Sample) were selected for further assessment, including 71 from the main sample and the 5 children with known DD. Based on parent-report from a related study, 10 of 71 were suspected of having ASD; these 10 children, as well as 21 other randomly selected children with "communication delay" and the 5 children with known DD formed a group of 36 children who were evaluated for clinical diagnoses. Overall, 18 children were diagnosed with ASD (9 with autism, 9 with PDD NOS), and 18 children with DD. Among the 5 children who were originally recruited due to known DD, 3 were ultimately diagnosed and included in the ASD group, and the other 2

(both with Down syndrome) were among the final DD group. A typically developing (TD) group was selected for comparison, including 18 nondelayed children who had completed the first three steps of the study. Seventeen of the 18 children in the ASD group (94.4%) had a positive screen on the ITC, as did 15 in the DD group (83.3%), and 2 in the TD group (11.1%). The sensitivity of the ITC was 88.9% for the combined ASD and DD groups (i.e., 32 of 36), although nonrandom selection and dropout may have inflated this estimate, given that screen negative children were underrepresented in the assessed sample relative to the original screened sample. Inclusion of participants with known DD at the outset also reduces the interpretability of the summary statistics. That being said, the study was one of the first to confirm that children with ASD could be identified using a broadband screener and thus referred for more specialized assessments. Additional insights were gained by comparison of toddlers in the ASD and DD groups using a videotape coding scheme developed by Wetherby and Woods (2004). The "Systematic Observation of Red Flags" (SORF) consists of 29 items derived from DSM-IV and studies of early signs of autism (e.g., home videotape studies; Osterling & Dawson, 1994), scored 0 (absent) to 2 (present at least 3 times), and is coded from videotapes of the Behavioral Sample. Significant differences between the ASD and DD groups were found for 9 items: (1) lack of appropriate gaze; (2) lack of warm, joyful expression with gaze; (3) lack of sharing enjoyment or interest; (4) lack of response to name; (5) lack of coordination of gaze, facial expression, gesture, and sound; (6) lack of showing; (7) unusual prosody; (8) repetitive movements or posturing of body, arms, hands, or fingers; and (9) repetitive movements with objects (Wetherby et al., 2004).

Wetherby, Brosnan-Madox, Peace, & Newton (Wetherby et al., 2008) conducted a more definitive evaluation of the ASD screening properties of the ITC in a cumulative community sample of 5385 6- to 24-month-olds recruited from health and childcare services (i.e., included the sample reported by Wetherby et al., 2004). Service providers were encouraged to administer the ITC each time the child was seen, thus, some children who entered the study at the early end of the age range were assessed on multiple occasions. Children were assessed using the Behavioral Sample of the CSBS DP if they met criteria for a positive screen on the ITC, or if parents reported concerns. Screening data were linked to an ongoing study of ASD prevalence in Florida, which identified potential ASD cases using 3 strategies: (1) SORF scoring from the Behavioral Sample; (2) responses to a questionnaire asking parents whether the child had received a clinical ASD diagnosis; and (3) information from state-funded ASD services. Identified children were invited for confirmatory diagnostic assessments by the research team. In total, 60 children were diagnosed with ASD, 56 of whom were screen positive on at least one ITC. Some ITCs were positive as early as 9–11 months, although in some cases, an initial screen was negative at 9–11 months, and did not become positive until a later administration. Some parents did not agree to have their child assessed

until 2 or more ITC were failed, illustrating the potential added value of serial screening over time, as well as the challenges associated with evaluating screening outcomes, given that follow-up is voluntary. Parental concerns were assessed independent of ITC status over time. Most parents of children with ASD expressed concern by age 24 months, but relying on parental concerns alone would have led to later identification than the ITC screen. Although the ITC is not specific for ASD (i.e., does not differentiate ASD from other communication disorders), its estimated sensitivity was very high, at 93% (i.e., 56 of 60). Notably, the SORF as coded from the CSBS DP Behavioral Sample appears to differentiate well between ASD and other communication disorders, as reported by Wetherby et al. (2004). Hence, although additional research and replication by other groups is needed, these two components of the CSBS DP may constitute an effective combined first- and second-level screening strategy for ASD.

Early Screening of Autistic Traits Questionnaire (ESAT)

The ESAT (Swinkels et al., 2006) is a 14-item two-stage screening instrument designed for use at 14–15 months of age. Items were initially selected based on review of findings from parents' retrospective reports and home video analyses. A preliminary 19-item version of the ESAT was pretested with a community sample of parents and other caregivers of 8- to 20-month-olds to assess the frequency of item endorsement in a low-risk sample, and then with a sample of 478 parents of children aged 14–226 months previously diagnosed with ASD, who were asked to retrospectively report on their children based on behaviors recalled at age 14 months. A comparison group of parents of 76 children aged 34–201 months who were diagnosed with ADHD also completed the ESAT retrospectively, based on 14-month behaviors. Fourteen items were selected that best differentiated children with ASD from the ADHD and low-risk groups based on retrospective report, which constituted the long version of the ESAT, with a screening cutoff of 3 or more items. A shorter, prescreening version of the ESAT was also established, consisting of 4 items that identified 94% of the children with ASD but only 2% of the low-risk sample. Further pilot testing of the 14-item ESAT was conducted by parents of 34 preschool children with ASD (aged 14–48 months), who also completed the screen retrospectively based on the child's behavior at age 14 months. As in the first retrospective sample, most parents endorsed the 3 or more items on the ESAT necessary to screen positive.

The ESAT was then evaluated in a random population sample of 31,724 toddlers at a mean age of 14.9 months (Dietz, Swinkels, van Daalen, van Engeland, & Buitelaar, 2006). Screening was carried out in two stages. First, the entire sample was screened at well-child visits by their health providers using the 4-item prescreen. Second, parents endorsed at least 1 item on the prescreen were asked to complete further screening using the 14-item ESAT during a home visit by a study psychologist. A total of 370 children were positive on the

prescreen (1.2% of the total sample), 255 of whom participated in the second stage. Of 100 who were screen positive on the 14-item ESAT, 73 were seen for a more comprehensive diagnostic assessment by a child psychiatrist on the study team, with 18 receiving an ASD diagnosis, consistent with a positive predictive value of 25% and an ASD rate of 0.57 per 1000, well below the expected prevalence rates. Of the remaining 55 screen-positive children who were seen for assessment, 13 were diagnosed with intellectual disability and 18 with language delay; the rest were considered to have other mental health or developmental problems, none were considered to be typically developing. Follow-up to age 42 months reclassified 2 children initially diagnosed with ASD with non-ASD developmental disorders, but 2 children from the delayed group (one with intellectual disability, one with language delay) were reclassified as ASD, so the total rate of ASD was unchanged (2 additional children diagnosed with ASD were lost to follow-up; (van Daalen et al., 2009).

Although the ESAT showed promise in differentiating ASD from typical development (as well as ADHD) in pilot work (Swinkels et al., 2006), the overall rate of 0.57 in 1000 is only about 10% of the expected population prevalence of ASD. Consistent with findings from the CHAT (Baird et al., 2000), screening children younger than 18 months (and perhaps limiting the prescreen to only 4 items) may have contributed to low sensitivity of the ESAT. Establishing screening cut-points based on retrospective data from older pilot samples may have also undermined the validity of the ESAT for prospective screening of younger children.

Screening Tool for Autism in Two-Year-Olds (STAT)

The STAT was developed by Stone and Ousley (Stone, Ousley, & Littleford, 1997) as a second-stage screen for autism for children between 24 and 35 months of age. Scoring is based on behavior observed during a structured interactive assessment of motor imitation, play skills, requesting, and directing attention. Cutoff criteria were established in a "development sample" of 7 children with autism and 33 children with other developmental disorders, and were then were evaluated in a "validation sample" of 12 children with autism and 21 children with other disorders. Both samples were recruited from consecutive referrals to a university-based clinic. Screening with the STAT and diagnostic assessment were completed independently at the same clinic visit, and clinical diagnoses were based on DSM-IV criteria, Childhood Autism Rating Scale (CARS) scores, and standard cognitive measures. Cutoff criteria were selected that best distinguished children with autism from clinical controls in the development sample. To pass each of the three domains (imitation, play, and directing attention) the child must receive credit on at least two items within that domain. These criteria were independently assessed in the validation sample: 10 of 12 children with autism failed at least 2 domains (sensitivity = 83%), compared to 3 of 21 in the nonautism group (specificity = 86%).

The STAT was further assessed in 26 children with autism (AUT) and 26 children with language impairment or other developmental delays (DD/LI; children with PDD-NOS were excluded) (Stone, Coonrod, Turner, & Pozdol, 2004) matched on age and mental age. As in the initial study, the sample was divided into development and validation samples. The revised STAT scoring weighted the 4 domains equally (maximum score of 1 for each domain), and was based on the total item score rather than the number of domains passed. ROC curves determined that a scoring cutoff of 2 was associated with maximal sensitivity (100%) and specificity = 81% in the developmental sample, and a sensitivity of 92% and specificity of 85% in the validation sample. The STAT was then evaluated in a sample of 50 children with autism, 39 with DD/LI, and 15 with PDD-NOS. There was excellent interobserver and test-retest reliability for the STAT classification of high-risk versus low-risk (kappas = 1.0 and .90, respectively) and excellent agreement between the STAT and ADOS (autism cutoff) when the sample was restricted to children with autism and DD/LI (only 2 of 52 children scoring in the STAT high-risk range failed to exceed ADOS threshold for autism). However, children with a clinical diagnosis of PDD-NOS were roughly equally divided into the "high-risk" and "low-risk" categories by the STAT (Stone et al., 2004).

Stone, McMahon and Henderson (2008) recently assessed the screening properties of the STAT in a group of high-risk 12- to 23-month-olds, including 59 younger siblings of children with ASD, and 12 toddlers referred for suspected ASD. A higher cutoff score than recommended for 2-year-olds was required for optimal classification of toddlers with and without ASD, as determined by follow-up diagnostic assessment after age 2. The STAT did not effectively discriminate 12- and 13-month-olds who later developed ASD from those do not; in contrast, a cutoff score of 2.75 was associated with a sensitivity of 0.93 and specificity of 0.83 for later diagnoses of ASD in 14- to 23-month-olds. These data should be considered preliminary, as validation in a second sample has not yet been completed, and the majority of ASD cases were identified from the referred sample.

The STAT has a number of strengths as a second-level screen. It can discriminate children with autism from those with DD/LI with a high degree of sensitivity and specificity, and there is excellent agreement between the STAT high-risk category and an ADOS classification of autism. Its interactive format also allows for greater standardization, assessment of relatively subtle differences between autism and DD/LI that may be difficult to ascertain in a questionnaire, and generates rich observational data. The potential limitations of the STAT are that it is less sensitive to PDD-NOS than to autism, and requires more training and expertise than parent questionnaires. Screening using the STAT is more resource intensive than a questionnaire such as the M-CHAT. However, in a clinical setting, the STAT provides an effective second-stage screen that is both sensitive and specific for autism, and may yield clinically informative data that can help guide both additional assessment, and initial intervention

planning for toddlers as young as 14 months at increased risk of ASD.

Pervasive Developmental Disorders Screening Test - II (PDDST-II)

The PDDST-II is a parent-report questionnaire that includes components designed for first-stage and second-stage screening. Its psychometric properties are described in a published manual (Siegel, 2004), but have not been reported in peer-reviewed publications.

The PDDST-II - Stage 1 was designed to be used in primary care settings, and includes 23 items based on behaviors "emerging between 12 and 24 months." The standardization sample included 656 preschool children who had been referred due to suspected autism (not all of whom actually had an ASD, but all had "at least a few autistic symptoms"), and 256 expreterm infants who were expected to show a high rate of early atypical development (but not autism). Sensitivity and specificity estimates are based on agreement between item and group classification. For example, a true positive is recorded when a child in the suspected autism group scores positive on a PDDST-II item. Hence, although this instrument is intended to be used as a first-stage screen, its evaluation is based on classification into groups defined by clinical suspicion rather than by individual diagnoses.

The PDDST-II - Stage 2 was designed for use in developmental clinics where children are often first assessed for possible developmental disorders. The index population was patients with diagnoses of Autistic Disorder or PDD-NOS (N = 318). The comparison group was patients clinically referred for an autism evaluation but who eventually received non–autistic spectrum disorder diagnoses such as mental retardation or developmental language disorders (N = 62). Estimates of sensitivity and specificity for the PDDST-II are not yet available.

Social Communication Questionnaire (SCQ)

The SCQ (formerly, Autism Screening Questionnaire; Berument, Rutter, Lord, Pickles, & Bailey, 1999) is a 40-item parent questionnaire based on the Autism Diagnostic Interview–Revised (ADI-R) (Lord, Rutter, & Le Couteur, 1994). Because of its close relationship to the ADI-R, the SCQ was designed for use in individuals age 4 and older, although it has subsequently been evaluated in younger samples. Screening criteria for the SCQ were initially established in a sample of 200 individuals aged 4–40 years (160 with ASD, and 40 with other developmental disorders, such as language disorders and intellectual disability). A score of 15 was associated with a sensitivity of .85 and specificity of .75 in this sample. There are relatively little data on the screening properties of the SCQ in younger children, and research to date suggests that classification accuracy is poorer than in children 4 and older. Corsello et al. (2007) reported on a consecutive referral sample of 590 children aged 2–16 years, including 200 who were age 4 and younger

(157 with ASD, and 43 with nonspectrum disorders). The original cutoff of 15 was associated with sensitivity = .68 and specificity = .74 in this age group (data in children 36 months and younger are not reported separately). Lowering the screening cut-point to 11 increased sensitivity to .80, but reduced specificity to .60; similarly, raising the cut-point to 17 increased specificity to .80 but reduced sensitivity to .58 (Corsello et al., 2007). At least 3 other groups have evaluated in the SCQ in children younger than age 5 referred for a suspected diagnosis of ASD (Lee, David, Rusyniak, Landa, & Newschaffer, 2007; Allen, Silove, Williams, & Hutchins, 2007; Eaves, Wingert, Ho, & Mickelson, 2006), reporting sensitivity of .54–.71 using the original cutoff score of 15. Only two of these studies included children 36 months of age and younger (Lee et al., 2007; Allen et al., 2007), and neither of these reported data in this younger subgroup separate from older preschoolers. As well, the samples in all 4 studies that have evaluated the SCQ in children younger than 5 (Lee et al., 2007; Allen et al., 2007; Corsello et al., 2007; Eaves et al., 2006) are drawn from children referred for specialized assessments at tertiary care centers, the majority of whom were ultimately diagnosed with ASD. In other words, these were highly select samples that may not easily generalize to other level 2 screening contexts. Hence, there are insufficient data to assess or recommend the SCQ as an early screening tool for ASD.

Summary and Recommendations

There are now a number of empirically supported screening measures that differentiate ASD from typical development (and to a lesser extent, from other developmental delays) in children younger than 36 months. The CHAT remains the only screener that has been assessed in a general population sample, and with sufficiently comprehensive follow-up to identify children with ASD who were missed by the initial screen. Estimates of CHAT sensitivity are very low (18% for the originally proposed "high-risk" criteria, 38% for "moderate risk" criteria), although differences in sensitivity compared to newer tools are magnified by the follow-up duration. The ESAT has been assessed in a total population cohort of 14-month-olds but its low case detection rate (which may have arisen from the brief "prescreening" component) raises questions about potential sensitivity.

In contrast, both the M-CHAT and ITC have shown considerable promise as ASD screens in community samples, although not "population samples" in the strictest sense—only selected health and childcare agencies participated in evaluation studies. The ITC has excellent sensitivity for ASD (93%, based on multimethod ascertainment of ASD cases among the screened sample), although as a broadband screener is not specific to ASD and thus must be combined with additional levels of assessment to differentiate ASD from other communication disorders (Wetherby et al., 2008). Other broadband screeners such as the Pediatric Evaluation of

Developmental Status have been less effective at identifying toddlers with early signs of ASD (Pinto-Martin et al., 2008), so there may be specific features of the ITC (e.g., a focus on communication development) that are critical. The sensitivity of the M-CHAT cannot be directly estimated from available data, as follow-up assessments have mainly been limited to screen-positive children. However, when the parent questionnaire was combined with a follow-up interview in two large community samples, the M-CHAT identified a high-risk group from which over 50% were diagnosed with ASD (i.e., PPV >50%) (Pandey et al., 2008; Robins, 2008). Both the ITC and M-CHAT identify toddlers at risk of autism who might not otherwise be detected through routine developmental surveillance using clinical judgment and/or parental concerns, yet do not appear to overidentify children who are typically developing (Robins, 2008; Wetherby et al., 2008). Hence, the ITC and M-CHAT could be effective first-stage screening options when part of a multistage early detection strategy for ASD. In contrast, the STAT is specifically designed to be used as a second-stage screener. In this context, the STAT has been reported to have excellent sensitivity and specificity for autism in 24- to 35-month-olds (Stone et al., 2004), and based on preliminary data in a high-risk sample, perhaps in children as young as 14–23 months (Stone et al., 2008).

Assessing the measurement properties of early detection tools is only the first step toward understanding the potential impacts of ASD screening programs. Evaluation of ASD screening should adopt a broader health systems perspective in order to more fully gauge its potential impacts, and to gain support among health care providers and policy-makers. Although ensuring that individual tools will accurately classify children with and without ASD is an essential prerequisite for implementing a screening program, there are other important considerations related to how screening ultimately impacts children, families, and society as a whole. The positive benefits of screening for children with ASD depend on timely access to specialized assessment and intervention services. Concerns about lengthy waiting lists and/or overreferral of children who meet screening criteria for reasons other than ASD (i.e., false positives) may contribute to low uptake of ASD screening into pediatric practice (Dosreis, Weiner, Johnson, & Newschaffer, 2006) and delays in referral of children with identified concerns (Kennedy, Regehr, Rosenfield, Roberts, & Lingard, 2004). Options for multistage screening that can take place in the community (e.g., the combined M-CHAT questionnaire and interview; the ITC followed by a second-stage screener such as the SORF or the STAT) could help limit the number of referrals for specialized assessment, without significantly sacrificing case detection rate. Screening programs also require clinicians with the expertise to make relevant differential diagnoses in children referred for assessment, as children with other disorders who are identified through the process of screening will have service needs as well. Specialized training may be needed to support clinicians faced with increasingly complex diagnostic questions as children are referred due to suspected ASD at younger ages: for example, differentiating

ASD from the broader range of impairments in emotional expression and referential communication that can be observed in infants with an older sibling with ASD, and assessing whether early joint attention behaviors are consistent with developmental level in toddlers with cognitive delays (see Zwaigenbaum et al., 2009 for detailed discussion). As well, screening is difficult to justify unless earlier initiation of treatment leads to improvements in long-term outcomes. Although children participating in ASD treatment research have generally been 3 years of age and older, consistent with the usual timing of diagnosis, recent studies suggest that substantial gains can be achieved by interventions initiated prior to 24 months (Vismara, Colombi, & Rogers, 2009; Dawson et al., 2010; see Chapter 61 in this volume for details). There are theoretical advantages to treating ASD earlier in development due to increased neural plasticity and less severe interfering behaviors than are observed in older children (Dawson, 2008). The degree to which child-related outcomes can be improved through earlier diagnosis and intervention is not yet known, but there may be added benefits to families including reduced parental stress and frustration associated with delays in diagnosis (Howlin & Asgharian, 1999) and increased sense of empowerment and efficacy related to active participation in intervention (Vismara et al., 2009).

The relative effects of implementing ASD screening, and enhancing the expertise and service capacity of specialized diagnostic and treatment programs remain to be assessed, but it seems likely that a comprehensive strategy that includes all of these components will better address the needs of children and families than screening alone. Evaluation of ASD screening should focus on meaningful end-points such as age of initial referral and diagnosis of ASD, treatment outcomes of children identified through positive screening, family experience related to screening misclassification, and health service costs/utilization related to additional referrals (both true and false positives). Screening uptake might be improved if stakeholders such as families, clinicians, and health and policy decision-makers are engaged from the earliest stages of implementation, in an effort to better understand community-specific challenges (e.g., access to diagnostic services), and to ensure outcomes of greatest interest to each group are targeted and measured.

Further research is clearly needed, but the availability of measures with adequate sensitivity and specificity lends important support to current pediatric practice guidelines recommending broader implementation of ASD screening (Johnson & Myers, 2007). As well, although community physicians have a critical role in identifying early signs of ASD, early intervention, daycare/preschool, and speech and language services are the "point-of-entry" to developmental services for many families. Providers in these settings are often the first to observe the at-risk child's development in sufficient depth to identify early markers of autism. The use of a standardized ASD screen may help ensure that children with ASD are detected earlier and more consistently, so that children can be referred for a specialized diagnostic assessment in a timely manner. Further research assessing the utility of ASD screening tools in a wide range of community-based therapeutic settings is warranted.

Conclusions

Detailed knowledge about early signs of ASD from retrospective and prospective research has helped guide the development of screening measures aimed at facilitating earlier diagnosis and entry into intervention programs. Although the evidence-base for ASD screening is not yet fully established, recent data suggest community-wide screening can effectively augment general surveillance efforts to identify appropriate children for referral. Future research evaluating ASD screening should adopt a broader health systems perspective and focus on outcomes meaningful to families, clinicians and health and policy decision-makers.

Challenges and Future Directions

- Future research aimed at improving early detection of ASD should consider whether biological differences such as accelerated head growth might add predictive power to current approaches based on early behavioral markers.
- Consistent with clinical heterogeneity in ASD, early developmental and behavioral trajectories can be variable, making early detection and diagnosis of children across the spectrum more difficult using a single strategy. Children with milder symptoms and/or more advanced intellectual development may be more difficult to identify using existing screening methods.
- Early detection and diagnosis of ASD must be accompanied by timely access to effective, developmentally appropriate interventions that lead to improved outcomes. However, the availability of specialized assessment and treatment services for ASD varies considerably across communities (both nationally and internationally), and there may be significant disparities related to factors influencing access to health care.
- Future research on early identification and screening of ASD should consider these "real-world" health systems challenges, and engage key stakeholders to ensure that findings lead to meaningful change in clinical practice and policy.

Epidemiology of Pervasive Developmental Disorders

Points of Interest

- The best estimate of prevalence for all PDDs combined is 0.7% (1 in 143 children is affected), and several recent surveys even point at figures closer to 1%.
- The proportion of children with cognitive functioning within the normal range is 30% for autistic disorder and 55% for all PDDs.
- There is a consistent male overrepresentation for autistic disorder, childhood disintegrative disorder, and all PDDs.
- Regression, or loss of skills in the developmental course, occurs in about 1 in 4 children with PDD.
- Upward trends in rates of prevalence cannot be directly attributed to an increase in the incidence of the disorder as changes in referral patterns and availability of services, heightened public awareness, decreasing age at diagnosis, and changes over time in diagnostic concepts and practices confound the interpretation of data.
- Diagnostic substitution (the reclassification as PDD of a child who had previously received a different diagnosis) has been shown to contribute to the increase of prevalence in several studies.

The aims of this chapter are to provide an up-to-date review of the methodological features and substantive results of published epidemiological surveys of the prevalence of pervasive developmental disorders (PDD). This chapter updates previous reviews (Fombonne, 2003a; Fombonne, 2005) with the inclusion of new studies made available since then. The specific questions addressed in this chapter are: (1) what is the range of prevalence estimates for autism and related pervasive developmental disorders, and what are the correlates of PDD in epidemiological surveys?; and (2) what interpretation can be given to time trends observed in prevalence rates of PDDs?

Selection of Studies

The studies were identified through systematic searches from the major scientific literature databases (MEDLINE, PSYCINFO, EMBASE) and from prior reviews (Fombonne, 2003a, 2003b; Fombonne, 2005; Williams et al., 2006). Only studies published in the English language were included. Surveys that relied only on a questionnaire-based approach to define caseness (for example, Ghanizadeh, 2008) were also excluded, as the validity of the diagnosis is uncertain in these studies. Overall, 61 studies published between 1966 and 2009 were selected that surveyed PDDs in clearly demarcated, nonoverlapping samples. Of these, 48 studies provided information on rates of autistic disorder, 13 studies on Asperger's disorder (later referred to as Asperger's syndrome; AS), and 12 studies on childhood disintegrative disorder (CDD). A total of 27 studies provided estimates on all PDDs combined, of which 14 provided rates for specific PDD subtypes as well, and 13 only for the combined category of PDD.

Surveys were conducted in 18 countries, including 16 studies from the UK, 13 from the United States, and 7 from Japan. The results of over half of the studies (N = 33) have been published since 2001. The age range of the population included in the surveys is spread from birth to early adult life, but most studies have relied on school-age samples. Similarly, there was huge variation in the size of the population surveyed (range: 826 to 4.9 million; mean: 267,000; median: 44,900), with some recent studies conducted by the U.S. Centers for Disease Control (CDC, 2007b; 2009) relying on very large samples of several hundreds of thousands of individuals.

Study Designs

In designing a prevalence study, two major features are critical for the planning and logistics of the study, as well as for the

interpretation of its results: case definition, and case ascertainment (or case identification methods) (Fombonne, 2007).

Case Definition

Over time, the definitions of autism have changed as illustrated by the numerous diagnostic criteria that were used in both epidemiological and clinical settings (see Figure 6-1). Starting with the narrowly defined Kanner's autism (1943), definitions progressively broadened in the criteria proposed by Rutter (1970), and then ICD-9 (1977), DSM-III (1980) and DSM-III-R (1987), and more recently in the 2 major nosographies used worldwide, ICD-10 (1992) and DSM-IV (American Psychiatric Association [APA], 1994). The early diagnostic criteria reflected the more qualitatively severe forms of the phenotype of autism, usually associated with severe delays in language and cognitive skills. It is only in the 1980s that less severe forms of autism were recognized, either as a qualifier for autism occurring without mental retardation (so-called "high-functioning" autism), or as separate diagnostic categories (Pervasive Developmental Disorders Not-Otherwise-Specified–PDD NOS) within a broader class of autism spectrum disorders (ASD) denominated "pervasive developmental disorders" (PDD, an equivalent to ASD) in current nosographies. While it had been described in the literature as early as 1944 (Asperger, 1944), one type of PDD, Asperger's disorder, appeared in official nosographies only in the 1990s, and then with unclear validity, especially with respect to its differentiation from "high-functioning" autism. Subtypes of PDD that existed in DSM-III subsequently disappeared (i.e., Autism–residual state). While there is generally high interrater reliability on the diagnosis of PDDs and commonality of concepts across experts, some differences persist between nomenclatures about the terminology and precise operationalized criteria of PDDs. For example, DSM-IV (1994) has a broad category of PDD NOS, sometimes referred to loosely as "atypical autism," whereas ICD-10 (1992) has several corresponding diagnoses for clinical presentations that fall short of autistic disorder, that include Atypical autism (F84.1, a diagnostic category that existed already in ICD-9), Other PDD (F84.8), and PDD-, unspecified (F84.9). As a result, studies that refer to "atypical autism" must be carefully interpreted, and no direct equivalence with the DSM-IV concept of PDD NOS should be assumed. In recent years, the definitions of syndromes falling on the autism spectrum have been expanded further with reference to the broader autism phenotype, and, with an increasing reliance on a dimensionalization of the autism phenotype. As no impairment or diagnostic criteria are available for these milder forms, the resulting boundaries with the spectrum of PDDs are left uncertain. Whether or not this plays a role in more recent epidemiological studies is difficult to know, but the possibility should be considered in assessing results for the new generation of surveys.

Broader autism phenotype: a pattern of mild developmental deficits similar to, but less severe than, symptoms of autism seen in relatives of subjects affected with a pervasive development disorder.

Case Identification

When an area or population have been identified for a survey, different strategies have been employed to find subjects matching the case definition retained for the study. Some studies have relied solely on existing service providers databases (Croen et al., 2002); on special educational databases (Gurney et al., 2003; Fombonne et al., 2006; Lazoff et al., 2010); or on national registers (Madsen et al., 2002) for case identification. These studies have the limitation in common of relying on a population group that happened to access the service provider or agencies rather than sampling from the population at large. As a result, subjects with the disorder who are not in contact with these services are yet unidentified and not included as cases, leading to a underestimation of the prevalence proportion.

Other investigations have relied on a multistage approach to identify cases in underlying populations. The aim of the first screening stage of these studies is to cast a wide net in order to identify subjects possibly affected with a PDD, with the final diagnostic status being determined at a next phase. The process utilized by the researchers often consists of sending letters or brief screening scales requesting school and health professionals and/or other data sources to identify possible cases of autism. Few of these investigations relied on systematic sampling techniques that would ensure a near complete coverage of the target population. Moreover, each investigation differed in several key aspects of this screening stage. First, the thoroughness of the coverage of all relevant data sources varied enormously from one study to another. In addition, the surveyed areas were not comparable in terms of service development, reflecting the specific educational or health care systems of each country and of the period of investigation. Second, the type of information sent out to professionals invited to identify children varied from simple letters, including a few clinical descriptors of autism-related symptoms or diagnostic checklists rephrased in nontechnical terms, to more systematic screening strategy based on questionnaires or rating scales of known reliability and validity. Third, variable participation rates in the first screening stages provide another source of variation in the screening efficiency of surveys, although refusal rates tended, on average, to be very low.

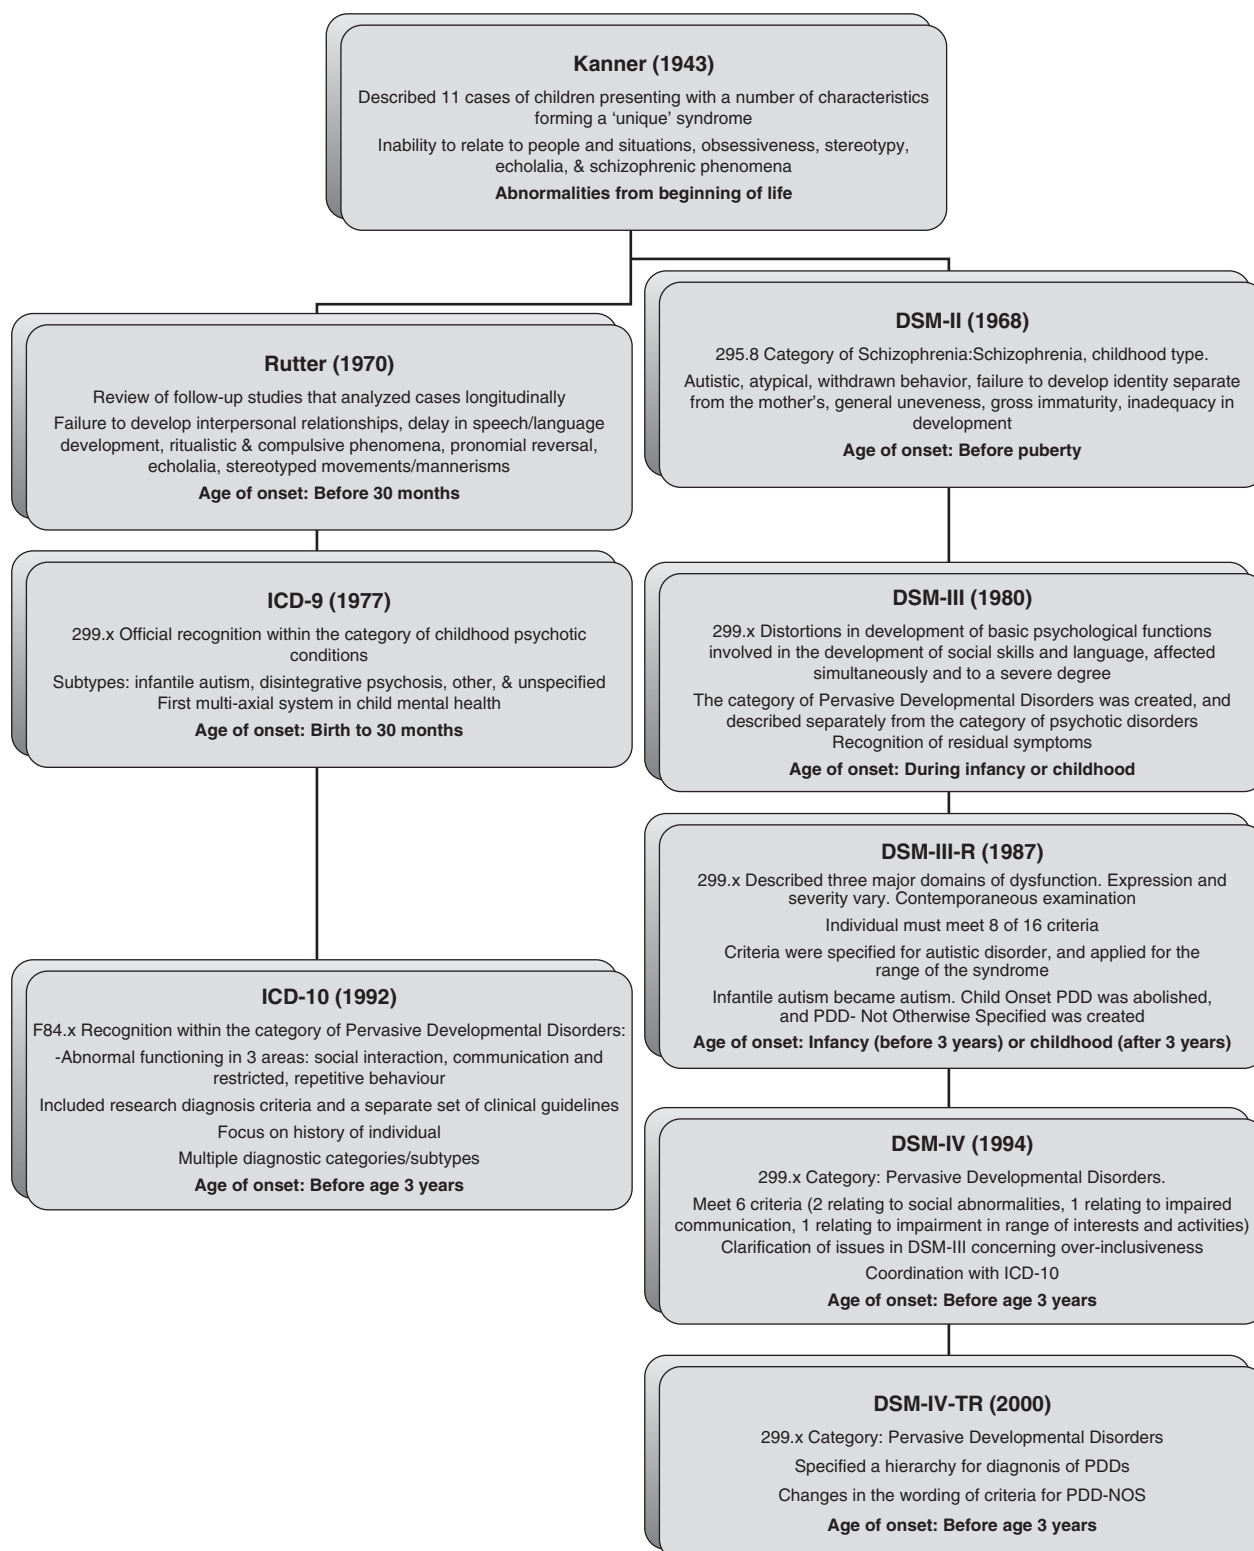
Few studies provided an estimate of the reliability of the screening procedure. The sensitivity of the screening methodology is also difficult to gauge in autism surveys and the proportion of children truly affected with the disorder but not identified in the screening stage (the "false negatives") remains generally unmeasured. The usual approach, which consists of sampling at random screened negative subjects in order to estimate the proportion of false negatives and adjusting the


Figure 6–1. Historical changes in diagnostic concepts and criteria.

estimate accordingly, has not been used in these surveys for the obvious reason that, due to the low frequency of the disorder, it would be both imprecise and very costly to undertake such estimations. As a consequence, prevalence estimates must be understood as underestimates of "true" prevalence rates. The magnitude of this underestimation is unknown in each survey.

When the screening phase is completed, subjects identified as positive screens go through the next step involving a more in-depth diagnostic evaluation to confirm their case status. Similar considerations about the methodological variability across studies apply to these more intensive assessment phases. In the studies reviewed, participation rates in second-stage assessments were generally high. The source of information used to determine caseness usually involved a combination of data coming from different informants (parents, teachers, pediatricians, other health professionals, etc.) and data sources (medical records, educational sources), with an in-person assessment of the person with autism being offered in some but not all studies. Obviously, surveys of very large populations as those conducted in the United States by the CDC (2007a, 2007b, 2009) or in national registers (Madsen et al., 2002) did not include a direct diagnostic assessment of all subjects by the research team. However, these investigators could generally confirm the accuracy of their final caseness determination by undertaking, on a randomly selected subsample, a more complete diagnostic workup. The CDC surveys have established a methodology for surveys of large populations that relies on screening of population using multiple data sources, a systematic review and scoring system for the data gathered in the screening phase combined with, in the less obvious cases, input from experienced clinicians with known reliability and validity. This methodology is adequate for large samples, and is likely to be used in the future for surveillance efforts.

When subjects were directly examined, the assessments were conducted with various diagnostic instruments, ranging from a typical unstructured examination by a clinical expert (but without demonstrated psychometric properties), to the use of batteries of standardized measures by trained research staff. The Autism Diagnostic Interview (Le Couteur et al., 1989) and/or the Autism Diagnostic Observational Schedule (Lord et al., 2000) have been increasingly used in the most recent surveys.

Prevalence Estimations

We now present the results of the 61 studies in several tables that summarize results by type of PDD or for PDD as a spectrum of disorders. Characteristics of samples surveyed in these studies are briefly summarized.

Autistic Disorder

Prevalence estimates for autistic disorder are summarized in Table 6-1. There were 48 studies (including 13 in the UK, 6 in the United States, and 6 in Japan), half of them published since 1999. The sample size varied from 826 to 4.95 millions, with a median of 35,300 (mean: 212,500) subjects in the surveyed populations. The age ranged from 3 to 15 years, with a median age of 8.5 years. The number of subjects identified with autistic disorder ranged from 6 to 5,032 (median: 51). Males consistently outnumbered females in 40 studies where gender differences were reported, with a male/female ratio ranging from 1.33:1 to 16.0:1 in 39 studies (1 small study had no girls at all), leading to an average male/female ratio of 4.4:1. Prevalence rates varied from 0.7/10,000 to 72.6/10,000 with a median value of 12.9/10,000. Prevalence rates were negatively correlated with sample size (Spearman's r: -0.71; p < .001), with small-scale studies reporting higher prevalence rates. The correlation between prevalence rate and year of publication was significant (Spearman's r: 0.69; p < .001), indicative of higher rates in more recent surveys. Therefore, a current estimate for the prevalence of autistic disorder must be derived from more recent surveys with an adequate sample size. In 23 studies published since 2000, the median rate was 21.6/10,000 (mean rate: 21.9/10,000). After exclusion of the 2 studies with the smallest and largest sample sizes, the results were very similar (mean rate: 22.4/10,000). Thus, the best current estimate for autistic disorder is 22/10,000. In 25 studies where the proportion of subjects with IQ within the normal range was reported, the median value was 30% (interquartile range: 17.5%–50%). In these surveys, there was a significant correlation between a higher proportion of normal IQ subjects and a higher male/female ratio (Spearman's r: 0.53; p = .007), a result consistent with the known association between gender and IQ in autism. Over time, there were minor associations between the year of publication of the survey and the sample male/female ratio (Spearman's r: 0.36; p = 0.024) and the proportion of subjects without mental retardation (Spearman's r: 0.32; p = 0.11). Taken in conjunction with the much stronger increase over time in prevalence rates, these results suggest that the increase in prevalence rates is not entirely accounted for by the inclusion of milder forms (i.e., less cognitively impaired) of autistic disorder, albeit this might have contributed to it to some degree.

Asperger's Syndrome

Epidemiological studies of Asperger's syndrome (AS) are sparse, due to the fact that it was acknowledged as a separate diagnostic category only in the early 1990s, in both ICD-10 and DSM-IV. Two epidemiological surveys have been conducted which *specifically* investigated AS prevalence (Kadesjö et al., 1999; Ehlers & Gillberg, 1993). However, only a handful (N < 5) of cases were identified in these surveys, with the resulting estimates being unacceptably imprecise. In addition, since there was no separate report for children meeting criteria for autistic disorder, it remains unclear if these subjects would have also met criteria for autistic disorder and how prevalence rates would be affected if hierarchical rules were followed to diagnose both disorders. A recent

[1]This number corresponds to the sample described in Wing & Gould (1979).

[2]This rate corresponds to the first published paper on this survey and is based on 12 subjects among children aged 5 to 14 years.

[3] In this study, mild mental retardation was combined with normal IQ, whereas moderate and severe mental retardation were grouped together.

[4] For the Goteborg surveys by Gillberg et al. (Gillberg, 1984; Steffenburg & Gillberg, 1986; Gillberg et al., 1991) a detailed examination showed that there was overlap between the samples included in the 3 surveys; consequently only the last survey has been included in this table.

[5] This proportion is likely to be overestimated and to reflect an underreporting of mental retardation in the CDER evaluations.

[6] This figure was calculated by the author and refers to prevalence data (not cumulative incidence) presented in the paper (the M:F ratio is based on a subsample).

[7] These figures apply to the whole study sample of 206 subjects with an ASD.

survey of high-functioning PDDs in Welsh mainstream primary schools has yielded a relatively high (uncorrected) prevalence estimate of 14.5/10,000, but no separate rate was available for AS, specifically (Webb et al., 2003).

Other recent surveys have examined samples with respect to the presence of both autistic disorder and Asperger's syndrome. Thirteen studies (already listed in Table 6-1), published since 1998, provided usable data (Table 6-2). The median population size was 16,200, and the median age 8.0 years. Numbers of children with AS varied from 6 to 427, with a median sample size of 32. There was a 160-fold variation in estimated rates of AS (range: 0.3 to 48.4/10,000) that demonstrates the lack of reliability of these estimates. The median value was 10.5/10,000. With the exception of one study (Latif & Williams, 2007), the number of children with autistic disorder was consistently higher than that of children with AS. The prevalence ratio (Table 6-2, right-hand column) exceeded 1, with a median value of 2.1, indicating that the rate of AS was consistently *lower* than that for autism (Table 6-2). The unusually high rate of AS relative to autistic disorder obtained in Latif and Williams's study (2007) appeared to be inflated due to the inclusion of high-functioning autism in the AS definition. The epidemiological data on AS are therefore of dubious quality, reflecting the difficult nosological issues that have surrounded the inclusion of AS in recent nosographies as well as the lack of proper measurement strategies that ensure a reliable difference between AS and autistic disorder.

Childhood Disintegrative Disorder

Twelve surveys provided data on childhood disintegrative disorder (CDD) (Table 6-3). In 5 of these, only 1 case was reported; no case of CDD was identified in 4 other studies. Prevalence estimates ranged from 0 to 9.2/100,000, with a median rate of 1.8/100,000. The pooled estimate, based on 11 identified cases and a surveyed population of about 560,000 children, was 1.9/100,000. Gender was reported in 10 of the 11 studies, and males appear to be overrepresented with a male/female ratio of 9:1. The upperbound limit of confidence interval associated to the pooled prevalence estimate (3.4/100,000) indicates that CDD is a quite rare condition, with about 1 case occurring for every 112 cases of autistic disorder.

Prevalence for Combined PDDs

A new objective of more recent epidemiological surveys was to estimate the prevalence of all disorders falling onto the autism spectrum, thereby prompting important changes in the conceptualization and design of surveys. However, before reviewing the findings of these studies mostly conducted since 2000, we examine to which extent findings of the first generation of epidemiological surveys of a narrow definition of autism also informed our understanding of the modern concept of autism spectrum disorders.

Unspecified Autism Spectrum Disorders in Earlier Surveys

In previous reviews, we documented that several studies performed in the 1960s and 1970s had provided useful information on rates of syndromes similar to autism but not meeting of the strict diagnostic criteria for autistic disorder then in use (Fombonne, 2003a, 2003b; Fombonne, 2005). At the time, different labels were used by authors to characterize these clinical pictures, such as the triad of impairments involving deficits in reciprocal social interaction, communication, and imagination (Wing & Gould 1979), autistic mental retardation (Hoshino et al., 1982), borderline childhood psychoses (Brask, 1970) or "autistic-like" syndromes (Burd et al., 1987). These syndromes would be falling within our currently defined autistic spectrum, probably with diagnostic labels such as atypical autism and/or PDD NOS. In 8 of 12 surveys providing separate estimates of the prevalence of these developmental disorders, higher rates for the atypical forms were actually found compared to those for more narrowly defined autistic disorder (see Fombonne, 2003a, Table 3, p. 172). However, this group received little attention in previous epidemiological studies, and these subjects were not defined as "cases" and therefore not included in the numerators of prevalence calculations, thereby underestimating systematically the prevalence of what would be defined today as the spectrum of autistic disorders. For example, in the first survey by Lotter (1966), the prevalence would rise from 4.1 to 7.8/10,000 if these atypical forms had been included in the case definition. Similarly, in Wing et al.'s study (1976), the prevalence was 4.9/10,000 for autistic disorder, but, adding the figure of 16.3/10,000 (Wing & Gould, 1979) corresponding to the triad of impairments, the prevalence for the whole PDD spectrum was in fact 21.1/10,000. For the purpose of historical comparison, it is important to be attentive to this earlier figure, bearing in mind that the study was conducted in the early 1970s for the field work and that autism occurring in subjects with an IQ within the normal range was not yet being investigated. Progressive recognition of the importance and relevance to autism of these less typical clinical presentations has led to changes in the design of more recent epidemiological surveys (see below), that are now using case definitions that incorporate upfront these milder phenotypes.

Newer Surveys of PDDs

The results of surveys that estimated the prevalence of the whole spectrum of PDDs are summarized in Table 6-4. Of the 27 studies listed, 14 also provided separate estimates for autistic disorder and other PDD subtypes; the other 13 studies provided only an estimate for the combined PDD rate. All these surveys were published since 2000, and the majority since 2006; the studies were performed in 8 countries (including 10 in the UK and 8 in the United States). Sample sizes ranged from 2,536 to 4,247,206 (median: 32,568; mean: 243,156).

The median age of samples ranged from 5.0 to 12.5, with 8.0 years being both the modal and median age. The diagnostic criteria used in the 25 studies where they were specified reflect reliance on modern diagnostic schemes by all authors (10 studies used ICD-10, 17 the DSM-IV or DSM-IV-TR, both schemes being used simultaneously in 2 studies). In 14 studies where IQ data were reported, the proportion of subjects within the normal IQ range varied from 30% to 85.3% (median:

57.1%; mean: 56.1%), a proportion that is higher than that for autistic disorder and reflects the lesser degree of association, or lack thereof, between intellectual impairment and milder forms of PDDs. Overrepresentation of males was the rule, with male/female ratio ranging from 2.7:1 to 15.7:1 (mean: 5.5; median: 4.9). There was a 6-fold variation in prevalence proportions that ranged from a low 30.0/10,000 to a high of 181.1/10,000. However, some degree of consistency is found

Table 6–4.

in the center of this distribution, with a median rate of 62.0/10,000 and a mean rate of 69.2/10,000 (interquartile range: 53.3–80.4/10,000). This mean rate coincides with the rate reported recently for PDDs in 14 sites (CDC, 2007b); the CDC value represents, however, an average, and that study conducted at 14 different sites utilizing the same methodology found a 3-fold variation of rate by state. Alabama had the lowest rate of 3.3/1,000 whereas New Jersey had the highest value with 10.6/1,000 (CDC, 2007b). As expected, a new CDC report on 307,000 U.S. children aged 8 and born 4 years later than children from the previous survey reported an average prevalence of 89.6/10,000 (CDC, 2009). Again, substantial variation across states was reported as prevalence ranged from 4.2/1,000 in Florida to 12.1/1,000 in Arizona and Missouri. One factor associated with the prevalence increase in the CDC monitoring survey was improved quality and quantity of information available through records, indicative of greater awareness about ASD among community professionals. As surveillance efforts continue, it is likely that awareness and services will develop in states that were lagging behind, resulting in a predictable increase in the average rate for the United States as time elapses. These CDC findings apply to other countries as well, and prevalence estimates from any study should always be regarded in the context of the imperfect sensitivity of case ascertainment that results in downward biases in prevalence proportions in most surveys.

As an illustration, the 4 surveys in Table 6-4 with the lowest rates probably underestimated the true population rates. In the Danish investigation (Madsen et al., 2002), case finding depended on notification to a National Registry, a method which is usually associated with lower sensitivity for case finding. The Hong Kong (Wong et al., 2008) and Australian (Icasiano et al., 2004) surveys have relied on less systematic ascertainment techniques. The Atlanta survey by the CDC (Yeargin-Allsopp et al., 2003) was based on a very large population and included younger age groups than subsequent CDC surveys, and age specific rates were in fact in the 40–45/10,000 range in some birth cohorts (Fombonne, 2003a, 2003b). Case finding techniques employed in the other surveys were more proactive, relying on multiple and repeated screening phases, involving both different informants at each phase and surveying the same cohorts at different ages, which certainly enhanced the sensitivity of case identification (Chakrabarti & Fombonne, 2005; Baird et al., 2006). Assessments were often performed with standardized diagnostic measures (i.e., ADI-R and ADOS) which match well the more dimensional approach retained for case definition.

Overall, results of recent surveys agree that an average figure of 70/10,000 can be used as the current estimate for the spectrum of PDDs.

Regression: a loss of skills including language (the child stops using 5 to 30 words that he had gained) often associated with contemporaneous changes in social and play skills.

Regressive Autism in Population Surveys

The studies of regression or loss of skills in the developmental course of PDDs has gained much attention in recent years. As there is evidence that regression is associated with younger age at identification (Shattuck et al., 2009), and with slight increase in severity of autistic symptoms and cognitive deficits (Meilleur & Fombonne, 2009; Fombonne & Chakrabarti, 2001; Parr et al., submitted), we examined how often regression was reported and how it was measured in population based studies, and, when available, the age at regression and the outcome (Table 6-5). Ten studies reported the frequency of regression in the survey sample. Interestingly, Lotter (1966) documented in the first epidemiological survey of autism that a "set-back" had occurred in almost one third of the children. There has been no standardized way to evaluate regression, and the methods have relied on record abstraction or parents' retrospective recall. Regression has often focused on the loss of language skills, with or without the loss of other (social, play) skills. Regression ranged from 12.5% (Sugiyama & Abe, 1989) to 38.6% (Baird et al., 2008), with a median rate of 23%. In the majority of studies, the age at regression is the 6 months preceding the 2nd birthday or close to age 2, which differentiates this pattern of loss from that seen in CDD. Symptoms of CDD are typically observed at the end of the 3rd year of life and are characterized by marked developmental and behavioral changes and deterioration that result in profound, lasting, autistic and cognitive impairments. Two studies provided separate figures for a strict definition of autism compared to atypical or milder forms. In one study (Taylor et al., 2002), regression occurs at comparable frequency in typical and atypical autism, whereas in the other (Baird et al., 2008) there is a marked difference between the 38.6% figure of regression (including both definite and lower level) in autism as opposed to a much lower corresponding figure of 10.6% in the broadly defined ASD group. Finally, in 3 studies where some kind of outcome data were reported, all studies pointed at higher symptom severity in the regressive group. Overall, these results do not differ from studies of regression based on clinical samples and they confirm that a loss of skills in the development of PDD children is common, affecting about 1 in 4 children with ASD.

In conclusion, conducted in different regions and countries by different teams, the convergence of estimates around 70 per 10,000 for all PDDs combined is striking especially when derived from studies with improved methodology. This estimate is now the best estimate for the prevalence of PDDs currently available. However, this represents an average and conservative figure, and it is important to recognize the substantial variability that exists between studies, and within studies, across sites or areas. The prevalence figure of 70/10,000 (equivalent to 7/1,000 or 0.7%) translates into 1 child out of 143 suffering from a PDD. It should be noted, however, that some studies have reported rates that are even two to three times higher (Baird et al., 2006; Kawamura et al., 2008), and that the most recent and reliable estimates point at a 0.9% to 1% prevalence.

Table 6–5.
"Regressive" autism in population-based studies

Authors	Measurement of Regression	Proportion of Study Sample with Regression/Loss	Age at Regression	Skills Lost	Diagnosis	Outcome
Lotter, 1966	"set-back" in development	31.2%	18–27 months (N = 3) 27–36 months (N = 4) 3 to 4.5 years (N = 3)[2]	Loss of some ability (i.e., speech) or failure to progress after a satisfactory beginning	Kanner's autism	All but 2 of the children with a set-back (80%) had a low (< 55) IQ, compared to 63.4% in the group without set-back
Sugiyama & Abe, 1989	Developmental checkups from 18 months to age 3	12.5%	2 years	Loss of a few words or of one-word sentences	DSM-III autism	
Bertrand et al., 2001	Question to parents during clinical evaluation[1]	24%	12–18 months	Single words and social smiling	All had autistic disorder	
Fombonne & Chakrabarti, 2001	ADI-R items on regression before age 5	15.6%	19.8 months	Any language, social, play, or motor skill	—	Trend (p = .08) for children with regression to have lower IQ scores (IQ < 70) than nonregressive children (21.5%)
Taylor et al., 2002	Abstraction of medical records	25%	—	Deterioration in any aspect of a child's development or reported loss of skills	Typical autism (23%); atypical autism (27%)	
Icasiano et al., 2004	Parental interview	27.1%[3] 5.6%[3]		Previously acquired language skills Previously acquired motor skills	Autism spectrum disorders	
CDC, 2007a	Abstraction of all records by an ASD clinician reviewer	19.0%[4]	24 months (median age across 6 sites)	Loss of previously acquired skills in social, communication, play, or motor areas	Autism spectrum disorders	
CDC, 2007b	Abstraction of all records by an ASD clinician reviewer	19.7%[5]	24 months (median age across 14 sites)	Loss of previously acquired skills in social, communication, play, or motor areas	Autism spectrum disorders	
Baird et al., 2008	ADI-R items (11–15, and 20) on regression	30.2% (8%)[7] 8.4% (2.6%)[7]	25 months 25 months	Definite language regression[6] Lower level regression[6]	Narrow autism (broad ASD)	Increase in severity of autistic symptoms in both regression groups
CDC, 2009	Abstraction of all records by an ASD clinician reviewer	21.9%[8]	19 months (median age across 11 sites)	Loss of previously acquired skills in social, communication, play, or motor areas	Autism spectrum disorders	

[1] "Did your child experience any loss of previously acquired skills?"

[2] In the 3 children with an onset after age 3, the setback was "severe and fairly rapid" (Lotter, 1966, p. 130) (these cases would probably meet criteria for CDD).

[3] Potential overlap between these 2 groups was not reported.

[4] Weighted average computed by the authors (238 out of 1252; range: 12.5%–26.9%).

[5] Weighted average computed by the authors (530 out of 2685; range: 13.8%–31.6%).

[6] Definite regression: at least 5 words used before regression, and strict language regression with or without regression of other skills; Lower level regression: loss of fewer words than five words, or of babble, or regression of other skills than language. The rates for definite and lower level regression can be summed up to derive a frequency of "any" regression.

[7] The first rate is for narrow autism, the figure within brackets is for broad ASD.

[8] Weighted average computed by the authors (603 out of 2757; range: 13.3%–29.6%).

Time Trends in Prevalence and Their Interpretation

The debate on the hypothesis of a secular increase in rates of autism has been obscured by a lack of clarity in the measures of disease occurrence used by investigators, or rather in the interpretation of their meaning. In particular, it is crucial to differentiate prevalence from incidence. Prevalence is useful to estimate needs and plan services; however, only incidence rates can be used for causal research. Both prevalence and incidence estimates will increase when case definition is broadened and case ascertainment is improved. Time trends in rates can therefore only be gauged in investigations that hold these parameters under strict control over time. These methodological requirements must be borne in mind while reviewing the evidence for a secular increase in rates of PDDs, or testing for the "epidemic" hypothesis. The "epidemic" hypothesis emerged in the 1990s when, in most countries, increasing numbers were diagnosed with PDDs leading to an upward trend in children registered in service providers databases that was paralleled by higher prevalence rates in epidemiological surveys. These trends were interpreted by some observers as evidence that the actual population incidence of PDDs was going up (what the term "epidemic" means); however, alternative explanations to explain the rise in numbers of children diagnosed with PDDs had to be ruled out first before attaining this conclusion.

> Prevalence: the proportion of individuals in a population who suffer from a defined disorder at any point in time.

> Incidence: the number of new cases occurring in a population over a period of time.

Several approaches to assessing this question have been used in the literature and these fall into 5 broad categories.

1. Use of Inappropriate Referral Statistics

Increasing numbers of children referred to specialist services or known to special education registers have been taken as evidence for an increased incidence of autism-spectrum disorders. Upward trends in national registries, medical, and educational databases have been seen in many different countries (Taylor et al., 1999; Madsen et al., 2002; Shattuck, 2006; Gurney et al., 2003), all occurring in the late 1980s and early 1990s. However, trends over time in *referred* samples are confounded by many factors such as referral patterns, availability of services, heightened public awareness, decreasing age at diagnosis, and changes over time in diagnostic concepts and practices, to name only a few. Failure to control for these confounding factors was obvious in some recent reports (Fombonne, 2001), such as the widely quoted reports from California Developmental Database Services (CDDS, 1999;

CDDS, 2003). First, these reports applied to numbers rather than rates, and failure to relate these numbers to meaningful denominators left the interpretation of an upward trend vulnerable to changes in the composition of the underlying population. For example, the population of California was 19,971,000 in 1970 and rose to 35,116,000 as of July 1, 2002, a change of +75.8%. Second, the focus on the year-to-year changes in absolute numbers of subjects known to California state-funded services detracts from more meaningful comparisons. For example, as of December 2007, the total number of subjects with a PDD diagnosis was 31,332 in the 3–21 age group (including all CDER autism codes) (California Department of Developmental Services, December 2007). The population of 3–21 year olds of California was 9,976,768 on July 1, 2007 (Census Bureau for the US, 2009). If one applies the 2007 average U.S. rate of 67/10,000 deriving from the CDC (2007b), one would expect to have 66,844 subjects with a PDD, within this age group, living in California. The expected number is twice as high as the number of subjects recorded in the public service at the same time. The discrepancy would be more pronounced if the latest CDC figures of 9/1,000 (Table 6-4; CDC, 2009) were used to estimate the expected number of Californian residents with a PDD. Certainly, these calculations do not support the "epidemic" interpretation of the California DDS data, and confirm the selective nature of the referred sample. Unfortunately, these data have been misused in many ways to infer population trends and causes for autism in California, for which they are simply not suited. The upward trends in the DDS database simply suggest that children identified in the California DDS database were only a subset of the population prevalence pool and that the increasing numbers reflect merely an increasing proportion of children receiving services. Third, with one exception (see below), no attempt was made to adjust the trends for changes in diagnostic concepts and definitions. However, major nosographical modifications were introduced during the corresponding years with a general tendency in most classifications to broaden the concept of autism (as embodied in the terms "autism spectrum" or "pervasive developmental disorder"). Fourth, age characteristics of the subjects recorded in official statistics were portrayed in a misleading manner where the preponderance of young subjects was presented as evidence of increasing rates in successive birth cohorts (Fombonne, 2001). The problems associated with disentangling age from period and cohort effects in such observational data are well known in the epidemiological literature and deserve better statistical handling. Fifth, the decreasing age at diagnosis leads in itself to increasing numbers of young children being identified in official statistics (Wazana et al., 2007) or referred to specialist medical and educational services. Earlier identification of children from the prevalence pool may therefore result in increased service activity that may lead to a misperception by professionals of an "epidemic"; however, an increase in referrals does not necessarily mean increased *incidence*. A more refined analysis of the effect of a younger age at diagnosis using cumulative incidence data by age 5 years showed that 12% of the

increase in incidence from the 1990 to the 1996 birth cohort could be explained by this factor, and up to 24% with an extrapolation to the 2002 cohort (Hertz-Picciotto & Delwiche, 2009). Although younger age at diagnosis can explain only a small proportion of the increase in diagnoses in this analysis, it does play a role in several published reports though its effect would attenuate as the cohort becomes older. Hertz-Picciotto and Delwiche's analysis (2009) of the California DDS data is also limited by their reliance on the DDS database that reflected changes in regional referral patterns, especially during that period.

Another study of this dataset was subsequently launched to demonstrate the validity of the "epidemic" hypothesis (MIND, 2002). The authors relied on DDS data and aimed at ruling out changes in diagnostic practices and immigration into California as factors explaining the increased numbers. While immigration was reasonably ruled out, the study comparing diagnoses of autism and mental retardation over time was impossible to interpret in light of the extremely low (< 20%) response rates. Furthermore, a study only based on cases registered for services cannot rule out that the proportion of cases within the general population who registered with services has changed over time. For example, assuming a constant incidence and prevalence at 2 different time points (i.e., hypothesizing no epidemic), the number of cases known to a public agency delivering services could well increase by 200% if the proportion of cases from the community referred to services rises from 25% to 75% in the same interval. In order to eliminate this plausible (see above) explanation, data over time are needed *both* on referred subjects *and* on nonreferred (or referred to other services) subjects. Failure to address this phenomenon precludes any inference to be drawn from a study of the California DDS database population to the California population (Fombonne, 2003a). The conclusions of this report were therefore simply unfounded.

2. The Role of Diagnostic Substitution

One possible explanation for increased numbers of a diagnostic category is that children presenting with the same developmental disability may receive one particular diagnosis at one time, and another diagnosis later. Such diagnostic substitution (or switching) may occur when diagnostic categories become increasingly familiar to health professionals and/or when access to better services is ensured by using a new diagnostic category. The strongest evidence of "diagnostic switching" contributing to the prevalence increase was produced in all U.S. states in a complex analysis of Department of Education Data in 50 U.S. states (Shattuck, 2006), indicating that a relatively high proportion of children previously diagnosed as having mental retardation were subsequently identified as having a PDD diagnosis. Shattuck showed that the odds of being classified in autism category increased by 1.21 during 1994–2003. In the meantime, the odds decreased significantly of being classified in the learning disability (LD) (odds ratio: OR = 0.98) and the mental retardation (MR) categories

(OR = 0.97). He further demonstrated that the growing prevalence of autism was directly associated with decreasing prevalence of LD and MR within states, and that a significant downward deflection in the historical trajectories of LD and MR occurred when autism became reported in the United States as an independent category in 1993–94. Finally, this author showed that, from 1994 to 2003, the mean increase for the combined category of *Autism + Other Health Impairments +Trauma Brain Injury + Developmental Delay* was 12/1000, whereas the mean decrease for MR and LD was 11/1000 during the same period. One exception to that was California, for which previous authors had debated the presence of diagnostic substitution between MR and autism (Croen et al., 2002; Eagle, 2004). The previous investigations have largely relied on ecological, aggregated data that have known limitations. Using individual level data, a new study has reexamined the hypothesis of diagnostic substitution in the California DDS dataset (King & Bearman, 2009) and has shown that 24% of the increase in caseload was attributable to such diagnostic substitution (from the mental retardation to the autism category). It is important to keep in mind that other types of diagnostic substitution are likely to have occurred as well for milder forms of the PDD phenotype, from various psychiatric disorders (including childhood schizoid "personality" disorders; Wolff & Barlow, 1979) that have not been studied yet (Fombonne, 2009). For example, children currently diagnosed with Asperger's disorder were previously diagnosed with other psychiatric diagnoses (i.e., obsessive-compulsive disorder, school "phobia," social anxiety, etc.) in clinical settings before the developmental nature of their condition was fully recognized.

> Diagnostic substitution occurs when an individual presenting with a diagnosis at one point in time receives another diagnosis later and is "re-classified".

Evidence of diagnostic substitution within the class of developmental disorders has also been provided in UK studies. Using the General Practitioner Research Database, Jick and Kaye (2003) have shown that the incidence of specific developmental disorders (including language disorders) decreased by about the same amount that the incidence of diagnoses of autism increased in boys born from 1990 to 1997. A more recent UK study (Bishop et al., 2008) has shown that up to 66% of adults previously diagnosed as children with developmental language disorders would meet diagnostic criteria for a broad definition of PDD. This change was observed for children initially diagnosed with specific language impairments, but even more so for those with a pragmatic language impairment.

3. Comparison of Cross-Sectional Epidemiological Surveys

As shown earlier, epidemiological surveys of autism each possess unique design features that could account almost entirely for between-studies variation in rates; therefore, time trends

in rates of autism are difficult to gauge from published prevalence rates. The significant correlation previously mentioned between prevalence rate and year of publication for autistic disorder could merely reflect increased efficiency over time in case identification methods used in surveys as well as changes in diagnostic concepts and practices (Kielinen et al., 2000; Webb et al., 1997; Magnusson et al., 2001; Shattuck, 2006; Bishop et al., 2008). In studies using capture-recapture methods, it is apparent that up to a third of prevalent cases may be missed by an ascertainment source, even in recently conducted studies (Harrison et al., 2006). Evidence that method factors could account for most of the variability in published prevalence estimates comes from a direct comparison of 8 recent surveys conducted in the UK and the United States (Fombonne, 2005). In each country, 4 surveys were conducted around the same year and with similar age groups. As there is no reason to expect huge between-area differences in rates, prevalence estimates should therefore be comparable within each country. However, there was a 6-fold variation in rates for UK surveys, and a 14-fold variation in U.S. rates. In each set of studies, high rates derived from surveys where intensive population-based screening techniques were employed whereas lower rates were obtained from studies relying on passive administrative methods for case finding. Since no passage of time was involved, the magnitude of these gradients in rates can only be attributed to differences in case identification methods across surveys. Even more convincing evidence comes from the large survey by the CDC on 408,000 U.S. children aged 8 and born in 1994 (CDC, 2007b) where an average prevalence of 66/10,000 was reported for 14 U.S. states. One striking finding of this report is that there was more than a 3-fold variation in state specific rates that ranged from a low 33/10,000 for Alabama to a high of 106/10,000 in New Jersey. It would be surprising if there were truly this much variance in the number of children with autism in different states in the United States. These substantial differences most certainly reflected ascertainment variability across sites in a study that was otherwise performed with the same methods and at the same time. In the more recent CDC 11 states study (CDC, 2009), the same variability is reported again. Prevalence was significantly lower (7.5/1,000) in states that had access to health sources only compared to that (10.2/1,000) of states where educational data was also available. The authors also reported that the quality and quantity of information available in abstracted records (the main method for case ascertainment) had increased between the 2002 and 2006. Together with a reported average decrease of 5 months for the age at diagnosis and a larger increase in the non–mentally retarded population, these factors suggest that improved sensitivity in case ascertainment in the CDC monitoring network has contributed substantially to the increase in prevalence. Thus, no inference on trends in the incidence of PDDs can be derived from a simple comparison of prevalence rates over time, since studies conducted at different periods are likely to differ even more with respect to their methodologies.

4. Repeat Surveys in Defined Geographical Areas

Repeated surveys, using the same methodology and conducted in the same geographical area at different points in time, can potentially yield useful information on time trends provided that methods are kept relatively constant. The Göteborg studies (Gillberg et al., 1991; Gillberg, 1984) provided three prevalence estimates that increased over a short period of time from 4.0 (1980) to 6.6 (1984) and 9.5/10,000 (1988), the gradient being even steeper if rates for the urban area alone are considered (4.0, 7.5, and 11.6/10,000, respectively) (Gillberg et al., 1991). However, comparison of these rates is not straightforward, as different age groups were included in each survey. Secondly, the increased prevalence in the second survey was explained by improved detection among the mentally retarded, and that of the third survey by cases born to immigrant parents. That the majority of the latter group was born abroad suggests that migration into the area could be a key explanation. Taken in conjunction with a change in local services and a progressive broadening of the definition of autism over time that was acknowledged by the authors (Gillberg et al., 1991), these findings do not provide evidence for an increased incidence in the rate of autism. Similarly, studies conducted in Japan at different points in time in Toyota (Kawamura et al., 2008) and Yokohama (Honda et al., 1996 and 2005) showed rises in prevalence rates that their authors interpreted as reflecting the effect of both improved population screening of preschoolers and of a broadening of diagnostic concepts and criteria.

Two separate surveys of children born 1992–1995 and 1996–1998 in Staffordshire in the UK (Chakrabarti & Fombonne, 2001, 2005) were performed with rigorously identical methods for case definition and case identification. The prevalence for combined PDDs was comparable and not statistically different in the 2 surveys (Chakrabarti & Fombonne, 2005), suggesting no upward trend in overall rates of PDDs, at least during the short time interval between studies. In two recent CDC surveys (2007a, 2007b), the prevalence at six sites included in the 2000 and 2002 surveys remained constant at 4 sites, and increased in 2 states (Georgia and West Virginia), most likely due to improved quality of survey methods at these sites. In the 2009 CDC report, an average increase of 57% in prevalence was reported in 10 sites with 2002 and 2006 data, with a smaller increase in Colorado. Increases of different magnitude and directions were reported in all subgroups, making it difficult to detect a particular explanation. The CDC researchers identified a number of factors associated with the change in prevalence but could not conclude on the hypothesis of a real change in the risk of ASD in the population.

5. Successive Birth Cohorts

In large surveys encompassing a wide age range, increasing prevalence rates among most recent birth cohorts could be

interpreted as indicating a secular increase in the incidence of the disorder, provided that alternative explanations can confidently be eliminated. This analysis was used in two large French surveys (Fombonne & du Mazaubrun, 1992; Fombonne et al., 1997). The surveys included birth cohorts from 1972 to 1985 (735,000 children, 389 of whom had autism), and, pooling the data of both surveys, age-specific rates showed no upward trend (Fombonne et al., 1997).

An analysis of special educational disability from Minnesota showed a 16-fold increase in the number of children identified with a PDD from 1991–1992 to 2001–2002 (Gurney et al., 2003). The increase was not specific to autism since, during the same period, an increase of 50% was observed for all disability categories (except severe mental handicap), especially for the category including ADHD. The large sample size allowed the authors to assess age, period, and cohort effects. Prevalence increased regularly in successive birth cohorts; for example, among 7-year-olds, the prevalence rose from 18/10,000 in those born in 1989, to 29/10,000 in those born in 1991 and to 55/10,000 in those born in 1993, suggestive of birth cohort effects. Within the *same* birth cohorts, age effects were also apparent since for children born in 1989 the prevalence rose with age from 13/10,000 at age 6, to 21/10,000 at age 9, and 33/10,000 at age 11. As argued by the authors, this pattern is not consistent with what one would expect from a chronic nonfatal condition diagnosed in the first years of life. Their analysis also showed a marked period effect that identified the early 1990s as the period where rates started to increase in all ages and birth cohorts. Gurney et al. (2003) further argued that this phenomenon coincided closely with the inclusion of PDDs in the federal Individual with Disabilities Educational Act (IDEA) funding and reporting mechanism in the United States. A similar interpretation of upward trends had been put forward by Croen et al. (2002) in their analysis of the California DDS data, and by Shattuck (2006) in his well-executed analysis of trends in the Department of Education data in all U.S. states.

Conclusion on Time Trends

As it stands now, the recent upward trend in rates of *prevalence* cannot be directly attributed to an increase in the *incidence* of the disorder, or to an "epidemic" of autism. There is good evidence that changes in diagnostic criteria, diagnostic substitution, changes in the policies for special education, and the increasing availability of services are responsible for the higher prevalence figures. It is also noteworthy that the rise in number of children diagnosed occurred at the same time in many countries (in the early 1990s), when radical shifts occurred in the ideas, diagnostic approaches, and services for children with PDDs. Alternatively, this might, of course, reflect the effect of environmental influences operating simultaneously in different parts of the world. However, there has been no proposed and legitimate risk mechanism to account for this worldwide effect. Most of the existing epidemiological data

are inadequate to properly test hypotheses on changes in the incidence of autism in human populations. Moreover, due to the relatively low frequency of autism and PDDs, power is seriously limited in most investigations, and variations of small magnitude in the incidence of the disorder are very likely to go undetected. Equally, the possibility that a true increase in the incidence of PDDs has also partially contributed to the upward trend in prevalence rates cannot, and should not, be eliminated based on available data.

Conclusion

Epidemiological surveys of autism and PDDs have now been conducted in many countries. Methodological differences in case definition and case finding procedures make between survey comparisons difficult to perform. However, from recent studies, a best estimate of 70/10,000 (equivalences = 7/1,000; or 0.7%; or 1 child in about 143 children) can be confidently derived for the prevalence of autism spectrum disorders. Current evidence does not strongly support the hypothesis of a secular increase in the incidence of autism, but power to detect time trends is seriously limited in existing datasets. While it is clear that prevalence estimates have increased over time, this increase most likely represents changes in the concepts, definitions, service availability, and awareness of autistic-spectrum disorders in both the lay and professional public. To assess whether or not the incidence has increased, methodological factors that account for an important proportion of the variability in rates must be tightly controlled. New survey methods have been developed to be used in multinational comparisons; ongoing surveillance programs are currently under way and will soon provide more meaningful data to evaluate this hypothesis. The possibility that a true change in the underlying incidence has contributed to higher prevalence figures remains to be adequately tested. Meanwhile, the available prevalence figures carry straightforward implications for current and future needs in services and early educational intervention programs.

Challenges and Future Directions

- The boundaries of the spectrum of PDDs with both severe developmental and neurogenetic disorders and mild forms of atypical development remain uncertain and unreliable. Measures of impairment will need to be added to symptom and developmental assessments in order to refine case definitions for epidemiological studies and other research endeavors.
- Future epidemiological surveys should estimate the proportion of "false negatives" in order to estimate the sensitivity of case ascertainment methods and obtain more

accurate rates. Current prevalence rates underestimate the "true" prevalence rates as they are not adjusted to compensate for missed cases.

- Monitoring trends in prevalence and incidence is needed. It will require methods that allow meaningful comparisons over time of cases defined and ascertained with stable approaches.

Culture and Autism Spectrum Disorders: The Impact on Prevalence and Recognition

Points of Interest

- Autism exists throughout the world, even in societies that have no name for it.
- Understanding how culture influences the recognition, definition, and treatment of autism may lead to better prevalence estimates.
- Public and private funding agencies now support epidemiological research in low and middle-income countries to explore how autism varies internationally in terms of its clinical manifestation and the extent of disability associated with the disorder.
- Autism spectrum disorders and *explanations* of developmental disorders (scientific or otherwise) are products of the interplay between biological, psychological, and cultural phenomena.
- Local factors affecting "administrative" prevalence estimates include poverty, access to services, racial discrimination, stigma, cultural beliefs about what kinds of behavior are "normal" and "abnormal," and a nation's health and public health infrastructure.

Awareness of the prevalence and phenotypes of autism spectrum disorders (ASD) has increased significantly over the past decade, especially in North America and the United Kingdom. Knowledge about ASD has also begun to spread internationally to countries such as India, South Korea, and Kenya, where the fields of developmental psychology, developmental pediatrics, and child psychiatry are less robust and where clinicians and educators do not generally distinguish ASD from other neurodevelopmental disorders, such as intellectual disability or learning disorders.

A search of published ASD research activities across the globe, however, might suggest that there is little knowledge about ASD outside of North America and Western Europe. Indeed, there are insufficient data to estimate the prevalence of autism in the Caribbean, Central and South America, Eastern Europe, the Middle East, South and Southeast Asia, and the entire continent of Africa (see Table 7-1; Figures 7-1 and 7-2). Mapping the prevalence of autism, as seen in Figure 7-2, can be misleading, as it does not reflect the history of autism research or the recent growth around the world in awareness and expertise. For example, Hans Asperger, whose studies of ASD were foundational to the field today and whose descriptions are, for the most part, still relevant today, was Austrian. Leo Kanner, the psychiatrist who first described autism, was Austrian-American and was deeply influenced by an Italian scientist, de Sanctis, who in 1906 published case reports on early onset "dementia praecox" (probably autism) in a group of children with intellectual disability.

In addition, despite the absence of international epidemiological studies, awareness, advocacy, and opportunities for treatment and education of children and adults with ASD are advancing rapidly throughout the world. Today, national autism societies exist in more than 100 different countries, and scientific research on ASD is underway in eastern and southern Africa, India, several Middle Eastern countries, Mexico, Venezuela, and a host of other nations.

For a number of reasons, continued growth of international research on ASDs, and neurodevelopmental disorders in general, should be expected. First, the number of child mental health professionals in non-Western countries is rising. Second, recent large-scale collaborations between UNICEF, WHO, the World Bank, and university-based scientists, have led to improved recognition of developmental and intellectual disabilities among children living in poverty in the developing world, as evidenced by a high-profile series of articles on child development in *The Lancet* in 2007. In war-torn countries, some United Nations peacekeepers are now trained to provide services to individuals with autism.

Third, as low and middle-income countries advance economically, and infectious diseases and child mortality

Table 7–1.
Autism prevalence around the world (2000–2009)

Continent/Region	Country	Prevalence	Reference
North America	United States	~90/10,000 = 1/110	ADDM 2009
	Canada	~65/10,000 = 1/154	Fombonne et al. 2006

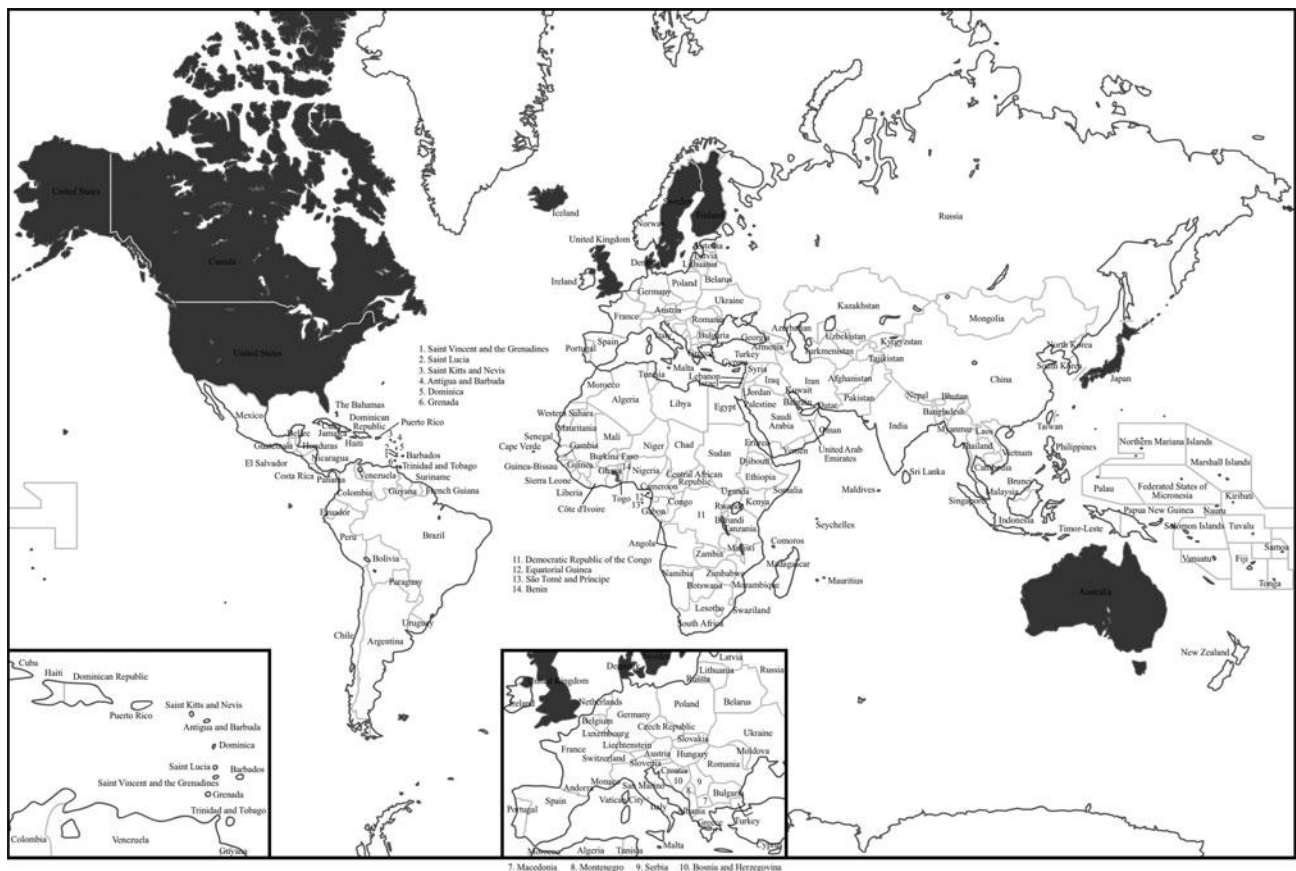

Figure 7–2. Map of autism prevalence studies around the world (2000–2008).

become less of a concern, disability and child development become more prominent as public health issues.

Nonetheless, researchers are just beginning to study the extent to which ASD varies across cultures. Although most researchers expect that the onset and core symptoms of ASD are consistent across cultures, this remains an assumption. ASD experts to date know little about how genetic heterogeneity and cultural differences interact to influence the kind and range of impairments that are essential to or associated with ASD, its prevalence, course, or familial patterns.

The most robust body of literature on autism as a global phenomenon is in the field of psychiatric epidemiology. Over the past 40 years, prevalence studies of autism have been conducted in numerous countries, with one major review citing English-language studies in 13 different countries, including France, Japan, Norway, Iceland, and Finland (Fombonne, 2003, 2009). Epidemiological findings are forthcoming from East Asia and South America (Montiel-Nava & Peña, 2008) and ASD screening tools have been tested in a wide range of locations (see, for example, Lung et al., 2010 on Taiwan, and Eldin et al., 2008 on the Middle East). However, the vast majority of prevalence studies have been conducted in the United Kingdom and North America.

A few case reports and screenings have been published for other countries, such as Malaysia (Kasmini & Zasmani, 1995), Taiwan (Chang et al., 2003), Zimbabwe (Khan & Hombarume, 1996), and the United Arab Emirates (Sartawi, 1999), with some studies reporting associated medical conditions such as mitochondrial respiratory chain disorders in Portugal (Oliveira et al., 2007) and Möbius sequence in Brazil (Bandim et al., 2002). Research on possible clusters of autism among Europeans and Americans of Somali origin is in the beginning stages (Barnevik-Olsson, Gillberg, & Fernell, 2008; Minnesota Department of Public Health, 2009). Some studies, such as La Malfa's epidemiological work in Italy, have examined the prevalence of pervasive developmental disorders (PDD) in an already identified pool of children with intellectual disabilities (La Malfa et al., 2004). Others examine ASD as one of a group of conditions in large-scale projects on challenging childhood behaviors or developmental disorders in general (Holden & Gitleson, 2006; Morton et al., 2002). At least one British study noted significantly higher prevalence of childhood cognitive disabilities, including autism, among citizens of Pakistani origin, whose high rate of consanguineal marriage is believed to be related to a rate of birth defects that is higher than the general population in the United Kingdom (Morton et al., 2002).

DSM criteria for ASD have been tested in multiple countries, and genetic research involves samples from populations throughout Western Europe. However, with the exception of Lotter's brief, anecdotal survey of autism prevalence in six African countries (1978) and Probst's exploratory survey of the stresses and demands of parents of children with autism in Brazil, Germany, Greece, and Italy (1998), there are, to our knowledge, no published cross-national studies that address the impact of culture on ASD. There is also very little information about how the genetics, biology, risk factors, treatment, and course of ASD differ across continents, countries, or ethnic groups. This chapter focuses on the international prevalence and diagnosis of autism because these are the areas in which international scientific publications exist. We consider the effect of culture on the conceptualization and identification of ASD, with special attention to the question of how studies of the sociocultural contexts of ASD, and neuropsychiatric disorders in general, can help us frame future international ASD research.

Given the fact that the majority of research on ASD has been carried out within the mental health field, we situate the research within the larger framework of psychiatric and psychological studies. However, we recognize that as research on ASD progresses, a greater number of studies will consider ASD from alternative, nonpsychiatric perspectives, such as within the context of a neurodevelopmental disorders framework.

Recognition and Epidemiology

Research to date has highlighted cross-national differences in the symptoms and course of psychiatric disorders. For example, although the age of onset and prevalence of both schizophrenia and obsessive-compulsive disorder are remarkably consistent across the globe, sex ratios, comorbid conditions, symptom expression, severity, and prognosis vary significantly (Hopper et al., 2007; Horwath & Weissman, 2000; Lemelson, 2003). Moreover, although researchers may use standardized assessments and criteria (at the very least, DSM and ICD criteria) to determine whether an individual constitutes a "case" of autism, clinicians who are not integrated into a research community—physicians and psychologists who see patients in private or clinic settings—may conform to folk categories of illness or rely on past training and personal clinical experience. Even with standardized criteria, considerable subjectivity and differences in clinical assessments exist, since the diagnosis depends on patient or caretaker narrative and behavioral observation rather than laboratory tests. Indeed, variations in diagnosis within and between societies can sometimes be explained in terms of the differences between research and clinical practice.

Cross-cultural variations in psychiatric diagnoses can be found, even between communities whose scientific traditions are often assumed to be similar, such as the United States and the United Kingdom. In a landmark study of the differences

between British and American psychiatrists (whose scientific cultures are not dramatically different), R. E. Kendell (1971) and his colleagues showed a video of a socially awkward man, described as a 30-year-old bachelor, and asked British and American psychiatrists to give a diagnosis based only on the video. Sixty-nine percent of the American psychiatrists diagnosed the man with schizophrenia; only 2% of British psychiatrists gave that diagnosis (a large number of the British clinicians gave a diagnosis of manic-depressive illness). Shifts in classification occur for many reasons—such as the need to screen and treat soldiers in military conflicts, shifts in the way the insurance industry conceptualizes appropriate reimbursements, and public attitudes about the stigma of mental illness—that have little to do with advances in science and much to do with social and historical context (Grinker, 2010a). The classifications of the most empirically verifiable disorders, such as bacterial or viral infections, evolve and are formed by consensus. A disorder, even one with a clear cause or biomarker, is only a disorder when a society construes it as such. Thus, although Asperger's disorder is scheduled for elimination from the proposed DSM-5, this does not mean that Asperger's once existed as a real disease and now has disappeared. Asperger's was useful when a non-stigmatizing term was needed for people with the disorder, but clinicians now question it for both cultural and scientific reasons. From the perspective of culture, Asperger's is fast becoming obsolete as a scientific category as the stigma of autism declines. Societies throughout the world are beginning to appreciate the strengths and capabilities of people with autism, and people with autism increasingly feel less self-stigma and may advocate for their needs in public forums. From the perspective of science, clinicians recognize that almost everyone with Asperger's also fits the profile of the more classic autistic disorder. Indeed, in the current diagnostic manual, the DSM-IV, a child who has good language acquisition and intelligence qualifies as autistic if, in addition to having restricted interests and problems with social interactions, he has just one of the following symptoms, which are common among children with Asperger's: difficulty conversing, an inability to engage in make-believe play or repetitive or unusual use of language. Even the best available diagnostic instruments, such as the ADOS and ADI-R, cannot clearly identify distinct subtypes on the autism spectrum (Grinker, 2010b).

The social construction of psychiatric classification can be illustrated by the differences between ASD diagnostic classification and research in the United States and France. In the United States, the American Psychiatric Association removed autism from the category of "psychosis" in 1980, but the French child psychiatric establishment, which uses its own indigenous manual of mental disorders, the *Classification Française des Troubles Mentaux de l'Enfant et de l'Adolescent* (CFTMEA), classified autism as a psychosis until November 2004. French health professionals also conceptualize the etiology of autism in a manner that is different from other European countries and consider the American classification of PDDs to be a product of Anglo-American culture.

Since French health professionals generally view autism as a problem that lies within family social relationships and with the mother-child relationship in particular, there are only a few psychiatric or medical centers with expertise on autism as a genetic or brain disorder.

In recent years, a battle has erupted between French parents, armed with scientific studies and classifications from the United States and the United Kingdom, and French child psychiatrists. French health professionals generally retain a more restricted concept of autism and are openly hostile to behavioral interventions, such as the Treatment and Education of Autistic and Related Communication-Handicapped Children (TEACCH) program or Applied Behavioral Analysis, and to parent and parent association efforts to shift the locus of autism treatment from the hospital to the school (Chamak, 2008). Despite the efforts of parents, autism research and treatment in France continues to be guided largely by psychoanalytic thought, in particular the idea that autism is a disorder of object relations. Research on treatment emphasizes play therapy and interactive techniques to facilitate the growth of autonomy and a sense of self.

A clinical trial is underway in Lille, France, on the controversial therapy called "packing," in which a child is wrapped tightly in wet, refrigerated sheets, for approximately sixty minutes while clinicians attempt to talk with them about their feelings. The therapy is based on an argument that a child's ability to establish a proper relationship between his internal world and his external, social reality depends on his ability to merge his body and his body image (Spinney, 2007).

One reason for the absence of a large number of cross-national studies in mental health is that, in addition to being expensive and difficult to coordinate, the standardized assessments and classifications needed for such studies are of somewhat recent origin. American psychiatrists and psychologists have become keenly interested in diagnostic classification only in the last 3 decades. As one result, psychiatric epidemiological studies using comparable methods did not begin in earnest until the 1970s, and there were few cross-national studies conducted until the 1990s. The World Health Organization (WHO) international studies of schizophrenia began in 1968 and eventually included thirty research sites in nineteen countries and involved a 26-year follow-up period. These studies represent the most ambitious and lengthy cross-cultural explorations of the manifestations, course, and outcomes of a mental illness. Yet, as recently as 2004, only two prevalence studies of mental disorders among European adults had used comparable methods of ascertainment at the same time in more than one country (ESEMeD/MHEDEA, 2004). However, if we accept Cohen and Volkmar's assertion about autism, in relation to the DSM-IV and ICD-9 criteria that "There is no other developmental or psychiatric disorder of children (or perhaps of any age) for which such well-grounded and internationally accepted diagnostic criteria exist," cross-national studies should be feasible (Cohen & Volkmar, 1997).

Although there is a rapidly growing literature on international studies of neurodevelopmental disorders, and ASD in

particular, there are few estimates of the prevalence of physical disabilities among children in low and middle-income countries and even fewer of behavioral disorders (Yeargin-Allsopp & Boyle, 2002). Researchers have made significant progress internationally, studying some disorders in childhood that have a neurodevelopmental component, such as cerebral palsy and epilepsy. Among psychiatric disorders, ADHD and conduct disorder have been studied extensively across the globe (Faraone et al., 2003; Polanczyk et al., 2007). However, epidemiological research on childhood onset disorders lags behind the epidemiology of such disorders in adults. Even within the area of the epidemiology of child mental disorders, more is known about psychiatric disorders in older children and adolescents than in younger children.

One area of progress in the diagnosis and epidemiology of autism across cultures has been at the level of screening, in particular the development of brief screening tools that can be validated in numerous languages and dialects and administered with minimal training. For example, the Childhood Autism Rating Scale (CARS) (Schopler et al., 1988), a 15-item, behavioral rating scale has been shown to be both sensitive and specific for ASD; the Autism Behavior Checklist (ABC) (Krug et al., 1980) includes 57 items but nonetheless takes less than 20 minutes to complete; and the Autism Spectrum Screening Questionnaire (ASSQ) (Ehlers et al., 1999), a 10-minute, 25-item rating scale appears to be particularly good at screening for high-functioning autism and Asperger's disorder. These scales have been used successfully in international research, have proved both reliable and specific, and are thus valuable in clinical and community-based settings. A broader approach, especially applicable in low and middle-income countries, is to screen children initially for an array of neurodevelopmental disabilities and then administer a condition-specific assessment for children who screen positive. This model was initially developed by Durkin et al. (1992) using a short questionnaire that includes only ten questions (known as the "ten questions screen"). More recently, the ten questions screen has been adapted by Indian researchers as part of the International Clinical Epidemiology Network (INCLEN) in India for a community-based screening study of autism and other developmental disorders among children ages 2–9 years.

In research settings in which scientists trained in the diagnosis of developmental disabilities are available, screenings are useful as a first-stage diagnostic tool. More lengthy and substantial diagnostic assessments are then performed with tools such as the Autism Diagnostic Observation Schedule (ADOS) (Lord et al., 1999) and the Autism Diagnostic Interview (ADI) (Rutter et al., 2003), both of which have been translated, validated, and are available for purchase in twelve European languages and Korean. Numerous other translations are underway, but more are needed. As one researcher in Thailand noted (where no translations of these tools have been validated), even when researchers and clinicians can characterize ASD as conforming to DSM-IV criteria, they cannot confirm the diagnoses in the absence of Thai-translated,

standardized investigator-based instruments and structured observational schedules (Chuthapisith et al., 2007).

Conducting Prevalence Studies in International Settings

In the United States and United Kingdom, investigators now ideally use a two-stage approach to estimate autism prevalence, and this approach is capable of detecting more cases than ever before. In general, the approach involves a screening phase to identify a pool of children who may have an ASD, followed by a diagnostic confirmation stage. The methods for both phases vary widely, and their validity is dependent on the clinical and educational infrastructure in the country or setting. The screening stage can range from a general population screen in a primary care setting, as done by Honda et al. (2005), to a screening of children identified in high-risk settings, such as special education schools. High-risk screening can be based on canvassing records in schools or health care settings that target children with developmental delays or administering an autism screening instrument to a knowledgeable informant, such as a parent, guardian or teacher, or a combination of these two.

The targeted approach to case screening has become easier in many countries in recent years due to better awareness of autism and, presumably, a combination of more accurate clinical diagnosis and critical policy level changes that promote identification. For example, in the United States, beginning in the 1991–1992 school year, autism became a separate area of "exceptionality," meaning that children with autism could receive special education services specifically designated for children with autism. The U.S. Department of Education required schools to report, as part of an annual "child count," the number of children receiving these services under the autism classification. The child count made it significantly easier to locate potential case children from school records. To add even more cases, the CDC studies examined records of children with educational classifications beyond autism, such as behavior disorders and intellectual disabilities, since all children with autism are not necessarily classified by schools as autistic. In low and middle-income countries, a records-based screening approach may not be feasible, because of the absence of records or because the diagnosis of autism is either unknown or rarely used. In such situations, researchers will have to screen individuals rather than records.

In the best of circumstances, a researcher can combine a record review with individual screening. During the individual screening, parents and teachers fill out standardized third-party questionnaires such as the Autism Screening Questionnaire (ASQ) or the Autism Spectrum Syndrome Screening Questionnaire (ASSQ). These questionnaires, which have been studied extensively for their reliability—i.e., to make sure that independent researchers using them with the same case would come to the same conclusion—help

epidemiologists identify potential cases, especially when two or more instruments with different sensitivities are used together. However, in some countries, it may be impractical to use parent self-administered screening tools for a variety of reasons. For example, many parents in low and middle income countries may have low literacy, especially mothers (since women often have more limited access to education then men), and may thus be unable to complete the surveys. Also, for political reasons, parents in some countries may be afraid of having their child's health condition codified in writing.

In the second stage—diagnostic confirmation—epidemiologists ideally use trained diagnosticians to confirm case status among those who screen positive. If the screening phase was based on a record review, a standardized review process is established to determine case status (for examples, see Barbaresi et al., 2005; Honda et al., 2005; Williams et al., 2005; Powell et al., 2000; Lauritsen et al., 2004; and Autism and Developmental Disabilities Monitoring Network [ADDM], 2009). Because the study population is much smaller at the confirmation stage, assessments can be done in person with each child, preferably with more than one structured, reliable diagnostic assessment, such as the combination of the ADOS (a *synchronic* observation schedule over one 2- to 3-hour period of time) and the ADI (an extended parent/guardian interview that provides a detailed history, or *diachronic* perspective, on the child). Ideally, for both methods (record-based and in-person assessments) the confirmatory diagnoses are then validated by outside consultants using a group of randomly selected cases (some with and some without an autism diagnosis). This second stage is especially important for validating the less clear-cut cases, such as the ones on the border between two different diagnoses or between a diagnosis and none at all.

We have entered a period in history in which autism awareness is at an all-time high and in which the diagnosis of autism has broadened to include a range of different people along a wide spectrum. This is largely due to the current use of the two-stage case-finding approach, which yields many more cases of autism than the older studies. In addition, researchers ideally employ quality control measures, such as blinded reviewers, to establish interrater reliability. However, it must be stressed that it is exceedingly difficult and expensive to use such thorough and rigorous methods. Implementation of the gold standard assessments for autism is particularly challenging in low-income countries. Extensive training is necessary to obtain test reliability. Considerable participant burden is associated with the length of time, often several hours, to administer the assessments. Furthermore, in countries in which little research has been conducted on child development, the validity of results from such protocols will be hampered by the absence of established, documented norms of child development for a given population. Epidemiological studies in the low and middle-income country setting will therefore benefit from the development of more efficient and affordable diagnostic assessments.

Challenges to ASD Surveillance

The epidemiology of ASD should be understood in the context of the many challenges inherent in applying diagnostic criteria to growing and developing children in different cultural contexts. It is not feasible to produce a list of criteria for a disability that will be relevant at all developmental levels, and what counts as normal or abnormal development will vary from culture to culture. There is the obvious problem that researchers who study school-age children face the difficult task of reliably defining cases on the basis of information presented in teacher reports (which can be heavily influenced by a multitude of factors, such as class size, teacher training, and the local, cultural attitudes toward discipline and about what kinds of behaviors are age appropriate) and parent reports (which are influenced by the particularities of the parent who completes the report). For some childhood onset psychiatric disorders, estimates may appear higher in a country with great awareness among parents, educators, and clinicians; access to services; or in which the national government mandates the use of "autism" as a diagnostic term. In contrast, estimates may be lower in a country with little awareness, few services, and lack of research studies, especially of administrative prevalence. For example, school and clinic records of "autism" and "traumatic brain injury" grew tremendously following the 1991–1992 school year, when the U.S. Department of Education first introduced these terms to the American public school system (Newschaffer et al., 2005).

Previous studies confirm significant variations among locations, even within the same country, as the Centers for Disease Control and Prevention showed from their multisite surveillance network. Recent prevalence estimates for Arizona and Missouri (12.1 per 1000) were higher than those from Florida (ADDM, 2009). Research in Australia has demonstrated considerable variability in diagnostic rates across states and between state and national records. In Queensland, the number of diagnoses of ASD exceeds that of other states, since Queensland requires a DSM-IV diagnosis for eligibility for services but other Australian states do not (Skellern et al., 2005).

Moreover, clinicians will not make or record a particular diagnosis, and parents will not seek it, unless the diagnostic term is meaningful and in current use. Thus, for example, the Navajo Indians of the American Southwest tend to classify autism as "perpetual childhood" (Conners & Donnellan, 1995), and throughout most of India, clinicians call autism *paagol*, the Hindi word for "madness" (Daley, 2002, 2003). School and clinic records for a child with ASD, if there are any records kept, will not list the word "autism." In rural South Korea, the catch-all "brain disorder" can be used for children with disorders including traumatic brain injury, autism, epilepsy, speech and language disorders, Down syndrome, and other clearly genetic disorders. In this setting, record reviews will yield few cases of autism.

Researchers should expect to encounter additional obstacles when attempting to do public health screening in general and ascertain and classify neurodevelopmental disorders in societies with low access to services. Illness categories are beneficial only if there is something one can do with them. Thus, for many American adults with ASD who require public assistance, it makes little sense to carry an autism diagnosis in states where services for adults with autism are provided only under the category of intellectual disability, or formerly "mental retardation." In urban India, where there are few autism-related services, a clinician is unlikely to give a diagnosis of autism since the clinician may believe that it would only confuse the family, the school system, and potential service providers (Daley & Sigman, 2002; Daley, 2003). Indian pediatricians interviewed by Daley (2003) and Grinker (2007) use a much more well-known category—mental retardation, popularly glossed as "madness"—even if it is sometimes inaccurate, and they will justify it by arguing that the treatments and educational services in India for someone with mental retardation are identical to those for someone with autism. For this reason, records-based approaches to the epidemiology of autism in societies where "autism" is uncommonly used as a diagnostic term are not feasible. Even in societies where the concept of autism does exist, people may not seek care from the experts who are familiar with the term. Indeed, epidemiologists should not assume that the population being studied shares the researchers' understanding about the relationship between the symptoms being studied and the name of the disease. In Korea, for example, despite dramatic changes in autism awareness, the word for autism (*chap'ae*) has quite negative connotations because many people mistakenly believe that all individuals with the diagnosis are profoundly intellectually disabled and nonverbal. The Korean research team in the first author's prevalence study of ASD worked hard to explain to teachers and parents the concept of an autism *spectrum* (Grinker, 2007). Toward this goal, researchers asked the child psychiatrists who led the information sessions at the "mainstream" elementary schools to remove from their presentations a film about autism because it depicted a quite impaired young man with autistic disorder.

Furthermore, in some developing countries there may be opposition to research on disorders that are not life threatening. It has been suggested that research on developmental disabilities in general is a low priority in many low-income countries where there are more pressing issues such as diseases that cause infant and child mortality (Durkin, 2002, p. 206). Consequently, in many countries, due to the lack of administrative records on child health, researchers need to be referred to potential cases by a wide range of individuals, such as priests and ministers, pediatricians, community leaders, and teachers. Researchers may need to conduct door-to-door household surveys and individual screenings of all children in a community (see, for example, Islam et al., 1993; Thorburn et al., 1992; Durkin, Hasan, & Hasan, 1998). Even then, parents and health officials may strongly oppose the introduction of a diagnostic category that is new and thus confusing.

Social stigma influences diagnosis. In South Korea, children that American clinicians might diagnose with autism are often diagnosed with reactive attachment disorder (RAD),

pejoratively referred to as "lack of love" (*aejŏng kyŏlpip*), a term that parallels the older American concept of the "refrigerator mother." In Korea, RAD is thought to be a condition mimicking autism, caused by a mother's absence of attachment to her child (Shin et al., 1999). Many parents prefer a RAD diagnosis to autism.

First, unlike autism, RAD or lack of love can be ameliorated by giving love and thus is not a permanent condition. Koreans widely consider autism to be untreatable (Grinker, 2007). Second, RAD, unlike autism, is not a genetic condition. Thus, while RAD may stigmatize the mother, autism would stigmatize the whole family—past, present, and future. This fear of autism as a genetic disorder is found in many other countries as well, where parents fear that a child's diagnosis of autism will marginalize the family from the social networks to which they feel they are entitled, and harm other family members' marriage prospects (such as the autistic child's siblings). Third, and perhaps most importantly, the diagnosis makes sense. Korea has been undergoing dramatic social change for the last 50 years, emerging from the total devastation of the Korean War to becoming the twelfth largest economy in the world, ahead of countries like Australia, Switzerland, and Sweden. Noting the increase in working mothers and nuclear, as opposed to extended, households, Korean sociologists and child health experts argue that children left with nannies or in daycare cannot form appropriate or lasting attachments with their mothers, and that the failure of attachment leads to RAD.

Such attitudes are not unique to Korea. Hypotheses about the causative role of environmental factors, such as poor parenting and social stressors, in ASD, attachment disorders, and other childhood onset problems, have considerable traction in impoverished or rapidly changing societies. In South Africa, for example, child psychiatrists argue that the role of such stressors have been grossly underrepresented in research on child development: young children are exposed to many forms of violence, parental substance abuse is common, and many children are orphaned or raised by multiple caretakers and with little continuity of care (Hugo et al., 2003).

Despite such obstacles at the clinical level, improvements in diagnostic specification with screening tools and "gold standard" assessments have opened the possibility for rigorous and comparable studies of ASD across cultures. Regardless of whether a society has a word for autism or maintains that autism is a rare condition, epidemiologists can ascertain cases. Children with ASD in a range of different countries have been identified in prevalence studies and can thus form cohorts for studies of etiology and intervention (Vogel & Holford, 1999).

As more diagnoses are made and recorded in school and clinic records, there will be greater opportunities for records-based epidemiological studies. In addition, advances in disability legislation and the growth of advocacy organizations in a number of countries, such as Brazil, China, India, Malawi, South Africa, and Uganda (Braddock & Parish, 2001) as well as at the transnational level (for example, the United Nations, UNICEF, PAHO, WHO, and the World Bank) have made it possible for children with autism to obtain appropriate educational placements and have their diagnoses recorded in school records. As just one example, the well-known TEACCH program has been studied and subsequently adopted in numerous countries and is currently under development in China, India, Mexico, Morocco, Nigeria, and the Philippines, among other places.

Despite the progress in the epidemiology of ASD, there are only a handful of studies that examined the incidence of autism: the rate of occurrence of new cases in a population over a specified period of time (Fombonne, 2007; Rothman and Greenland, 1998; Kleinbaum et al., 1982). This absence is understandable due to the fact that the emergence of ASD in early childhood is insidious, and it is thus often difficult to determine disease onset, which is necessary to examine incidence. Of the studies that have examined incidence, the date of first diagnosis is usually used as a proxy for onset of the disorder. Incidence studies are particularly challenging in a low or middle-income country setting where autism is not routinely diagnosed and symptom onset is not well documented (Figure 7-3).

Despite all of these challenges, there are ongoing efforts to facilitate and standardize the epidemiologic approach to autism research from an international perspective. However, the approaches to autism epidemiology have to be based on local capacity and other attributes in a country. A large-scale initiative sponsored by the parent advocacy organization Autism Speaks distinguishes three separate approaches: one exclusively using records for those settings where most children with an ASD can be identified in schools and health care settings; another utilizing disease registry systems established in some countries as a mechanism to track the health of the population; and a third approach, for those countries with an undeveloped service system, which requires community canvassing or more generalized screening. The intent is to facilitate research within each of these settings and to explore how autism varies in terms of its clinical manifestation and the extent of disability associated with the disorder.

Effect of Social Organization, Culture, and Language on Prevalence Studies and Services

Social Organization and Culture

The WHO studies of schizophrenia constituted the first large-scale effort to explore the role of social organization and culture in influencing the prevalence and outcomes of a mental illness. However, the concept of "culture," broadly defined as the system of meanings through which people organize and make sense of their lives, has long been a central feature of psychiatric description and should not be used only in reference to non-Western societies. For example, researchers have considered how poverty, occupation, social class, and marriage systems affect mental illness in the United States. Epidemiological studies of schizophrenia as early as the 1930s (Faris & Dunham, 1939) noted differences in the prevalence of schizophrenia in urban and rural areas in the United States.

Figure 7–3. Hindi poster. Autism experts in India are promoting autism awareness through educational programs and posters, such as this one, in Hindi, that depict and describe a range of symptoms. For example, the poster describes the symptom at the top left as "Aloof in Manner"; the caption at the bottom right is "Unusual behavior of body movement such as flapping hands, rocking, or jumping." Courtesy of Merry Barua, Action for Autism (India).

Numerous studies highlight racial disparities in the diagnosis of schizophrenia (Mishler, 1965; Ruiz, 1982), with most researchers agreeing that the disparities are the result not of true differences in prevalence but rather racism, cultural misunderstandings, misdiagnosis, and mismanagement (Whaley, 2001). Among the mentally ill, poor people are also overrepresented, perhaps a legacy to the day when insane asylums also served as poorhouses.

As recently as 1984, Sanua, echoing Lotter (1978), argued that autism was not a universal phenomenon, but a culture-bound disorder, "an illness of Western Civilization" (Sanua, 1984). And for decades following Kanner's original description of the parents of children with autistic disorder as highly educated, upper-middle-class workers, researchers focused on social class as a possible risk factor for autism, one result of which was the concept of the refrigerator mother (usually the educated, working, professional mother). Even today, some scientists continue to argue that ASD occurs more often in the offspring of scientists, engineers, mathematicians, and computer experts, and those with a sociobiological perspective have hypothesized that the increase in the prevalence of higher-functioning autism and Asperger's

disorder in the United States and the United Kingdom is the result of intermarriage between highly educated parents (Baron-Cohen, 2004). The development of computer technologies, they argue, makes it possible for autistic adults to find gainful employment, marry, and reproduce. The delay in finding a suitable mate may lead to an increase in parental age, which has been shown in some studies, but not all, to be a risk factor for ASD (Durkin et al., 2008; Croen et al., 2007; Shelton et al., 2010; Grether et al., 2009).

The hypothesis of an association between autism and high socioeconomic status (SES) stands in stark contrast to the large body of research consistently showing that low socioeconomic status is the strongest predictor of childhood disabilities (Durkin, 2002). It is important to point out that none of the claims associating autism or changing prevalence rates to computer technology or to higher SES has been proven. One research team (Cuccaro et al., 1996) did find that school-based clinicians, pediatricians, and psychiatrists were biased in favor of giving autism diagnoses to children of parents of high SES. In a survey of pediatricians, Stone (1987) found that a majority believed there was a true association between autism and SES. It is possible that such a bias explains, at least in part, the fact that African American children subsequently diagnosed with autism are at least 2.5 times less likely to receive a diagnosis at their first specialty visit than a white child with autism (Mandell et al., 2002). With respect to diagnosis, Bearman and colleagues (Liu, King and Bearman 2009; Fountain, King, and Bearman 2010) correlate lower age of diagnosis and increased diagnosis with higher socio-economic status, and social networks. All of these studies indicate that cultural attitudes about SES influence diagnostic practice, but SES does not appear to determine whether or not someone actually has autism.

Nevertheless, poverty, racial discrimination, and marginalization have real effects on outcomes among children with mental illnesses and disabilities (Brown & Rogers, 2003). Researchers have paid special attention to the differences in prevalence and course of mental illnesses between rural and urban environments. Rutter's comparison of the prevalence of psychiatric disorders among 10-year-olds showed significantly higher prevalence of disorders (25.4%) in London than in the Isle of Wight (12%). Rutter et al. (1975) concluded that higher rates of family conflicts, parental psychopathology, and poverty in London were positively associated with higher rates of psychiatric disorders in the children (Rutter et al., 1975). Similarly, in the Ontario Child Health Study, Offord et al. found higher rates of all psychiatric disorders in 4- to 16-year-olds in urban areas (Offord et al., 1987).

The World Health Organization studies on schizophrenia, conducted in the 1970s, showed that prevalence was consistent across rural and urban areas but that outcomes differed significantly depending on geographic location. Although schizophrenia occurs with similar frequency all over the world, people with schizophrenia in the sites in developing countries, such as Agra, India, do better over time than those in industrialized countries. They need less care, fewer medicines, and have fewer traumatic, psychotic episodes. For example, as

Hopper (2003) documents, psychiatrists in Madras, India, note that individuals with schizophrenia have had surprising success finding spouses. Thara, Padmavati, and Srinivasan (2004) attribute this success to the importance of one aspect of *dharma*, the duty to marry for the sake of the extended family and the continuity of the lineage. The institution of marriage "adapts and endures, accommodating even those whose nuptial capital would seem to be seriously devalued, given the persistent stigma attached to mental illness in India" (Hopper, 2003, p. 78). Hopper associates marriage of disabled persons with a measure of "social recovery" (2007). We need similar information about ASD to know if certain cultural conditions help people with ASD improve their ability to learn, communicate, and participate in social and economic life. Comparisons to schizophrenia may be useful. For example, in comparison to ASD, is there less stigma attached to the person with schizophrenia in some cultures because the onset of the disorder is in late adolescence, after a family and a community have had nearly two decades to form an attachment to the person? Is there greater stigma attached to a person with autism because the onset is so early?

Both developmental disorders and *explanations* of developmental disorders (scientific or otherwise) are products of the interplay between biological, psychological, and cultural phenomena. In part, as the result of the WHO studies, public health officials increasingly see disabilities as simultaneously both neurologically and culturally constructed. By including culture as a variable in medical research, scientists understand that an illness motivates behaviors in multiple areas of social life. A diagnosis of autism, for example, mobilizes kin groups toward common action or conflict and influences financial planning, choices about residence, reproduction, and employment. In the research community, changes in epidemiological methods produce different rates that can directly influence government policies and educational practices. Changes in educational practices also influence scientific research. Thus, in Italy, mandatory inclusion of children with disabilities, following national inclusion legislation in the 1970s, facilitated lively scholarly work on the course of ASD among children who are educated alongside unimpaired peers, as well as research on early diagnosis of autism (Levi & Bernabei, 2005).

Health services research is one area in which mental health professionals have shown that cultural differences within a single population, like the United States, can lead to disparities in recognition, diagnosis, and care. Availability of clinical services, access to and utilization of services, and cultural appropriateness of services vary considerably among ethnic minorities in the United States. As a result of centuries of racism and discrimination, many African Americans, for example, do not trust government health care institutions and so may not seek care. (Indeed, there is a long history of psychiatric misdiagnosis in African American patients.) Native Americans, a largely rural population, not only live in areas with low access to services, but often utilize traditional healers rather than doctors in clinic settings; some do not see ASD as pathological and may not seek any care at all (Conners &

Donnellan, 1995). Asian Americans underutilize the mental health care system in the United States because of the shame and stigma associated with mental illness. Latinos underutilize the mental health care system because of language barriers (USDHHS, 1999), and Latino parents of autistic children are more likely than the general population to use "nontraditional" treatments (Levy & Hyman, 2003).

For ASD, David Mandell showed that, on average, white children in the United States receive an autism diagnosis approximately 18 months earlier than African American children (Mandell et al., 2002). In the United States, rural children with autism received a diagnosis approximately 5 months later than urban children, and near-poor children received a diagnosis approximately 1 year later than children whose families had an income >100% above the poverty level (Mandell, Novak, & Zubritsky, 2005). Mandell and Novak (2005) urge researchers to conduct research on "the complex relationship between culture and treatment, focusing on cultural differences in the behavioral phenotype of ASD, recognition of symptoms, interpretation of symptoms, families' decisions regarding medical and educational interventions, and interactions between families and the healthcare system" (2005, p. 114). One implication of this recommendation is that even as researchers begin to study autism in other cultures, Americans have not yet resolved the questions that exist in our own society about when and how race, ethnicity, and class, among other cultural factors, influence diagnosis.

In most low and middle-income countries, where there are few or no services for children with special needs, family management and treatment of children with developmental disabilities are influenced directly by socioeconomic and demographic changes. As societies rapidly urbanize (today, for example, one fourth of the population of South Korea lives in Seoul) nuclear families replace extended ones. Parents thus lose the primary source of social support for disabled persons and are compelled to seek help elsewhere, from charitable organizations and other associational communities (such as churches and newly formed autism societies) and from local and national governments. The demands become even greater in households with two working parents.

Taken together, the impact of sociocultural factors on autism recognition, epidemiology, and services reveals an additional and important aspect of our contemporary understandings of autism: the degree to which autism can be conceptualized as a disability as well as a disorder. Disability is fundamentally about a person's interaction with an environment of discrimination, exclusion, and barriers to functioning. The concept of "environment" comprises attitudes, natural or built physical barriers, and policies or systems that may limit an individual's potential. Toward the goal of providing a common language for defining and comparing disabilities across cultures, the WHO developed the International Classification of Functioning, Disability, and Health (ICF). The ICF (which classifies health status), together with the ICD

(which classifies disease status), can help experts predict functional outcomes, the need for services, work potential, and possibilities for successful integration into community life (WHO, 2001).

Language

Researchers conducting international studies of developmental disabilities should remain vigilant about preconceived notions of culture. First, at a time of unprecedented population movements across national borders, "culture" is no longer synonymous with place. The rich person in India and the rich person in England may be more culturally similar in terms of values associated with health and disease than the rich and the poor person in either one of those countries (Gupta & Ferguson, 1992). Thus, "culture" should not necessarily be equated with race, class, ethnicity, or nationality only. Second, culture cannot be easily measured and perhaps should not be. Each location demands different methods and types of description. An ethnographic study of help-seeking for ASD in the United States would likely focus primarily on the relationship between parents and health care providers, while the same study in Kenya would likely focus on an extended-family disease management group and how the family negotiates a plurality of coexisting medical and religious systems. Recognizing the particularities of each location leads to a third point: autism may be universal, but the contexts in which it occurs are distinctive. This claim can be illustrated with reference to children's acquisition of language and use of language in social situations.

Language delay and the ability to use language for social interaction are central features of the diagnostic criteria for ASD, and the two are inextricably related. Indeed, though language acquisition is universal, the process and speed of language acquisition varies across cultures, in large part because of differences in socialization. Samoan children, for example, learn certain forms of language much later than one would expect them to, not because they are developmentally delayed but because they are restricted from doing so (Duranti & Ochs, 1996). In Samoa, some syntactic operations are restricted to highly formalized occasions in Samoan society from which children are excluded, and so they do not learn them until adulthood. However, Samoan children learn how to use emotion-marked particles (words, prefixes, or suffixes, that index internal states, such as "oops!" or "wow!") very early in childhood—earlier than American children do—because emotion-marked particles are considered part of "baby language." This Samoan example highlights the fact that language is not a single entity. Children learn different aspects of language at different times in different societies, depending on the way a society organizes its verbal resources and exposes children to them.

Another way of approaching the relationship between language and social behavior is to study how children are both socialized through language and socialized to use language

(Ochs & Schieffelin, 1984; Ochs, 1998). Caregivers not only communicate to their children about the kinds of social behaviors that are acceptable, but they give children explicit instructions about how and when to speak in different social situations. For example, the Kaluli of Papua New Guinea do not consider babbling or any form of vocalization other than speech to be a mode of communication, and a Kaluli child who does not use words is not expected to respond to the vocal communication of others (Schieffelin, 2005). In this area of Papua New Guinea, a parent or teacher report on communicative skills in early childhood would no doubt be influenced by these perspectives.

Similarly, to return to the Samoan example, Samoan children interact with caregivers in a way that restricts direct, dyadic exchanges of meaning. Samoan society is highly stratified, with social interaction organized according to rank. A child who wants something will make the request only of someone who is of higher rank, perhaps an adult. But this adult will not respond directly to the child. Instead he will pass on the request to a third person, someone of lower rank. It is not known what impact such triadic patterns of communication might have on screening for abnormalities in social behavior using measures of social responsiveness designed in the United States, but the mere existence of such variations suggests that researchers should pay close attention to how communication can be shaped by society and culture.

In developing screening tools for autism, for example, items can be tailored to language impairment in particular languages and cultures. It is well known, for example, that English speakers with autism exhibit features such as echolalia, delayed echolalia, and monotonic speech. In addition, a commonly reported impairment is pronominal reversal; in fact, it was one of the diagnostic criteria for autism in the DSM-III. But pronominal reversal would seldom be observed in Korea, since pronouns are rarely used. In Korea one would find other abnormalities. In Korea, as one example, people on the autism spectrum commonly exhibit a particular language impairment: they generally cannot use language to distinguish social rank. The Korean language employs suffixes as honorifics that denote levels of politeness and respect and which are used in nearly every sentence a person speaks. However, a young person with autism may, for example, thank an elderly man with the equivalent of "Thanks, Dude," and thank his younger sister as if she is an elderly woman, "Thank you, Madame." In Korea, and most likely in other societies that employ grammatical forms to convey respect or mark one's place in a hierarchy, abnormalities in language and communication suggestive of an ASD can be identified in a screening instrument that includes a question about the appropriate or inappropriate use of honorifics.

Apart from screening, researchers face the problem of validating assessments in the native language of the community being studied. Unfortunately, researchers all too often use an assessment in a non-native language, such as English in India,

or a lingua franca in sub-Saharan Africa (e.g., Swahili in East Africa). There are other related issues. In communities that are ethnically and linguistically heterogeneous, what language does one use to conduct the research, and in particular, the assessments? When studying the role of culture, where does one draw the line between cultural groups? In India, for example, a single community or school system may consist of families from more than a dozen cultural and language groups. In that setting, what language should be chosen for the assessments?

Even when a translation has been validated, it is useful to do focus groups with parents and teachers prior to the beginning of the study to discuss language issues. For example, prior to beginning a prevalence study of elementary school-aged children in Korea, the first author conducted a focus group in which several mothers objected to some of the vocabulary used by the Korean child psychiatrists who translated and validated the protocols. The most objectionable word was *isanghan*, a word the Korean survey translators used to screen for odd behaviors because it means "unusual" but which parents interpreted to mean "bizarre" or "freakish." Thus, even native health care practitioners may not be able to anticipate problems with translation, since the meaning of a concept in the medical community may differ significantly from that in the general public (the classic American example being "hypertension," which Americans have long defined as excessive strain or nervousness, but which the medical community has defined as high blood pressure).

Interventions from a Global Perspective

Numerous interventions have been developed for the treatment of ASD in North America and Western Europe—behavioral/educational, medical, nutritional, and pharmacologic—although many are untested. However, there have been several reviews of the benefits of behavioral/educational interventions in children with ASD, and the results are encouraging (NRC, 2001; Dawson & Osterling, 1997; Evans et al., 2003; Rogers and Vismara, 1998, 2008). Although the specifics of these educational interventions vary, there is general consensus that the core components of a "successful" program include at least the following: entry into intervention as soon as an ASD diagnosis is seriously considered; active engagement of the child in intensive, daily instructional programs for a minimum of the equivalent of a full school day throughout the year; low, adequate student-to-teacher ratios; and promotion of opportunities for interaction with typically developing peers. A recent report of a randomized, controlled trial in the United States of an intervention with toddlers, the Early Start Denver Model, shows tremendous promise (Dawson, 2010). Nonetheless, some interventions in Western Europe, and South America, continue to focus on the treatment of maternal psychopathology, since the refrigerator mother hypothesis persists in those

areas where psychoanalytic theory still dominates child psychology and psychiatry.

In the Netherlands and in several Scandinavian countries, there is extensive government support for both children and adults with ASD, providing both groups with behavioral treatment programs, even for mildly autistic individuals. In the Netherlands, the government provides a residence ("Work Home") for adults who are unable to live independently. Multidisciplinary teams located in the Regional Institutions for Outpatient Mental Health Care (RIAGG) provide diagnostic and treatment services, including in-home training, daycare programs, placement in special educational centers, and residential placement. However, despite these services, the waiting lists for assessment by the RIAGGs are long, and educational programs are lacking. Moreover, as in many countries, autism services in the Netherlands are technically available under the Dutch disability laws only for people with a diagnosis of autistic disorder and not the other PDDs (van Engeland, 2005). In Sweden, the government has focused largely on the establishment of treatment homes, in the tradition of Rudolph Steiner's concept of curative education (or Heilpedagogie) (Rydelius, 2005), some of them arranged into villages. A similar model has been adopted by organizations in other countries, such as the Camphill communities in the United Kingdom, Ireland, Scotland, the United States, and Canada.

However, while progress has been made in increasing the number and availability of treatments for ASD throughout the world, a search of the English language literature (Pub Med, 2000 to the present) yielded little information on interventions for neurodevelopmental disorders (including autism) in low-income countries. Three articles discussed behavioral modification, early intervention, and medication for children with autism in India (Daley, 2002, 2003; Kalra, 2005; Karande, 2006). Kalra (2005), in an evaluation of behavior modification and early intervention, found improvement in core symptoms of autism in some children. Karande (2006) recommended the use of psychotropic drugs and counseling for parents and teachers in the treatment of autism in India. Daley (2002) emphasized that the responsibility for interventions lies primarily with the parents since there are few special education services for autism and few psychologists and speech/language pathologists available for treating autism.

Because information on interventions for autism in non-Western countries is scarce, we can use other neurodevelopmental disorders as a model for how a successful intervention plan can be implemented. Olusanya (2007) described a program in Nigeria to detect hearing loss in infants. A pilot program for neonatal screening for hearing loss was developed with financial support from a local nongovernmental organization (NGO). In the first year, more than 3,000 children were screened and fitted with hearing aids at no cost to the parents. This public-private partnership for screening and intervention was noted as a model for other low and middle-income countries. While not focusing on autism per se, in South Africa there was an audit of referrals from primary care facilities (mostly managed by nurses) for a range of mental health services, many of which were for intellectual disability and scholastic problems in children under 19 years old. Following the audit, a recommendation was made that a professional "counselor" be responsible for providing psychological assessment and intervention services at the primary care level (Petersen, 2004). One would imagine that these "counselors" would be the first professionals to identify and diagnose children with autism as well as other developmental disabilities.

There are few estimates of the prevalence of autism in China, although one recent study in Hong Kong suggests a comparatively low rate of 16.1 per 10,000 among children less than 15 years old (Wong & Hui, 2008). Given the Chinese government's March 2009 census, showing 251,660,000 persons ages 0–14 (approximately 19% of the total population), even such a low rate would mean there are at least 402,656 children in that age group with autism in China (National Population and Family Planning Commission, 2009). Unfortunately, although the Ministry of Education in China has recently become concerned about services for children with disabilities overall, there are not enough programs and trained personnel to provide for children with disabilities, including autism.

There are few child psychiatrists in China, and these practice in the largest cities. Common diagnoses for Chinese children with autism include intellectual disability, hyperactive syndrome, childhood schizophrenia, and sporadic encephalitis (Tao & Yang, 2005). There is, nonetheless, a Chinese classification of mental disorders adopted from the ICD-9 but which uses the term "childhood autism" instead of autistic disorder.

Autism services in China, when available, include a mix of traditional treatments (i.e., herbs and acupuncture, which are increasingly popular as treatments for autism in China, although there are no studies of their effectiveness) and more contemporary treatments (i.e., sensory integration and Applied Behavioral Analysis/ABA) (Clark & Zhou, 2005). Part of the reason for the paucity of services for autism lies in the fact that it was not until the 1980s that special education of any type began in China, and when services are available, most of the resources have been put into services for children with physical disabilities. There is one exemplary private program, the "Stars and Rain" Education Institute for Children with Autism in Beijing. It is reported to have served nearly 500 children (ages 3–6) across China since 1993. The program uses an ABA approach to treatment along with a parent training model. However, at a cost of approximately $36 per week, it is not feasible for most Chinese families. There are also limited programs in psychiatric facilities and no public school programs designed specifically for children with autism. There may, however, be some children who receive special services because they have an accompanying intellectual disability in addition to autism.

Future Growth in Global Research

Greater global awareness of both the characteristic features and prevalence of ASD has led to a range of new research activities on ASD supported by public institutions in both the United States (i.e., the Centers for Disease Control and Prevention [CDC], the National Institute of Mental Health [NIMH], and the National Institute for Child Health and Development [NICHD]) and in other countries (i.e., the National Institute of Mental Health and Neurosciences in India [NIMHANS], the National Institute for Health and Medical Research [INSERM] in France, and the National Health Research Institutes [NHRI] in Taiwan). Biological and genetic research on autism is expanding in Europe. In France, for example, the Paris Autism Research International Sibpair genome study has been analyzing samples from Italy, Sweden, France, Norway, the United States, Austria, and Belgium (Phillipe et al., 1999).

As reported prevalence estimates increased, funding increased. Between 1997 and 2008, when government funding for most medical research was unchanged, annual funding for autism studies at the National Institutes of Health increased from $22 million to $118 million (http://www.iacc.hhs.gov/portfolio-analysis/2008/index.shtml). Progress has also been made through new laws: the Combating Autism Act (signed into law by President Bush in February 2007) was designed to support autism research, and the French Chossy Act (December 1996) reclassified autism as a handicap rather than solely a psychiatric illness and thus ensured disability rights for autistic individuals.

Even more noticeable than these forms of public participation, philanthropists and the families of autistic individuals have founded private foundations to support basic scientific research on ASD and improve the availability and quality of services. Donors are contributing millions of dollars to parent advocacy organizations, private schools, and foundations in the United States (e.g., for example, the Autism Science Foundation, Autism Speaks, and the Simons Foundation) and in the United Kingdom (e.g., the National Autistic Society or NAS). The NAS, founded in 1962, has grown considerably over the past decade to include more than 17,000 members. It has launched a telephone helpline that, according to their website, took 38,000 telephone calls in 2007. As a result, even scientists who never before had an interest in autism, but worked in a related area such as neuroscience or genetics, are joining an increasingly long parade of autism researchers who are able to secure funding through these private foundations. Between 2003 and 2004 the number of grant applications to the National Alliance for Autism Research, then the leading private foundation for autism research (before its merger with Autism Speaks), doubled. In 2009 alone, the Simons Foundation and Autism Speaks awarded $51,526,058 and $23,416,615 respectively for autism research projects (http://iacc.hhs.gov/events/2010/102210/materials.shtml). Much of

the force behind the growth of research and advocacy has come from funding through the telecommunications or entertainment field: for example, Bob Wright, former president and CEO of NBC Universal, founder of Autism Speaks; the Fondation France Télécom in France, which supports Autisme France; and Carlos Slim, the magnate who controls the Mexican telecommunications company Teléfonos de México.

Conclusions

This chapter described a significant number of obstacles to conducting international research on ASD but also highlighted opportunities for advancing knowledge about how autism varies across different settings. Even a preliminary cross-cultural exploration of the epidemiology of autism and the role that culture plays in diagnosis and treatment shows that ASD exists throughout the world, even in societies that have no name for it. The study of the cultural variations in ASD is therefore not so much a matter of whether ASD exists, but rather the *contexts* in which it takes shape. The increased funding for research by private and public institutions constitutes just one important step to meet the challenges of epidemiological research on autism across cultures. This chapter also argued that ASD should be conceptualized as a cultural phenomenon and as a disability—not just as a phenomenon of Western civilization, and not just a disease. Understanding how culture influences the recognition and definition of autism spectrum disorders will facilitate cross-cultural adaptations of screening and diagnostic tools, and generate knowledge that can one day be translated into a better understanding of its etiology and improved treatments, services, education, and community integration of people on the autism spectrum.

Challenges and Future Directions

- Provide support to low and middle-income countries for community education and awareness.
- Develop more efficient and affordable diagnostic assessments that are reliable and valid in multiple languages and societies.
- In addition to ascertaining prevalence, epidemiological studies should develop low cost, appropriate services for children identified through screening, surveillance, and research efforts.
- In order to develop culturally appropriate services, including educational programs, future epidemiological studies should study the impact of autism on the child as well as his/her family.

Appendix: Selected epidemiological studies

Europe

Gillian Baird, F. R.C. Paed Guy's and St Thomas' Hospital London, UK Tony Charman, PhD Behavioural & Brain Sciences Unit Institute of Child Health University College London, UK	The South Thames Special Needs and Autism Project (SNAP)	UK (South Thames)	Birth cohort study of the prevalence of ASD from 12 districts in the South Thames area.	56,946 children (18 month birth cohort July 1990–Dec 1991) screened at age 9 years; in-depth assessment age 9 to 14 years.	ASD subgroup(s): All ASD subgroups Diagnostic criteria: ICD-10 Source of cases: ongoing assessments
Jean Golding, PhD Institute of Child Health University of Bristol, St Michael's Hill, BS2 8BJ Bristol, UK	Avon Longitudinal Study of Parents and Children (ALSPAC)	UK (Avon)	Prospective cohort starting in pregnancy to identify the environmental and genetic antecedents of the autistic spectrum disorders, and of the traits that make up the autistic spectrum.	Children born in 1991–1992	ASD subgroup(s): All ASDs Diagnostic criteria: ICD-10 Source of cases: Service provider records for ascertainment of ASD; traits identified from maternal completion of sets of questions completed at different ages
Eric Fombonne, MD, FRCPsych(UK) McGill University and Montreal Children's Hospital Montreal, Quebec	Staffordshire Surveys	UK (Staffordshire)	Successive prevalence studies of PDDs among preschoolers, to examine temporal trends and changes in risk factors overtime.	160 case children identified from children born from 1992 to 1998	ASD subgroup(s): All ASD subgroups Diagnostic criteria: DSM-IV, ICD-10 Source(s) of cases: repeated screening of the general population
Camilla Stoltenberg, MD, PhD, Norwegian Institute of Public Health (NIPH), Oslo, Norway Nydalen, 0403 Oslo, Norway	The ASD Healthcare and Registry Project	Norway	Pilot study to monitor the prevalence of ASD in Norway, and possibly providing the foundations for a permanent national ASD registry.	Children born in Norway 1999 or later who have been given an ASD diagnosis in the Norwegian health care system	ASD subgroup(s): All ASD subgroups Diagnostic criteria: All ICD-10; F84.0–F84.9 will be included. Expected sample size: 1000–2000 cases.

(Continued)

Table 7–2. (*Contd.*)

Christopher Gillberg, MD, PhD Gothenburg University Gothenburg, Sweden	**Bergen Child Study: the Autism Spectrum Study**	Norway (Bergen)	Cross-sectional study to determine prevalence rates of ASD, test the ASSQ as a screening device for ASD, assess ASD risk factors using screening devices and neuropsychological/ neuroimaging.	Case children identified from 7- to 9-year olds in 2003 in Bergen, Norway.	ASD subgroup(s): All ASD subgroups Diagnostic criteria: DSM-IV (plus Gillberg criteria for Asperger's syndrome) Source of cases: general population screen- and clinic-referred cases
W. Ian Lipkin, MD Center for Infection and Immunity Mailman School of Public Health Columbia University New York, NY 10032	**Gene-Environment Interactions in an Autism Birth Cohort (ABC)**	Norway	Nested case-control study focused on the role of gene-environment interactions in the etiology of ASD. The ABC study builds on the Norwegian Mother and Child Cohort Study (MoBa).	Children born in 1999 through May 2008 and screened at 36 months for ASD.	ASD subgroups: All ASD subgroups Diagnostic criteria: DSM-IV Source of cases; Screening of the MoBa cohort of children at 36 months; referrals (parents or provider-based); search of health registries
Christopher Gillberg, MD, PhD Gothenburg University Gothenburg, Sweden	**Göteborg Prevalence studies of Autism Spectrum Disorders.**	Sweden (Göteborg)	Cross-sectional prevalence study of ASD.	Case children identified from clinic and population screening of 7- to 9-year-olds in Goteborg, Sweden.	ASD subgroup(s): All ASD subgroups included Diagnostic criteria: DSM-IV criteria (plus Gillberg criteria for Asperger's syndrome) Source of cases: general population screen- and clinic-referred cases
Paul Lichtenstein, PhD Department of Medical Epidemiology, Karolinska Institute, Stockholm, Sweden	**Child and Adolescent Twin Study in Sweden (CATSS)**	Sweden	Cohort study of liveborn twins to examine genetic and environmental influences for ASD and comorbid conditions (e.g., ADHD).	All twins (n = 24,000) born in Sweden during 1994–2001. (Expected number of twin pairs with ASD = 800.)	ASD Subgroup(s): All ASD subgroups Diagnostic criteria: DSM-IV (plus Gillberg criteria for Asperger's syndrome). Source of cases: general population screening with A-TAC and clinical testing
Christopher Gillberg, MD, PhD Gothenburg University Gothenburg, Sweden	Faroe Islands ASD Genetic Epidemiology Study	Faroe Islands, Denmark	Cross-sectional prevalence study to estimate the prevalence of ASD and examine the genetic and environmental (mercury) risk factors for ASD in a genetically homogeneous population.	All children in the Faroe Islands, aged 7–15 years (n = 44 ASD cases).	ADS subgroup(s): All ASD subgroups included Diagnostic criteria: DSM-IV criteria (plus Gillberg criteria for Asperger's syndrome) Source of cases: school-based screening and clinic-referred cases

Table 7–2. (*Contd.*)

Paul Thorsen, MD, PhD, Institute of Public Health, NANEA at Department of Epidemiology, University of Aarhus Aarhus, Denmark	Danish national case-control study on infantile autism	Denmark	Case-control study to examine the association between genetic factors and the development of infantile autism, and to develop the methodological expertise for studying genetic markers for autism.	473 case children born in Denmark from 01/01/1990 to12/31/1999 and diagnosed before age 10 years.	ASD subgroup(s): Infantile autism diagnosed before age 10 years Diagnostic criteria: ICD-8 and lCD-10 Source(s) of cases: Danish Psychiatric Central Registry and Danish National Patient Registry
Marko Kielinen, PhD and Marja-Leena Mattila, MD Department of Paediatrics Clinic of Child Psychiatry University of Oulu Oulu, Finland	Autism in Northern Finland	Finland (Oulu and Lapland)	Retrospective cohort study to estimate the prevalence of autism in Oulu and Lapland, and to examine secular changes in incidence.	152, 732 children born between 1979–1994 and age 3–18 in 1996–1997 (time period for case ascertainment)	ADS subgroup(s): Autistic disorder and Asperger's disorder Diagnostic criteria: DSM-IV, ICD-10 (Gillberg & Szatmari, et al. criteria) Sources of Cases: Hospital records and the records of the central institutions of the intellectually disabled
Marko Kielinen, PhD and Marja-Leena Mattila, MD Department of Paediatrics Clinic of Child Psychiatry University of Oulu Oulu, Finland	An Epidemiological and Diagnostic Study of Asperger´s disorder	Finland (Oulu and Lapland)	Retrospective cohort study to evaluate the diagnostic process and prevalence rates of Asperger´s disorder.	5484 children born in year 1992 and screened in 2000–2001; 125 screened positive and 110 examined; 19 Asperger case children and 13 children with autistic disorder	ADS subgroup(s): Autistic disorder and Asperger's disorder Diagnostic criteria: DSM-IV, ICD-10 (Gillberg and Szatmari et al. criteria) Sources of Cases: Population screening followed by semistructured observation and testing
Evald Sæmundsen, PhD State Diagnostic and Counseling Center Kopavogur, Iceland	Prevalence of autism spectrum disorders in Iceland in children born in 1994–1998.	Iceland	Cross-sectional survey too examine the prevalence of ASD in Iceland and to identify risk factors associated with ASD.	Children born 1994–1998 identified through medical and other service system records through January 2008	ASD subgroup(s): All ASD subgroups listed in the ICD-10 Diagnostic Criteria: ICD-10 Source of cases: Service records of the referral center for autism and other developmental disabilities
Manuel Posada, PhD, MD, Research Institute for Rare Diseases, Health Institute Carlos III 28029. Madrid, Spain,	Spanish Autistic Spectrum Disorders Register (TEAR in Spanish and SASDR in English)	Spain (four regions)	Population-based registry and a nested case-control study to study the feasibility and costs of a population screening program using the M-CHAT and analyze risk factors for in incident cases.	Children 18–36 months of age in 2006	ASD subgroup(s): All ASD subgroups Diagnostic Criteria: DSM-IV-TR Source of cases: population-based screening in the following venues: Public Health Care System-Well Child Care visits (WCC) and Compulsory Vaccination Program Parent's organizations, ASD settlements and educational and social services

Table 7–2. (Contd.)

Astrid Moura Vicente, PhD Instituto Nacional de Saúde Av. Padre Cruz 1649-016 Lisboa, Portugal	Epidemiology of Autism in Portugal	Portugal	Cross-sectional study to estimate the prevalence of autism and to describe its clinical characterization and associated medical conditions.	Children born in 1990, 1991, and 1992, living in mainland Portugal or the Azores and attending elementary school in the school year of 1999/2000	ASD subgroup(s): Autistic disorder Diagnostic criteria: DSM-IV Source(s) of cases: School-based screening followed by clinical assessment

The Americas

Eric Fombonne, MD, FRCPsych(UK) McGill University and Montreal Children's Hospital Montreal, Quebec	Prevalence of Pervasive Developmental Disorders in Montreal, Quebec	Canada (Quebec)	Retrospective cohort study to evaluate time trends in relation to use of thimerosal-containing vaccines and MMR.	180 case children identified from children born between 1997 and 1998 and ascertained in 2003	ASD subgroup(s): All ASDs Diagnostic criteria: DSM-IV Sources of Cases: special educational registers
CDC: Diana Schendel, PhD National Center on Birth Defects and Developmental Disabilities Centers for Disease Control and Prevention Atlanta, GA 30333 California: Lisa Croen, PhD Colorado: Lisa Miller, MD, MSPH Maryland: Craig Newschaffer, PhD North Carolina: Julie Daniels, PhD Pennsylvania: Jennifer Pinto-Martin, PhD, MPH,	The CADDRE Study: Child Development and Autism	USA (6 sites: California, Colorado, Georgia, Maryland, North Carolina, and Pennsylvania)	Population-based case-cohort study to investigate risk factors for ASD and phenotypic subgroups of ASD.	Children born from September 2003 through August 2005; Eligible children must be 30–60 months of age during data collection. Expected sample size is 650 children with ASD across 6 sites.	ASD subgroup(s): All ASDs subgroups Diagnostic criteria: DSM IV Source of cases: intensive screening and case finding in clinics and special programs for young children with developmental delays
Catherine Rice, PhD National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention 1600 Clifton Road, MS-E-86 Atlanta, GA 30333	Autism and Developmental Disabilities Monitoring Network (ADDM)	USA (Alabama, Arizona, Colorado, Florida, Georgia, Maryland, Missouri, North Carolina, Pennsylvania, South Carolina, Wisconsin)	Ongoing population-based surveillance of ASD in 8-year-old children in 11 sites in the United States to determine prevalence and trends.	Children who are 8 years old (selected states) beginning in 2000 and monitored biannually	ASD subgroups included: All ASDs Diagnostic criteria: Systematic review of service provider records—education (selected sites) and medical— by expert clinicians using DSM-IV criteria Sources of case: school, medical, and other service provider records
Lisa Croen, PhD Kaiser Permanente Northern California Division of Research Oakland, CA 94612	Childhood Autism Perinatal Study (CHAPS)	USA (Northern California)	Case-control study to investigate prenatal and perinatal risk factors for autism spectrum disorders.	Children born 1995– 1999 in a Kaiser Permanente hospital in northern CA	ASD subgroup(s): All ASD subgroups Diagnostic criteria: DSM-IV Source of cases: Kaiser Permanente electronic medical records

Table 7–2. (*Contd.*)

Lisa Croen, PhD Kaiser Permanente Northern California Division of Research Oakland, CA 94612	Early Autism Risks Longitudinal Investigations (EARLI)	USA (multisite study—Northern California, Pennsylvania, and Maryland)	Prospective, longitudinal, cohort study to identify early autism risk factors and biomarkers based on an enriched-risk pregnancy cohort.	Women who have at least one ASD-affected child who have a subsequent pregnancy. Women will be followed through their pregnancies and the infants will be followed through age 3.	ASD subgroup(s): All ASD subgroups Diagnostic criteria: DSM-IV Source of cases (proband child) clinical care providers, service providers, educational system, self-referrals.
Lisa Croen, PhD Kaiser Permanente Northern California Division of Research Oakland, CA 94612	Early Markers for Autism Study (EMA)	USA (Northern California)	Case-control study to identify early (prenatal and neonatal) biomarkers for autism spectrum disorders.	Children born July 2000–Sept. 2001	ASD: All ASD subgroups Diagnostic criteria: DSM-IV Source of cases: Regional Center of Orange County (review of service provider records)
Michaeline Bresnahan, PhD Columbia University School of Public Health New York City	Aruba Autism Project	Aruba	Retrospective birth cohort study to examine prevalence and cumulative incidence of ASD in Aruba.	All children born in Aruba in 1990–1999 and followed through 2003.	ASD subgroup(s) included: Autistic Disorder, PDD-NOS, Asperger, Rett, disintegrative Diagnostic Criteria: DSM-IV Source of Cases: clinical/medical records
Cecilia Montiel-Nava, PhD School of Education La Universidad del Zulia. Maracaibo, Estado Zulia, Venezuela	Epidemiological Findings of Autism Spectrum Disorders in Maracaibo County	Venezuela (Maracaibo County)	Cross-sectional survey to estimate the prevalence of autism spectrum disorders (ASD) among children between 3 and 7 years of age in Maracaibo County.	Children aged 3 to 7 years, and children born in the 2003 (5 years old).	ASD subgroup(s): All ASDs Diagnostic criteria: DSM-IV criteria Source of cases: School-based screening and clinic-referred cases
Cristiane Silvestre de Paula Pervasive Developmental Disorders Program; Mackenzie Presbyterian University, Brazil São Paulo, Brazil.	Prevalence of pervasive developmental disorders in southeast Brazil: A pilot study	Brazil (Atibaia)	Cross-sectional survey to estimate the prevalence of pervasive developmental disorders in southeast Brazil.	7- to 12-year-old children	ASD subgroup(s): All ASDs combined Diagnostic Criteria: DSM IV criteria Source of cases: population based screening study

Middle East, Africa, Asia, and Australia

Shlomo (Sol) Eaglstein, PhD Department of Research, Planning and Training State of Israel Ministry of Social Affairs Jerusalem 93,420 Israel.	The Israeli Ministry of Social Affairs (MOSA) Autism Registry.	Israel (Jerusalem)	Population-based registry to estimate the prevalence of autism/ASD in Israel, by means of detecting the number and age of people diagnosed who apply for services and to track placement (home, special education, assisted living, etc).	Expected sample size 4,000 case children (12/07)	ASD subgroup(s) included: Autism, Asperger's syndrome, and PDD-NOS. Diagnostic criteria: DSM-IV Source of cases: children applying for services.

(Continued)

Table 7–2. (*Contd.*)

Hideo Honda, M.D. Ph.D. Yokohama Rehabilitation Centre Yokohama, Japan	Cumulative incidence and prevalence of childhood autism in children in Japan Japan (Yokohama)	Japan (Yokohama City)	Cumulative incidence study of "childhood autism." Attempt to replicate earlier epidemiological study using identical methods in a large population with screening beginning at 18 months.	Cumulative incidence up to age 5 years was calculated for childhood autism among a birth cohort from four successive years (1988 to 1991).	"Childhood Autism:" (ICD-10) Source of cases: Yokohama City Routine Health Checkup (18 months).
MKC Nair, MD, PhD Professor of Pediatrics & Director, Child Development Centre, Medical College Campus, Thiruvananthapuram, Kerala, India 695,011 Dr. Narendra K. Arora Executive Director-INCLEN The INCLEN Trust International New Delhi, India 110,049	Neuro-developmental Disabilities among Children In India: An INCLEN Study	**India (5 regions)**	Cross-sectional study to examine the prevalence of 10 neurodevelopmental disabilities, including ASDs, in children aged 2–9 years in India and gather information on potentially modifiable risk factors.	9,000 children aged 2–9 years old will be screened with a neurodevelopmental disability screening tool. Children with autism will be determined based on a clinical examination applying agreed on study criteria for ASDs	ASD subgroup(s): All subgroups of ASD Diagnostic criteria: DSM-IV Source of cases: Community based household screening
Richard Grinker, PhD George Washington University, Washington, DC 20052 Young Shin Kim, MD, MS, MPH, PhD Yale Child Study Center New Haven, CT 06520	Study 1: The Prevalence of Autistic Spectrum Disorder (ASD) in Korean School-age Children Study 2: Prospective Examination of 6-year Cumulative Incidence of ASDs: A Total Population Study	South Korea (Ilsan)	Study 1: Birth cohort study to examine the prevalence of ASD; to establish a population-based cohort of children with ASD for future genetic and environmental studies, to investigate public attitudes about ASD; and to examine patterns of service utilization in Korean children with ASD. Study 2: Prospective birth cohort study to examine the incidence proportion of ASD in children followed from birth to age 6 years.	Study 1: 36, 592 cases screened 9/2005-8/2006, confirmative diagnoses completed 2/2006-7/2009, among children born 1995-2000. Study 2: 2001–2002 birth cohort; screened at age 6 years in 2007–2008	ASD subgroups: All ASD subtypes Diagnostic criteria DSM IV using ADOS and ADI-R Source of cases: Study: community based screening; family referrals; and disability registry

Issues in the Classification of Pervasive Developmental Disorders

Introduction

The rationale for classifying childhood onset mental problems, including neurodevelopmental disorders such as autism, is that it aids in communication and the nosological entities predict aspects of the natural history of the condition, its response to treatment as well as the causes of the phenomena. By their nature, classification systems can never be complete and perfect, as they continually need to be revised and updated as knowledge accrues (Taylor & Rutter, 2002; Angold & Costello, 2009).

Approaches to the classification of mental problems have evolved over the years and have moved from a system based on psychoanalytic theory to more phenomenologically based approaches. Modern schemes really began with the introduction of DSM-III and ICD-9 in the 1970s, both of which are based largely on descriptions of patterns of symptomatology.

One of the key developments in the nosology of childhood psychopathology was the implementation of a multiaxial diagnostic scheme. The need for a multiaxial scheme stemmed from the recognition that psychopathology is often multifaceted in its presentation and that multiple factors, often occurring in combination, may be etiologically relevant. For example, both the presence of a specific medical condition and certain psychosocial stresses may be relevant in the development of a child's problems.

Although the advent of ICD-10 and DSM-IV represented a major step in nosological classification, several advances in knowledge have taken place over the last 15 years, and this has led to a realization of the need to revise our diagnostic scheme and work toward the publication of new editions of the main classificatory systems for psychopathology, ICD-11 and DSM-V.

Within this context it is timely, therefore, to consider the classification of the pervasive developmental disorders and the areas in which revisions might need to be made.

Unresolved Issues in ICD-10 and DSM-IV

The term Pervasive Developmental Disorder (PDD) was coined in order to reflect the fact that autism, the prototypical form of Pervasive Developmental Disorder, is characterized by problems in development that pervade both social, language/communication, play, and intellectual development. The need for an umbrella term that encompassed a number of different possible conditions falling under the generic heading PDD, reflected the fact that there was some uncertainty as to whether different subtypes or forms of presentation were meaningfully associated with different causes, natural history, and response to treatment. The conditions listed under the Pervasive Developmental Disorder category in DSM-IV and ICD-10 are summarized in Table C1-1. Although the two classificatory

Table C1–1.
ICD-10 and DSM 1V classification of pervasive developmental disorders

DSM 1V	ICD-10
Autism	Autism
Asperger's	Asperger's
	Atypical Autism
PDD NOS	PDD Other
	PDD Unspecified
Rett Syndrome	Rett Syndrome
	Childhood Disintegrative Disorder
Childhood Disintegrative Disorder	Overactive disorder associated with mental retardation and stereotyped movements

schemes were similar in many respects, there were some notable differences.

First, The World Health Organization (WHO) published two versions of ICD-10: a clinical diagnostic scheme as well as research diagnostic scheme (WHO, 1993). The clinical diagnostic scheme provided prototypical descriptions of the specific disorder (e.g., autism), and the onus was on the clinician to determine whether or not the child's presentation best fitted with one or other prototype. By contrast, the research diagnostic criteria followed a similar approach to that adopted in DSM-IV by specifying a list of symptoms that had to be present in different domains of function: to meet diagnostic criteria individuals had to manifest a specific number of symptoms within each domain. The rational for adopting these different approaches in ICD-10 was that it was considered that the approach of pattern matching to a "gestalt" that was exemplified in the clinical diagnostic scheme better reflected expert clinical practice, whereas the symptom count approach was better suited for research, as more detailed operationalization of the diagnostic criteria was likely to increase the reliability of diagnosis. The drawback of the symptom count approach was that the criteria were not externally validated and potentially led to premature conceptual closure, with critics pointing out that diagnosis is not simply an exercise in counting symptoms. Of course, the two approaches are not mutually exclusive and, in practice, it is possible to adopt a combined approach by specifying that a case meets clinical and research diagnostic criteria.

Second, ICD-10 and DSM-IV adopted different multiaxial schemes. Although both systems place PDD on axis 1, DSM 1V classifies personality disorders and the degree of intellectual disability on axis 2, the presence of medical conditions on axis 3, associated psychosocial and environmental problems on axis 4, and the overall level of function on axis 5. By contrast, in ICD-10, axis 2 is used to classify specific developmental disorders, axis 3 the intellectual level, axis 4 medical conditions, axis 5 psychosocial influences, and axis 6 the level of functioning. Personality disorders are classified on axis 1 in ICD-10.

At this stage there seems to be little reason to argue that PDD should be moved from axis 1 to another axis. However, clear guidance on how associated features of PDD such as language delays and impairments should be dealt with is necessary, as speech and language delay is currently one of the diagnostic criteria for autism, but is not a necessary feature. As language level is a key predictor of outcome, it would arguably make sense to separately classify the presence of language impairment on axis 2.

Third, when the two classificatory systems were being formulated, there was a good deal of uncertainty as to where the boundaries should be drawn between autism and other pervasive developmental disorders and what other possible subtypes of PDD should be delineated. The main dilemmas centered on the degree of possible heterogeneity and how to classify cases that did not meet all the criteria for a diagnosis of autism. At the time, the main questions focused on whether

and how to separately classify cases of Asperger's syndrome and Rett's syndrome and what to do with atypical presentations in terms of atypical symptom profiles and atypical ages of onset. Asperger's paper and description of the eponymous syndrome had only recently been translated from German into English (Wing, 1981), and some differences from autism in the presenting and associated features raised the possibility that it might represent a different condition. The findings from studies of schizoid disorder of childhood (Wolff & Barlow, 1979; Wolff & Chick, 1980; Wolff, 1991), fueled the speculation that children presenting in these ways may constitute a separate subgroup. Accordingly, Asperger's syndrome was included as a separate category in both schemes. Similarly, Rett's syndrome had also only relatively recently been characterized on the basis of symptomatology, regression, and course (Rett, 1986), but as the cause was unknown at that time, it was classified as a PDD rather than a genetic disorder, despite the fact that it was strongly suspected to be a single gene disorder.

The two classificatory systems took quite different approaches to the classification of other atypical presentations. In DSM-IV they were all lumped together and classified as PDD Not-Otherwise-Specified (PDD-NOS). There were no operationalized criteria for PDD-NOS. By contrast, four additional diagnostic categories were created in ICD-10.

1. Atypical autism was used to classify cases that nearly met the full criteria for a diagnosis of autism, but there were insufficient symptoms in one domain to meet criteria for autism or the presentation was atypical in terms of age of onset.
2. PDD "other" was used to classify cases that were thought to have a PDD but did not meet criteria for autism or atypical autism. There were no operationalized criteria for this diagnosis.
3. The category of PDD unspecified was created for cases where findings were conflicting, inconsistent, or incomplete. For example, if findings from observational assessments did not agree with parental reports of the child's development, or if observational assessments suggested the diagnosis, but there was no informant available to provide details of the early developmental history.
4. ICD-10 also included a diagnostic category of uncertain nosological status termed "over active disorder with mental retardation and stereotyped movements."

The aim in ICD-10 was to attempt to split PDD into various different putative subtypes.

Fourth, the operational definition of Asperger's syndrome has given rise to some confusion over how to differentiate it from high functioning autism (i.e., cases where there was no significant speech/language delay and where the individual is of normal intelligence, yet speech and language development was deviant). The dilemma has been that these cases could meet criteria for both autism and Asperger's syndrome (Volkmar, Klin, et al., 1996; Volkmar, Klin, et al., 1998).

An additional concern was that PDD "other" and PDD unspecified in ICD-10 and PDD-NOS in DSM-IV were not

operationally defined, so there was a good deal of uncertainty as to when these diagnoses should be made.

Clearly one of the issues to address in future revisions of the nosological scheme concerns the approach to subtyping and the number of subtypes to be included under the rubric of pervasive developmental disorders (see below).

Fifth, the two classificatory systems took rather different approaches to hierarchical rules within the schemes. In ICD-10 the diagnosis of one condition often precluded the diagnosis of other disorders, whereas in DSM-IV this was less frequently the case, although a hierarchical approach was sometimes adopted. As a consequence in DSM-IV it was more often possible to diagnose two conditions concurrently. The rationale for including hierarchical rules was that the significance of symptoms may be different when they occur in the presence of a major disorder (Matson & Nebel-Schwalm, 2007). For example, high levels of activity were thought to be common features in individuals with autism and not necessarily indicative of the presence of hyperkinesis/attention deficit/hyperactivity. Accordingly, the diagnosis of ADHD/hyperkinesis was precluded in individuals with a diagnosis of autism both in ICD-10 and DSM 1V. Here again, the findings over the last 15 years highlight the need to reconsider some of these hierarchical rules and the best approach to adopt for classifying complex presentations that are characterized by admixtures of symptomatology of various kinds (Matson & Nebel-Schwalm, 2007).

In addition to these extant issues, a number of new issues have emerged as methods have developed and the evidence base has advanced. These are outlined below.

Recent Advances and New Issues

The Concept of "Autism Spectrum Disorder"

One of the most significant conceptual shifts has been the adoption of the notion that autism is part of a "spectrum of disorder." Lorna Wing was the first to put forward the idea that autism is a spectrum disorder and proposed a typology based on the pattern of social impairment (Wing & Gould, 1979; Wing, 1997). Subsequent genetic epidemiological data has helped underpin the concept of autism as a spectrum disorder. For example, findings from family and twin studies have clearly shown that the liability to autism confers a risk not just for autism, but for a range of manifestations that can include several PDD variants such as Asperger's syndrome, atypical autism and PDD other/PDD-NOS (Bolton, Macdonald, et al., 1994; Bailey, Le Couteur, et al., 1995; Bailey, Palferman, et al., 1998). The findings provide unequivocal support for the concept of a spectrum of manifestations, but the spectrum typology proposed by Wing has not been widely adopted or extensively investigated.

The genetic epidemiological data also showed that the liability to autism confers a risk for social and communication difficulties and unusual patterns of interests and activities that extend well beyond the traditional concepts of a pervasive developmental disorder, to include impairments in just one domain of function (Bolton, Macdonald, et al., 1994; Bailey, Le Couteur et al., 1995; Bailey, Palferman et al., 1998).

These findings have led to uncertainty over where the line should be drawn between autism spectrum disorder and normal variation in personality, social behavior, and function. Indeed, the lack of any clear demarcation between the broader autism phenotype and normal variation in behavior has been used to argue that autism is the extreme of a normally distributed set of traits, in much the same way that obesity can be considered to be the extreme of normal variation in weight. Accordingly, researchers have developed and investigated dimensional models of the phenotype (Constantino & Todd, 2003; Constantino, Gruber, et al., 2004). The findings from these studies have provided interesting new insights, but it should nevertheless be emphasized that the absence of a clear discontinuity in the distribution of trait questionnaire scores does not unequivocally prove that autism is the extreme of normal variation in autistic traits for several reasons.

First, the distribution of scores in siblings of individuals with autism has a long upper tail, raising the possibility that there may be a discontinuity. Second, the autism phenotype is associated with features that are not commonly found in the general population, such as macrocephaly, epilepsy, and intellectual disability. The findings indicate that at some point there is a discontinuity or threshold at which point there is a qualitative change in manifestation. The findings are potentially consistent with the liability threshold model. Alternatively, they may reflect a second hit event or heterogeneity. For example, it may be that, as for intellectual disability, a mixed model applies, where individuals fall at the extreme of the distribution either because they have a specific genetic or medical problem or because the factors responsible for variation within the normal range have conspired together to place individuals at the extreme of the normal distribution.

As such, although the development and construction of a dimensional measure of the autistic traits has much to commend it, there are a number of methodological challenges to overcome in developing a suitable measure, conceptual issues to resolve, and uncertainties about when a dimensional or categorical model is most informative. Until these issues have been resolved, most effort has gone into the development of measures of the severity of autism spectrum disorder.

Measuring the Severity of Autism Spectrum Disorder

The reasons for developing a scale of the severity of autism spectrum disorder are in order to use the measure: (1) as an index of liability to the condition, (2) to predict outcome, (3) to assess response to treatment. The approach to constructing a measure will differ in each of these circumstances. For example, a measure to quantify response to treatment will need to be a measure of current severity and be sensitive to change. By contrast a measure for the purpose of predicting outcome

will need to be designed to assess severity at a particular time point in development, when the scale is going to have good predictive properties and be of maximal clinical use for planning future service provision and advising families.

For the purpose of classification, the primary goals are to quantify liability and predict outcome. Typically severity is estimated on the basis of symptomatology and symptom severity can be quantified in a number of ways. These include (1) counting the total number of symptoms, (2) measuring the intrusiveness or contextual sensitivity of symptomatology, (3) determining the persistence and duration of symptoms over time.

Symptom Count

Up to now the majority of studies have chosen to examine the number of symptoms as a metric of severity. However, the approach is not as simple as it might at first seem. For example, the list of symptoms has to be delineated and a decision made as to how to score them and whether to give each symptom equal weight in computing the score. So far the choice of symptoms has been determined on the basis of the instrument used to evaluate them and in part, therefore, on the instruments' ability to discriminate between cases and controls. Obviously selecting symptoms in this way can affect the properties of the distribution observed. Moreover each symptom has typically been given equal weight, yet the rating scales tend to have more items covering some symptom domains than others, so again this has the potential to influence the distributional properties of the scale.

A related challenge in deriving a severity score is to develop a means of equating scores in individuals with no speech to scores in those with speech, where a higher score is potentially possible simply because individuals with speech can manifest phenomena such as neologism, pronominal reversal, and stereotypic and repetitive speech. The limited investigation of this issue so far conducted suggests that language impairments may not lead to long-lasting differences in severity (Loucas, Charman, et al., 2008). Similar considerations apply to the estimation of symptom severity in individuals with an associated intellectual disability, where again the repertoire of symptoms will be modified by the presence of the intellectual disability.

Developmental Changes

Another issue is that the type and number of symptoms will change and vary with age and over time. To some degree the problem can be circumvented by focusing on a particular age and stage of development and evaluating the symptomatology at that time point. This is the approach taken for example by the Autism Diagnostic Interview-Revised (Lord, Pickles, et al., 1997; Lord, Rutter, et al., 1994), which focuses in part on symptomatology that is exhibited between the ages of 4 to 5 years. Clearly, this approach leaves open the issue of what to do with children younger than 4 to 5, where the number and type of symptoms develops and unfolds considerably. Focusing on a specific age period also leads to inherent problems in accurately assessing symptom count in older individual or young adults, where recall bias is likely to be present.

Sources of Information

Reports on symptomatology can be obtained from various sources, including parents and teachers, but symptomatology can also be evaluated during observational assessments using instruments such as the Autism Diagnostic Observation Schedule-Generic (Lord, Rutter et al., 1989). The comparative validity of measures derived from an observational assessment lasting an hour compared with reports of behavior occurring over the course of months or a year is unknown. It may be that a combination of questionnaire, interview-based reports, and observational methods will be the most accurate way of quantifying symptom severity, but as yet the best approach to combining information from various sources is still unclear.

Dimensions of Severity

Another consideration concerns our conceptualization of autism spectrum disorder as a cohesive unitary phenomenon. Recent findings have challenged this view and have raised the possibility that autism spectrum disorder represents a "compound phenotype" comprising several interrelated dimensions relating to social, communication, and repetitive behaviors. These ideas have stemmed in part from twin study data that have suggested that there may be overlapping as well as distinct genetic and environmental determinants of each dimension (Ronald, Happe, et al., 2005; Ronald, Happe, et al., 2006; Happe & Ronald, 2008). If autism spectrum disorder were a compound phenotype, then this would have implications for assessing severity and indicate that it should be assessed on a number of different dimensions. Currently, the notion that autism spectrum disorder represents a compound phenotype has not been conclusively established (Constantino, Gruber, et al., 2004). For the time being therefore, it is best to focus on the development of a unitary measure of symptom severity.

Other Approaches to Measuring Severity

An alternative way of estimating the severity of a condition is to assess change in symptomatology over time, but although it is known that autistic symptomatology can wax or wane, the relationship to liability and outcome has not been systematically investigated. Similarly, the degree to which symptoms vary across situations (e.g., home or school) or intrude into other activities or disrupt family life can be used as a metric of severity. But here again, the approach has not been evaluated.

Yet another approach to measuring severity is to evaluate the level of social role impairment associated with the symptoms and quantifying this, for example by using the Childhood Global Assessment Scale (Bird, Yager, et al., 1990) or by measuring the level of adaptive function. Severity estimates using

these approaches are likely to be influenced by intellectual level, as well as the presence of any comorbid disorders and other features associated with autism (e.g., speech and language impairment). Nevertheless, these approaches could potentially capture severity more comprehensively, but whether such measures relate more closely to liability or better predict outcome is uncertain, with variable findings with respect prognosis (Nordin & Gillberg, 1998; Szatmari, Bryson, et al., 2003; Howlin, Goode, et al., 2004; Baghdadli, Picot, et al., 2007).

The current published research on the utility of each of the approaches to quantifying severity is extremely limited. Most research has focused on estimating severity from symptom count. Even here, the data are inconsistent with some, but not all, studies suggesting that symptom count is associated with the familial liability to autism spectrum disorder (Bolton, Macdonald, et al., 1994; Szatmari, Jones, et al., 1996; Spiker, Lotspeich, et al., 2002; Szatmari, Merette, et al., 2008). The evidence from studies of identical twins (one of whom has an autism spectrum disorder) suggests however, that symptom severity is only weakly correlated with liability if at all (Le Couteur, Bailey, et al., 1996) or exhibits correlations in only some domains (Kolevzon, Smith, et al., 2004). It remains uncertain, therefore, how closely symptom severity indexes liability.

Similarly, it remains unclear how well symptom count predicts prognosis, after the presence of associated features such as speech/language and intellectual level has been taken into consideration. Findings from some studies suggest that symptom severity is associated with outcome, others do not (Nordin & Gillberg, 1998; Szatmari, Bryson, et al., 2003; Howlin, Goode, et al., 2004; Baghdadli, Picot, et al., 2007; Billstedt, Gillberg, et al., 2007).

In the absence of any data on the utility of other approaches, the simplest way forward is to quantify severity using symptom count anchored developmentally within a specific time period such as the 4- to 5-year period adopted by the ADI(R) Interview, perhaps supplemented with measures derived from observational assessments.

There still remains one important issue. This concerns the criteria to adopt for the diagnosis of autism spectrum disorder and how broadly to define the concept. The dilemma here is that very little is known about the development and outcome of individuals with the broader autism phenotype (BAP), so it is unclear to what extent social role impairment is associated with the broader phenotype. Also, as the criteria for diagnosing the BAP are not well developed, the sensitivity and specificity of the criteria for diagnosis are not known. For the time being it seems sensible, therefore to retain a category of PDD other for diagnosing individuals with the BAP, but operationalized criteria will have to be created.

Developmental Issues

Although autism spectrum has by definition an onset within the first 3 years of life, it is evident that in some individuals symptomatology emerges within the first year or two, before the full syndrome has become manifest (Rogers, 2004; Elsabbagh & Johnson, 2007; Stefanatos, 2008). This is evident for example from the studies of infant siblings of individuals with autism spectrum disorders which have revealed that early social and communication difficulties can be identified prior to the manifestation of the full syndrome. At this stage, the specificity of these early manifestations is under investigation, but the findings nevertheless highlight the need to develop a system for classifying these phenomena. In the diagnostic scheme for children aged 0 to 3 (DC 0–3) (Zero-Three, 2005), the only option at present is to diagnose a multisystem developmental disorder in children under the age of 2 and pervasive developmental disorder for children aged 2+. However, these diagnoses have not been fully operationalized. At present, we know too little about the specificity of the early signs to be able to classify them under the rubric of PDD. However, there is no reason to refrain from diagnosing PDD in children under the age of 2 years if they meet diagnostic criteria. Otherwise, until we have a better understanding of the precursors of ASD, it would seem best to specify the type of developmental problem using the DC 0–3 scheme.

In addition to the question of classification of precursor symptomatology there is also the issue as to whether or not the occurrence of regression in development is an important feature to record in the classification scheme. Here again the findings are inconsistent, with some reports suggesting that the presence of regression may be associated with different manifestations, course, and possibly etiology, but other studies failing to identify any significant differences in those with and without regression (Rogers, 2004; Stefanatos, 2008). The picture has been further complicated by the recent suggestion that regression may be an almost universal feature in autism spectrum disorder albeit unobservable or unmeasurable in the subset of cases where regression occurs very early in development (Baird, Charman, et al., 2008; Pickles, Simonoff, et al., 2009). It will also have to be decided whether to subclassify the type of regression and stipulate the areas in which regression is observed (e.g., language, social, motor, intelligence, etc).

Another consideration concerns the fact that autism symptomatology also changes later on in development either becoming significantly more or less marked with age. There has been a tendency to consider autism as a disorder that is lifelong in manifestations, and certainly this is the case in many individuals (Howlin, Goode, et al. 2004). However, there are also reports of individuals who largely if not completely outgrow their autism. These findings raise the question as to whether or not autism should be a permanent lifelong diagnosis. It is perhaps worth emphasizing here that in the current DSM classification scheme it is possible to stipulate that the condition is in partial or full remission or the diagnosis was based on prior history. It makes sense to retain this subspecification.

Presentations in adulthood also raise issues about the differentiation of autism spectrum disorder and PDD other

from schizoid and schizotypal personality disorder. This question has been little studied, but potential differentiating features include the developmental history, pragmatics of communication, form of prosody, and pattern of interests and activities.

Associated Features

Quite apart from the challenge of estimating symptom severity, there is an additional need to provide a means for quantification of the level of function in key features associated with autism, including speech/language and intellectual level. That is because these associated features constitute some of the best indices of prognosis (Nordin & Gillberg 1998; Szatmari, Bryson, et al., 2003; Baghdadli, Picot, et al., 2007; Billstedt, Gillberg, et al., 2007). One way of achieving this would be to specify the level of speech and language attainment using some standardized measure of speech language skills and to record this on axis 2, rather than simply the presence of speech language impairment. Similarly, intellectual ability (e.g., full scale IQ) can be recorded on axis 3, rather than simply specifying the degree of intellectual disability.

With respect to the measurement of the degree of social role impairment, both DSM and ICD-10 record the overall level of social impairment on axis 6 in ICD-10 and axis 5 on DSM, but agreed methods for measuring the degree of impairment would be desirable.

Heterogeneity

It is well established that autism spectrum disorder is etiologically heterogeneous, with an identifiable, probably causal medical condition found in some 10% of cases (Rutter, Bailey, et al., 1994). For example individuals with tuberous sclerosis, Fragile X syndrome, and abnormalities of chromosome 15 are at increased risk for developing an autism spectrum disorder, although they are not necessarily destined to do so (Feinstein & Reiss, 1998; Bolton, Dennis, et al., 2001; Bolton, Park, et al., 2002; Milner, Craig, et al., 2005). With the recent discovery of the association between autism spectrum disorder and copy number variants it is likely that other genetic and other submicroscopic chromosomal abnormalities will soon be established as new causes of autism spectrum disorder (Sebat, Lakshmi, et al., 2007; Christian, Brune, et al., 2008; Geschwind, 2009; Kumar & Christian, 2009). There is some evidence to suggest that the manifestations of autism spectrum disorder in individual with these comorbid medical conditions may differ in certain respects. For example, individuals with Fragile x syndrome are said to be socially avoidant and anxious (Cohen, Fisch, et al., 1988; Cohen, Vietze, et al., 1989). In many circumstances, individuals with a comorbid genetic condition also have an associated intellectual disability and epilepsy. Accordingly, there is a need to make allowances for this within the classificatory scheme. At present, all medical disorders are

recorded on axis 4 in ICD-10 and axis 3 in DSM-IV, but there is no way of indicating which of the medical disorders is probably causal. One solution is to include a subcategory on axis 1 for individuals with autism spectrum deriving from an associated, likely causal medical condition, recording the associated medical disorder on axis 4. The list of currently accepted medical cause of autism spectrum disorder includes Fragile x syndrome, tuberous sclerosis, and abnormalities of chromosome 15 involving 15q11-13, but the list is likely to grow in the near future.

In addition to genetic and medical causes, it is now also apparent that individuals who experienced severe early deprivation may exhibit quasi-autistic-like manifestations that tend to resolve with time and nurturance (Rutter, Andersen-Wood, et al., 1999). Again, consideration needs to be given as to how to differentiate between these presentations and autism spectrum disorder and whether to classify the disturbance in social and communication development observed after extreme deprivation as a PDD or a form of attachment disorder.

Childhood disintegrative disorder, which currently is separately characterized on the basis of the prior period of normal development up until at least 2 years of age followed by a regression and loss of skills and the emergence of an autistic-like syndrome (Volkmar & Rutter, 1995; Mashiko, 2003; Kurita, Koyama, et al. 2004; Rogers, 2004), should be retained as a subtype of PDD, but consideration should be given to renaming it, as the current label can give a rather misleading impression. The rational for subtyping this group of children stems from the fact that rare neurological disorders are more often identified in these individuals.

A further potential subtype includes the children who have early difficulties in peer and social relationships as well as some language and communication difficulties and unusual experiences, who are later prone to develop psychotic illness, such as schizophrenia (Buitelaar & van der Gaag, 1998; Remschmidt & Theisen, 2005; de Bruin, de Nijs, et al., 2007). Current research suggests that among the individuals with a diagnosis of pervasive developmental disorder not otherwise specified in DSM there are a subset of children who meet criteria for so called multiple complex developmental disorder, and that this subgroup seems to be particularly at risk for developing psychotic illnesses later in development. It remains unclear as to quite how best to distinguish these children from children with autism spectrum disorders, but the limited available evidence indicates that some means of classifying these individuals is needed. Whether they should be classified under the rubric of pervasive developmental disorder or as a subtype of schizophrenia clearly needs to be decided.

Comorbidity

Although the diagnosis of some comorbid disorders has been precluded in ICD and DSM, recent reports have suggested that there are individuals who seem to meet criteria for autism and ADHD/hyperkinesis and that, at least in some cases,

the associated hyperkinesis or ADHD can be treated reasonably successfully with the same medications used for ADHD. However, in many children with PDD and concurrent overactivity, restlessness, and impulsivity, medication is ineffective or gives rise to very problematic side effects. This has led to increasing speculation over the extent and basis of co-occurrence between autistic spectrum disorder symptomatology and ADHD/hyperkinetic symptomatology. There is some evidence to suggest that there are shared genetic risk factors for this symptomatic overlap (Ronald, Simonoff, et al. 2008; Mulligan, Anney, et al. 2009) but equally other evidence to suggest that the risk factors for ADHD/hyperkinesis in individuals with autism spectrum disorder may be rather different from those that ordinarily underlie pure ADHD/hyperkinesis (Simonoff, Pickles, et al., 2008). The issue clearly requires further research to resolve; but it is evident the classificatory systems in the future need in some way to be able to accommodate the situation when two sets of problems are present. There are various approaches that could be adopted to achieve this. For example, one approach is to set aside a diagnostic category for autistic hyperkinesis, just as there is a category for hyperkinetic conduct disorder in ICD-10. The alternative approach is to abandon the hierarchical structure of the classificatory scheme so that dual diagnosis of autism spectrum disorder and ADHD/hyperkinesis can be made. At present it is not really clear which of these options is to be preferred. The potential drawback of the dual diagnosis approach is that the ADHD/hyperkinetic disorder may have different origins, prognosis, and response to treatment when in the presence of autism spectrum disorder. It is evident, however, that there has been no research to support the retention of the category "overactive disorder with mental retardation and stereotyped movements" in ICD-11.

A review of the hierarchical rules relating to dual diagnosis with other disorder will also be required.

Future Approaches to Diagnosis and Classification

Currently, diagnosis and classification is based entirely on behavioral criteria, and this will be so for some time yet. In the future, however, it may be possible to better parse heterogeneity and classify cases by incorporating information on associated features, such as cognitive profile, structural and functional brain imaging findings, gene expression profile (Nishimura, Martin, et al., 2007; Geschwind, 2008; Hu, Sarachana, et al., 2009), other biomarker findings, and genotype. The multiaxial classification system may need to be adapted to allow findings from investigations in these domains to be included, perhaps by broadening the scope of each axis or by creating new axes.

Conclusions

It is evident that there have been a considerable number of advances in our understanding of the pervasive developmental disorders, and it is time for revisions to the current classificatory schemes. Equally it is evident that much remains to be determined and, in some areas, it is still uncertain as to what the best approach to classification should be. This is inevitable, and classificatory schemes continually need to be developed and honed for their purpose. It is hoped that at least with respect to the pervasive developmental disorders there will be an opportunity for closer integration of the ICD-10 and DSM-IV approaches as a comprehensive and unified approach has much to offer.

The Social Behavior of Autism: A Parallel and Distributed Information Processing Perspective

Points of Interest

- Joint attention impairments are a first-year onset symptom of autism, and a pivotal domain of development for early intervention and diagnosis.
- Hypothetically, joint attention impairments in autism are cardinal early behavioral symptoms of developmental neural interconnectivity impairments.
- In infancy frequent practice with the social coordination of attention to external object or events is internalized and becomes the ability to socially coordinate mental attention with others to internal representations of object or events. Hence, reduced practice with joint attention among children with autism is a source of their subsequent social-cognitive, symbolic, and social learning impairments.
- Joint attention impairments in autism entail problems in constructive self-referenced, self-regulated, and self-motivated behaviors, as much they involve problems in perceiving and interpreting the social behaviors of others.

Translational research has changed the way we think about, diagnose, and treat the social impairments of autism. Application of basic science to autism has begun to encourage new ways of thinking about the phylogenetic and ontogenetic development of human social-cognition. In particular, human social-cognition may be viewed as the outgrowth a special form of human information processing that we call joint attention (Mundy & Newell, 2007). As this chapter will describe, joint attention requires the parallel processing of information about one's own attention and the attention of other people. This requires the activation and functions of a distributed system of frontal and posterior cortical networks in the brain. Recognizing and understanding the parallel and distributed nature of joint attention impairment contributes to new perspectives about the development of social cognition, the social brain in all people including those with autism (Mundy, 2003). This new framework has emerged from the interplay between cognitive neuroscience, developmental science, and the science of psychopathology in autism. As such it provides a seminal illustration of a school of translational research that began more than two decades ago when a farsighted group outlined the new discipline of *developmental psychopathology* (Cicchetti, 1984; Sroufe & Rutter, 1984).

The chapter begins with a brief description of the history of thought and research on autism. One message of that first section is that a lack of precise understanding of social behavioral development impeded the accurate diagnosis of autism until the early 1990s, which was fifty years after it was initially described by Asperger (1944) and Kanner (1943). The second section of the chapter illustrates how social developmental research continues to be a vital source of information about the nature of autism. Indeed, research on autism has led to insights about the precise nature of joint attention development in infants that have contributed to the framework for a new model of human social-cognition development. As previously noted this model adopts a parallel and distributed information processing perspective on joint attention and social cognition. An advantage of this model is that it explicitly attempts to link developmental behavioral research on social pathology to a range of recent observations from research on neural connectivity, genetics, intervention, and ocular motor control in autism.

A Brief History of Research on the Social Impairments of Autism

Autism is a biologically based disorder that is characterized by impaired social development, impaired language and/or pragmatic communication skill acquisition, and the presence of

repetitive behaviors and thoughts (Asperger, 1944; Bailey, Philips, & Rutter, 1996; Dawson, Osterling, Rinaldi, Carver, & McPartland, 2001; Kanner, 1943). The symptoms of autism may be observable by 24 months of age or earlier (Stone, Coonrod, & Ousley, 1997; Zwaigenbaum et al., 2005), with children expressing at least four different paths of symptom onset (Ozonoff, Heung, Byrd, Hansen, & Hertz-Picciotto, 2008). Some children may display clear symptoms by the end of the first year, some may display more typical development through the early part of the second year but reach a plateau. Still others may express mixed pictures of early delays, gains, and losses of developmental milestones.

Leo Kanner (1943) displayed impressive clinical acumen when he was able to discern three common characteristics that distinguished children with autism from those in a larger, varied clinical sample of children. He noted that children with autism appeared to have: (1) a common biological impairment, (2) of affective relatedness to others, which (3) resulted in a developmental disorder that primarily impaired the capacity for typical social interactions. The recognition of the biological, affective, and social behavioral syndrome triumvirate of autism was a remarkable achievement, and is as valid today as it was in 1944. Unfortunately, Kanner's initial perspective did not fit well with the psychodynamic zeitgeist of the time. The psychodynamic perspective emphasized the primacy of environmental over biological factors in the etiology of all psychopathology. Sufficient challenges were brought to bear in this regard that Kanner (1949) recanted his initial biological view of autism.

In the ensuing thirty years the science of autism drifted from conceptual model to conceptual model. Autism was characterized as a disorder caused by an aloof parenting style in which the children grew up to be emotionless (Bettelheim, 1959). Convincing evidence against the parenting style hypothesis was quickly marshaled (Rimland, 1964). However, the prototype of people with autism as emotionless and aloof remained for a long time. Little data were available to critically appraise this view because the social and emotional development of children with autism was rarely a focus of empirical inquiry through the 1970s. Rather, theory at that time suggested that sensory, perceptual or language impairments were primary in the etiology of autism (Mundy & Sigman, 1989). Although this was a scientifically valid perspective at the time, it implicitly relegated the social-emotional impairments of autism to the status of epiphenomenon.

The relegation of social-emotional symptoms to secondary status constrained the theory and methods used to establish the initial diagnostic criteria for autism. So, in the first attempts to establish a systematic diagnostic definition of autism (e.g., American Psychiatric Association [APA], 1980) only five criteria were proposed: (1) onset before 30 months of age; (2) a pervasive lack of responsiveness to other people; (3) gross deficits in language development; if speech is present, peculiar speech patterns such as immediate and delayed echolalia, metaphorical language, and pronominal reversal; (4) bizarre responses to various aspects of the environment,

e.g., resistance to change, peculiar interest in or attachments to animate or inanimate objects; and (5) absence of delusions, hallucinations, loosening of associations, and incoherence as in schizophrenia.

Note that *only one criterion* was specific to the social deficits of autism and this was the broad and vague descriptor of a *pervasive lack of responsiveness to other people.* There had been so little research on defining the nature of the social deficits of autism through 1980 that we simply had no idea what was involved in this domain of autism, even though Kanner had argued that it was central to nature of the syndrome. Pat Howlin (1978) made this limit to our knowledge clear in an early review of research on the social deficits of autism. Howlin was able to cogently summarize the field of social developmental research on autism with 7 pages of text and 39 citations. Only a handful of the latter involved peer reviewed empirical research publications. Fortunately, in the intervening decade there was a virtual explosion of research on the social deficits of autism. When Howlin published a second review of research on the social development of autism, eight years later, her review required 24 pages and 116 citations to adequately cover the field (Howlin, 1986).

This welcome increase in information on the social nature of autism occurred because of translational research. Several groups in the United States, the United Kingdom and throughout the world began to recognize that theory and methods from the study of human infant and primate social development could provide useful tools to examine and define the social deficits of autism (e.g., Dawson & McKissick, 1984; Rogers & Pennington, 1991; Sigman & Ungerer, 1984). This new wave involved the translation of basic science on infant imitation, social learning, social cognition, preverbal communication, attachment, and other domains of early social development to autism. One fairly immediate and vital impact of this surge of translational research was the dawning awareness that the description of the social impairments of autism singularly as a "pervasive lack of responsiveness to others" was at best limited and, at worst, misguided. It established a narrow categorical prototype that many individuals with autism did not resemble (Mundy & Sigman, 1989; Wing & Gould, 1979).

Studies began to show that children with autism displayed a significant phenotypic range of social styles and social behaviors. Some children, often also affected by severe or moderate levels of mental retardation appeared to be aloof, and came closest to the description of "a pervasive impairments in responsiveness to others." However, many other children with mild mental retardation, or normal IQs were not pervasively underresponsive. Instead, some were passive but socially responsive in structured situations, and others were even proactive in initiating interactions. However, these "active but odd" children were atypical and maladaptive in conducting their interactions with other people (Wing & Gould, 1979; Volkmar et al., 1989; Fein et al., 1999).

By the end of the 1980s research had also shown that many children with autism had social strengths as well as weaknesses, rather than a *pervasive lack of responsiveness to others.*

They responded when others imitated them, some could learn from social modeling, many increased their social output in structured situations, and they varied greatly in their use of gestures and eye contact to communicate (Curcio, 1978; Lewy & Dawson, 1992; Mundy & Sigman, 1989). Perhaps most remarkably children with autism often displayed levels of attachment behaviors that were commensurate with their mental development and *not atypical* relative to other groups of children with commensurate developmental delays (Shapiro, Sherman, Calamari, & Koch, 1987; Sigman & Ungerer, 1984; Sigman & Mundy, 1989).

Consequently, by the early 1990s translational developmental research indicated that key elements of the nosology of autism were incorrect. Children with autism, as a group, did not display a *pervasive* lack of responsiveness to others. Not only was this inaccurate, it promoted a constricted view of autism that excluded many children with the syndrome who frequently made eye contact, or displayed caregiver attachment, or any of a number of other social abilities. The perseverance of this inaccurate taxonomic prototype likely contributed to a historic underestimation of the prevalence of autism (Wing & Potter, 2002). Indeed, only with the publication of the most recent nosology (e.g., American Psychiatric Association [APA], 1994) have we had had sufficiently well defined guidelines to begin to capture something of the full range of phenotypic variability expressed across individuals with this syndrome. Prior to this we simply could not identify all the children with autism in the 1970s, 1980s, and early 1990s because we limited ourselves to those that just met a very limited and restrictive social criterion.

The empirically based revisions of social diagnostic criteria of autism culminated in the criteria now common to both the systems used in the United States, Europe, and the world (APA, 1994; 2000; World Health Organization, 1992). In both systems the qualitative impairment in social interaction in autism became defined as the expression of at least two of the following: (1) a marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction; (2) a failure to develop peer relationships appropriate to developmental level; (3) a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest); and (4) lack of social or emotional reciprocity.

The criterion of a lack of appropriate peer skills is extremely useful, but not until 3 or 4 years of age. As a result, the early identification and diagnosis of the social deficits of autism relies on observation of the other three social symptoms. This chapter attempts to provide a detailed consideration of why the third symptom, a *lack of spontaneous seeking to share experience, enjoyment, interests, or achievements with other people*, is central to the description of the social pathology of autism. In the research literature we study the early development of spontaneously seeking to share experience with others with measures of joint attention development. While other domains of social behavior such as imitation, face processing, empathy,

and pragmatic communication skills are prominent in the literature (Travis & Sigman, 1998), none of these is as central to the current social nosology of autism. Moreover, intervention and behavioral research indicate that the degree of early joint attention impairment is pivotal to the nature of autism because it is predictive of collateral social symptom, language, and cognitive outcomes (e.g., Bruinsma et al., 2004; Dawson et al., 2004; Charman, 2004; Kasari et al., 2006; Mundy & Crowson, 1997; Sigman & Ruskin, 1999). The recognition of the centrality of this social deficit in autism followed from the translation of basic research on how infants develop the ability to share experience with other people (Bruner, 1975).

How Infants Share Experiences with Other People

Well before infants learn to use symbols and language they begin to spontaneously share information with other people. They do so by coordinating their attention with another person and by using eye contact and gestures to show objects to others, or request aid obtaining and manipulating objects.

In 1975 Scaife and Bruner reported in *Nature* that between 6 to 18 months of age infants increasingly displayed the ability to follow the direction of gaze of a social partner. When a tester turned their head to the left or right many infants tracked and followed the visual attention of the testers with their own line of regard. This observation was groundbreaking. It was inconsistent with the prevailing notion of egocentrism or the idea that infants could not adopt dual perspectives, such as the perspective of self and another person, until late in the second year (Piaget, 1952). Scaife and Bruner's (1975) observations suggested that infants begin to discriminate and adapt their own visual perspective relative to another person's perspective much earlier in life than that.

Bruner (1975) adopted the general term "joint attention" for this domain of infant development. He recognized that this ability allowed infants and caregivers to adopt co-reference to the same object or event. One of Bruner's goals was to understand how young children learn in order to improve early educational curriculums. Instead of studying only how knowledge was acquired (learning), he studied how the ability to share knowledge in "social learning" develops, because this is essential to all forms of pedagogy. His work suggested that the development of the ability to participate in joint attention marked a critical turning point in some unknown set of early cognitive processes that were foundational to human social learning and education. More specifically, Bruner understood that co-reference was elementary to our human ability to perceive shared meanings and necessary for the development of symbolic thinking and language development.

In the early days of empirical research it became apparent that infants did not just develop one type of joint attention behavior. Rather they developed multiple forms of joint attention. The previously referred to type that involves infants'

ability follow the direction of another person's gaze (Scaife & Bruner, 1975) is often called Responding to Joint Attention (RJA; Seibert, Hogan, & Mundy, 1982). It can be reliably assessed beginning at about 3 to 6 months of life by determining if infants correctly turn their head and/or eyes to follow the visual line of regard of another person (see Figure 8-1). Another dimension called Initiating Joint Attention (IJA) arises sometime in the first year, but no later than 8 to 9 months. It involves the infant's use of alternating eye contact or gestures (i.e., pointing or showing) to spontaneously "declare" and direct and coordinate attention to share an experience with a social partner (Bates, Benigni, Bretherton, Camaioni, & Volterra, 1979; Mundy et al., 2007; Figure 8-1).

The declarative, social information sharing functions of IJA and RJA can be juxtaposed with other early nonverbal behaviors that involve attention coordination for more instrumental and imperative purposes. Young infants also learn to prelinguistically direct the attention of other people to request aid in obtaining object or actions (Initiating Behavioral Requests-IBR). In addition they learn to respond to the attention directing bids that adults use to request objects or actions from infants or Responding to Behavioral Requests (RBR; Figure 8-1).

As the theory and measurement concerning infant joint attention was developing in the 1970s, the important practical issue of identifying valid markers of *infant* cognition came to the fore. The types of sensory motor measures used to assess infant "intelligence" and cognitive "risk" at the time were not sufficiently reliable or valid (Lewis & McGurk, 1972). Without valid measures it was challenging to identify many infants who were at risk for developmental disorders. It was also difficult to know what constituted valid targets for early cognitive intervention. This impasse began to clear as applications of basic research indicated that measures of infant visual attention could be used as valid indicators of current and future cognitive development in infancy (Bornstein & Sigman, 1986).

One laboratory for the translation of research on infant attention to clinical applications was created by Jeff Seibert
Figure 8–1. Illustrations of different types of infant social attention coordination behaviors: (a) Responding to Joint Attention-RJA, involving following an other person's gaze and pointing gesture; (b) Initiating Joint Attention-IJA, involving a conventional gesture "pointing" to share attention regarding a room poster; ($c_{1,2,3}$) IJA involving *alternating eye contact* to share attention with respect to a toy; (d) Initiating Behavior Request, involving pointing to elicit aid in obtaining an out-of-reach object; and (e) Responding to Behavior Requests, involving following an adult's open-palm "give it to me" gesture.

and Anne Hogan at the Debbie School of the University of Miami. The Debbie School served preschoolers who had moderate to severe motor and developmental impairments. Their motor impairments made the use of sensorimotor-based cognitive assessments and interventions extremely problematic. So Seibert, Hogan, and their graduate students began to develop an early assessment and intervention curriculum that focused on joint attention and preverbal communication skill development. This resulted in the Early Social Communication Scales (ESCS), which organized precise observations of joint attention and social attention coordination into a measurement instrument that could also be used to guide to early intervention (Seibert et al., 1982). A lasting contribution of the ESCS, along with related measures (see Stone, Coonrod & Ousley, 1997; Wetherby, Allen, Cleary, Kublin, & Goldstein, 2002) was that joint attention assessment turned out to be a powerful instrument for the study of the social pathology of autism.

Joint Attention and Defining The Social Deficits of Autism

To the best of my knowledge it was Frank Curcio (1978) who first noted that many children with autism capably initiated nonverbal requests but not joint attention bids in social interactions. Indeed, 50% of the elementary school–age children with autism he observed in classrooms systematically used eye contact and conventional gestures to express their requests. However, few if any children with autism displayed evidence of the use of eye contact or gestures to initiate nonverbal "declaratives" (i.e., display an IJA bid). Curcio concluded that impairments in the capacity to initiate declarative communicative functions, or what we now call initiating joint attention bids, could be central to the nature of the social impairments of autism. Numerous subsequent studies have indicated that Curcio was correct (e.g., Charman, 2004; Dawson et al., 2004; Loveland & Landry, 1986; Mundy et al., 1986; Sigman & Ruskin, 1999; Wetherby & Prutting, 1984).

In work with Marian Sigman at UCLA we compared mental age, chronological age, and IQ matched samples of 4- to 7-year-old children with autism or mental retardation as well as a mental-age matched sample of typically developing children. We found the children with autism displayed deficits in joint attention in interactions with unfamiliar testers as well as their familiar parents relative to both comparison groups (Mundy et al., 1986; Sigman et al., 1986). However, just as Curcio had observed, our sample of children with autism displayed levels of requesting that were comparable to those observed in the MR sample. Also similar to Curcio's data from older children, we observed that young children with autism did not display pervasive differences in eye contact relative to children with mental retardation on the ESCS, but rather strengths and weaknesses. They displayed comparable levels of eye contact in requesting and turn-taking social

interactions. However, an eye contact disturbance specific to autism was clearly manifested in their diminished use of alternating gaze to spontaneously initiate sharing of their experience of a mechanical toy with the tester. This type of behavior is illustrated in Figure 8-1.

We cannot definitively know why a child does or does not engage in IJA during a social interaction. Nevertheless, during the administration of the ESCS adult testers often arrive at the impression that IJA behaviors, such as alternating eye contact, serve to share experience of an event or garner attention to the child's own experience of the event (Figure 8-1). Hence, it was not too surprising to find that higher or lower frequencies of alternating eye-contact in young children, with or without autism, were significantly related to parents' independent perceptions of their child's social relatedness (Mundy et al., 1994). Thus, it seemed reasonable to begin to consider to us the possibility that diminished IJA alternating eye-contact was crucial to what Kanner had characterized as impairments in relatedness and positive affective contact with others in autism (e.g., Mundy & Sigman, 1989).

The idea that IJA was related to a disturbance in positive social-affective contact in autism was subsequently supported by research that showed that about 60% of the IJA bids displayed by typical infants and children with mental retardation involved the conveyance of positive affect (Kasari, Sigman, Mundy, & Yirmiya, 1990; Mundy, Kasari, & Sigman, 1992). However, positive affect was much less frequently part of the IJA behaviors of children with autism (Kasari et al., 1990). It was not the case, though, that children with autism displayed significantly lower positive affect in requesting or turn-taking interactions. Hence, it was unlikely that the diminished positive affect in joint attention reflected a general aversion to social interactions. More recently we've come to suspect that the onset of the systematic conveyance of positive affect as part of IJA bids begins to develop early in life at about 8 to 10 months of age (Venezia, Messinger, Thorp, & Mundy, 2004). Thus, joint attention impairments reflect what are likely to be early arising deficits in the tendency of children with autism to socially share positive affect. This in turn may involve a disturbance in their early appreciation of the positive social *value* of shared attention. That is to say motivation factors or sensitivity to reward value of social gaze may play a role in joint attention disturbance in autism (Mundy, 1995).

Joint Attention Impairments and The Social-Cognitive Hypothesis

During the time that joint attention impairments in autism were first being described another kind of social developmental translational research was beginning to emerge. Premack and Woodruff (1978) began to describe observational methods that enabled them to evaluate whether primates were aware of the thoughts or intention of conspecifics. That is, they began to study if apes had a theory of mind (ToM). In the

United Kingdom Wimmer and Perner (1983) further operationalized the construct of theory of mind with the development of the false belief task. With this paradigm they began to study the course of development of ToM and social cognition in young preschool and elementary school–age children. Very quickly thereafter, other research groups in London began to translate Wimmer and Perner's basic "false belief" developmental paradigms to the study of autism. This led to another sequence of seminal observations regarding the defining features of social impairments in autism. Children with autism appeared to have more difficulty with the development of social cognition than other aspects of cognitive development (e.g., Baron-Cohen, Leslie, & Frith, 1985; Leslie & Happe, 1989; Frith, 1989).

Theory had previously linked the development of joint attention to the emergence of social cognition (Bretherton, 1991). However, the parallel observations of deficits in joint attention development and theory of mind development in autism during the mid-1980s provided the first empirical, albeit indirect, link between these two domains of development. Consequently, the social cognitive view of autism and typical social development became so compelling in the literature that joint attention disturbance began to be interpreted as a manifestation of social cognitive impairment in autism (Baron-Cohen, 1989; Leslie & Happe, 1989). This was also true for theory on typical development, where a prominent view remains that joint attention is not possible without social cognition (Tomasello & Call, 1997).

So, some have argued that social cognition, or the knowledge that other people's behavior is guided by mental, goal-directed intentions precedes and gives rise to joint attention (Tomasello, Carpenter, Call, Behne, & Moll, 2005). Therefore, impairments in social cognition may explain the cause of joint attention impairment in autism (Baron-Cohen, 1989). Alternatively, we have proposed that it may be inadvisable to use later arising knowledge base cognition (e.g., ToM) to explain what may be best viewed as a form of early developing social information processing that provides an essential foundation for subsequent social and cognitive development in people (Mundy, 2003; Mundy & Newell, 2007; Mundy & Sigman, 1989; Mundy, Sigman, & Kasari, 1993). This idea has emerged, in part, from considering the differences in IJA and RJA in autism and typical development.

The Dissociation of Joint Attention Impairment in Autism

To interpret the nature of IJA and RJA impairments in autism it is important to recognize that they dissociate in development. Both RJA and IJA are useful in the early identification and diagnosis of autism (e.g., Lord et al., 2000; Stone, Coonrod, & Ousley, 1997). However, RJA impairments are less evident for children with more advanced levels of cognitive development (Mundy et al., 1994, see Figure 8-2). Indeed, across studies of

different age group of children there is at best inconsistent evidence of a robust syndrome-specific impairment in the ability to process the direction of gaze or respond to joint attention in people with autism (Nation & Penny, 2008). On the other hand, IJA deficits are observed in children with autism from preschool through adolescence, *and* IJA is a better discriminator of children with autism relative to children with other developmental disorders (e.g., Charman, 2004; Dawson et al., 2004; Hobson & Hobson, 2007; Mundy et al., 1986; Sigman & Ruskin, 1999). The correlates of IJA and RJA also diverge as much as they converge in studies of autism. Both IJA and RJA are related to executive inhibition and language development in autism (Bono et al., 2004; Dawson et al., 2002; Dawson et al., 2004; Griffith et al., 1999; Sigman & McGovern, 2005). However, to our knowledge, only IJA is significantly associated with individual differences in social and affective symptom presentation (Charman, 2004; Kasari et al., 1990; Kasari et al., 2007; Lord et al., 2003; Mundy et al., 1994; Naber et al., 2008; Sigman & Ruskin, 1999).

This literature emphasizes that joint attention deficits are neither absolute nor uniform in autism, and the impairment of IJA and RJA likely constitutes different developmental processes that are vital to symptom presentation in the syndrome. Moreover, of the two, deficits in initiating joint attention behavior appears be the more pathognomonic feature of autism (Mundy, 1995). Observations from intervention research also emphasize that autism is a disturbance of the spontaneous *generation* of social behaviors, as much as or more than a disturbance of perception and *response* to the social behaviors of others (Koegel et al., 2003). A similar interpretation is suggested by recent research with infant siblings of children with autism (Zwaigenbaum et al., 2005). Indeed, the centrality of initiating deficits, especially IJA, is highlighted in current nosology where it is "a lack of *spontaneous* seeking to share enjoyment, interests, or achievements with other people, (e.g., by a lack of showing, bringing, or pointing out objects of interest to other people)" that is described as one of the
Figure 8–2. Illustration data on the moderating affect of mental age on diagnostic group differences on RJA versus IJA reported in Mundy et al. (1994).

primary social symptoms of autism (APA, 1994). Furthermore, the "gold standard" diagnostic observation instrument, the Autism Diagnostic Observation Schedule (ADOS), recognizes the primacy of IJA symptoms. Measures of both IJA and RJA are used in Module 1 diagnostic algorithms for the youngest children. However, Module 2 for older children only includes IJA measures in its diagnostic criteria (Lord et al., 2000).

Evidence of a developmental dissociation between IJA and RJA is also apparent in studies of typical infant development. Frequency measures of IJA and RJA are characterized by different growth patterns, and these domains display weak to nonsignificant correlations in infant development (e.g., Meltzoff & Brooks, 2008; Mundy et al., 2007; Sheinkopf et al., 2004; Slaughter & McDonald, 2003). They also have different patterns of correlations with childhood IQ (Ulvund & Smith, 1996), frontal brain activity (Caplan et al., 1993; Mundy et al., 2000); reward-based behavioral goal-inhibition and self-monitoring behaviors (Nichols et al., 2005), attention related self-regulation (Morales et al., 2005), and attachment (Claussen et al., 2002). These observations imply that the nature of the differences, as well as commonalities between IJA and RJA may be a key to conceptualizations of the joint attention impairments of autism.

Initiating Joint Attention Behaviors and Autism

It is essential to be precise about the nature of the behavioral expression of IJA impairments in autism, which are often equated with problems with pointing and showing gestures. However, diminished alternating gaze behavior (Figure 8-1) is a more powerful measure of IJA impairment in autism. This type of measure was superior to point and showing and correctly identified 94% of 54 preschool children with autism, mental retardation, and typical development (Mundy et al., 1986). Others have observed that IJA measured with the Early Social Communication Scales (ESCS; Seibert, Hogan, & Mundy, 1982) had a sensitivity of 83% to 97% and a specificity of 63% to 67% in discriminating fifty-three 3- to 4-year-olds with autism from controls (Dawson et al., 2004). Recent research indicates that most of the variance in ESCS-IJA scores is carried by alternating gaze behavior (Mundy et al., 2007). The IJA alternating gaze of 2-year-olds also predicts 4-year-old symptom outcomes in children with autism (Charman, 2004), as well as social cognition in typical 4-year-old children (Charman et al., 2000).

These developmental and measurement details are important for models of joint attention disturbance in autism. Often joint attention problems are viewed as growing out of developmental antecedent or successor processes that are considered to be more fundamental. A nonexhaustive list here includes affective processes, reward-sensitivity, executive attention control, social-orienting, identification, imitation and mirror neurons, intersubjectivity, and most prominently social cognition (e.g., Baron-Cohen, 1989; Charman, 2004;

Dawson et al., 2004; Mundy et al., 1986; Williams, 2008). This reductionism has lead to a paradox where joint attention deficits are viewed as pivotal to autism, but also as an outgrowth of more basic processes. Charman (2004) recognized this paradox in noting that we often think of joint attention not as "a starting point [for autism], but merely a staging post in early social communicative development, and hence a 'postcursor' of earlier psychological and developmental processes… [which may] underlie the impaired development of joint attention skills in autism" (p. 321).

There are at least three problems with this perspective. First, stable individual differences in IJA alternating gaze are well established by 8 to 9 months in typical development (Mundy et al., 2007; Venezia et al., 2004), and the onset of cortical control of alternating gaze likely begins between 4 to 6 months (Mundy, 2003; Striano, Reid, & Hoel, 2006). Joint attention precursors would need to be present prior to this time. Second, there is little evidence that the association of joint attention with the etiology or outcomes of autism is mediated by more basic antecedent or successor processes. Dawson et al. (2004) observed that neither social-orienting measures nor empathy measures could account for relations between IJA and language development in a large sample of children with autism. Joint attention disturbance in autism also cannot be explained in terms of affect regulation or social relatedness measured with attachment measures (Capps, Sigman, & Mundy, 1994; Naber et al., 2008). Moreover, joint attention accounts for significant portions of variance in the language, symbolic play, and symptom development of children with autism above and beyond variance associated with executive functions, imitation, knowledge about others' intentions, or global measures of mental development (e.g., Charman 2004; Royers et al., 1998; Kasari et al., 2007; Naber et al., 2008; Rutherford et al., 2008; Sigman & Ruskin, 1999; Smith et al., 2007; Thurm et al., 2007; Toth et al., 2006).

A third issue is that precursor and successor process hypotheses rarely account for the dissociation of IJA and RJA (Mundy et al., 2007). Social-cognitive hypotheses suggest that RJA and IJA should be highly related because they are precursors of a common "mentalizing" ability involved in perceiving the intentions of others (e.g., Baron-Cohen, 1995; Tomasello, 1995). Executive attention or social-orienting hypotheses don't explicitly account for why IJA deficits are more pervasive than RJA deficits, even though both ostensively involve comparable attention inhibition and attention reorienting processes (e.g., Dawson et al., 1998; Mundy & Burnette, 2005). Imitation and mirror neuron theory emphasizes the role of deficits in processing and responding to the behavior of other people in the development of autism (e.g., Williams, 2008). Hypothetically, though, this should be more related to responsive joint attention than the spontaneous initiation of joint attention bids. Why then do IJA deficits appear to be the more robust form of joint attention disturbance in autism than RJA deficits? An answer may be perceived from a constructivists vantage point on joint attention and human social-learning (e.g., Bruner, 1975, 1995).

Learning and The Importance of Joint Attention

Early language learning often takes place in unstructured, incidental situations where parents spontaneously refer to a new object (Figure 8-3). How do infants know how to map their parents' vocal labels to the correct parts of the environment amid a myriad of potential referents? Baldwin (1995) suggested that they use RJA and use the direction of gaze of their parent's to guide them to the correct area of the environment, thereby reducing "referential" mapping errors. Infants' use of IJA also reduces the chance of referential mapping errors. IJA serves to denote something of immediate interest to the child. This assists parents to follow their child's attention to provide new information in a context when the child's interest and attention is optimal for learning (Tomasello & Farrar, 1986). Hence, joint attention may be conceived of as a self-organizing system that facilitates information processing in support of social learning (Mundy, 2003). This "learning function" is fundamental to joint attention (Bruner, 1975) and continues to operate throughout our lives (e.g., Bayliss et al., 2006; Nathan et al., 2007). Without the capacity for joint attention, success in many pedagogical contexts would be difficult. Imagine the school readiness problems of a 5-year-old who enters kindergarten but

Figure 8–3. Illustration from Baldwin (1995) depicting the referential mapping problem encountered by infants in incidental social word learning situations. Source: Baldwin, D. (1995). Understanding the link between joint attention and language. In C. Moore & P. Dunham (Eds.), *Joint Attention: Its origins and role in development* (pp. 131–158). Hillsdale, NJ: Erlbaum.

is not facile with coordinating attention with the teacher. Similarly, children, adolescents and adults who cannot follow, initiate, or join with the rapid-fire exchanges of shared attention in social interactions may be impaired in any social learning context, as well as in their very capacity for relatedness and relationships (Mundy & Sigman, 2006).

If joint attention helps self-organize social learning, then the more that children engage in joint attention, the more optimal social-learning opportunities they help create for themselves. This may help to explain why the frequency with which infants engage in joint attention is positively related to their language acquisition and childhood IQ status (e.g., Mundy et al., 2007; Smith & Ulvund, 2003). More direct evidence of the two links between joint attention and early learning is provided by the observation that coordinated social attention to pictures elicits electrophysiological evidence of enhanced neural activity (Striano, Reid, & Hoel, 2006) and recognition memory associated with greater depth of processing in 9-month-olds (Striano, Chen, Cleveland, & Bradshaw, 2006).

In light of the assumption that joint attention is basic to early learning, reconsider the observation that IJA and RJA dissociate in development. Theory and research suggest that this occurs because these forms of joint attention involve functions of two distinct neural networks (Mundy & Newell, 2007). In conjunction with this idea note that parallel and distributed cognitive theory suggests that learning occurs best in the context of the simultaneous activation of multiple neural networks during encoding (e.g., Munakata & McClelland, 2003; Otten et al., 2001). Taken together, these ideas raise two hypotheses. First, joint attention may involve the early development of a form of social information processing across multiple distributed neural networks. Second, impairments of joint attention may reflect deficits in the development of this parallel and distributed activation of cortical neural networks in autism.

Research has indicated that IJA is associated with frontal cortical activity (Caplan et al., 1993; Henderson et al., 2002; Mundy et al., 2000; Torkildsen et al., 2008), while RJA and related gaze-following behaviors are more closely tied to parietal and temporal cortical processes (e.g., Frieschen, Bayliss, & Tipper, 2007; Materna, Dicke, & Thern, 2008; Mundy et al., 2000). One interpretation of these data is that joint attention involves developments of functions of both the anterior and posterior cortical attention networks that have been described by Michael Posner and others (Posner & Rothbart, 2007), which is essential to typical human social learning. The basis for the first hypothesis is outlined in the next section.

The Two Neural Systems of Joint Attention and Social Cognition

The functions of the posterior network are common to many primates, but the anterior network is not well represented in primates other than humans (Astafiev et al., 2003; Emery, 2000; Gilbert & Burgess, 2008; Jellema, Baker, Wicker, &

Perrett, 2000). RJA appears to be most closely associated with the posterior system, which regulates relatively involuntary attention, begins to develop in the first 3 months of life, and prioritizes orienting to biologically meaningful stimuli. It is supported by neural networks of the parietal/precuneus and superior temporal cortices (Figure 8-4). These neural networks are active in the perception of the eye and head orientations of others, as well as the perception of spatial relations between self, other, and the environment. The posterior system is especially involved in control of orienting on a trial-by-trial basis, and the development of cognitive representations about the world built from information acquired through external senses (Dosenbach et al., 2007; Fuster, 2006; Cavanna & Trimble, 2006).

Initiating joint attention is supported by the later developing anterior attention network involved in the cognitive processing, representation, and regulation of self-initiated goal-directed action. This network includes the anterior cingulate, rostral medial superior frontal cortex, including the frontal eye fields, anterior prefrontal cortex, and orbital frontal cortex (e.g., Dosenbach et al., 2007; Fuster, 2006). The development of the intentional control of visual attention begins at about 3 to 4 months of age, when a pathway from the frontal eye fields (BA 8/9) that releases the superior colliculus from inhibition begins to be actively involved in the prospective control of saccades and visual attention (Canfield & Kirkham, 2001; Johnson, 1990). The function of this pathway may underlie 4-month-old infants' ability to suppress automatic visual saccades in order to respond to a second, more attractive stimulus (Johnson, 1995), and 6-month-olds' ability to respond to a peripheral target when central, competing stimuli are present (Atkinson, Hood, Wattam-Bell, & Braddick, 1992). We assume that the functions of this pathway also enable intentional gaze alternation between interesting events and social partners (Mundy, 2003). It is instructive to note at this juncture that research has long indicated that neonates and young infants at risk for cognitive delays, but not necessarily autism, display problems with visual disengagement from a visual stimulus (Sigman, Cohen, & Beckwith, 1997). So it is not clear if this early phase of the development of intentional control of visual attention should be considered to be a prime candidate in developmental models specific to joint attention disturbance in autism.

Differences in the functions and developmental timing of the anterior and posterior attention networks help to explain why IJA and RJA dissociate in development (Mundy et al., 2000; Mundy et al., 2007). However, although IJA and RJA follow distinct biobehavioral paths of development, it is also likely that they integrate in development. Indeed, EEG data indicates that activation of a distributed anterior and posterior cortical system predicts IJA development in infants (Henderson et al., 2002), and fMRI data indicate that activation of a distributed anterior-posterior cortical network is associated with the experience of joint attention in adults (Williams et al., 2005). These observations, among others, have motivated the description of a parallel and distribute information processing
Figure 8–4. Illustration from Mundy & Newell (2007) depicting the lateral (top) and medial (bottom) illustrations of Brodmann's cytoarchitectonic areas of the cerebral cortex associated with Initiating Joint Attention and the anterior attention system, as well as RJA and the posterior attention systems. The former include areas 8 (frontal eye fields), 9 (prefrontal association cortex), 24 (anterior cingulate), and 11 and 47 (orbital prefrontal and insula association cortices—*not illustrated*). The latter include areas 7 (precuneus, posterior parietal association area), 22, 41, and 42 (superior temporal cortex), and 39 and 40 (parietal, temporal, occipital association cortex).

model (PDPM). In this model the integrative processing internal self-referenced information about one's own visual attention, with the processing of external information about the visual attention of other people is a defining feature of joint attention (Figure 8-5; Mundy & Newell, 2007; Mundy, Sullivan, & Mastergeorge, 2009). Indeed, neurocognitive theory has begun to claim that an emergent function of the human rostral medial frontal cortex is the capacity to switch attention between self-generated and perceptual information in support of social cognition (Gilbert & Burgess, 2008). The PDPM suggests that this utility is "allocated" to the rostral medial frontal cortex with development in large part as a function of the adequate biobehavioral exercise of joint attention in infancy.

According to the PDPM the joint attention, or the integration of information about self-attention and the attention of others, is a form of parallel processing that occurs across a distributed cortical network. It is first practiced in infancy and contributes to an information processing synthesis that plays a crucial role in human social cognition. The basic idea here is that human levels of self-awareness cannot develop without bidirectional interactive processing of information about self and others (e.g., Piaget, 1952). The potential role of parallel and distributed processing in synthesis in human social cognition has previously been recognized (Decety & Sommerville, 2003; Keysers & Perrett, 2006). However, the developmentally

primary role of joint attention in this synthesis is less well recognized.

Social Cognition, Joint Attention, and The PDPM

Social-cognitive models often describe joint attention in terms of incremental stages of knowledge about the intentionality of other people. Baron-Cohen (1995) described a sequence of cognitive modules that included the *intentionality detector* (ID), a dedicated cognitive facility that attributes goal-directed behavior to objects or people; and the *eye direction detector* (EDD), which senses and processes information about eyes. These combine to form the *shared attention mechanism* (SAM), a cognitive module that represents self and other as attending to the same referent *and* attributes volitional states (intentionality) to direction of gaze of *other* people. As infancy ebbs the *theory of mind mechanism* replaces SAM and enables representation of the full range of mental states of others and enables us to make sense of others behaviors.

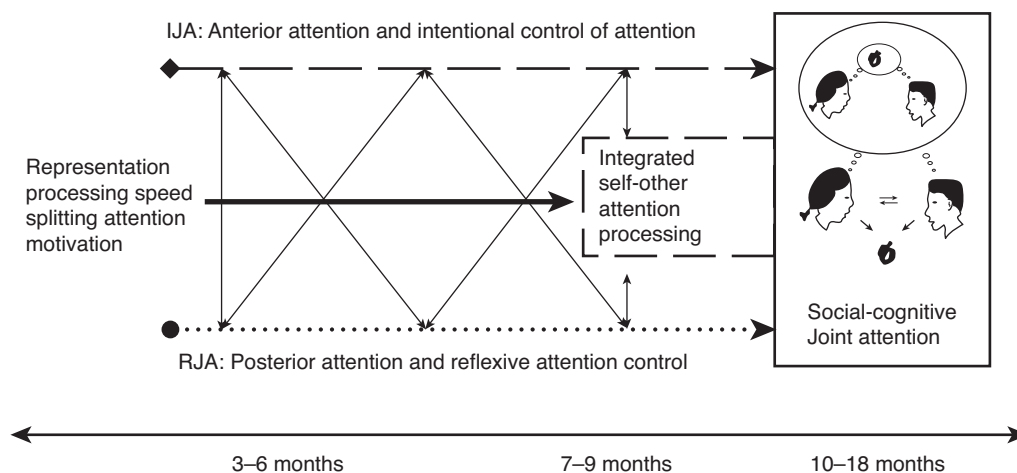
Tomasello et al. (2005) more explicitly described joint attention development in terms of three stages of what infants *know about other people*. In *understanding animate action*, 3- to 8-month-old infants can perceive contingencies between


Figure 8–5. An illustration of the development of the parallel and distributed information processing system of joint attention and social cognition, from Mundy & Newell (2007). In this model, different types of lines depict the multiple paths of joint attention development. The posterior attention system path associated with RJA development is illustrated with a dotted line and the anterior attention system path associated with IJA development is illustrated with a dashed line. The central solid line in the figure depicts the developments of other processes during infancy that influence joint attention development such as representational ability, speed of processing, motivation, and the executive attention control, as well as each other during infancy. The diagonal arrows connect all paths throughout early development. This reflects the dynamic and coactive nature of joint attention development whereby the maturation of attention, cognitive, and affective systems interact in reciprocal cause-and-effect relations with experience, including the experiences children create for themselves through their own actions. Finally, the development of integrated self- and other-attention processing is considered to be a social attention executive function of the anterior system that emerges in the 4- to 9-months period. This is represented by the box. The capacity to integrate and share overt aspects of attention provides a foundation for the ability to share covert aspects of attention, such as representations, and social cognition.
Source: Mundy, P., & Newell, L. (2007). Attention, joint attention, and social cognition. *Current Directions in Psychological Science*, *16*, 269–274.

their own animate actions and emotions relative to the animate actions and affect of others. However, they cannot represent the internal mental goals of others that are associated with these actions. In the next *understanding of pursuit of goals* stage, 9-month-olds become capable of shared action and attention on objects (e.g., building a block tower with parents).

Tomasello et al. (2005) suggest this stage involves *joint perception,* rather than *joint attention,* because the social-cognitive capacity to represent others' internal mental representations necessary for true joint attention is not yet available. However, this ability emerges between 12 and 15 months in the *understanding choice of plans* stage. This stage is heralded when infants become truly active in initiating episodes of joint engagement by alternating their eye-contact between interesting sights and caregivers (Tomasello et al., 2005). This shift to active alternating gaze indicates infants' appreciation that others make mental choices about alternative actions that affect their attention. Infants also now know themselves as agents that initiate collaborative activity based on their own goals. Hence, the development of "true" joint attention at this stage is revealed in the capacity to adopt two perspectives analogous to speaker-listener.

The capacity to adopt two perspectives is also assumed to be an intrinsic characteristic of symbolic representations. In this regard, Tomasello et al. (2005) raise a truly seminal hypothesis that symbolic thought is a *developmental transformation* of joint attention. They argue that symbols themselves serve to socially coordinate attention so that the intentions of the listener align with those of the speaker. In other words, *linguistic symbols both lead to and are dependent on the efficient social coordination of covert mental attention to common abstract representations among people.* This hypothesis fits well with the parallel and distributed information processing model (PDPM) of joint attention, but the PDPM places it in a substantially different developmental framework.

The PDPM does not emphasize functional segregation of cognitive systems implicit to modular perspectives, but instead emphasizes the cortically multidetermined nature of human cognition because of the "massively parallel nature of human brain networks and the fact that function also emerges from the flow of information between brain areas" (Ramnani et al., 2004, p. 613). Furthermore, cognitive development need not be construed only in terms of changes in discontinuous stages of knowledge. It can also be modeled as a continuous change in the speed, efficiency, and combinations of information processing that give rise to knowledge (Hunt, 1999). Specifically, the PDPM envisions joint attention development in terms of increased speed, efficiency, and complexity of processing of: (1) internal information about self-referenced visual attention, (2) external information about the visual attention of other people, and (3) the neural networks that integrate processing of self-generated visual attention information with processing of information about the visual attention behavior of other people (Mundy & Newell, 2007; Mundy et al., 2009).

Consequently, the notion that *true* joint attention does not emerge until requisite social-cognitive knowledge emerges at 12–15 months (Tomasello et al., 2005) is not germane to the PDPM. Rather, consistent with a growing empirical literature, the PDPM holds that the true joint processing of attention information begins to be practiced by infants by 3 to 4 months of age (D'Entremont, Hains, & Muir, 1997; Farroni, Massuccessi, & Francesca, 2002; Hood, Willen, & Driver, 1998, Morales et al., 1998, Striano Reed, & Hoel, 2006; Striano & Stahl, 2005). Indeed, even the types of active alternating gaze behaviors thought to mark the onset of true joint attention at 12–15 months (Tomasello et al., 2005) develop no later than at 8–9 months of life, and quite possibly earlier (Mundy et al., 2007; Venezia et al., 2004).

Equally important, the PDPM assumes that joint attention is not replaced by the subsequent development of social-cognitive processes. Instead, joint attention is thought to remain an active system of information processing that supports cognition through adulthood (Mundy & Newell, 2007; Mundy et al., 2009). As an example, recall the hypothesis that linguistic symbols enable the social coordination of covert attention to common mental representations across people (Tomasello et al., 2005). According to the PDPM symbolic thinking *involves* joint attention but does not *replace* joint attention. Just as 12-month-olds can shift eye contact or use pointing to establish a common visual point of reference with other people, 4-year-olds can use symbols to establish a common reference to covert mental representations with other people. Symbolic representations are often, if not always, initially encoded during the joint processing of information about the overt attention of self and of others directed toward some third object or event (Adamson et al., 2004; Baldwin, 1995; Werner & Kaplan, 1963). The PDPM combines that hypothesis with the connectionist notion that "representations can take the form of patterns of activity distributed across processing units" that occurred during encoding (Munakata & McClelland, 2003, p. 415). Together these two ideas lead to the assumption of the PDPM that *symbol acquisition incorporates the distributed activation of the joint self-attention and other-attention neural processing units, which were engaged during encoding, as part of their functional neural representational mappings.* Hence, the distributed joint attention processing system may always be activated as a network encoding that contributes to the intersubjectivity (i.e., shared attention and meaning) of symbolic thought.

In infancy the distributed joint attention processing system is initially effortful. However, thousands of episodes of practice allow the joint information processing of self-other attention to become efficient, less effortful, and even automatically activated in social engagement. As this occurs, joint attention becomes a social-executive "subroutine" that runs in support of symbolic thought, as well that capacity to maintain a shared focus in social interactions and in social-cognition (Mundy, 2003). The distributed neural activation patterns associated with joint attention are part of infants' sense of developing sense of relatedness to others (Mundy & Hogan, 1994; Mundy,

Kasari, & Sigman, 1993). Moreover, the distributed neural activation associated with joint attention can be thought of as an enduring stratum of a more *continuous spiral* of human social-neurocognitive development that supports, if not enables, later emerging human symbolic, linguistic, and social cognitive facilities (see Figure 8-6).

Inside-Out Processing and The PDPM

In addition to parallel and distributed processing, the PDPM may be distinguished from other models by its constructivist perspective on development. Rather than focusing on the development of knowledge *about others,* the PDPM gives equal footing to the significance of infants' development of their own intentional visual behavior in joint attention and social cognitive development (Mundy et al., 1993). The assumption here is that neonates and young infants receive greater quantities and fidelity of information about self-intended actions (e.g., active looking) through proprioception than they receive about other's intended actions through exteroceptive information processing. Thus, infants have the opportunity to learn as much *or more* about intentionality from their own actions as from observing the actions of others. A corollary of this assumption of the PDPM is that joint attention is an embodied form of cognition (Feldman & Narayanan, 2004). Its development is a constructivist process that involves self-perception as a foundation for the attribution of meaning to the perception of others behaviors.
Figure 8–6. An illustration of the continuous nature of joint attention development. Development is modeled as a spiral in which the initial acquisition of the capacity for integrated processing of information about self and other attention (joint attention) remains an active but deeper layer of cognitive activity throughout life that supports symbolic thought, language, and cultural social exchange. Numbers of the spiral bands represent changing phases of development. The letters on each side of the spiral bands represent change and continuity in multiple developmental factors that may impact joint attention development, such as speed of information processing, representational development, and memory.

We have referred to this as the "inside-out" processing assumption of the PDPM (Mundy & Vaughan Van Hecke, 2008).

The general tenor of this constructivist assumption is nothing new. Bates et al. (1979) suggested that a sense of self-agency was basic to joint attention. More generally Piaget (1952) argued that infants do not learn through the passive perception of objects [or others] in the world. Rather, infants take action on objects and learn from their [causal] actions. They then modify their actions, observe changes in causal relations, and learn new things about the physical world. Thus, Piaget viewed the processing of self-initiated actions on objects as a singularly important fuel for the engines of cognitive development. The constructivist viewpoint is not only central to the PDPM, it is also a mainstay of contemporary connectionist biological principles of typical and atypical neurocognitive development (e.g., Blakemore & Frith, 2003; Elman, 2005; Mareschal et al., 2007; Meltzoff, 2007; Quartz, 1999).

The vast number of functional neural connections that are made in early postnatal brain development are thought to be too numerous to be specified by genes alone. Instead, genes specify relatively wide channels of potential neurodevelopmental architecture (e.g., Quartz, 1999). Within these prescribed channels the specifics of important functional connections in the developing nervous systems are sculpted by our experience. Since most of us experience relatively similar environments and experiences in early life developmental, brain organization displays significant similarities across most people (Mareschal et al., 2007). Greenough, Wallace, & Black (1987) refer to this gene-by-environment interaction in the ontogeny of neural connections as "experience expectant" neurodevelopment. Greenough et al. (1987) also explicitly noted the that infants' generation of actions, and observations of social reactions, likely play a role in experience expectant processes specific to neurodevelopmental basis of human social behavior. So, just as Piaget envisioned that infants learn about the physical world from their self-generated actions on objects, it is reasonable to think that a significant portion of what infants learn about the social world comes from their self-generated actions with people. One type of self-generated action that may be developmentally key in this regard is active vision.

Active Vision and The PDPM

One of the first and most vitally informative types of actions infants take involves the self-control of their looking behaviors, or active vision. The science of vision has moved away from the study of "seeing" or passive visual perception, to the study of "looking" or intentional, *active-vision* and attention deployment (Findlay & Gilchrist, 2003). Active vision in infancy begins to develop at 3–4 months (e.g., Canfield & Kirkham, 2001; Johnson, 1990, 1995). It involves the goal-directed selection of information to process, and can elicit contingent social behavior responses from other people,

such as parental smiles, vocalizations, or gaze shifts. It also is one of the first types of volitional actions that infants use to control stimulation to order to self-regulate arousal and affect (Posner & Rothbart, 2007).

Vision and looking behavior have unique properties. Vision provides information regarding the relative spatial location of ourselves and other people. Moreover, direction of gaze conveys the distal and proximal spatial direction of our attention to others, and vice versa. Comparable information on the spatial direction of attention is not as clearly available from the other senses. This is especially true in the first 9 months of life, and for distal information. The importance of spatial visual information for the development of joint attention was emphasized by Butterworth and Jarrett (1991) in their influential article "What Minds Have in Common Is Space."

In some sense primate eyes are specialized for *social* spatial attention processing (e.g., Tomasello, Hare, Lehman, & Call, 2006). Frontal binocular eye positions allow for enhanced spatial processing and depth of perception through parallax perception. Intricate musculatures allow for rapid visual focus on objects that are far or near. Equally important, precise information about the spatial direction of attention is available from human eyes because of the highlighted contrast between the dark coloration of the pupil and iris versus the light to white coloration of the sclera. These observations have led to the suggestion that the ease of processing the direction of attention of *other peoples' eyes* contributed to the human phylogenetic and ontogenetic development of social cognition (e.g., Tomasello et al., 2006).

It is also the case, though, that these characteristics of the human eye allow the saccades of infants to be readily observed by other people. Consequently, infant saccades can effectively act as elicitors of contingent social feedback. When infants shift attention to an object, their parents may pick up and show them the object. When infants shift attention to their parents' eyes they may also receive a vocal, affective, or physical parental response. Thus, just as the characteristics of eyes make it easier for infants to perceive the attention of others, the signal value of eyes makes the active control of vision a likely nexus of infants' developing sense of agency. A corollary here is that a sense of visual self-agency may play a role in joint attention and social-cognitive development.

The notion that active vision has primacy in social development relates back to the time-honored observation that visual behavior is at least as important to human social development as physical contact (Rheingold, 1966; Robson, 1967). However, the contemporary literature on social-cognitive development emphasizes only the importance of the information infants gather from processing the visual attention of others (e.g., Johnson et al., 2005). It neglects the potential importance of the information infants' process about their own active vision, and socially contingent responses.

Alternatively, the active vision assumption of the PDPM offers one plausible explanation for why activation of the frontal eye fields (a cortical area involved in volitional saccadic control) is a consistent significant correlate of social cognition in imaging studies (Mundy, 2003). This is because the volitional control of active vision, via the frontal eye fields, may be central to developing an integrated sense of the relations between self-attention and other-attention, which is fundamental to joint attention and subsequent social cognition. This hypothesis leads to the testable prediction that the frontal eye fields should be less active in social-cognitive processing in older congenitally blind individuals than in sighted individuals (Mundy & Newell, 2007). If true, this hypothesis may also help to explain some of the developmental commonalities observed for children with autism and blind infants (Bigelow, 2003; Hobson, Lee, & Brown, 1999).

Dynamic Systems, Integrated Processing, and The PDPM

The PDPM emphasizes inside-out processing, constructivism, and the role of active vision in the development of joint attention. However, it *does not* maintain that the inside-out processing of self-attention is more important for social-cognitive development than outside-in processing of other's-attention. This is because the PDPM holds that social meaning, and even conscious self-awareness, cannot be derived from processing either self-attention or other's-attention in isolation (cf. Decety & Sommerville, 2003; Keysers & Perrett, 2006; Vygotsky, 1962). Ontogeny may be best viewed as a dynamic system that, through interactions of multiple factors over time and experience, coalesce into higher order integrations, structures, and skills (e.g., Smith & Thelen, 2003). The development of joint attention, or the joint processing of the attention of self and other, is such a dynamic system. Indeed, the pertinence of joint attention for human development derives in no small part from the unique synthesis that arises from of the rapid, parallel processing of self-attention and other-attention across distributed neural networks. Consequently, it is not possible to account for the role of joint attention in typical or atypical development with research or theory that focuses on only one of its elements in isolation.

The dynamic system of joint attention begins to synergize as frontal executive functions increasingly enable attending to multiple sources of information during infancy. According to one definition, executive functions involve the transmission of bias signals throughout the neural network to selectively inhibit comparatively automatic behavioral responses in favor of more volitional, planned, and goal-directed ideation and action in problem-solving contexts (Miller & Cohen, 2001). These bias signals act as regulators for the brain, affecting visual processes and attention as well as other sensory modalities and systems responsible for task-relevant response execution, memory retrieval, emotional evaluation, etc. *The aggregate effect of these bias signals is to guide the flow of neural activity along pathways that establish the proper mappings between inputs, internal states, and outputs needed to perform a given*

task more efficiently (Miller & Cohen, 2001). According to this definition, joint attention development may be thought of as reflecting the emergence of frontal bias signals that establish the proper mappings across: (1) outside-in posterior cortical [temporal-precuneus] processing of inputs about the attention behaviors of other people and, (2) rostral medial frontal [BA 8-9, anterior cingulate] inside-out processing of internal states and outputs related to active vision. This mapping results in the integrated development of a distributed anterior and posterior cortical joint attention system.

It is conceivable that the early establishment of this mapping of the joint processing of attention is formative with respect to the shared neural network of representations self-other that Decety and Grezes (2006) suggest is essential to social cognition. It also may a play a role in what Keysers and Perrett (2006) have described as a Hebbian learning model of social cognition. Neural networks that are repeatedly active at the same time become associated, such that activity [e.g., representations] in one network triggers activity in the other (Hebb, 1949). Keysers and Perrett (2006)suggest that *common* activation of neural networks for processing self-generated information and information about conspecifics is fundamental to understanding the actions of others. This Hebbian learning process is fundamental to the hypothesized functions of simulation (Gordon, 1986) and mirror neurons (i.e., Decety & Summerville, 2003; Williams, 2008) that are commonly invoked in current models of social-cognitive development.

The PDPM is consistent with these interrelated ideas *and* suggests that Hebbian mapping in social cognition begins with integrated rostral medial frontal processing of information about self-produced visual attention and posterior processing of the attention of others. Moreover, the PDPM specifically operationalizes the study of development of this dynamic mapping system in terms of psychometrically sound measures of early joint attention development (Mundy et al., 2007). Indeed, IJA assessments may be relatively powerful in research on social cognitive development and autism, because they measure variance in the whole dynamic system, rather than any one of its parts alone.

Once well practiced the joint processing of attention information requires less mental effort. As the basic joint attention process is mastered and its "effort to engage" goes down it can become integrated as an executive function that contributes to the initial development and increasing efficiency of social-cognitive problem-solving. Thus, joint attention development may be envisioned as shifting from "learning to do joint attention" at 6 to 9 months to "learning from joint attention" in the second year of life (Mundy & Vaughan Van Hecke, 2008; Figure 8-7). In the learning-from phase the capacity to attend to multiple sources of information in "triadic attention" deployment becomes more common (Scaife & Bruner, 1975). Triadic attention contexts provide infants with rich opportunities to compare information gleaned through processing internal states associated with volitional visual attention deployment and the processing of the visual attention of others

in reference to a common third object or event. Through simulation (Gordon, 1986) infants may begin to impute that others have intentional control over their looking behavior that is similar to their own.

The role of simulation in the learning-from phase of joint attention development is well illustrated by a recent sequence of elegant experimental studies. Twelve-month-olds often follow the "gaze direction" of testers, even if their eyes are closed. After 12 months, though, infants discriminate and follow the gaze of testers whose eyes are open but not closed. This suggests that infants' understanding of the meaning of the eye gaze of others may improve in this period leading older infants to inhibit looking in the "eyes closed" condition (Brooks & Meltzoff, 2002).

To examine this interpretation Meltzoff and Brooks (2008) conducted an experimental intervention. They provided 12-month-olds with the experience of blindfolds that occluded their own looking behavior. After gaining that experience, 12-month-olds did not follow the head-turn of blindfolded testers, but did follow the head-turn and gaze of non-blindfolded testers. Meltzoff and Brooks also provided 18-month-olds with experience with blindfolds that looked opaque but were transparent when worn. After this condition the 18-month-olds reverted to following the gaze of blindfolded social partners. These data strongly suggest that the infants demonstrated inside-out learning and constructed social-cognitive awareness about others' gaze based on the experience of effects of blindfolds on their own active vision.

The Distributed Information Processing Model and Autism

Assumptions of the PDPM bridge theory on the development of joint attention with phenomena observed in other disciplines of research with autism. Several of these will be briefly considered in this final section of the chapter. The first of these involves links with theory and research on neural connectivity impairments in autism.

Neural Connectivity and Activity Dependent Genes in Autism

Over the last 10 years several research groups have suggested that problems in functional connectivity between brain regions contribute to autism (e.g., Courchesne & Pierce, 2005; Geschwind & Levitt, 2007; Horowitz et al. 1998;Just et al., 2004; Lewis & Elman, 2008; Wickelgren, 2005). However, rather than specific to autism, impaired connectivity may be central to many forms of mental retardation and developmental disorders (Dierssen & Ramakers, 2006). So how do neurodevelopmental connectivity impairments lead to the specific social symptom impairments of autism, and how are these different from the connectivity impairments that characterize other developmental disorders?

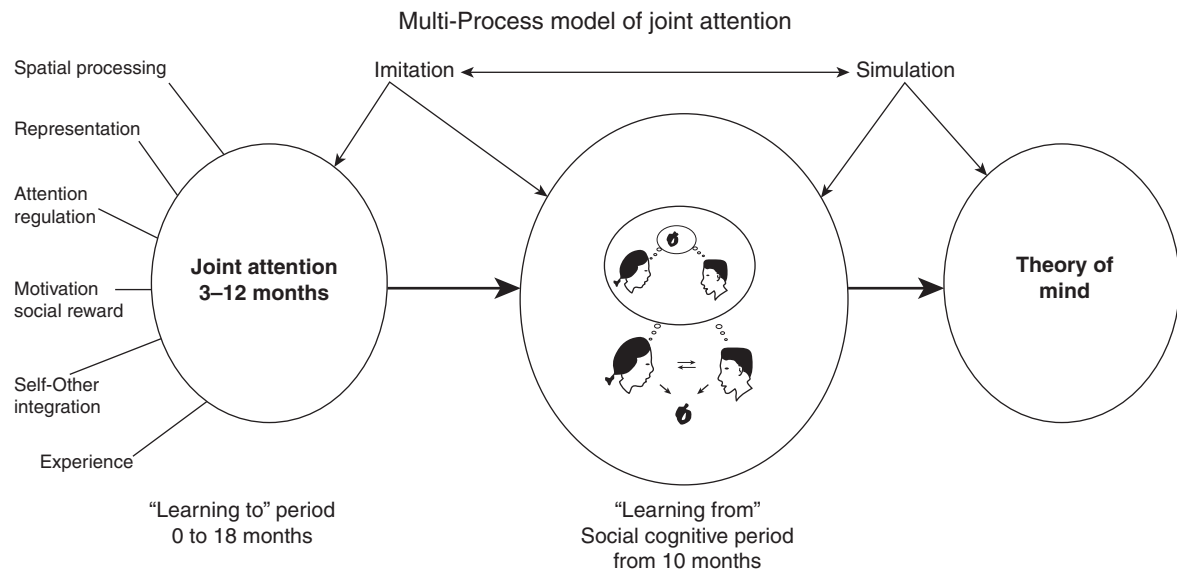
Multi-Process model of joint attention


Figure 8–7. In the first year the development of joint attention involves the "learning to" integration of executive, motivation, and imitation processes to support the routine, rapid, and efficient (error free) execution of patterns of behavior that enable infants to coordinate processing of *overt* aspects of visual self attention with processing of the social attention of other people. In the latter part of the first year and the second year infants can better monitor their own experiences and integrate it with information about the social partners during joint attention events. This provides a critical multimodal source of information to the infants about the convergence and divergence of self and others' experience and behavior during sharing information in social interactions. Theoretically, this provides the stage for the "learning from" phase of joint attention development. In this stage infants can control their attention to self-organize and optimize information processing in social learning opportunities. The integration of anterior and posterior self-other attention processing (Figure 8-5) provides a neural network that enriches encoding in social learning. The internalization of the overt joint processing of attention to the covert joint processing of attention to representations is part of an executive system that facilitates symbolic development and the social cognition. Indeed both symbolic thought and social cognition may be characterized by a transition from learning to *socially coordinate overt attention* to the capacity to *socially coordinate covert mental representations of the attention of self and others.*

One possibility is that mental retardation may be associated with connectivity impairments within proximal brain networks, but that autism may be characterized by more distal connectivity problems (Courchesne & Pierce, 2005; Lewis & Elman, 2008). Indeed, several studies suggest that distal connectivity problems between frontal and temporal parietal networks may be especially prominent in autism (Cherkassky, Kana, Keller, & Just, 2006; Courchesne & Pierce, 2005; Murias, Webb, Greenson, & Dawson, 2007; Wicker et al., 2008). The PDPM offers a moderately explicit developmental account of how the impairment of distal frontal-parietal pathways may have an early and robust effect specific to a disturbance of joint attention and related social symptom of autism, such as a lack of spontaneously sharing experiences with other people. The PDPM's focus on the fundamental relations between the joint processing of attention information, learning, and symbolic development also provide a means for understanding why variations in the strength of the disturbance of anterior-posterior connectivity could contribute to phenotypic variability in autism, such as the co-occurrence of mental retardation or specific language impairments.

The connectivity assumptions of PDPM also lead to the prediction that differences in the development of joint attention in typical and atypical children should be associated

with measures of synchrony or coherence in cortical activity. There is some support for this, but currently available data are no more than suggestive in this regard (Mundy et al., 2000; Mundy et al., 2003). Nevertheless, the PDPM offers a conceptual framework that emphasizes the benefits of a multidisciplinary approach to neurodevelopment, attention, connectionist network models of development and autism. This emphasis is in line with the recent call for the multidisciplinary examination of relations between EEG or imaging coherence in developmental and intervention studies of autism (Dawson, 2008).

It also may be that mental retardation is associated with impairments of prenatal neural connectivity that are less activity dependent, but that autism involves a greater degree of postnatal connectivity impairments that are more activity dependent (Morrow, Yoo, Flavell, Kim, & Lin, 2008). Morrow et al. have recently observed several genome deletions in families of children with autism. The expression of three genes associated with the two largest deletions (*c3orf*58, NHE9, and PCDH10) is regulated by neuronal activity. From this observation Morrow et al. (2008) reasoned that defects in activity-dependent gene expression may be a cause of cognitive deficits in autism. They note that these genes likely have a defined temporal course of greater or lesser vulnerability to atypical

expression depending on the timing and quality of the young child's postnatal activity and experience-dependent processes.

The PDPM proposes that problems with initiating joint attention activity may be especially key to understanding activity-dependent alterations of gene expression associated with autism. Some evidence consistent with this proposition stems from the observation that the activity of children with autism may affect and modify the attempts of caregivers to scaffold the development of joint attention in their children (Adamson et al., 2001). If the PDPM is correct in this regard, it will be important to build a better understanding of genetic influences on the typical range of expression individual differences in IJA in infant development. Little if any information currently exists on this topic. Fortunately, the recent observation of a surprising degree of longitudinal stability of individual differences in a sample of the 100 typical infants (Mundy et al., 2007) suggests that behavioral or metabolic genetic methods may be brought to bear in large-scale studies of the typical development of infant joint attention.

The PDPM, Visual Attention Control, and Autism

The work of several research groups indicates that basic mechanism of visual control may play a role in autism (Brenner, Turner, & Muller, 2007; Landry & Bryson, 2004; Johnson et al., 2005). Brenner et al. (2007) have noted that one of the essential issues for this line of research is to understand precisely, "how an ocular-motor system that is over-specialized for certain tasks and under-specialized for others early in life might affect later development in [social] domains such as joint attention" (p. 1302). The PDPM offers a guide in this regard. First, it encourages the research community to recognize the possibility that joint attention may not be a "later" development, but one that begins as part of the development of volitional visual attention control by the 4th month of life. In addition, the PDPM provides means for understanding how significantly altered early visual preferences could have a cascading effect on the development of intentional joint attention and autism (Mundy, 1995). In this regard, consider two recent studies.

McCleery et al. (2007) observed that magnocellular visual processing may be atypically enhanced in a sample of 6-month-old infant siblings of children with autism. Similarly Karmel et al. (2008) observed visual attention patterns that are consistent with a magnocellular bias in 6-month-olds in neonatal intensive care who later received the diagnosis of autism at 3 years of age. The magnocellular visual system contributes to orienting based on movement and contrast-sensitivity related to small achromatic differences in brightness. This system dominates early visual orienting. However, by 2- to 4-months visually orienting is increasingly influenced by the parvocellular system, which contributes to orienting based on high-resolution information about shape, or low-resolution information about color and shades of grey. The studies of Karmel et al. (2008) and McCleery et al. (2007) raise the

possibility that a delay in the developmental shift from the magnocellular to parvocellular visual systems could alter what children with autism choose to attend to early in life.

Hypothetically, the maintenance of a magnocellular bias may lead to a relatively long-standing visual preference for stimuli or objects characterized by movement or achromatic contrasts, such as surface edges, power lines, spinning objects, the outlines of faces, or mouth movement. Reciprocally, the decreased influence of the parvocellular system could lead to developmental delays in the emergence of a visual attention bias to targets that are socially informative but involve differentiation based on high resolution of shape and color information, such as distal processing of eyes and facial expressions. Thus, the alteration of visual preferences during early critical periods of development could degrade the establishment of the dynamic system of internal information processing about active looking, relative to contingent social feedback, and information about the attention of other people (Mundy, 1995; Mundy & Burnette, 2005). Moreover, if magnocelluar guidance bias and connectivity impairments are orthogonal processes, combinations of varying levels of their effects could present as phenotypic differences in joint attention processing and social symptom expression in autism.

Early Intervention, Learning, Motivation, and the PDPM

The assumptions of the PDPM may also help to explain why joint attention is a pivotal skill in early intervention for children with autism (Bruinsma, Koegel, & Koegel, 2004; Charman, 2004; Mundy & Crowson, 1997). Improvements in pivotal skills, by definition, lead to positive changes in a broad array of *other* problematic behaviors. This appears to be the case with joint attention. It can be improved with early intervention (e.g., Kasari et al., 2006, 2007; Pierce & Schreibman, 1995; Rocha et al., 2007; Yoder & Stone, 2006), and joint attention improvement has collateral benefits on language, cognitive, and social development (Kasari et al., 2007; Jones, Carr, & Feely, 2006; Whalen & Schreibman, 2006). Joint attention also appears to mediate responsiveness to early intervention among children with autism (Bono et al., 2004; Yoder & Stone, 2006).

According to the PDPM, joint attention is a pivotal skill in autism because its improvement has multiple effects on social learning. Recall that joint attention facilitates the self-organization of information processing to optimize incidental as well as structured social learning opportunities (Baldwin, 1995). Hence, impairment in joint attention may be viewed as part of a broader social constructivist learning disturbance in autism. By the same token, effective intervention likely improves social constructivist learning in autism.

Second, the PDPM proposes that joint attention serves as a foundation for social cognitive development. Social cognitive development is defined in terms of advances in the processing of information about self and other, rather than

singularly in terms of changes in knowledge about intentionality. Following connectionist cognitive theory (McClelland & Rogers, 2003; Otten et al., 2001), the PDPM assumes that information encoded during learning is stored as a distributed neural network activation pattern that involves parallel activation of networks of related semantic information. Additionally, whenever information is acquired during social learning and joint attention it is also encoded in parallel with the activation of a frontal-temporal-parietal neural network that maps relations between representations of information about self-directed attention and information about the attention of other people. Thus, every time we process information in social learning we encode it as an activation pattern in a distributed semantic network *in conjunction with* an activation pattern of the anterior-posterior cortical joint attention network (see Figures 8-4 & 8-5). Recall that deeper information processing and learning occurs best in the context of the simultaneous activation of multiple neural networks during encoding (Otten et al., 2001). If so, joint attention may lead to deeper processing because it adds activation of the distributed social attention network (a form of episodic encoding) to the network activation associated more directly with semantic information. This conjecture provides one interpretation of the observation that joint attention facilitates depth of processing in 9-month-olds (Striano, Chen, et al., 2006; Striano, Reid, et al., 2006). It also suggests that part of the learning disability of autism occurs because children with this disorder do not reap the full benefits of encoding semantic information in conjunction with episodic memory encoded within the integrated processing of self- and other-attention. This, in turn, may help to explain the attenuation of self-referenced memory effects in autism (Henderson et al., 2009).

Third, the PDPM argues that overt joint attention becomes increasingly internalized as a social executive function that supports the social coordination of covert mental attention to cognitive representations. The spontaneous coordination of mental attention cognitive representations is an essential element of symbolic thought (Tomasello et al., 2005). The PDPM assumes that months of practice of the social coordination of overt attention (i.e., joint attention) in the first years of life is required before this function can be internalized and transformed to an executive facility for the socially coordinated covert mental attention and symbolic thought. Thus, symbolic thought processes incorporate, but do not replace activation of the self-other joint attention system. Joint attention however does not necessarily involve symbolic process (Mundy et al., 1987).

These assumptions of the PDPM are consistent with two recent observations. Joint attention is a unique predictor of pretend play development in children with autism relative to measures of imitation or executive functions (Rutherford et al., 2008). Moreover, successful symbolic play intervention, which according to the PDPM must involve effects on joint attention, *is* associated with parallel collateral improvements in joint attention in autism. However, intervention with joint attention has less immediate impact on symbolic play behavior (Kasari et al., 2006).

Fourth, the joint processing of attention information also plays a fundamental role in social cognition defined in terms of the development of knowledge about intentions in self and other (Mundy & Newell, 2007). The assumption here is that when infants or primates practice monitoring others attention (RJA), statistical learning ultimately leads to the associative rule *where others' eyes go, their behavior follows* (Jellema, Baker, Wicker, & Perrett, D., 2000). Similarly, anterior monitoring or *self-awareness* of control of visual attention likely leads to awareness of the self-referenced associative rule that *where my eyes go, my intended behavior follows* (Mundy & Newell, 2007). An integration of the development of these "concepts" leads to the logical cognitive output *where others eyes go → their intended behavior follows,* which is a building block of social cognitive development (Mundy & Newell, 2007). Social cognition of this kind is thought to enable new and more efficient levels of social or cultural learning is atypical in autism.

Finally, the constructivist assumptions of the PDPM stress that motivation factors are part of a crucial fifth path of association between joint attention and social learning. Initiating joint attention requires "choosing" between behavior goals, such as fixated looking at an event, or alternating looking at the event and another person. Choosing among behavior goals is thought to involve frontal and medial cortical processing of the relative reward associated with different goals (Holroyd & Coles, 2002). Therefore, IJA impairment in autism may be expected to be related to deficits in biobehavioral processes associated with reward sensitivity and motivation (Dawson, 2008; Kasari et al., 1990; Mundy, 1995). Such a deficit, however, could take several forms.

Social stimuli could be aversive in some way for children with autism. However, the aversion hypothesis is complicated by observations of behaviors indicative of relatively intact caregiver-attachment in many children with autism and a willingness to engage in playful physical interactions with strangers (e.g., Mundy et al., 1986; Sigman & Ungerer, 1984). On the other hand, social stimuli may not be aversive. Rather, they may simply not be sufficiently positive to compel social-orienting and joint attention early in the life of children with autism (Dawson et al., 1998; Mundy, 1995). Finally, social stimuli could have a positive valence for children with autism, but be overshadowed by an atypically strong visual preference that make objects, rather that social elements of the world more "interesting" (Karmel et al., 2008; McCleery et al., 2006; Mundy & Crowson, 1997).

The construction of effective empirical approaches to address these alternatives is one of the outstanding challenges in the science of autism (Dawson, 2008; Koegel et al., 2003). Research on joint attention in relation to motivation and the perceived valence of objects in adults (Bayliss et al., 2006) offers one potential route for developmental and functional neurocognitive studies on this topic. For now, though, the literature on early intervention may be the best source of

information in this regard. Early interventions studies offer some of the most systematic investigations to date of how to structure social engagements with young children with autism to modify and increase their motivation to initiate episodes of shared attention and shared experience with others (e.g., Kasari et al., 2006, 2007).

Conclusions

Only in its most expansive or grandiose interpretation can the PDPM be viewed as an explanatory model of joint attention, or autism. Nevertheless, the PDPM does serve a purpose. It presents a new perspective on joint attention that suggests its impairment in autism is more than an epiphenomenon associated with other fundamental precursor or successor processes. This alternative perspective can be summed up in terms of several general principles. First, autism is as much about impairments in self-generated activity as it is about problems in perceiving or responding to the behavior of others. Hence, we need to consider the neurodevelopmental processes and networks involved in initiating behavior and attention control, as well as those involved in perceiving and responding to the behaviors of others to understand this disorder (Mundy, 2003). Second, joint attention is a form of information processing that gives rise to social-cognitive knowledge. Third, joint attention is a form of *parallel and distributed processing* that involves the conjoint analysis of information from anterior cortical system for guidance of goal-directed attention and behavior, with posterior cortical processing external information about the attention related behavior of other people. Ultimately, joint attention becomes a social executive process that supports all subsequent cognition and learning that demands the rapid social coordination of mental attention to internal representations of object and events. Thus, neural network activation associated with joint attention is an enduring substrate that plays a role in the unique characteristics of human cognition throughout the lifespan (Mundy & Newell, 2007). Indeed, it may be one example of the type of "hot" executive functions that Zelazo, Qu, and Muller (2005) theorize are central to social cognition. Hot executive functions are those that entail motivation processes and affect-regulation specific to the support of successful goal-directed behavior in social engagements. It follows from this notion that individual differences in the operation of the social-executive function of joint attention, including the extreme variation displayed by people with autism, may be an expression of variance in motivation process.

Challenges and Future Directions

- To fully appreciate the significance of joint attention impairments in autism requires a deeper appreciation of the typical development of joint attention. This may necessitate a shift away from a singular emphasis on the stages of acquisition of social cognitive "knowledge" in the study of joint attention, to research on the development of joint attention as an information processing system associated with learning.
- Recent research suggests that the etiology of autism is associated with complex polygenetic processes. Studies also suggest that the early development joint attention is characterized by stable sources of individual differences by 9 months of age. One challenge for future research is to determine if the behavioral and metabolic genetic study of typical joint attention development in large samples of infants provides for identifying a subset of genetic contributions to autism.
- The constructivist hypothesis of the PDPM raises the challenge of creating paradigms for the study of neurocognitive systems involved in the generation and self-regulation of social behavior, as well as the perception and interpretation of the social behaviors of others. Without the former we will likely have a most incomplete picture of the development of the "social brain."
- Examination of parallel and distributed processing of joint attention requires measurement that is sensitive to temporal, parallel nature of information processing and well as localized-functional activation of distributed neural networks. Hence, future informative research on joint attention may be effectively joined with diffusion tensor imaging technology, as well as advances in EEG and MEG coherence analysis.
- The most direct tests of the PDPM of joint attention will likely require an integration of advances in biometric measurement (e.g., advances in EEG coherence methods) with advances in behavioral and pharmacological interventions that change the course of joint attention expression and development in children with autism. Fortunately, research on the latter has begun to emerge, and now studies of this kind await integration with the former.

Language and Communication in Autism Spectrum Disorders

Helen Tager-Flusberg, Lisa Edelson, Rhiannon Luyster

Points of Interest

- Unique clinical features of language in ASD include stereotyped speech patterns, pronoun reversal, echolalia, and idiosyncratic words and phrases.
- There are universal impairments in pragmatic aspects of language: the use of language in social contexts, which are closely linked to deficits in theory of mind.
- Language skills, including articulation, vocabulary, and grammar, are quite heterogeneous. Different subtypes have been identified within the ASD population that may be associated with differences in etiology and neurobiological factors.
- Brain areas associated with language are often reduced in size in ASD. There are differences in brain organization, with less reliance on the left hemisphere for processing language and reduced connectivity between different brain regions that are critical for language perception and production.
- Atypical developmental trajectories within and across different domains of language are found. These may be grounded in infancy, and associated with impairments in prelinguistic developments in social engagement, gesture, imitation, and vocal productions.

When Leo Kanner (1943) first introduced his newly discovered syndrome, autistic disorder, impairments in language and communication were not listed among the core diagnostic features. The same held for Hans Asperger's (1944/1991) presentation of what is now referred to as Asperger's syndrome. Nevertheless, the detailed descriptions of the children by these pioneers included numerous examples of unusual speech and communication patterns that were evident in all their cases, and it is now recognized that, at least for autistic disorder, deficits in language and communication are defining criteria for diagnosis. Furthermore, most clinicians and researchers acknowledge the presence of aberrant communication among

highly verbal people with Asperger's syndrome (Paul, Orlovski, Marcinko, & Volkmar, 2009; Tager-Flusberg, 2003).

By the end of the first year of life, most children are babbling, using gesture and vocalization to communicate with others, responding appropriately to words and simple phrases, and even speaking a few words that at least their parents understand. When these milestones are not met as expected, this can be an early warning sign that something may be awry. Indeed, surveys of parents whose children were later diagnosed with autism indicated that the most common causes for initial concern were delays in language and social-communicative abilities (Chawarska, Paul, Klin, Hannigen, Dichtel, & Volkmar, 2007; De Giacomo & Fombonne, 1998; Siklos & Kerns, 2007). Infants later diagnosed with autism spectrum disorder (ASD) show less joint attention behavior and produce fewer gestures and consonants (Landa, Holman, & Garrett-Mayer, 2007), all of which are key precursors to the acquisition of language (Luyster, Kadlec, Carter, & Tager-Flusberg, 2008). Given the critical role of language functioning in predicting outcomes in children with autism (Bennett et al., 2008; Billstedt, Gillberg, & Gillberg, 2007; Szatmari, Bryson, Boyle, Streiner, & Duku, 2003), there is now heightened interest in investigating this domain, with particular focus on targeting language and communication skills in early intervention programs (Dawson, 2008). In this chapter we provide an overview of the key features of atypical language and communication in ASD from a developmental perspective and then discuss some neurocognitive models that have been proposed as explanations for these impairments in ASD.

Defining the Language and Communication Impairment in ASD

Description of Language

Language is a multifaceted, hierarchically organized system that can be analyzed into specific components, each of which

has expected patterns of development. The smallest linguistic unit is the *phoneme*, defined as a sound that can be discriminated from others within a language. For example, by changing a /b/ to a /p/, English has two words with different meanings, *bat* and *pat*. Phonology describes the way phonemes can be combined and used. It also encompasses nonspeech *suprasegmental* aspects, defined as those vocal patterns that are at a higher level than the phoneme, such as prosody, rhythm and melody that serve linguistic functions.

The smallest meaningful units of speech are called *morphemes*. These can be unbound, able to stand alone as lexical words (e.g., "walk"), or can be bound, requiring another morpheme for their usage, for example the past tense ending added to verbs -ed, or the negative morpheme un- that can be added to nouns, verbs, and other parts of speech. Morphemes can be combined to form words with new meanings, which in turn can be linked together to form sentences following predictable patterns of combinations, referred to as *syntax*. Within linguistics, morphology and syntax describe the rules governing each of these processes, and together form the *grammar* of a particular language. Sounds and rules cover the basic structure of a language, but these are all in service of expressing meaning, or *semantics*, in words and sentences. The semantic level of language connects most closely to world knowledge. For words, this includes both *intension*, the definition of a word, and *extension*, the range of exemplars to which that word refers. Sentential meaning is derived from the combination of words and grammatical rules.

Together, phonology, morphology, syntax, and semantics form our core linguistic knowledge. The domain of *pragmatics* refers to how context contributes to the interpretation of the meaning of language as it is used in social situations. It includes the functions served by utterances, also called *speech acts* (e.g., statements, requests), the rules of effective communication in discourse (e.g., conversation, narrative), and inferences about the intentions of the speaker, covering literal and nonliteral expressions (e.g., lies, sarcasm). Interpreting language in social contexts often goes beyond the spoken word, relying also on nonverbal cues such as gesture, facial and vocal expressions of affect, and body language.

Language is a highly complex system that is dependent on the interaction of multiple factors over the course of development. These include the input provided to the child that may vary in both quantitative and qualitative ways, and child-specific variables such as the motivation, cognitive, or neurological status of the individual. It is therefore not surprising that in ASD, core social and other neurocognitive impairments contribute significantly to the delays and deficits that are seen in the acquisition of language.

Deficits in Language and Communication

According to the *Diagnostic and Statistical Manual of Psychiatric Disorders* (DSM-IV-TR: American Psychiatric Association, 2000) autistic disorder is defined on the basis of at least one qualitative impairment in the domain of communicative abilities. These include: delay in, or total lack of, the development of spoken language; in individuals with adequate

speech, marked impairment in the ability to initiate or sustain a conversation with others; stereotyped and repetitive use of language or idiosyncratic language; or lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level. These criteria are now viewed as reflecting distinct underlying mechanisms. Delays and deficits in language are associated with nonuniversal comorbid impairments in language processing (Bishop & Norbury, 2002; Rapin & Dunn, 2003, Tager-Flusberg, 2004); conversational problems reflect difficulties in theory of mind (Paul, Orlowski, Marcinko, & Volkmar, 2009; Tager-Flusberg, 2000); stereotyped language is an example of repetitive behavior (Bodfish, Symons, Parker, & Lewis, 2000; Gabriels, Cuccaro, Hill, Ivers, & Goldson, 2005); and the absence of play is a reflection of deficits in socialization and symbolic capacity (Naber et al., 2008).

Certain features of the language spoken by children with ASD are relatively unique and specific to this syndrome. One salient symptom of autism is the presence of odd or stereotyped speech patterns. Kanner (1943, 1946) noted several verbal rituals in his early observations of children with autism. Children with autism may quote scripts from favorite television shows or movies, engage in verbal rituals, or echo the speech of others (Rydell & Mirenda, 1994). Other children might use odd phrasing, perhaps incorporating vocabulary that is not age-appropriate (Ghaziuddin & Gerstein, 1996). Another striking feature of autistic children's use of language is their reversal of pronouns—referring to themselves as "you" and their conversational partner as "I." Although reversing personal pronouns is not unique to autism, it does occur more frequently in this group than in any other population (Lee, Hobson, & Chiat, 1994). Odd vocal patterns were noted in many early descriptions of autistic children's language both in echolalic and non-echolalic speech (Pronovost, Wakstein, & Wakstein, 1966). Kanner (1946) also commented on the autistic child's tendency to use words with special or unique meanings, not shared by others. The use of idiosyncratic lexical terms, or "neologisms," has been found even in higher functioning children and adults with autism (Volden & Lord, 1991).

Across the ASD population, including people with Asperger's syndrome, certain aspects of language are universally impaired. One example is the domain of pragmatics, as individuals with ASD have difficulty with the social aspects of language use, including turn-taking (Eales, 1993), conversational discourse (Paul et al., 2009; Tager-Flusberg & Anderson, 1991), processing contextually and socially appropriate comments (Eales, 1993; Loukusa et al., 2007), and understanding nonliteral language such as irony, sarcasm, and metaphor (Happé, 1995; MacKay & Shaw, 2004; Martin & McDonald, 2004). Another problem area is the appropriate use of prosody, or intonation patterns, when speaking. Individuals with ASD can produce grammatically correct sentences, but they may come across as sounding flat, robotic, or otherwise odd (Peppé, McCann, Gibbon, O'Hare, & Rutherford, 2007; Shriberg, Paul, McSweeny, Klin, Cohen, & Volkmar, 2001). They may also have trouble decoding the meaning of an utterance based on its stress patterns (Peppé et al., 2007) or miss

affective content encoded in the voice (Korpilahti et al., 2007; Rutherford, Baron-Cohen, & Wheelwright, 2002).

In contrast to the universal nature of pragmatic deficits in autism spectrum disorders, other language skills vary on a broad continuum from intact linguistic abilities to failure to acquire any language (Diehl, Bennetto, Watson, Gunlogson, & McDonough, 2008; Kjelgaard & Tager-Flusberg, 2001; Lewis, Murdoch, & Woodyatt, 2007). One study of 9-year-old children found that, while a quarter of the children were able to speak fluently using complex sentences, another quarter were still effectively nonverbal (Anderson et al., 2007). Longitudinal studies suggest that variability in language skills increases with time, possibly due to mixed results of interventions (Charman, Taylor, Drew, Cockerill, Brown, & Baird, 2005).

Development of Language and Communication in ASD

Preverbal Period (0–12 Months)

From the moment they are born, infants come prepared to acquire language with a suite of mechanisms that include general learning systems, a bias toward attending to social stimuli in their environment including faces and voices, as well as domain-specific speech processing systems. Within a few short years they have mastered one of the most complex challenges they face, with seemingly little effort or explicit tuition. For children with ASD, the developmental pathway is affected, even before the acquisition of first words, and difficulties continue throughout childhood. Early in life most children communicate with their social partners. They begin to smile reciprocally, vocalize in response to other people, and engage in simple social routines. These early-appearing behaviors form an important foundation for the development of language. Children later diagnosed with ASD have been shown to have deficits in these reciprocal social communication skills within the first year of life. Early impairments have been noted in eye contact, imitation, social interest, shared positive affect, play skills, and joint engagement (Baranek, 1999; Bryson et al., 2007; Landa, Holman, & Garrett-Mayer, 2007; Zwaigenbaum et al., 2005).

Toward the end of the first year, infants typically exhibit a variety of communicative behaviors that are not usually seen in autism. These nonverbal communicative gestures express the same intentions for which words will be used in the coming months, such as requesting objects, rejecting offered actions, calling attention to objects or events, and commenting on their appearance. Gestural ability has been shown to be a strong predictor of later language in typically developing children (Rowe, Özçalışkan, & Goldin-Meadow, 2008; Watt et al., 2006) as well as children with developmental disabilities (Brady, Marquis, Fleming, & McLean, 2004) and ASD (Charman, Baron-Cohen, Swettenham, Baird, Drew, & Cox, 2003; Luyster, Kadlec, Carter, & Tager-Flusberg, 2008).

Parallel to these impairments in social communication during infancy, are early abnormalities in speech perception and preference. Typically developing children, when given a choice of listening to a nonspeech analog or infant-directed speech, consistently prefer to listen to the latter (Kuhl, 2004). This preference is viewed as instrumental in language development, in that the child is motivated to "tune in" to the sounds of their caregiver's speech. Infant-directed speech, moreover, is characterized by exaggerated phonetic and prosodic features that facilitate the emergence of early language. Young children identified with ASD do not show a preference for infant-directed speech, choosing instead to listen to the nonspeech analog (Kuhl, Coffey-Corina, Padden, & Dawson, 2005) or to other environmental sounds (Klin, 1991). There are important early language implications for these observations in ASD: A stronger preference for nonspeech sounds is associated with a greater degree of impairment in early expressive language (Kuhl et al., 2005).

By late infancy, these early disturbances in communication and speech development result in language differences for children later diagnosed with ASD. The majority show delays in the attainment of early milestones, in the production of babbling and first words, gestural communication, as well as in language comprehension (Colgan et al., 2006; Landa & Garrett-Mayer, 2006; Mitchell et al., 2006; Zwaigenbaum et al., 2005).

Early Language (12–30 Months)

The toddler years are characterized by language impairments for most children on the autism spectrum. Delays are evident in both receptive and expressive language. The receptive language deficits are quite striking and not usually seen in children with other language disorders, but these show up more on standardized testing than in parental reports of early language in ASD (Luyster et al., 2008), and are most likely related to the children's overall lack of social responsiveness.

Other atypical patterns may also be observed in the trajectory of language development. A significant minority (estimates usually ranging from about 15 to 40%) of children with ASD experience a loss (or *regression*) of verbal and nonverbal communication skills sometime in the second year of life (Goldberg et al., 2003; Hansen et al., 2008; Lord, Shulman, & DiLavore, 2004; Luyster et al., 2005). Several studies have found that these children show undetected symptoms of ASD within their first year of life, but they also often attain important early milestones in social and communication development. These early gains are followed by a loss of skill, usually some time between 16 and 21 months of age (Goldberg et al., 2003; Lord, Shulman et al., 2004; Luyster et al., 2005; Meilleur & Fombonne, 2009). Historically, these losses were defined strictly on the deterioration of language skills. Typically, children had mastered single words but not yet progressed to phrases, and then lost a substantial number of words

during the regression. Recent conceptualizations of regression have included documentation of social-communication losses as well, particularly in the realm of social interest and reciprocity (Goldberg et al., 2003; Hansen et al., 2008; Luyster et al., 2005). Importantly, children who experience a regression generally do regain the lost skills, although the implications for later outcome remain unclear (Bernabei, Cerquiglini, Cortesi, & D'Ardia, 2007; Hansen et al., 2008; Ozonoff, Williams, & Landa, 2005; Richler et al., 2006; Werner, Dawson, Munson, & Osterling, 2005).

The close connection between language and social-communicative development is also evident when examining early predictors of language development in ASD. Just as the two domains are linked in the loss of skills, they are also linked in the mastery of skills. Language emergence is associated with a number of other symbolic and social-communicative skills. Joint attention (Adamson, Bakeman, Deckner, & Romski, 2009; Carpenter, Pennington, & Rogers, 2002; Charman et al., 2003; Dawson et al., 2004; Mundy, Sigman, & Kasari, 1990; Mundy, Sigman, Ungerer, & Sherman, 1987; Sigman & McGovern, 2005), imitation (Carpenter et al., 2002; Charman et al., 2003; Stone, Ousley, & Littleford 1997; Stone & Yoder 2001), gesture (Luyster et al., 2008), and play (Mundy et al., 1987; Sigman & McGovern, 2005) have all been found to be associated with language ability both concurrently and longitudinally. In addition to social-communicative factors, other child factors including general cognitive skills are highly correlated with language outcomes in children with ASD (Luyster et al., 2008; Thurm et al., 2007), and recent work by Sigman and her colleagues has highlighted the significance of parental responsiveness to the child's focus of attention and play as predictors of later language abilities, independent of the IQ or initial language skills of the child (Siller & Sigman, 2008).

During this period, children acquire a rich and varied vocabulary. By the age of 18 months, typically developing children show an exponential growth curve, learning several words each day. They do so by "fast-mapping" meaning to new words using a number of cues present in the environment. Several studies of children with ASD have found that they are able to exploit some, but not all, of these cues for learning the meanings of nouns, which may partially account for the slower growth and in certain cases, idiosyncratic meanings attached to some words. One cue that children with ASD are capable of using involves the inference that different objects are labeled with different words—the principle of "mutual exclusivity" (Preissler & Carey, 2005). In contrast, children with ASD are less able to use some social cues, such as the direction of a speaker's eye gaze (Baron-Cohen, Baldwin, & Crowson, 1997; Preissler & Carey, 2005), though if the objects are especially interesting and the speaker adds gestural or touch cues, children with ASD can rapidly learn the meanings of new words (McDuffie, Yoder, & Stone, 2006; Parish-Morris, Hennon, Hirsh-Pasek, Golinkoff, & Tager-Flusberg, 2007). At the heart of their difficulty is the use of combinations of social cues (eye gaze, facial expressions, etc.)

that signal the speaker's intention, rather than simply a failure to attend to their social partner (Parish-Morris et al., 2007).

Caregivers also notice that their child's pragmatic uses of language are quite restricted. Whereas children with ASD may proficiently use language to meet their needs and wants (e.g., "More cookies"), they are less likely to use language in prosocial ways—directing someone's attention to an object or event of interest (e.g., "A doggie!"), or to use language to engage in a reciprocal exchange of thoughts or experiences (e.g., "Baby went night-night") (Loveland, Landry, Hughes, Hall, & McEvoy, 1988; Wetherby, Watt, Morgan, & Shumway, 2007). The speech acts missing among young children with ASD all involve social, rather than regulatory functions (Wetherby, 1986).

⸬

Later Language (30–48 Months)

During the preschool years, children acquire the morphosyntax of their language, continue to add new words to their vocabulary, and develop basic conversation skills. There are few longitudinal studies of grammatical development in ASD. Tager-Flusberg and her colleagues recruited a small group of preschoolers and found that they followed the same developmental path as typically developing children and children with Down syndrome (Tager-Flusberg et al., 1990). The children with autism and Down syndrome showed similar growth curves in the length of their utterances (MLU - Mean Length of Utterance), which is usually taken as a hallmark measure of grammatical development. In a follow-up study using the same language samples, Scarborough et al. (1991) compared the relationship between MLU and scores on a different index of grammatical development, which charts the emergence of a wide range of grammatical constructions: The IPSyn (Index of Productive Syntax). The main findings were that at higher MLU levels, MLU overestimated IPSyn scores for the children with ASD, because they used a narrower range of constructions and asked fewer questions, which accounts for a significant portion of the IPSyn score. These findings have been replicated in a cross-sectional study of preschoolers with ASD (Eigsti, Bennetto, & Dadlani, 2007).

Several studies of English-speaking children with ASD investigated the acquisition of grammatical morphology, using data from spontaneous speech samples. For example, Bartolucci, Pierce, & Streiner (1980) found that children with ASD were more likely to omit certain morphemes, particularly articles (*a, the*), auxiliary and copula verbs, past tense, third-person present tense, and present progressive. Tager-Flusberg (1989) also found that children with ASD were significantly less likely to mark past tense than were matched controls with Down syndrome. Similar findings were obtained on elicited production tasks of grammatical tense in children with lower overall levels of language (e.g., Bartolucci & Albers, 1974; Roberts, Rice, & Tager-Flusberg, 2004) as well as on grammaticality judgment tasks (Eigsti & Bennetto, 2009).

In comparison to grammatical development, lexical knowledge is an area of strength for children with ASD (Eigsti et al., 2007; Tager-Flusberg, Lord, & Paul, 2005). High-functioning children often score well on standardized vocabulary tests (Jarrold, Boucher, & Russell, 1997; Kjelgaard & Tager-Flusberg, 2001), they extend or generalize words they know to a broad range of exemplars, and their lexicons are organized in hierarchical semantic groups as in typically developing children (Boucher, 1988; Tager-Flusberg, 1985; Walenski, Mostofsky, Gidley-Larson, & Ullman, 2008). At the same time, certain classes of words may be underrepresented in the vocabularies of children with ASD. Tager-Flusberg (1992) found that children with ASD rarely used mental-state terms, particularly terms for cognitive states (e.g., *know, think, remember*) when conversing with their mothers. Other studies suggest that children with ASD have particular difficulties understanding social-emotional terms as measured on vocabulary tests such as the Peabody Picture Vocabulary Test (Eskes, Bryson, & McCormick, 1990; Hobson & Lee, 1989; van Lancker, Cornelius, & Needleman, 1991). Thus, while overall lexical knowledge is a relative strength in autism, acquiring words that map onto mental-state concepts may be specifically impaired.

In contrast to their typically developing peers who are successfully mastering early conversational skills, young children with ASD show difficulties in reciprocal and flexible dialogue. At a basic level, question-asking and question-answering may be diminished. More complex abilities such as introducing new topics of discussion, offering additional information, or providing clarification to ongoing discourse topics are also significantly affected (Capps, Kehres, & Sigman, 1998; Tager-Flusberg & Anderson, 1991). These difficulties emerge in early childhood (Hale & Tager-Flusberg, 2005a; Lord, Rutter, DiLavore, & Risi, 1999) and persist throughout the lifespan (de Villiers, Fine, Ginsberg, Vaccarella, & Szatmari, 2007; Dobbinson, Perkins, & Boucher, 1998; Volden, 2004).

Language in Older Children

For many children with ASD, the school years are characterized by continued growth of core language skills (Anderson et al., 2007). However, along with increased skills come new language difficulties that have particular impact on their social interactions with peers and to their academic success. Even for children who have optimal outcomes, losing their diagnosis of ASD and becoming fully integrated into academic settings, subtle impairments remain in the domains of semantics and pragmatics (Kelley, Paul, Fein, & Naigles, 2006).

Complex aspects of language prove to be particularly challenging for individuals with ASD. One example of this is language used in a nonliteral manner. Understanding irony (Kaland et al., 2005; Martin & McDonald, 2004), humor (Emerich, Creaghead, Grether, Murray, & Grasha, 2003; Lyons & Fitzgerald, 2004), idioms (Kerbel & Grunwell, 1998; Norbury, 2004), and metaphor (Happé, 1995) is often impaired in children with ASD, because they tend to interpret words or utterances in a literal or concrete way, rather than the intended meaning, which is often dependent on the context or delivery of the language through a combination of verbal and nonverbal signals.

This difficulty of interpreting intended meaning is especially salient in conversational discourse (Mitchell, Saltmarsh, & Russell, 1997) and reflects the fact that pragmatic deficits in language are more often found in unstructured social contexts than in structured tasks. These deficits, which are found in both Asperger's syndrome and high-functioning autism, take different forms including overly formal or pedantic speech, lack of reciprocal exchanges, problems with topic management, or handling breakdowns and repairs in conversation (Paul et al., 2009). But not all aspects of social language usage are impaired in ASD. For example, older children are quite able at judging and producing requests at different levels of politeness, depending on the status of their discourse partner (Volden & Sorenson, 2009). Sparing of these kinds of skills may be related to their intact knowledge of social stereotypes such as gender and race (Hirschfeld, Bartmess, White, & Frith, 2007).

Another area of deficit is in the production of narratives, which has implications for their ability to perform well in language arts and social studies classes in school. Children with ASD generally produce less coherent and complex stories (Diehl, Bennetto, & Young, 2006; Losh & Capps, 2003), they tend not to be able to flexibly use different referring expressions such as pronouns (Arnold, Bennetto, & Diehl, 2009), they are less likely to take the perspective of another person in a story (Garcia-Perez, Hobson, & Lee, 2008), and they often ignore the motivations of characters or causal connections in a plot line (Tager-Flusberg, 1995). Their personal narratives also tend to focus more on facts than in providing a meaningful interpretation of autobiographical events (Goldman, 2008).

Processing nonverbal aspects of communication continues to be an area of significant impairment for children and adults with ASD, which may partially explain their strong preference for communicating with others through the Internet. One example is in the use of prosody. Difficulties arise both in using prosody to clarify linguistic ambiguity (Diehl, Bennetto, Watson, Gunlogson, & McDonough, 2008) and in understanding its social significance (see McCann & Peppé, 2003, for a review; McCann, Peppé, Gibbon, O'Hare, & Rutherford, 2007), though these deficits in prosody are more apparent at the level of sentences rather than single words (Järvinen-Pasley, Peppé, King-Smith, & Heaton, 2008). Other nonlinguistic communicative cues, such as gestures, continue to show impairment through childhood into adolescence and beyond. For instance, individuals with ASD are less likely to use "beat gestures" while speaking (Lord et al., 1999), employ nonverbal cues of reciprocity such as nodding their head when a conversational partner is speaking (Garcia-Perez, Lee, & Hobson, 2007), respond to such cues in their conversational partner, or modulate eye contact (Paul et al., 2009). Thus, it is clear that even when structural aspects of language are

acquired, people with ASD continue to experience significant problems in communicating effectively and appropriately in everyday social contexts.

Neurocognitive Models of Language and Communication in ASD

Variability in the Language Phenotypes

A hallmark feature of ASD is heterogeneity in etiology, neurobiological substrate, behavioral characteristics, developmental trajectory, and comorbidity. In an effort to distill some of the essential features that have both clinical and theoretical relevance, our review of the language characteristics and their development in ASD glosses over the fundamental variability that is seen in every study. Within language, heterogeneity takes on particular significance, in part because language itself is multifaceted, composed of intersecting systems of knowledge—sounds, words, morphosyntax, meaning— serving a full range of social-communicative functions. In ASD, any one or all of these systems can be affected. In recent years, considerable effort has been made to explore this heterogeneity to advance understanding about the mechanisms that may underlie the different phenotypes that are observed.

At a superficial level, three primary subtypes can be distinguished. At one end are the verbally fluent individuals who acquire a full and rich system of linguistic knowledge at the structural level (phonology, morphosyntax, vocabulary) that is indistinguishable from nonautistic individuals. For this group, language deficits are primarily limited to the domain of pragmatics. Interestingly, studies have shown that some proportion of older children who fit within this group experienced early delays in language, however once they reached initial milestones, the rate of acquisition was normal or even accelerated and by the end of the preschool period they were indistinguishable from children who experienced no delays in the early timing of language development (Bennett et al., 2008). At the other end are nonverbal individuals who fail to acquire the ability to speak (or communicate via other systems) beyond a rudimentary level of single words or short phrases. In general, the prognosis for acquiring useful speech is very poor for children who have not done so by age 5, however there are a number of cases in the literature of children who do achieve some success after this age if they continue to receive highly intensive behavioral treatment programs (Pickett, Pullara, O'Grady, & Gordon, 2009). The majority of children fall into a third group: They acquire language, albeit later, at a slower rate, and without fully catching up to age expectations. As more children with ASD receive early diagnoses and interventions, the proportion of children who acquire some degree of functional spoken language is increasing (Tager-Flusberg et al., 2005).

A diagnosis of ASD, even classic autism, does not require that a child has impaired language; conversational impairments are sufficient to meet criteria. Thus, the children who have linguistic deficits may be viewed as forming subtypes within the spectrum. Several researchers have proposed that children who are verbal but with impairments in phonology and morphosyntax (in addition to pragmatics) have a comorbid disorder of specific language impairment (SLI), because of the parallel deficits that are seen in these children (e.g., Bishop & Norbury, 2002; Tager-Flusberg, 2006). Clinical characteristics of SLI include lower overall language scores on standardized tests, impaired phonological processing as measured by repetition of nonsense words, and for English-speakers, morphosyntactic problems, particularly in the omission of tense markers and other grammatical features (Tager-Flusberg & Cooper, 1999). Like ASD, SLI is a heterogeneous disorder. For example, some children with SLI have articulation deficits, others do not; some have both receptive and expressive impairments, others only expressive; some have comorbid dyslexia, others do not (Tomblin & Zhang, 1999). A range of similar language deficits are seen in children with ASD (Rapin, Dunn, Allen, Stevens, & Fein, 2009; Tager-Flusberg, 2006; Tager-Flusberg et al. 2005; Whitehouse, Barry, & Bishop, 2008), though the added triad of autism-specific impairments contributes to how these are uniquely expressed in ASD on both structured tasks and in everyday language use. There is very little language research on the children at the nonverbal end of the continuum. These children are likely to have more severe autism-specific impairments, are more likely to be intellectually disabled (Luyster et al., 2008), and there is evidence that oral-motor impairments may explain why some children with ASD fail to acquire spoken language (Gernsbacher, Sauer, Geye, Schweigert, & Goldsmith, 2008). These children may have a comorbid dyspraxia, though this is a poorly understood developmental language disorder.

Given these different subtypes (or comorbidities), it is clear that no single etiology, neurological deficit, or theoretical framework can be developed to explain the language phenotypes associated with ASD. Instead, in recent years, researchers have attempted to exploit the variability in language to parse the population for genetic (e.g., Alarcon, Cantor, Liu, Gilliam, & Geschwind, 2002; Alarcon et al., 2008; Bradford et al., 2001), neurobiological (de Fossé et al., 2004), and cognitive (e.g., Norbury, Brock, Cragg, Einav, Griffiths, & Nation, 2009) studies with considerable success.

Neurobiology of Language in ASD

The classic language network is composed of Broca's area (regions in the inferior frontal gyrus) and Wernicke's area (regions in the posterior superior temporal gyrus and planum temporale). These areas are connected by a series of dorsal and ventral pathways, the most significant of which is the arcuate fasciculus, and they are supplemented by other cortical and subcortical regions, including the basal ganglia,

thalamus, and cerebellum (for a recent review, see Friederici, 2009). Typically, portions of Broca's and Wernicke's areas (particularly in the pars triangularis and planum temporale) are asymmetric, larger in the left hemisphere; and functionally, the left hemisphere assumes a primary role in processing phonological, semantic, and grammatical aspects of language, although findings across studies using different methods are not consistent, and there is greater variability among females and non–right handed individuals (Keller, Crow, Foundas, Amunts, & Roberts, 2009; Wallentin, 2009). Developmental studies have found that with age, there is continued developmental growth in the structure and asymmetry of language-related cortices into early adulthood (Gogtay, et al., 2004; Sowell, Thompson, Leonard, Welcome, Kan, & Toga, 2004).

In children with developmental language disorders such as SLI and dyslexia, both structural and functional differences have been found in studies using magnetic resonance imaging. In general, these children have reduced volumes in the primary cortical language areas, reduced asymmetry in the frontal areas, and are functionally less left-lateralized (Tager-Flusberg, Lindgren, & Mody, 2008). In ASD, similar atypical structural patterns have been found, although findings across different studies vary, depending on the methods used (e.g., manual or automatic) and the age and characteristics of the participants. The majority of studies, which primarily have included only boys with ASD, report reduced volume of the pars triangularis and posterior language regions (e.g., McAlonan et al., 2005; Rojas, Camou, Reite, & Rogers, 2005; but see also, Knaus et al., 2009). Interestingly, a recent study suggested that reduced volumes in these regions may be associated with later onset of language (McAlonan et al., 2008). Reductions in left hemisphere asymmetry of frontal language regions has also been found in several studies and is associated with greater impairment in language abilities, or comorbid SLI (Herbert et al., 2002; Herbert et al., 2005; de Fossé et al., 2004). Several studies have found exaggerated left hemisphere asymmetry in the planum temporale, again associated with comorbid SLI (Herbert et al., 2002; de Fossé et al., 2004; but for different findings see Knaus et al., 2009; Rojas et al., 2005). Only one MRI study, conducted by Munson and his colleagues (Munson et al., 2006) included very young children with ASD to explore the relationship between brain structure and developmental trajectories in communication development, as measured by the Vineland Adaptive Behavior Scales (Sparrow, Balla, & Cicchetti, 1984). Interestingly, they found a significant inverse relationship between the size of the right amygdala and growth in communication scores, which may be taken as evidence for the role of atypical development of subcortical structures associated with social functioning in the acquisition of language use in young children with ASD.

Functional imaging studies of language have found atypical patterns of activation in children and adults with ASD. Several studies have found reduced activation in frontal areas in adults with ASD, but increased activation in posterior regions, on both syntactic (Just et al., 2004) and semantic processing tasks (Harris et al., 2006). However, this pattern was not found in adolescents with ASD, who demonstrated increased activation, relative to controls in both frontal and posterior language areas (Knaus et al., 2008). The most consistent findings across studies is reduced asymmetry of language processing, especially in Broca's area, and reduced correlations in activation patterns across language regions (Just et al., 2004; Harris et al., 2006; Kleinhans et al., 2008; Knaus et al., 2008; Muller et al., 1999), which is consistent with other work suggesting impaired connectivity in the brains of people with ASD (e.g., Courchesne & Pierce, 2005). A recent study found atypical activation to speech in toddlers with ASD (Redcay & Courchesne, 2008). In contrast to the control children, who activated the left hemisphere language network, toddlers with ASD primarily activated corresponding regions in the right hemisphere, confirming that these atypical patterns begin early in development. It is not known, however, the extent to which these differences in functional organization of language in ASD are related to fundamental differences in neuroanatomy that are present at birth, to behavioral language skills, or to compensatory mechanisms. Finally, it is surprising to note that, to date, there are no published studies of the neural processing of pragmatic aspects of language in individuals with ASD.

Mechanisms Associated with Language and Communication Impairments in ASD

Most researchers argue that more than one set of mechanisms is needed to explain the full range of language impairments that is seen across the different language phenotypes in ASD. Given the complexity of the language system itself, as well as its interactions with perceptual (visual, auditory), motor (articulation), memory, social, executive, and general cognitive capacities we are still many years from having anything close to a complete theoretical account that is grounded in a dynamic, developmental framework. Still, some progress has been made in specifying the neurocognitive mechanisms associated with the universal pragmatic impairments as well as with the linguistic deficits that characterize some portion of the population.

Pragmatic aspects of language typically entail an appreciation of the intentions, knowledge, and other mental states of a discourse partner (Sperber & Wilson, 1986). Such mental state understanding, or "theory of mind" skills, are important for the interpretation of intended meaning, nonliteral language, and conversational and narrative skills, all of which are impaired in individuals with ASD. According to this view, the pragmatic deficits in ASD are explained on the basis of deficits in theory of mind, and thus, are closely linked to aspects of the core social symptoms (Baron-Cohen, Tager-Flusberg, & Cohen, 2000). Studies have found significant relationships between performance on theory of mind tasks and conversational impairments (Hale & Tager-Flusberg, 2005b) as well as

in understanding nonliteral meaning (Happé, 1993, 1994) that are independent of general cognitive and language skills. Thus, according to this model, impairments in theory of mind mechanisms underlie the pragmatic language problems that are found across most individuals with ASD (Paul et al., 2009; Tager-Flusberg, 2000).

There is less agreement on what might underlie the deficits in other language skills. At a neurobiological level, the evidence suggests that these deficits are associated with altered asymmetry, structural and functional impairments in inferior frontal regions in the left hemisphere, and reduced connectivity between frontal and temporal language regions.

These atypical neuroanatomical and functional patterns are also found in individuals with other developmental and acquired language disorders, and one theory that has been proposed as a unifying explanation for phonological and grammatical impairments across a range of disorders, including ASD, is the procedural deficit hypothesis, which claims that these impairments are related to neurocognitive abnormalities in the procedural memory system (Ullman, 2001; Walenski, Tager-Flusberg, & Ullman, 2006). The procedural memory system is involved in the learning and maintenance of cognitive and motor skills, particularly those that involve sequences, such as rule-governed combinations in phonology and grammar. This system is based on networks of interconnected brain regions, particularly in the left hemisphere, including frontal-basal ganglia, and frontal-cerebellar circuits (Ullman, 2001). The procedural deficit hypothesis proposes that the language impairments in ASD (and related disorders such as SLI; Ullman & Pierpont, 2005) are rooted in this neurocognitive system, and are thus associated with impairments in other functions (e.g., temporal processing, motor skills) that also depend on this network of structures. Because of the complexity of the neural bases of the procedural memory system, it is predicted that there will be significant individual variation in the specific nature and extent of the language (and other) impairments, that reflect the specific structures and connections that have been affected, as well as the compensatory systems that may be activated, such as the declarative memory system (Walenski et al., 2006). The nature of the deficits found among language-impaired individuals with ASD is consistent with this theoretical model, however, no studies have yet related language deficits to structural or functional abnormalities in the basal ganglia or cerebellum, both of which are central components of the procedural memory system.

Conclusions

Considerable progress has been made in advancing knowledge about the development and neurobiological bases of language and communication in ASD. For the majority of children with ASD, impairments in this domain involve fundamental alterations in the onset and rate of acquisition of major language milestones (Tager-Flusberg et al., 2005). Hallmark

characteristics of the profile of language development involve dissociations in the developmental trajectory for different components of language. One example is the dissociation seen between form and function—or between structural and pragmatic aspects of language development (Tager-Flusberg, 1994). Other examples include relative dissociations between expressive and receptive processing systems and between lexical and phonological development (see Paul, Chawarska, Cicchetti, & Volkmar, 2008). These dissociations reveal differences in developmental timing that influence the interactions among language components, and between these components and other aspects of cognition.

Atypical developmental trajectories within and across domains of language and social cognition are grounded in atypical patterns of brain organization for language and associated functions, particularly hemispheric specializations that are typically present early in development (Flagg, Cardy, Roberts, & Roberts, 2005; Kuhl et al., 2005; Redcay & Courchesne, 2008). Infants are born biased to attend to human speech. Toward the end of the first year, infants' speech processing skills are rapidly changing as they are molded to their native language, resulting in an increase in cortical specialization for language (Kuhl, 2007). All experience is now deeply embedded in a social and cultural environment; infants no longer discriminate speech sounds that are not part of their everyday world. These developmental changes, which reflect advances in linguistic development, are crucially dependent on socially grounded experience (Kuhl, 2007). Indeed, change in speech perception and early language development are dependent on interactions with people, referred to as the "social gating" model (Kuhl, 2007). One possibility is that these early stages of development, between 6 and 12 months, mark the beginning of the atypical developmental pathways that can lead to ASD, including core language and communicative impairments. Failures to attend fully to socially mediated learning opportunities for language acquisition may have profound developmental consequences (Meltzoff, Kuhl, Movellan, & Sejnowski, 2009). This view is consistent with the developmental timing of changes in head size in some infants with ASD as reported in retrospective studies (e.g., Redcay & Courchesne, 2005) as well as in the genetic mechanisms relating to synaptic plasticity that have been implicated in recent studies (cf. Morrow et al., 2008). Even during this early period, there is likely to be heterogeneity, both in the mechanisms crucial for responding to the social environment, and in the mechanisms crucial for linguistic development (including perceptual, motor, and learning systems). Future research will investigate these very early developmental patterns using prospective longitudinal approaches (cf. Zwaigenbaum et al., 2007). In turn, these studies may shed light on the mechanisms that underlie the profound impairments seen in some children with ASD who fail to acquire any spoken language.

This review of the research on language and communicative impairments in ASD has a number of important clinical implications. First, it is now clear based on several studies that

a history of delay in early language is not nearly as important from a diagnostic perspective as is a comprehensive evaluation of current language skills (e.g., Bennett et al., 2008). Second, we know that early intervention can jumpstart and significantly accelerate the rate of language acquisition in young children with ASD (Dawson, 2008). Finally, we should also be optimistic that since language skills continue to develop in older children (e.g., vocabulary, discourse and narrative abilities) and the neural substrates for language do not reach full maturity until the end of adolescence, ongoing treatment may also lead to continued growth in children with ASD throughout this period.

Challenges and Future Directions

- Little is known about the neurocognitive mechanisms associated with the failure to acquire language in some children with ASD. Methodological challenges of obtaining valid behavioral data and in acquiring measures of brain structure and function have slowed research into these important issues.
- Given the pervasive and lifelong impairments in pragmatic aspects of language that are universally found in individuals with ASD, an important priority for future research will be advancing our understanding of the neurobiology of these deficits.
- Evidence-based treatments for older children and adults with ASD, including interventions for pragmatic aspects of language and nonverbal communication skills need to be developed and implemented in the community.

Cognitive and Neural Correlates of Language in Autism

Points of Interest

- The language impairments in autism are much more extensive than captured by the current diagnostic criteria, and even in relatively able subjects with autism, include phonological, semantic, syntactic, and pragmatic deficits.
- The language impairments in autism are linked to the neural architecture in autism.
- There is not only symptomatic overlap between autism and specific language impairment (SLI) but likely also shared neural substrates and shared genes.
- Future research into language impairments in autism should integrate studies in emotion understanding and in manipulating emotional context with that of language issues.
- Future research into language impairments in autism should combine a neural systems and a neurogenetic approach and integrate the still mostly separate research fields of autism and SLI.

To communicate with other people and to describe our thoughts and feelings, we use the faculty of language. This faculty relies on a complex set of cognitive processes and representations carried out by an intricate network of neural regions distributed across cortical and subcortical structures (Hillis, 2007). Since autism is a disorder in which the development of cortical (Courchesne & Pierce, 2005) and subcortical (Herbert et al., 2003) structures is affected, it is not surprising that the faculty of language is affected in autism as well. There is not only an impairment in verbal and nonverbal communication as described by formal DSM-IV and ICD-10 diagnostic criteria, the ability to use and understand language is affected as well. The linguistic deficits are, however, much more variable than the universal deficits in communication (Kjelgaard & Tager-Flusberg, 2001), and their neural

correlates are therefore difficult to investigate. Nevertheless, there have been converging efforts from different disciplines to document the neural correlates underlying language in autism. In this chapter we aim to discuss recent evidence from structural, electrophysiological, and functional studies on the neural correlates of linguistic abnormalities in autism. We will argue that the linguistic features in autism cover a wider range of impairments than described in the DSM-IV criteria for autistic disorder and are more linked to the neural architecture in autism than earlier behavioral studies have suggested. Functional brain-imaging data show aberrant neural activation in semantic, syntactic, and pragmatic tasks of higher-order language functions, as well as in low-level sensory processes. Furthermore, we will argue that the abnormalities of low-level sensory processing of linguistic stimuli can be interpreted in the light of connectivity models in autism. Finally, we will discuss the relationship between language impairments and the other functional impairments in autism (social interaction and stereotyped and rigid behavior patterns), as well as the relationship between autism and specific language impairment (SLI). First of all, however, some background will be given on the current views of the typical cognitive architecture underlying language production and comprehension and discuss the anatomy of language. We will also briefly discuss the development of language in typically developing children.

Neural Architecture of Language

Linguists commonly describe language and language disorders in terms of phonology, semantics, syntax, and pragmatics. Whereas phonology deals with the perception and production of sound units whose concatenation produces words, semantics deals with the meaning of lexical items, syntax with the structure of words in sentences, and pragmatics with the

conventions and rules governing the use of language for communication. From a neuroscientific perspective, however, there is no clear-cut relation between linguistic categories and cortical function.

Recent functional imaging studies have furthered the idea that the language system is organized in a large number of small but tightly clustered modules in both the left and right hemispheres with unique contributions to language processing. There is also increasing evidence that cortical language regions are not specific to language, but involve more reductionist processes that give rise to language as well as nonlinguistic functions (Bookheimer, 2002). The areas involved in language processing include the dorsolateral prefrontal cortex, premotor cortex, middle and inferior temporal cortices, anterior cingulate gyrus, supplementary motor area, supramarginal, and angular gyri in the posterior-inferior parietal cortex. The cerebellum and the thalamus also play a role (Price et al., 1999).

Among the regions already recognized in the nineteenth century are the left inferior frontal gyrus (Broca's area), which includes Brodmann area 44 and 45, and the posterior auditory association cortex (Wernicke's area) on the superior temporal gyrus (Brodmann area 22). Broca's area and Wernicke's area, along with the arcuate fasciculus that connects the two, play a key role in the traditional language model. This model essentially states that Wernicke's area controls language comprehension, and Broca's area language production (Dronkers, 2000). The model was mainly derived from lesion studies, in which damage to Wernicke's area typically results in impaired comprehension with less impairment in producing fluent, well-articulated speech. Damage to Broca's area results in relatively intact comprehension but poor speech fluency, which makes speakers with such lesions unable to create grammatically complex sentences. Yet, with the onset of neuroimaging techniques, researchers consistently found that not all patients with Broca's aphasia (relatively intact comprehension but poor speech fluency) have lesions in Broca's area and vice versa. The same applies to Wernicke's aphasia. Thus, speech perception is not always normal in patients with Broca's aphasia, and articulation of speech sounds is not always normal in patients with Wernicke's aphasia (Dronkers, 2000).

Growing insight in the cognitive processes underlying language has led to a refinement of the traditional twentieth-century language model. Current cognitive language models assume that language tasks are decomposable into discrete representations and, furthermore, assume that these representations are composites of features distributed across regions of the brain (Hillis, 2007). For example, the semantic representation of "train" includes features on how it moves, represented in cortical areas such as the middle temporal visual area dedicated to motion recognition. Features on how people get on trains may be represented closer to motor systems, so that semantic representations might be distributed across the temporal, parietal, and frontal cortex. So, for naming a picture of a train, a number of processing steps must be performed. These include abstracting the features that allow recognition of something familiar, access to its

semantic representation, access to its syntactic role, access to its phonologic representation, and finally motor planning for articulating the word. However, overlapping networks of brain regions are essential for these tasks. Damage to the same regions, for example, can disrupt naming, written word, and spoken word comprehension. Yet, some areas are more likely to disrupt each of these tasks. In this model, Wernicke's area might be critical for linking the widespread representations to specific words. Broca's area might be critical for selecting certain types of semantic information to accomplish specific tasks (Hillis, 2007).

Development of Language in Typical Populations

Typically, infants show communicative behaviors such as eye gaze, facial expression, and vocal turn-taking from the first months of life. At 12 to 15 months of age, infants are able to understand and express a number of words. Combined with nonverbal communication, infants use their vocabulary to produce 1-word sentences with which they request objects, reject offered actions, or call attention to objects or events (Bates, 1976). In the second year of life, there is a gradual increase in receptive and expressive vocabulary, until at an average age of 18 months, children combine words into 2-word sentences with basic semantic relations. It is in that time that the word "explosion" begins, as children begin to understand the referential nature of words (Nazzi & Bertoncini, 2003). At the age of 2, children understand around 900 words and actively use around 300 words in 2-word sentences. At the age of 3, the average mean length of utterance is 3 (Tager-Flusberg et al., 2005). Using nonverbal clues such as eye gaze, children are then able to make fine distinctions between an object that an adult is naming and other objects. At the age of 4, almost all sounds are produced correctly. At the age of 6, children understand and use thousands of words, and are able to use them in complex syntactic forms.

Language and Cognitive Theories in Autism

Several psychological theories, such as the Weak Central Coherence (WCC) theory (Frith, 1996) and the impaired theory of mind (ToM) (Baron-Cohen et al., 1985), have attempted to explain the high-order language deficits in autism. The weak central coherence theory predicts that, since people with autism are biased toward local versus global processing, their ability to integrate contextual information into a composite whole is diminished. The high-order core deficit in central processing supposedly results in altered low-level processing. Several studies have indeed demonstrated a reduced ability to infer word-meaning from sentence context (Happe, 1997) or to infer global meaning from sentences

(Jolliffe & Baron-Cohen, 2000), yielding empirical evidence for the WCC account for at least the semantic and pragmatic language deficits in autism. However, WCC would also predict a superior performance on single-word tasks, as is the case in hyperlexia. Yet, hyperlexia is only rarely seen in autism. The majority of people with autism have difficulties with the meaning of isolated words as well as whole sentences.

ToM refers to the specific cognitive ability to infer other people's mental states and to understand that others have beliefs, desires, and intentions that are different from our own. It has been argued that early stages of ToM are necessary for the ability to use symbols such as words (Tager-Flusberg, 2000), and that impairment in ToM in autism therefore causes an inability to comprehend the meaning of words. Furthermore, acquisition of language may be mediated by shared or joined attention, which, in case of an impaired ToM, would be impaired as well (Kuhl et al., 2003). Semantic ability and false belief have indeed been found to correlate in children with autism (Tager-Flusberg, 2000).

The psychological framework provided by these top-down theories assumes that an impaired high-level cognitive function is causing the impairments in autism. This assumption has been criticized for several reasons. First, converging evidence suggests that abnormalities of the processing of low-level sensory information may lead to impairments in higher-order cognitive functions, rather than the other way around (Happe & Frith, 2006; Bertone et al., 2005). That is to say, altered low-level perceptual processing in autism should not be considered a by-product of weak central coherence. Quite on the contrary, perceptual abnormalities may give rise to weak central coherence. Second, these neuropsychological top-down theories are descriptive rather than explanatory, and finding the neural correlates of these theories has proven difficult, since their predictions of cortical functioning are too general to be falsifiable.

The Phenotype of Language Disorders in Autism

Impaired language function is frequently observed in people with autism, often in combination with mental retardation. Language dysfunction in autism is, however, much more variable than the universal deficits in communication (Kjelgaard & Tager-Flusberg, 2001). At one end of the autism spectrum there are children whose verbal abilities are within the normal range of functioning, and at the other there are some who never start to speak (Lord & Paul, 1997). In those with sufficient language and cognitive abilities, i.e., people with high functioning autism (HFA) and Asperger's syndrome, social communicative abilities remain impaired. Language tends to be used one-sidedly, nonreciprocally, and instrumentally rather than for social purposes (Fine et al., 1994). In their original descriptions of ASD, Kanner and Asperger both gave account of the typical language anomalies encountered in

autism such as echolalia, pronoun reversal, utterances not related to the conversational context, and a lack of drive to engage in communication (Asperger, 1991; Kanner, 1943).

Articulation

It has been a widely held belief that the development of phonology progresses at a slower rate, but is not impaired in autism since phonologically correct echolalia is commonly found in low-functioning autism, suggesting that phonological perception and production is intact even in severely affected individuals (Tager-Flusberg, 1996). However, there is converging evidence for an articulation deficit in a subgroup of autistic children. A delayed developmental trajectory of phonology has been reported (Bartolucci et al., 1976), as well as a greater number of articulation distortion errors in people with HFA and the Asperger group than in typically developing speakers (Shriberg et al., 2001). Recently, Kjelgaard and colleagues found phonological processing deficits (as measured by repeating nonsense words) in autistic children, although only in those with concurrent impaired vocabulary and higher-order semantic and syntax deficits (Kjelgaard & Tager-Flusberg, 2001). This language profile was also found by another group in half of the children with poor communicative abilities (Rapin & Dunn, 2003). It thus seems that, in a subgroup of autistic children, phonology is impaired along with language comprehension and production. This clustering of symptoms may suggest that common causes underlie phonology and syntactic abilities in autism and also in other disorders such as specific language impairment.

Word Use

Difficulties in both understanding and expressing lexicon are the most widely recognized linguistic impairments in autism. Semantic impairments are most severe in people with low-functioning autism (LFA) and least severe in those with HFA and AS (Boucher, 2003). Delay in speech acquisition is one of the primary diagnostic characteristics, and the degree of language impairment is a key prognostic factor (Lord & Paul, 1997; Venter et al., 1992). Yet, the course and development of semantic difficulties is an underresearched area in autism. One comprehensive study revealed marked difficulties in lexical comprehension and expressive vocabulary in the majority of children with autism (Kjelgaard & Tager-Flusberg, 2001). Furthermore, a strong correlation was found between full-scale IQ and performance on tests for comprehension (Peabody Picture Vocabulary Test) and expression (Expressive Vocabulary Test) (Dunn & Dunn, 1997; Williams, 1997). This correlation suggests that semantic comprehension and expression are unimpaired in the most able people with autism, and especially in those with Asperger syndrome. Subtle semantic impairments are however also present in HFA and AS. Howlin and colleagues found a poor performance on tests for productive (British Picture Vocabulary Scale) and receptive (Expressive One Word Picture Vocabulary Test) semantic

abilities for both AS and HFA (Gardner, 1982; Howlin, 2003; Dunn et al., 1997). While there was no significant difference for language comprehension between HFA and AS, ratings for language expression revealed a small but significant difference favoring the AS group. Thus, in accordance with clinical experience and anecdotal evidence, language abilities in people with HFA and AS differ mainly with respect to expressive abilities.

It has been suggested that the semantic difficulties in autism are a consequence of deficits in advanced conceptualization, since simple concepts referred to by lexical items are not affected in autism (Tager-Flusberg, 1981) and comprehension of terms referring to emotional states (Tager-Flusberg & Sullivan, 1995; Hobson & Lee, 1989) or abstract terms (Frith & Snowling, 1983) is more affected than comprehension of concrete words. Other studies, however, do not support this finding. Interference during a reading task was not different for concrete and abstract words (Eskes et al., 1990), and abstract terms that exist through human agency such as "war" and "peace" were not found to be used anomalously in autism (Perkins et al., 2006). Thus, the exact nature of the semantic deficits in autism remains to be established.

Syntax

As with the phonological properties of language in autism, syntactic impairments have not been well researched. Recent findings, however, do provide evidence for distinct and specific syntactic deficits in autistic children who acquire spoken language, and more noteworthy, they also show that, in those who do not acquire speech, the ability to acquire the grammar (and vocabulary) of signed language is impaired as well (Boucher, 2003). The distinct syntactic deficits in autism entail reduced expressive and receptive syntactic abilities, which have been found using the Clinical Evaluation of Language Fundamentals (CELF) (Kjelgaard & Tager-Flusberg, 2001) and mean utterance length in free play sessions (Eigsti et al., 2007). Contrary to the consistent findings on the length of syntactically complex utterances, the findings on grammatical morphemes such as verb tense markers and articles are inconsistent. Whereas earlier studies found more grammatical errors (Bartolucci & Albers, 1974; Bartolucci et al., 1980), a more recent well-matched study found no such errors in spontaneous autistic speech (Eigsti et al., 2007). Yet, Roberts and colleagues did find high rates of omissions of tense marking in a subgroup of children who were language impaired (Roberts et al., 2004). The inconsistency of findings on grammatical morphemes probably reflects the fact that subgroups are affected rather than all autistic people, so that sufficiently large subject groups are needed.

It has been a long-held belief that people with autism are better at language production than at language comprehension. The main reason for this assumption was a series of studies conducted in the seventies that compared autistic children with children with severe receptive language disorder. These studies revealed significant differences in comprehension of

vocabulary and the production of syntactically complex utterances, favoring the children with receptive language disorder (Bartak et al., 1975; Cox et al., 1975; Cantwell et al., 1978). It was therefore argued that syntactic comprehension was more affected than production. However, in contrast with the above finding for syntax, a more recent study did not replicate a difference between *semantic* comprehension and expression (Kjelgaard & Tager-Flusberg, 2001). A language profile in autism with better production than comprehension could thus not be replicated. Nevertheless, evidence was found for two distinct language profiles in autism. The language profile in one subgroup entailed worse performance on tests of grammatical ability than vocabulary (Kjelgaard & Tager-Flusberg, 2001), possibly clustering with phonological impairments (Rapin & Dunn, 2003) (see also the "Phonology" section). The language profile in the other subgroup entailed impaired semantics and pragmatics (Rapin & Dunn, 2003). These subtypes suggest that syntactic and phonological deficits have a common cause, as have semantic and pragmatic deficits in autism. However, the distinction of subtypes was based on a number of studies with an autistic sample that was preselected for the presence of difficulties in language comprehension, so the extent to which these findings can be generalized to the broad autism spectrum remains to be established.

In summary, syntactic abilities in autism are characterized by sparse expressive language with immature syntax in a majority of children. There is some evidence for a clustering of syntactic/phonological deficits in a subgroup of children and a clustering of semantic/pragmatic deficits in a subgroup, but this will require confirmation in an unselected autistic population.

Pragmatics and Prosody

Pragmatics entails both the linguistic and nonlinguistic items that are covered by the defining criteria of autism. Linguistic pragmatics implies difficulties in the ability to disambiguate meaning, to structure coherent discourse, and to understand irony and implied meaning. The ability to understand other people's intentions, social rules of conduct, and nonverbal communication gestures is regarded as nonlinguistic pragmatics. Deficits in pragmatic functioning are evident at all developmental stages, even in highly verbal adults with autism (Lord & Paul, 1997; Tantam et al., 1993; Happe, 1993; Martin & McDonald, 2004; Baron-Cohen, 1997).

It should be noted that most research in autism on nonlinguistic pragmatic abilities, such as the ability to understand other people's intentions, as measured by ToM tests, involve language. Data on whether the deficit in ToM extends to people with autism with little or no language is sparse, making it difficult to disentangle the relative contributions of linguistic and nonlinguistic deficits in the sociocommunicative deficits in autism. Moreover, it has been argued that the syntactic ability to build subordinate clauses allows children to reason about mental states that are at odds with reality (e.g., "Jane *thinks* the cookies are in the cabinet") (De Villiers & De Villiers, 1995). Syntax mastery has indeed been found to

correlate with performance on ToM tasks. However, using a nonverbal ToM test, Colle et al. found that children with autism selectively failed false-belief tasks, whereas children with SLI or typically developing children did not (Colle et al., 2007), indicating dissociation between verbal and pragmatic abilities.

A pragmatic ability closely related to language comprehension is the ability to perceive and use intonation, rhythm, tone of voice, and stress, referred to as prosody. The use of aberrant prosody is mentioned in the DSM-IV description of autism, and the perception of prosody in autism has been investigated by several authors. Rutherford and colleagues, for example, compared the ability of adults with ASD to attribute emotions to sentences spoken with an emotional tone of voice, and found that individuals with HFA or Asperger's syndrome have difficulties extracting mental-state information from vocalizations (Rutherford et al., 2002). Researchers found deficits in the perception and production of stress, intonation, and phrasing (Paul et al., 2005), as well as a preference for nonverbal sounds and an indifference to the mother's voice in children with autism (Dawson et al., 1998; Klin, 1991). The latter finding seems to indicate that deficits in the perception of prosody do not reflect an innate inability, but arise as a consequence of nonsocial orientation. However, the direction of causality may also be the other way around, or even be bidirectional. Finally, the relation between prosodic and verbal abilities in autism is not clear. Although using a relatively small study sample, Heaton et al. did not find a relation between the ability to perceive pitch in speech and nonspeech sounds and verbal ability (Heaton et al., 2008). This suggests that the WCC account does not adequately explain the relation between local auditory processing and global language ability.

In summary, linguistic and nonlinguistic pragmatic deficits and prosodic deficits are part of the most commonly affected domains of functioning measured across the spectrum of autism disorders. It appears that linguistic abilities facilitate pragmatic abilities, although they are not necessary per se for pragmatic competence.

The Neural Correlates of Language Disorders in Autism

Although autism is a heterogeneous disorder that includes many contradictory neurophysiological findings, several neural correlates underlying the linguistic deficits of autism have been reproduced in different investigative modalities. Some researchers focused on structural abnormalities (Herbert et al., 2002), while others addressed the perception of simple linguistic stimuli (Boddaert et al., 2003; Ceponiene et al., 2003) and higher-level linguistic functions (Harris et al., 2006; Kana et al., 2006). The results indicate that individuals with autism activate alternative and possibly less flexible networks during phonetic, semantic, syntactic, and pragmatic language processing. Abnormalities at an early level of information

processing contribute to the hypothesis of a bottom-up etiology in which, for example, an alteration of auditory cortical processing leads to abnormal language development in early childhood.

Structural Abnormalities

After a long period of inconsistent findings in structural neuroimaging studies, data of recent studies converge to elucidate the underlying abnormalities in autism (see Palmen & van Engeland, 2004, for a review, as well as the chapters on Neurobiology of Autism in this book). The cortical areas that are most consistently affected in autism (the frontal, temporal, and cerebellar structures) all subserve language functions, although the cerebellum is only considered to play a facilitating role (Allen et al., 2004). Consequently, morphometric findings on the frontal and temporal language areas have been associated with language impairments in autism. Asymmetry reversal of the frontal language-related cortex was found (DeFosse et al., 2004; Herbert et al., 2002; Abell et al., 1999), as well as anterior and superior shifting of the left inferior frontal sulcus and superior temporal sulcus bilaterally (Levitt et al., 2003) and decreases of grey matter concentration bilaterally in the superior temporal sulcus (Boddaert, Chabane, Gervais, et al., 2004). Although cognitive functions are difficult to relate to morphometric findings in a one-to-one manner, the main conclusion of these studies is that the cortical development of language-related areas follows a different trajectory in autism, possibly in the context of a reduced left-lateralized hemispheric dominance. Whether these findings of aberrant development and collaboration between cortical areas are specific for autism is, however, not clear. As a consequence, there is a need to directly compare the neurobiological development and functioning in autism with other disorders of language such as SLI and dyslexia (see also Herbert et al., 2007 and the chapters on Neurobiology of Autism in this book).

Auditory Perception and Lower-Level Language Paradigms

Several authors have focused on clarifying two main questions in the field of language in autism: whether or not early sensory processes are deficient in autism and whether or not these early sensory processes are speech-specific. These questions are highly relevant to better understand the nature of language deficits in autism, since they allow inferences on the contribution of top-down versus bottom-up processes in the functional impairments in autism. Basically, bottom-up theories assume that early sensory deficits give rise to deficient high-level operations such as language and social behavior (e.g., the inability to speak in deaf people). Alternatively, top-down theories assume that the ability to perceive stimuli is not impaired. Yet, deficits in high-level processes such as social behavior could give rise to undirected attention, or attention directed to non–socially relevant clues, so that word-object associations do not develop efficiently in autistic children. In healthy children,

joint attention has indeed been shown to be a prerequisite for acquiring language (Kuhl et al., 2003), suggesting a role for top-down influences in autism. Yet, it is still possible that sensory deficits give rise to deficits in joint attention. To shed light on this chicken-and-egg problem, much data has been collected using neurophysiological experiments that measure neural responses to stimuli at a millisecond scale.

Čeponienè et al. used an ERP oddball paradigm to examine the sensory and early attentional processing of speech and non-speech sounds in children with HFA (Ceponiene et al., 2003). They found no differences in mismatch negativity (MMN, an index of automatic sound change detection, situated in time after the N1c wave and before the P3a wave), which suggests intact early perceptual abilities in autism. However, involuntary orienting (P3a) was different for speech sounds but not for nonspeech sounds in the HFA group. This finding supports the hypothesis of a speech-specific *post*sensory auditory impairment, suggesting that people with autism may perceive but not attend to linguistic stimuli. Contrary to Čeponienè's findings, Kasai et al. did find a delayed magnetic mismatch field for vowels (but not for tones) by using magnetoencephalography (Kasai et al., 2005). Thus, early perceptual processing in autism appeared to be deficient and speech-specific.

Others studies have confirmed the early perceptual processing deficits, but the speech specificity was not replicated: They reported smaller N1c waves in children with autism in an event-related paradigm with simple tones (Bruneau et al., 1999) and delayed MMN for both speech and nonspeech sounds (Oram Cardy et al., 2005). Whether or not cortical sound processing impairments are speech-specific, sound processing impairments may be fundamentally associated with language impairments. In a behavioral study, Groen et al. found no differences between children with and without autism in the ability to distinguish the parametrically morphed gender of speakers, but the response times differed between the groups (Groen et al., 2008). The authors argued that focus on different features in the voices, as a consequence of a difference in salience, caused the differences in response time. The results suggest that focus on different features in auditory objects may lead to a different development of higher-order cognitive systems such as language or pragmatics.

In an fMRI study that contrasted voices with environmental sounds, no differential activation between the two conditions was found in the autism group, suggesting that speech was not processed by a speech-specific cortical region (Gervais et al., 2004). The control group, on the other hand, showed greater activation for voices along the upper bank of the superior temporal sulcus bilaterally. The abnormal pattern of cortical activation in the autism group might reflect a bottom-up sensory impairment, or alternatively, it may be caused by an attention bias toward nonvocal sounds, which in turn may lead to the development of linguistic deficits in autistic children. This problem was tackled by a positron emission tomography (PET) study that investigated the auditory cortical processing of prelinguistic speech-like sounds that have an acoustic structure similar to speech (Boddaert et al., 2003; Boddaert,

Chabane, Belin, et al., 2004). The study reported a reversed hemispheric dominance in the autism group and, compared with controls, less left-temporal activation and greater right middle frontal gyrus activation. The elegance of the study design was that top-down processing of language was less likely because the sounds were not perceived as language but rather as strange electronic tones. The acoustic structure was made to resemble speech sounds, such that any cortical processing differences reflected bottom-up linguistic abnormalities. The authors therefore speculated that the observed abnormal auditory processing led to an abnormal early stage of language development rather than that it reflects the consequences of abnormal language development.

The above-mentioned studies converge to the idea that impairments of information processing may lead to an abnormal developmental trajectory of language in autism. Studies of the maturational path of cortical language processing do indeed indicate an abnormal developmental trajectory in the form of reversed hemispheric dominance. Dawson et al. reported a strong relationship between language ability and hemispheric asymmetry in ERP, on the one hand, and vowel stimuli in autism, on the other (Dawson et al., 1989). Furthermore, in a MEG study using simple vowel stimuli, Flagg et al. found rightward instead of typical leftward hemispheric lateralization (Flagg et al., 2005). Reduced leftward hemispheric activation was also found in nonlinguistic neuroimaging studies (Gendry-Meresse et al., 2005; Chiron et al., 1995). Yet, the association of cortical processing impairments and impaired language in autism does not per se imply causality. That is, cortical sound processing impairments may cause language deficits, but language deficits may also cause cortical sound processing impairments. Alternatively, another factor such as a genetically programmed maldevelopment of neuroarchitecture in autism may give rise to both cortical sound processing impairments and language deficits.

In short, impaired cortical sound processing is reproduced reliably in autism. Whether or not the auditory processing abnormalities are speech-specific is still unclear, but early sensory impairments and their interplay with the maturational path of the cerebral cortex are likely to play a part in the abnormal language acquisition in autism.

Higher-Level Language Paradigms

Given the neuroimaging data found so far, it is unlikely that a deficit in a single cortical area can account for the phenotypic language deficits in autism, as is the case in poststroke aphasia. In the autistic brain, cortical regions seem to collaborate in a different fashion, and cortical areas that show hypoactivation or hyperactivation for one task may show normal activation for another task.

The first functional imaging study of higher-level language perception and generation in autism was a small exploratory PET study conducted in 1999 (Muller et al., 1999). In five autistic participants, sentence perception was associated with the reversal of normal left-hemisphere dominance, while

sentence generation showed normal left inferior frontal activation. In a re-analysis of the data on the same subjects, which focused on three regions of interest, participants with autism had a reduced Broca's area (Broca's area is situated in the opercular and triangular sections of the inferior frontal gyrus) activation during language perception and production (Muller et al., 1998). A more recent fMRI study, using a reading paradigm that required the attribution of complex mental states contrasted with rest states, demonstrated more right frontal activation in the autism group, also indicating a reversal of hemisphere dominance (Takeuchi et al., 2004). These studies should, however, be considered exploratory because of their small sample sizes and multiple comparisons.

In an fMRI study by Harris et al., the semantic and perceptual processing of single words was assessed (Harris et al., 2006). Semantic processing (evaluating words as positive or negative) and perceptual processing (evaluating words as lower or UPPER case) were contrasted as well as processing of concrete and abstract words. The participants with autism had weaker left and right frontal activation, but greater temporal activation for semantic processing, relative to perceptual task conditions. More importantly, compared with the control group, there was little differential activation between semantic and perceptual processing in the autism group. The concrete versus abstract contrast also demonstrated less activation differences between the two conditions in the autism group.

Groen et al. investigated pragmatic and semantic language in adolescents with autism using fMRI. They hypothesized that the left inferior frontal gyrus (Broca's area), which has an integrating role, would be less activated during tasks that demand integration of social-pragmatic information such as speaker's age or gender with the content of the speaker's utterance. In the semantic-knowledge condition, activation of the LIF region did not differ between groups. In sentences that required integration of speaker information, the autism group showed abnormally reduced activation of the LIF region. The results suggest that people with autism may recruit the LIF region in a different manner in tasks that demand integration of social information.

In another fMRI study, abnormal Broca's and Wernicke's area (Wernicke's area is situated in the posterior section of the superior temporal gyrus and the Sylvian fissure) activation in autism was also demonstrated using a sentence comprehension task with syntactically demanding probes (Just et al., 2004). The autism group had less activation of Broca's area and adjacent areas and more Wernicke's area activation. Furthermore, the study showed a reduced synchronization of neural activation across the large-scale cortical network for language processing. The greater Wernicke's area activation was interpreted as a tendency for more extensive processing of the meanings of the individual words that make up a sentence in autism. The authors hypothesized that the reduced Broca's area activation may reflect a reduced ability to integrate the meaning of individual words into a coherent conceptual and syntactic structure. This may still hold, but Harris's study showed that Broca's area and Wernicke's area are also abnormally activated during the processing of single words when no syntactic demands are made (Harris et al., 2006).

The findings on underconnectivity were elaborated in an fMRI study in which autistic participants processed sentences with a high-imagery or low-imagery content (Kana et al., 2006). Measures of functional connectivity showed a reduced functional synchronization between the frontal and parietal areas. Again, the controls had greater Broca's area and adjacent area activation. In contrast to the control group, there were little activation differences between the two conditions in the autism group: The autism group seemed to process high- and low-imagery sentences similarly.

Thus, the neuroimaging data give rise to four main conclusions. First, the data indicate that people with autism tend to rely more on Wernicke's area (temporal region) and less on Broca's area (frontal region) for processing sentences and single words. Since Broca's area subserves integration processes (Hagoort et al., 2004) and Wernicke's area is more associated with semantic retrieval, the neuroimaging data present an intriguing parallel between the WCC's piecemeal processing style and the greater reliance on Wernicke's area neurally. It might thus well be that early sensory processes that highlight individual components in a composite whole give rise to the greater Wernicke's area activation rather than that Wernicke's area itself is malfunctioning.

Second, the neuroimaging data suggest that, during high-level processing in autism, cortical areas are used in a different manner and in reaction to other stimuli rather than that certain cortical areas are malfunctioning per se. An elegant example of this are two studies by the same group that assessed the neural basis of irony comprehension in autism. One study found hypoactivation of prefrontal and temporal regions during judgment of scenarios that involved irony (Wang et al., 2007). However, the other study, in which also scenarios that involved irony were presented, used a paradigm that demanded explicit attention to socially relevant clues, and found greater activation of the prefrontal and temporal regions (Wang et al., 2006).

Third, the task indifferent pattern of activation during language tasks in autism supports the idea that the neural networks that are temporarily recruited for a cognitive task cannot be reset as easily as in controls when the task is changed. There is theoretical evidence that suggests that less flexible network regrouping could be the result of abnormalities in low-level sensory processing (Gustafsson, 1997) in the sense that high-level processes are flooded with irrelevant information from low-level centers and the extra processing demand impedes the flexibility required for neural assemblies to form (Belmonte, Cook, et al., 2004). As such, less flexible network regrouping has been associated with models of aberrant connectivity in autism. This matter will be further discussed below. Interestingly, less flexible network regrouping might also be involved in the part of the triad of symptoms that involves rigidness and repetitive/restricted behavior. The correspondence between the triad of symptoms in relation to their putative causes will be also addressed below.

Fourth, autism is a heterogeneous disorder, and the same can be said about the neuroimaging results on language in autism. Some of the conflicting findings can be explained by the wide range of phenotypic variation with different intellectual levels and age groups studied. As a consequence of the difficulty to obtain large enough sample sizes, only a minority of the neuroimaging studies have evaluated the results at a search volume correct p-value and have used a random effects analysis and a direct group comparison.

Neural Architecture, Cortical Connectivity, and Language

Over two decades of research have shown that linguistic deficits are present in the majority of individuals with autism. Neurophysiological studies that sought the neural basis of these deficits have shown abnormalities at a basic, early level of sensory information processing in autism (Boddaert et al., 2003; Ceponiene et al., 2003). Quite likely, these findings reflect developmental abnormalities, and as such, they are in accordance with hypotheses on impaired integration of cortical information in autism. Basically, these theories state that cortical regions do not operate in synchrony, but show disorganized and inadequately selective development of connectivity (Rippon et al., 2007; Just et al., 2004; Belmonte, Allen, et al., 2004). Especially impaired connectivity between the frontal lobe and other systems has been implicated in autism (Courchesne, & Pierce, 2005). A growing body of evidence lends support for aberrant connectivity in autism, including deficits in physical connectivity, such as histopathology findings of neuroinflammatory microglial activation (Vargas et al., 2005), the abnormal developmental trajectory of brain size (Redcay & Courchesne, 2005), decreases in white matter structure integrity measured with DTI (Keller et al., 2007; Barnea-Goraly et al., 2004; Alexander et al., 2007), and deficits in computative connectivity measured as the synchrony of time series of activation of cortical regions (Kana et al., 2006; Wilson et al., 2006). Although it is tempting to ascribe a unidirectional causal relation to deficits in connectivity and impairments in autism such as abnormal language development, a bidirectional relation between connectivity and functional impairments in autism is more likely. In healthy adults, white matter integrity changes over time (Snook et al., 2005), suggesting that experiences influence neural connectivity. The sociocommunicative deficits in autism could likewise give rise to abnormal connectivity.

Yet, it has been argued that, in autism, genetic factors in interaction with environmental influences lead to an abnormal neural architecture that causes either increased or reduced neural connectivity, or both (Belmonte, Cook, et al., 2004). Both conditions could cause an abnormally low signal-to-noise ratio in developing neural assemblies, given the fact that there is excess noise in hyperconnected systems and the signal gets lost in the noise in hypoconnected systems. This may result in a failure to delimit activation in perceptual processing centers, forcing higher processing mechanisms to actively suppress irrelevant sensory information at a later, less efficient stage. These compensatory mechanisms can presumably not be reset as quickly as the normal mechanisms of selective attention. Empirically, the allocation of neural resources during higher-order language tasks does indeed seem to be more task-indifferent in autistic individuals than in controls. The observation of less flexible network regrouping in autism during different language task conditions (see also "Higher-Level Language Paradigms," above) can possibly be explained by the high neural demands that active filtering of relevant stimuli imposes (Belmonte, Cook, et al., 2004).

More direct evidence suggesting reduced cortico-cortico connectivity during language tasks in collaborating cortical areas has been provided as well (Just et al., 2004; Kana et al., 2006). Intraregional underconnectivity during a simple auditory task has also been reported (Wilson et al., 2006). The high-level processing deficits of linguistic stimuli might arise when an unfiltered flood of linguistic information reaches higher information processing units that have to evaluate and actively suppress irrelevant sensory inputs. The greater reliance on Wernicke's area for linguistic processing in autism (Just et al., 2004) might thus result from compensatory developmental processes that lead to a more self-reliant Wernicke's area. In a MEG study on contextual integration, semantic violations induced greater gamma-oscillations in the autism group (Braeutigam et al., 2008). Gamma oscillations reflect an increase in local collaboration, or local binding (Tallon-Baudry & Bertrand, 2006). Thus, this finding may reflect a failure to delimit activation in perceptual processing centers. There is a certain charm to this model of local over- and interregional underconnectivity in autism, since it elegantly explains behavioral findings of reduced integration of information in autism. Smith et al. found that individuals with autism benefited less from the addition of visual information (lipreading) in audiovisual speech perception (Smith & Bennetto, 2007). The integration of the two information streams was uniquely affected in the autism group. Data by Groen et al. demonstrated that children with autism were less able to integrate speech fragments so that they could be perceived as words (Groen et al., 2009). However, interpreting these behavioral data as evidence for impaired cortical synchronization in autism would be circular reasoning. More direct evidence of abnormal cortical synchrony in autism is needed to add strength to this model.

The Relationship Between Linguistic Impairments and Social and Restricted/ Repetitive Impairments in Autism

It should be noted that linguistic and communicative impairments comprise only one third of the triad of impairments in autism. Whether or not abnormal connectivity and the genetic

constellation associated with communicative abilities contribute to the other behavioral domains in autism (social interaction and restricted and repetitive behaviors and interests) is unclear. This issue will be further discussed below.

The core deficits in autism are traditionally viewed as inherently intertwined, i.e., communicative, social and restricted/repetitive difficulties influence each other and are highly interdependent. Indeed, the acquisition of language is one of the strongest predictors of long-term positive academic and social outcome in children with autism (Gillberg, 1991). Conversely, joint attention and immediate imitation predict language ability at ages 3–4, and toy play and deferred imitation predict communication development at ages 4–6 (Toth et al., 2006). However, recent behavioral-genetic data from a large general population-based twin-pair study indicate that phenotypic correlations between traits usually associated with autism (social interaction, repetitive-restrictive behaviors, and communication) are low (Ronald et al., 2006). Even social interaction and communicative abilities were only modestly clustered with correlations of 0.2 to 0.4 (Happe et al., 2006). Furthermore, although each aspect of the triad of impairments was found to be highly heritable, cross-trait, cross-twin correlations were low, suggesting that most genetic effects are specific to one of the core symptoms. One might argue that these behavioral-genetic findings suggest that the neural underpinning of the separate parts of the triad of symptoms is trait-specific as well. However, a different pattern of genetic and environmental causal factors for each of the symptom domains of autism does not preclude the possibility of a common neural deficit. In fact, each of these causal patterns may lead to a common neural deficit that further compromises other neural functions and give rise to the triad of symptoms in various degrees.

Genetic, Endophenotypical, and Behavioral Correspondence Between Autism and Language Impairments

In the DSM-IV, there is an explicit contrast between autism and specific language impairment. Children with SLI have a specific disability to acquire age-appropriate language, while development in all other domains is normal (American Psychiatric Association, 1994). Children with autism, by contrast, may not only have a delay in language development, other developmental domains are affected as well, and there are also linguistic deviations that are not normal for any stage of development (Bishop, 2002). Nevertheless, the linguistic deficits observed in specific language impairment resemble the language impairment in autism. Children with SLI usually have limited vocabularies, produce immature speech sounds, and use basic grammatical structures (Newbury et al., 2005). The profile of language performance among a subgroup of children with autism mirrors the profile of SLI: Poorer performance on tests of grammatical ability than vocabulary, and difficulties with nonword repetition (Tomblin & Zhang, 1999; Dollaghan & Campbell, 1998; Kjelgaard & Tager-Flusberg, 2001). The overlap in both disorders suggests that autism and

SLI involve a shared neural substrate and one or more shared genes (Kjelgaard & Tager-Flusberg, 2001). Family members of probands with autism have a higher than chance rate of language impairments, and family members of probands with SLI are at risk for autism (Piven & Palmer, 1997; Tomblin et al., 2003). However, parents of children with autism and parents of typically developing children did not differ in their language abilities, while parents of children with SLI performed less well on language tasks (Whitehouse et al., 2007). This may indicate that there are additional genes involved in SLI that are not present in families with autism. Interestingly, phenotypic similarity at a neural level has been found between language impaired boys with autism and boys with SLI (DeFosse et al., 2004). Segmented MRI scans showed larger right than left frontal language association cortexes in both groups. Since the inversed asymmetry was not present in the autism group that was linguistically unimpaired, these results also suggest that there is a common underlying (genetic) cause for the language impairments in autism and SLI. The CNTNAP2 gene on 7q32, involved in nerve cell communication, is associated with autism and SLI (Alarcon et al., 2008), which suggests that this genetic pathway could bridge the common elements of both disorders.

⁙

Conclusion

Parents often start being concerned about the development of their child when they notice delays in the development of speech, and a delay or lack of speech is one of the defining criteria in autism. Yet, linguistic functioning is highly variable among people with this disorder. At one end of the autism spectrum there are children whose verbal abilities are within the normal range of functioning, and at the other there are some who never start to speak. In those with sufficient language and cognitive abilities, social communicative abilities remain impaired. Language tends to be used one-sidedly, nonreciprocally, and instrumentally rather than for social purposes. When examined systematically, semantic, syntactic, and pragmatic deficits can be seen in most people with autism. A smaller number are known to have deficits in articulation.

Autism is a neurodevelopmental disorder with a complex, probably polygenic origin (Fisch, 2008), and the development of the brain is a dynamic process that is constantly evolving and changing in concert with the environment. It is therefore not surprising that research on the neural correlates of language deficits in autism has produced many different results that are hard to cover under one umbrella-model. However, a growing number of findings converge to the idea that early sensory impairments and atypical neural connectivity are likely to play a part in abnormal language acquisition in autism. That is, abnormal processing of low-level linguistic information points to perceptual difficulties, and impairments of information processing may lead to an abnormal developmental trajectory of language in autism. Abnormal high-level

Table 10–1.

Phenotype, brain structure, brain function, and genetics in autism and specific language impairment

	Autism Spectrum Disorders	Specific Language Impairment
Phenotype	• School age: Deficits in higher order language skills (comprehension and production of discourse and pragmatic language skills) are more severe than deficits in and syntax and semantics. Phonology is least affected. • Preschool age: All levels of language, both in expressive and receptive language. In the majority of children the phonologic and most of the syntactic impairments resolve over time. • Note: Some authors report subtypes with affected syntax-phonology and affected semantics pragmatics. • Echolalic and idiosyncratic utterances and pronoun reversal are common. • Language function is highly variable. Some individuals have superior language skills, sometimes present at a very young age.	• School age: Deficits in phonology and syntax are more severe than deficits in higher order lexical or pragmatic language skills, both in expressive and receptive language. • Preschool age: All levels of language, both in expressive and receptive language. The phonologic and syntactic typically do not resolve. • Note: Different subtypes are reported: Expressive phonological impairment, mixed receptive phonologic and syntactic impairment, lexical syntactic impairment, semantic-pragmatic impairment. • Echolalic and idiosyncratic utterances and pronoun reversal are rare.
Brain structure	• Larger head size in majority of children. • Reduced left-right hemispheric asymmetry.	• Larger head size in fraction of children. • Reduced left-right hemispheric asymmetry.
Brain function	• Increased activation of Wernicke's area and decreased activation of Broca's area. • Reduced left-right hemispheric asymmetry. • Task indifferent pattern of activation during language tasks (possibly reflecting less flexible network regrouping).	• Decreased activation of both Wernicke's and Broca's area. (not replicated, as a sufficient number of studies on this subject is lacking)
Genetics	• Linkage to 13q21 is involved in (language impairments in) autism. • Linkage to 7q is related to autism, but FOXP2 on 7q31 was found to be unrelated to autism (despite previous reports). • CNTNAP2 on 7q35 is associated with autism and is thought to be involved in nerve cell communication.	• 13q21 involved in literacy impairment but not in SLI. • The FOXP2 gene on 7q31 is related to a language disorder with orofacial dyspraxia, but it is not related to common forms of SLI. • CNTNAP2 is associated with SLI.

linguistic processing of the frontal and temporal language association cortices suggests that neural subsystems may be more self-reliant and less connected. In addition to these processes, the development of the brain in autism also relies on the environment that children with autism create for themselves. The double handicap of linguistic and pragmatic-social impairments prevents individuals with autism to fall back on adequate compensation strategies. Future interventions and investigations will need to carefully consider how the biological, environmental, and developmental features of language in autism are intertwined, and perhaps differently so for different individuals.

Challenges and Future Directions

• Future research should attempt to increase our understanding of the language problems in autism at various levels. Issues that ask for further exploration are:

○ the context-dependency of semantic, syntactic, and pragmatic language skills in autism, and the influence of implicit versus explicit learning processes to extract meaningful information from ongoing verbal discourse and communication.

○ It is unclear how the emotional context impacts linguistic understanding and production of subjects with autism. So far, research in emotion understanding and responding in autism has been focused almost exclusively on processing of visual stimuli, such as facial expressions of emotions. Much psycholinguistic research has been done on processing emotion words. An important finding is that valence and arousal of emotion words are processed separately by different brain areas. The amygdala, dorsomedial prefrontal cortex (PFC), and ventromedial PFC have been found to be associated with the arousal value of stimuli (Lewis et al., 2007; Kensinger et al., 2006), while valence is correlated with differential activity in the orbitofrontal cortex (Lewis et al., 2006) and the lateral regions

of prefrontal cortex (Kensinger et al.2006), although some studies have found amygdala response to valence as well (Anders et al., 2008). These two separate strings of research, i.e., research in emotion understanding and research in language abnormalities, should be brought more closely together.

- Another challenge is to integrate research in autism with that in SLI. This would include not only aggregating molecular-genetic data of samples with autism and SLI and testing for shared genetic risk factors, but also developing standardized neural system approaches to produce structural and functional maps of key language functions. For example, activations to the inferior frontal cortical areas in speaker identity paradigms (Groen et al., 2009) and functional connectivity between Broca and Wernicke's language areas may serve as intermediate phenotypes to define more homogeneous samples for molecular genetic studies. This will all converge in significant advances in our understanding of the molecular base of autism and the neural pathways to language impairments as one of the key symptom domains of autism.

Repetitive Behaviors in Individuals with Autism Spectrum Disorders

▦ Points of Interest

- A wide variety of discrete types of repetitive behaviors occurs in persons with autism spectrum disorders, including stereotyped movements, rituals and elaborate routines, insistence on sameness, and circumscribed interests, preoccupations, and attachments.
- Repetitive behaviors can be among the earliest recognized signs of autism in infants who go on to receive an ASD diagnosis and they tend to persist into adulthood in individuals with ASD.
- Repetitive behaviors can be associated with significant functional impairments; in at least a subset of cases repetitive behaviors and interests can significantly interfere with learning and socialization, and can be associated with mood and behavior problems that drive the need for intervention.

Repetitive behavior is one of three core features of autism (ICD-10, World Health Organization, 1990; DSM-IV, American Psychiatric Association, 1994). Repetitive behaviors frequently dominate the daily activity of children with autism, can significantly interfere with opportunities to develop functional behaviors, and are frequently the target of intervention and treatment. This is a rapidly growing area of research in autism, and much is now known about the clinical phenomenology, developmental course, neurobiology, and treatment of repetitive behaviors. Further, gaps in the current knowledge base on repetitive behaviors represent critical new areas for research in the pathogenesis and treatment of autism.

A central theme in the recent research findings in repetitive behavior is that while all cases by definition have expressed repetitive behaviors, several distinct subtypes of repetitive behavior appear to exist across persons with autism spectrum disorders. These subtypes may represent a viable strategy for uncovering at least some of the multiple pathogenic factors responsible for the clear heterogeneity of phenotypic expression in autism. In addition, isolation and understanding of specific discrete subtypes may help direct the development of novel forms of intervention.

▦ Phenomenology

Varieties of Repetitive Behavior in Autism

The term "repetitive behavior" is an umbrella term used to refer to a broad class of actions linked by repetition, rigidity, and inappropriateness. In the *Diagnostic and Statistical Manual of Mental Disorders–4th Edition* (DSM-IV; APA, 1994), criteria for repetitive behavior can be met by a person exhibiting at least one of the following: "(a) encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus; (b) apparently inflexible adherence to specific, nonfunctional routines or rituals; (c) stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting or complex whole-body movements); or (d) persistent preoccupation with parts of objects." What becomes clear on examination of these criteria is that they are very broad, ranging from repetitive movements of the body to more cognitively mediated symptoms such as intense interests or hobbies. Although no single type of repetitive behavior may be specific to autism, previous studies have found that it is a pattern of multiple types of repetitive behavior that can best distinguish autism from other disorders (Bodfish et al., 2000; Bartak & Rutter, 1976).

Stereotyped Movements

Repetitive motor movements (e.g., hand flapping, body rocking, arm waving, hand and finger movements, repetitive postures) are commonly observed in normally developing

infants and young children (e.g., Evans et al., 1997; Thelen, 1979), and are also commonly observed in other developmental and psychiatric conditions such as Tourette's syndrome, Fragile X syndrome, Rett syndrome, Parkinson's disease, and schizophrenia (Frith & Done, 1990; Turner, 1996). Although few studies have sought to compare the nature of repetitive motor behavior across clinical groups, there is evidence to suggest that there are important differences in the display of at least some forms of this behavior in autistic and nonautistic populations. In persons with mental retardation, the occurrence of stereotyped movements appears to be related to mental age (Smith & Van Houten, 1996). In contrast, individuals with autism engage in more frequent, severe, and longer bouts of stereotyped movements compared to age and ability matched controls (Freeman et al., 1981; Hermelin & O'Connor, 1963; Lord, 1995; Lord & Pickles, 1996; Szatmari, Bartolucci, & Bremner, 1989). Szatmari et al. (1989) showed that motor stereotypies were significantly more common in high-functioning adults with autism than in age and ability matched control subjects referred to outpatient psychiatry services for problems with social relationships (86% vs. 14%). Lord (1995), in her 12-month follow-up study of 2-year-olds referred for possible autism, reported that those who met diagnostic criteria for autism at age 3 showed significantly higher rates of stereotyped movements at ages 2 and 3 than those children failing to meet diagnostic criteria, despite the fact there was no difference between the groups in age of ability.

Repetitive Self-Injurious Behavior

There is evidence that certain forms of lower-order repetitive behavior such as repetitive self-injurious behavior (e.g., head hitting or banging, hand or arm biting) are not unique to autism. The self-injurious behavior described in autism is similar in prevalence to those described for individuals with non-specific mental retardation (Freeman et al., 1981; McKenna, Thornton, & Turner, 1998). Furthermore, in autism, as in mental retardation, self-injury is negatively associated with IQ and positively correlated with severity of illness (Bartak & Rutter, 1976; Campbell et al., 1990; Freeman et al., 1981). Thus, it appears that repetitive self-injurious behavior in persons with autism is related to more nonspecific factors such as level of intellectual ability, or other associated developmental impairments.

Rituals and Routines

It can be difficult to distinguish the rigid and invariant routines that are described in autism (e.g., ordering, arranging, touching/tapping, hoarding), and the routines and rituals that are commonplace in individuals with obsessive compulsive disorder (e.g., de Silva, 1994), mental retardation (Lewis, Bodfish, Powell, & Golden, 1994), Tourette's syndrome (Swedo, Rapoport, Leonard, Lenane, & Cheslow, 1989), and many normal individuals. There has been little systematic

comparison of the routines and rituals of autistic and nonautistic individuals. However, the limited evidence available indicates that these behaviors are significantly more prevalent and marked in individuals with autism relative to age and ability matched control subjects (Bartak & Rutter, 1976; Lord & Pickles, 1996). The extreme distress and catastrophic reaction shown by many autistic people in response to changes in routine is rarely described in nonautistic individuals. Similarly, rituals in autism are likely to be highly elaborate and extend to many areas of daily living (e.g., routines around self-care and dressing, eating routines, travel routines), whereas rituals in nonautistic individuals are largely restricted to personal activity (Turner, 1996). In support of these differences, Wing and Gould (1979) reported that the presence of elaborate routines differentiated those children and adolescents with a history of autism from those without (94% vs. 2%). To date, two studies have directly compared repetitive behavior presentation in autism and OCD (McDougle et al., 1995; Zandt, Prior, & Kyrios, 2006). Both studies found evidence for significant differences in repetitive behavior phenomenology; however, both focused primarily on compulsive/ritualistic kinds of repetitive behavior and consequently neither included a specific examination of the types of discrete repetitive behaviors frequently seen in autism (e.g., stereotyped movements, insistence on sameness, circumscribed interests).

Sameness and Resistance to Change

Although "insistence on sameness" is often considered to be specific to autism, only one study has explored the relative frequency of this class of behavior. Szatmari et al. (1989) reported such behavior to be significantly more common in high-functioning individuals with autism and Asperger's syndrome than in socially odd psychiatric control subjects, although specific prevalence rates were not given. The results of a study by Evans et al. (1997) indicate that this type of behavior is also characteristic of normally developing children between 2 and 4 years of age.

Interests, Preoccupations, and Attachments

Circumscribed interests in autism were originally described by Leo Kanner in his seminal paper in 1943 (Kanner, 1943). One case, Alfred L., was described in the following way:

> He has gradually shown a marked tendency toward developing one special interest which will completely dominate his day's activities. He talks of little else while the interest exists, he frets when he is not able to indulge in it (by seeing it, coming in contact with it, drawing pictures of it), and it is difficult to get his attention because of his preoccupation.

Circumscribed interests (also known as restricted behavior) range from preoccupations with highly unusual aspects of the environment (such as the serial numbers of electrical

appliances) to intense and all-absorbing interests in more common hobbies (such as trains or computers). Szatmari et al. (1989) reported that 86% of a normally intelligent sample of individuals with autism had circumscribed interests in comparison to 37% of individuals diagnosed with Asperger's syndrome and 9% of outpatient control subjects. In contrast, Kerbeshian, Burd, and Fisher (1990) noted rates of 31% for high-functioning individuals with autism and 92% for individuals with Asperger's syndrome. It is sometimes assumed that circumscribed interests are more common in high-functioning individuals because they demand a higher level of ability. Although it is true that certain sophisticated circumscribed interests may be beyond the ability of some autistic individuals, it is likely for even severely disabled individuals with autism to demonstrate insistence on sameness or show very restricted patterns of interest and activity. The only study to compare levels of repetitive behavior in high and low ability individuals with autism reported that insistence on sameness was more commonly observed in mentally retarded, relative to normally intelligent, individuals with autism (82% vs. 42%), and both groups showed similar levels of circumscribed interests (71% vs. 84%) (Bartak & Rutter, 1976). DeLoache, Simcock, and Macari (2007) examined circumscribed interests in typically developing children and found that "extremely intense interests" (e.g., interest in tea sets, interest in brushes, interest in pouring liquids) occurred in 29% of their sample of 1 to 6 year olds. However, no clinical comparison group was included, and no screening or assessment of potential autism features/diagnoses was reported. Thus, while it is clear that focused interests and even perhaps unusual or circumscribed interests can occur in typically developing children, it is not clear if these persist in the same way that they do in autism or if they are associated with the same degree of functional impairment as appears to be the case in at least a subset of children and adults with autism.

While circumscribed interests (CI) per se are not indicative of autism, the results of previous studies of such interests in ASD provide information about the ways that interests in autism differ from interests seen in the course of typical development. Baron-Cohen and Wheelwright (1999) reported that persons with ASD were more likely to have interests that could be characterized within the knowledge domain of "folk physics," which involved knowledge about mechanical aspects of the world, as opposed to the domain of "folk psychology," which involves knowledge about social aspects of the world. Consistent with this finding, South et al. (2005) reported some common forms of circumscribed interests that were manifested by persons with ASD including an interest in vehicles, electronics, dinosaurs, particular animals, schedules, or numbers (South et al., 2005). Sasson et al. (2008) reported that images representing the types of objects commonly involved in circumscribed interests elicited a unique pattern of visual attention in children with ASD that was characterized by a more perseverative and repetitive attentional style relative to noncircumscribed interest images. Further, for children with ASD but not typically developing children the presence of CI images reduced overall visual exploration and especially exploration of social images. This latter finding suggests one way in which circumscribed interests could be associated with functional impairment in ASD: the presence of strong *nonsocial* interests could potentially diminish the types of social experiences that are important for experience-dependent brain and behavioral development.

Subtypes of Repetitive Behavior in Autism

As commonly conceptualized in autism, repetitive behaviors are assumed to represent a unitary domain of behavioral expression (e.g., DSM IV category 3 criteria for autism; ADI-R and ADOS repetitive behavior subdomain). However, there is growing evidence that there is considerable structure within the overall domain of repetitive behavior.

Several research groups have taken the concept of repetitive behavior variety an important step further by exploring whether the various discrete forms of repetitive behavior can be reliably and validly grouped into discrete subtypes. More than a psychometric exercise, a subtyping approach may have heuristic value in genetic, neurobiologic, and treatment response studies. For example, neuroimaging studies of OCD have demonstrated that distinct OC symptom subtypes are associated with dysregulation of separate but partially overlapping neural systems (Mataix-Cols, Rosario-Campos, & Leckman, 2005). To date, several studies have examined subtyping of repetitive behaviors (Cuccaro et al., 2003; Shao et al., 2003; Szatmari et al., 2006; Hus et al., 2007). These studies have typically identified two factors: a "lower-order" category called "Repetitive Sensory and Motor Behaviors" (RSMB), and a "higher-order" category labeled "Insistence on Sameness" (IS). Based on the findings of these studies, the 2-factor (lower-order, higher-order) has become the assumed model for the structure of repetitive behaviors. However, it is important to recognize that other subtyping studies of repetitive behaviors in autism have yielded more than 2 factors (Lam & Aman, 2007). In a study by Honey et al. (2006) of 2–4 year old children with autism, a third factor that included circumscribed interests was isolated, suggesting that circumscribed interest may be an independent subtype of repetitive behavior. In addition, closer examination of the items excluded in the earlier 2-factor studies suggests that there may be more structure present. In particular, in the solutions provided by Cuccaro et al. (2003) and Szatmari et al. (2006), the ADI-R items "Unusual Preoccupations," "Unusual Attachments," and "Circumscribed Interests" do not load on either factor and were therefore excluded. These types of repetitive behavior may be of particular interest in autism, because unlike motor stereotypies and compulsions (which are found in other disorders such as OCD, Tourette's syndrome, and mental retardation), these behaviors may be particularly characteristic of autistic disorder. In addition, the 2-factor solutions have accounted for a small amount of variance in each study (between 32 and 36%), suggesting the presence of other factors.

Lam, Bodfish, and Piven (2008) completed a large scale (n = 316) study of the structure of repetitive behaviors in autism in an attempt to systematically extend previous 2-factor studies by specifically including analysis of circumscribed interest items. They found evidence for a distinct interest/pre-occupation/attachment factor and were able to account for significantly more variance in phenotypic expression than previous 2-factor models (Lam, Bodfish, & Piven, 2008). Also, 88% of the sample exhibited circumscribed interests as defined by this third factor, and, in contrast to the RSMB and the IS factors, only the circumscribed interest factor was unrelated to either IQ or severity of social-communication symptoms. These findings suggest that circumscribed interests are prevalent in autism, and their independence from co-occurring autism features indicates that circumscribed interests may be associated with unique pathogenic factors relative to the other symptoms of autism.

Factors That Moderate the Type and Severity of Expressed Repetitive Behaviors

Existing research findings suggest that several factors can influence the severity of repetitive behavior expression. Chronological age is likely to be one such moderating factor for the expression and severity of repetitive behaviors. It is now clear that both lower- and higher-order forms of repetitive behavior are present in many cases of autism by 2 to 3 years of age (Bishop, Richler, & Lord, 2006; Mooney, Gray, & Tonge, 2006; Militerni et al., 2002; Honey et al., 2006) and manifest with sufficient severity to warrant intervention (Bishop et al., 2006). Further, lifespan studies have indicated that repetitive behavior symptoms and associated impairment (behavioral rigidity) persists into adolescence and adulthood in most cases (Rumsey, Rappoport, & Sceery, 1985; Piven, Harper, Palmer, & Arndt, 1996). In the largest study of moderator variables to date (Bishop, Richler, & Lord, 2006; N = 830), nonverbal IQ was found to be more related to the presence of repetitive behavior in older (6–11 years) than younger (2–5 years) children with autism. Family factors, including parent/family accommodation of repetitive behaviors can also moderate the expression of repetitive behaviors (Lenane et al., 1990; Reaven & Hepburn, 2003; Boyd, Woodard, Storch, & Bodfish, 2007). Parents and siblings often become involved in a child's repetitive behaviors in efforts to reduce associated impairment such as the behavior problems or "meltdowns" that can occur when rituals, sameness behaviors, or circumscribed interests are not accommodated. Although such efforts are often well intentioned, they typically result in greater impairment and symptom severity by virtue of impacting family life and reinforcing symptom engagement. Thus, indirectly, mood and behavior problems (e.g., irritability, agitation, aggression, self-injury, screaming, disruptive behavior) may also moderate the expression of repetitive behaviors in children with autism (Bodfish et al., 2000; Gabriels et al., 2005). There is evidence that unique profiles of repetitive behaviors occur in specific genetic disorders associated with

autism such as Fragile X syndrome, Williams syndrome, and Angelman syndrome (Moss, Oliver, Arron, Burbridge, & Berg, 2009), indicating that specific genetic factors in persons with autism may moderate the expression of specific subtypes of repetitive behavior. These various factors (e.g., age, cognitive ability, family factors, genetic factors) most likely interact in ways that are poorly understood at present to influence the specific pattern of repetitive behaviors seen clinically in persons with autism.

Developmental Course

The findings of early research in autism suggested that repetitive behaviors may not be clinically significant primarily because they did not appear to be early features of the disorder and they were presumed to be related to comorbid mental retardation and, thus, not an autism-specific core feature. Recent research findings call these early assumptions into question and more clearly establish the clinical significance of repetitive behaviors in autism. Recent developmental studies of autism have now shown that repetitive behaviors are among the earliest signs of the disorder during infancy (Landa, Holman, & Garrett-Mayer, 2007; Ozonoff et al., 2008; Watt, Wetherby, Barber, & Morgan, 2008), and the degree of severity of early repetitive behaviors (RBs) uniquely predicts the overall severity of autism in adolescence (Lord et al., 2006). Recent research has demonstrated that RBs can be identified as early as 12–18 months in infants who go on to develop autism (Morgan, Wetherby, & Barber, 2008; Ozonoff et al., 2008; Watt et al., 2008).

Retrospective developmental studies have found that there is some improvement in repetitive behavior severity with age but that age-related improvements are less pronounced on average than that seen for other core features of autism (Piven et al., 1996; Fecteau et al., 2003). In the longitudinal cohort study described by Rutter et al. (1967), some improvements in repetitive behavior severity were noted; however, all subjects with RBs in childhood continued to report difficulties in this domain 10 years later, and there was a tendency for increase in the frequency and complexity of these behaviors with age. Approximately 90% of adolescents and adults with autism report difficulties with repetitive behaviors (Seltzer et al., 2003; Howlin et al., 2004).

In support of the concept that repetitive behaviors in autism may not be a unitary phenomenon, there appear to be different developmental trajectories for discrete subtypes of repetitive behavior. For example, in a large scale (N = 320) study of children and adults with autism spectrum disorders (3–48 years of age) stereotyped movements were less frequent among older individuals, self-injurious behaviors and compulsive behaviors were comparable across age groups, and ritualistic/sameness were found to be more frequent among older individuals (Lam & Aman, 2007). In a comparison of younger and older children with ASD, younger children were more likely to exhibit motor and sensory repetitive behaviors, and older children were more likely to exhibit more complex

repetitive behaviors (Militerni, Bravaccio, Falco, Fico, & Palermo, 2002). In another study of children with ASD who ranged in age from toddlers to 12-year-olds, most RBs, including self-injury, desire for sameness, restricted interests, and compulsions, were more frequent among the older than the younger children (Bishop, Richler, & Lord, 2006). However, when taking into account nonverbal IQ, the pattern of findings changed. Some repetitive behaviors did not show age-related patterns (such as restricted interests), whereas others (such as self-injury, desire for sameness, and compulsions) were less frequent among older children. Although there are discrepancies, there is some convergence in the findings relating to age and repetitive behaviors. A trend is observed of specific subtypes appearing to become less frequent with age (e.g., stereotyped movements), while other subtypes appear to increase in prevalence during middle and late childhood and often persist into adulthood (e.g., circumscribed interests). While the pattern of findings across studies is not strong enough to define the age-related pattern of this aspect of the behavioral phenotype of ASD, and there is a need to examine in more detail the age-related patterns across the lifespan, the results of these developmental studies do clearly support the concept that repetitive behaviors are a heterogeneous group of behaviors and that discrete subtypes likely exist.

Functional Significance

Disorders such as Tourette's syndrome and obsessive compulsive disorder (OCD) are characterized by repetitive behaviors, however the need to perform them is aversive and distressing. In part due to the communication deficits that are diagnostic of autism, it is not known whether repetitive behaviors in autism are aversive and distressing, or, whether repetitive behaviors represent an appetitive motivation to approach certain stimuli. Many functions have been hypothesized for repetitive behaviors in autism, including stress reduction, sensory stimulation, and reward (Lewis & Bodfish, 1998). For example the persistence of repetitive behaviors even in the face of aversive consequences has been taken by some as evidence of the rewarding nature of the behaviors. Several theorists have emphasized the apparently "self-stimulatory" nature of stereotyped movements and behaviors (Berkson & Davenport, 1962). This sensation/perception perspective has taken two theoretical forms. The perceptual reinforcement hypothesis (Lovaas et al., 1987) holds that repetitive behaviors are learned, operant self-stimulatory behavior for which the reinforcers are the perceptual stimuli automatically produced by the behavior. The sensorimotor integration hypothesis (Ornitz, 1971) holds that sensory deficits leave the individual reliant on kinesthetic (sensorimotor) feedback derived from the behavior. A functional analysis perspective (Iwata et al., 1982) emphasizes social consequences (e.g., social attention, escape from instruction/demands/interaction, tangible reinforcement), but also invokes "automatic" reinforcement which is similar to both the notion of sensory/perceptual reinforcement and also internal (biological) reward. Such internal factors could include

increases in arousal (Hutt & Hutt, 1970) or reductions in stress. The functional consequences and maintaining factors of RB are far from firmly established however.

Given the evidence in support of the existence of discrete subtypes of repetitive behavior in autism, it is plausible that distinct subtypes may be associated with distinct psychological/motivational factors and thus distinct underlying psychobiology. If this is true, then heterogeneity in the expression of these underlying factors may contribute to the marked heterogeneity in both clinical expression and treatment response seen in autism. OCD can be conceptualized as an avoidance phenomenon (compulsions serve to neutralize or avoid obsessive or fearful thoughts). Further, OCD is presumed to be ego-dystonic with affected persons actively wanting to *not* engage in either compulsions or obsessions. These functional features do not seem to apply as easily to all forms of repetitive behavior in autism. While comorbid autism and OCD (i.e., an OCD overlay on top of autism) has been reported in the literature (Cath et al., 2008; Storch et al., 2007) this is not the typical presentation of repetitive behaviors in autism. A larger question is how much of the repetitive behavior symptomatology in autism is mediated by underlying anxiety, as is the case in OCD. Often in the case of autism, behaviors like stereotyped movements (e.g., hand-flapping) seem to be motivationally neutral or affectively linked to excitement/pleasure as much as anxiety or fear (Schultz & Berkson, 1995). This also seems true for behaviors like circumscribed or restricted interests (e.g., intense interest in trains) in persons with autism (Sasson et al., 2008). In these situations the distress/anxiety appears to come as a *consequence* of not having access to the behavior or interest (Powell et al., 1996) much like the case of frustrative nonreward. Thus repetitive behaviors in autism may involve functional manifestations similar to OCD (e.g., avoidance phenomenon like compulsions, rituals, or insistence on sameness) as well as those dissimilar to OCD (e.g., approach phenomenon like preoccupations, attachments, and circumscribed interests) (Lam, Bodfish, & Piven, 2008). One potential overarching commonality however is that in both OCD and autism, repetitive behavior can be mediated by its reward properties—presumably negative reinforcement in the case of OCD and some forms of repetitive behaviors in autism, and presumably positive reinforcement in the case of other forms of repetitive behavior in autism. If so, then the anticipatory-reward nature of the circumscribed interest subtype of repetitive behavior in autism may distinguish autism from other psychiatric disorders characterized by repetitive behaviors (e.g., OCD or OC spectrum disorders) that involve purely anxiety-reduction.

Repetitive Behaviors and Cognitive or Attentional Style in Autism

Part of the functional significance of repetitive behaviors may relate to the way in which repetitive behaviors are associated with particular cognitive features in autism. Baron-Cohen (1989) proposed that repetitive behavior develops in autism to combat a specific cognitive impairment, and that this behavior

may develop as a coping strategy that allows the autistic individual to reduce the high level of anxiety resulting from a primary impairment in this ability to understand and infer the mental states of others. Similarly, Carruthers (1996) suggests that repetitive behavior functions to withdraw persons with autism from social contexts that are unpredictable and perhaps frightening. These cognitive accounts predict that levels of repetitive behavior will be highest when in novel and unpredictable social contexts. However, a number of studies have compared the frequency of repetitive behaviors during periods of social interaction and periods in which limited or no interpersonal demands are made, and have shown that rates of repetitive behavior are lowest during periods of social interaction and highest during periods devoid of interaction (Charlop, Schreibman, Mason, & Vesey, 1983; Clark & Rutter, 1981; Dadds, Schwartz, Adams, & Rose, 1988; Donnellan, Anderson & Mesaros 1984; Runco, Charlop, & Schreibman, 1986). In addition, studies that have examined the correlation of the severity of the repetitive behavior and social-communicative aspects of autism have found that these domains vary largely independent of one another (Bodfish et al., 2000; Happe, Ronald, & Plomin, 2006; Lam, Bodfish, & Piven, 2008) Thus, the model of repetitive behaviors occurring as a secondary consequence of core social-cognitive deficits in autism does not seem to be a viable model of repetitive behaviors in autism.

The executive dysfunction account of autism conceptualizes symptoms of restricted and repetitive behaviors to reflect the impaired ability to adapt flexibly to changing environmental contingencies (Russell, 1997; Turner, 1999). Executive functions refer to a range of abilities, including behavioral inhibition, planning, working memory, and mental flexibility (Lezak, 1995). These abilities require the integration of a variety of basic abilities (e.g., language and working memory) to achieve the higher-order processing of information, goal attainment, and appropriate emotional responses (Christ, Holt, White, & Green, 2007). Difficulties with cognitive flexibility are consistent with the clinical phenomenon of the repetitiveness and rigidity that characterizes autism: cognitive inflexibility is manifest as repetitive motor behaviors, perseverative responding, and difficulty with modulating ongoing cognitive and motor behavior (Lopez, Lincoln, Ozonoff, & Lai, 2005). Numerous studies have documented impaired executive function abilities in autism spectrum disorders (Ozonoff et al., 2004; Pennington & Ozonoff, 1996; Sergeant, Geurts, & Oosterlaan, 2002), and some have found that executive function deficits correlate with clinical ratings of repetitive behavior severity (Lopez, Lincoln, Ozonoff, & Lai, 2005). However, clearly not all studies of executive functioning indicate deficits in autism (e.g., Minshew, Goldstein, Muenz, & Payton, 1992). These seemingly contradictory results may reflect the fact that executive function is not a unitary construct, but may be subdivided into more elemental components (see Kenworthy, Black, Wallace, Ahluvalia, Wagner, & Sirian, 2005, for a review). Conceptually, this may map onto the notion of repetitive behavior subtypes such that specific executive functions may map onto specific types of repetitive behavior.

In line with the notion of separable executive subprocesses, Turner (1997) proposed two distinct and dissociable hypotheses: (1) an impaired capacity to regulate behavior via the inhibition of ongoing but inappropriate behavior may lead to repetition as the individual, unable to control attention and action in the usual manner, becomes "locked into" one line of thought or behavior; and (2) an inability spontaneously to generate novel behavior without prompting may lead to a lack of variety in responding, manifest as the repeated display of a restricted set of behaviors. In support of this model, performance on tasks designed to tap each of these key abilities has been shown to be related to the display of specific classes of repetitive behavior (Turner, 1996, 1997). However, results in this area are not entirely consistent. Barnard and colleagues (2008) examined word and design fluency and found no differences in the autism group relative to learning disabled controls. Additionally, phonological fluency has been found to be both intact (Minshew, Goldstein, & Siegel, 1997; Kleinhans, Akshoomoff, & Delis, 2005) and impaired (Rumsey & Hamburger, 1988, 1990) in high-functioning autism relative to both adult controls and adults with severe dyslexia. Further, two studies that attempted to replicate the association between repetitive behavior and generativity both failed to find such a relationship and instead both found generative ability to be correlated with severity of communication impairment in autism (Bishop & Norbury, 2005; Dichter et al., 2009).

Frith and Happe (1994) have suggested that the expression of repetitive behavior may be explained by the notion that individuals with autism do not show the drive for "central coherence" that characterizes normal information processing. The cognitive style of individuals with autism is characterized by preferential processing of local rather than global features of the environment and this may lead to a focus on seemingly insignificant details. This theory is particularly intriguing in light of certain subtypes of repetitive behavior such as insistence on sameness and circumscribed interests. To date, evidence in support of weak central coherence in autism has been mixed, and significant associations with specific forms of repetitive behavior have not been examined.

Atypical attentional processing has also been posited to be a mechanism associated with both downstream cognitive and behavioral deficits in autism (Burack, 1994; Casey et al., 1993; Courchesne et al., 1994; Dawson et al., 1998; Sasson et al., 2008; Wainwright-Sharp & Bryson, 1993). Perseverative attention, or an inability to disengage could also account for variance within the rigid and repetitive behaviors domain associated with the autism phenotype, especially higher order repetitive behaviors (Lewis & Bodfish, 1998; Turner, 1999). Recent evidence has linked circumscribed patterns of attentional orienting to specific aspects of clinical behavior in children and adolescents with autism (Sasson et al., 2008). Of particular relevance, significant correlations between perseverative attention (average duration of fixation during a passive viewing visual exploration task) and composite scores

from the Repetitive Behavior Scales-Revised (RBS-R) in a sample of children and adolescents with autism. Circumscribed attentional patterns also have been shown to differentiate 12- to 24-month-olds who go on to receive a diagnosis of autism, reflected through the repetitive and stereotyped manipulation of objects (Morgan et al., 2008; Ozonoff et al., 2008; Watt et al., 2008).

Functional Impairment Associated with Repetitive Behaviors

Repetitive behaviors can cause significant impairment in individuals with autism and their families. In more severe cases these behaviors may consume the majority of waking hours of an individual and interfere with daily family activities. Moreover, children and adults with autism tend to become agitated, disruptive, or even aggressive when repetitive behaviors are interrupted. The presence of circumscribed interests, preoccupations, or unusual attachments may be particularly clinically significant because the presence of strong unusual interests or preoccupations may diminish the saliency of and response to more natural or typical rewards and sources of information and experience. As a result, experience-dependent learning and development may be constrained in a more direct way by persistent circumscribed interests as compared to other forms of repetitive behavior (e.g., stereotyped movements) which may not alter the saliency or reward value of ambient environmental events.

Despite clear indicators of functional impairment associated with repetitive behaviors, parents and clinicians sometimes debate whether or not to make repetitive behaviors the target of intervention. Some parents are struck by how "proficient" their child is in certain areas (e.g., memorizing facts, reciting movie scripts) and how this stands in contrast with all the other things their child is not able to do (e.g., socialize with peers, communicate clearly, adapt to preschool, etc.). In these situations parents sometimes express a fear to tread on these "islands of ability" (Mercier, Mottron, & Belleville, 2000). Another common scenario involves parents who have seen the "meltdowns" and negative side effects on their child's behavior that are related to preventing these repetitive behaviors and interests (Gabriel et al., 2005; Mercier et al., 2000). From a clinical perspective it is apparent that in at least a subset of cases repetitive behaviors and interests can significantly interfere with learning and socialization, and can become a motivating factor underneath the development of mood and behavior problems.

Phenomenologic and behavioral studies of autism have shown that repetitive behaviors persist into adulthood and can be the "residual symptom" of autism once social-communicative deficits improve (Shattuck et al., 2007; Piven et al., 1996). Thus, treatment directed at reducing the severity of repetitive behaviors carries the potential to increase the child's overall degree of flexibility and adaptability and thereby improve the overall trajectory of adaptive behavior development and functioning. In support of this clinical perspective, recent large-scale studies of family and parent functioning in the context of a child with autism have reported that repetitive and related problem behaviors are associated with elevated parent stress (Orsmond, Lin, & Seltzer, 2007), engender negative parenting styles (Smith et al., 2007; Orsmond & Seltzer, 2007; Lounds et al., 2007), and are among the most difficult aspects of autism that parents must deal with on a daily basis (South et al., 2005; Mercier et al., 2000). Thus repetitive behaviors and interests have the potential for interfering with experience-dependent brain and behavioral development and family well-being, and treatment can be seen as necessary when viewed as an approach to expand the child's behavioral repertoire rather than simply thwarting or punishing the child's repetitive behaviors and interests.

Pathogenesis

Deficits and Disorders Associated with Basal Ganglia Pathology

There is a confluence of evidence that implicates altered basal ganglia function in the mediation of repetitive behavior disorders. Historically, examinations of the functions of the basal ganglia have been limited to its role in motor control and movement disorders. Currently, the functions of the basal ganglia are grouped into circuits that include motor, cognitive, and behavioral/personality divisions (Visser, Bar, & Jinnah, 2000; Alexander, Delong, & Strick, 1986). Of interest is the fact that animal lesion studies and human neuropsychological studies of neurosurgery patients with well-defined lesions have demonstrated that abnormality of these basal ganglia circuits produces both the types of restricted repetitive behaviors seen in autism and the types of cognitive flexibility deficits presumed to be related to the expression of repetitive behaviors (Cummings, 1993; Masterman & Cummings, 1997).

A large number of studies using chemical lesioning and site-specific drug administration support the importance of basal ganglia structures in the mediation of drug-induced stereotypies (Lewis et al., 1994). In addition, there is growing evidence that OCD is associated with perturbations in basal ganglia function. For example, there is a significant degree of comorbid OCD in a variety of diseases of the basal ganglia, including Sydenham's Chorea, postencephalitic Parkinson's, toxic lesions of the striatum, and Tourette's syndrome (Rapoport, 1988). The ritualistic-repetitive behaviors that are a defining feature of autism are also observed in (OCD) and Tourette's syndrome (TS) (APA, 1994). Individuals with autism and OCD both exhibit compulsive rituals and rigidity while individuals with autism and TS share repetitive stereotyped motor behaviors (Eapen et al., 1997). Further, abnormalities in the basal ganglia have been implicated in all three of these disorders on the basis of multiple converging findings from structural and functional neuroimaging studies

(Rosenberg et al., 1998; Peterson & Kline, 1997; Peterson et al., 1993; Swedo et al., 1989; Scarone et al., 1992).

MRI Studies of Basal Ganglia in Autism

To date, seven studies have used MRI to investigate the neurobiology of repetitive behavior in autism. Two of these have reported enlarged basal ganglia volumes proportional to an increase in total brain volume (Herbert et al., 2003; study 1 in Sears et al., 1999), and five reported a disproportional increase in caudate nucleus volume (study 2 in Sears et al., 1999; Hollander et al., 2005; Langen et al., 2007; Rojas et al., 2006; Langen et al., 2009). McAlonan et al. (2002) reported no differences in caudate size between autism and typical control groups but did report that autism subjects had significantly decreased gray matter density in striatal areas. In several of these studies a correlation between repetitive behavior severity and caudate size was found (Langen et al., 2007; Rojas et al., 2006; Langen et al., 2009), however in some the magnitude of the correlation differed as a function of discrete type of RB (Sears et al., 1999; Hollander et al., 2005).

fMRI Studies of Fronto-Striatal Circuitry in Autism

The "frontostriatal hypothesis" of autism implicates the basal ganglia and its afferents to the frontal cortex (Robbins, 1997) and is supported by both neuropsychological and animal studies (Visser, Bar, & Jinnah, 2000; Masterman & Cummings, 1997; Lewis, Gluck, Beauchamp, Keresztury, & Mailman, 1990; Robbins, Mittleman, O'Brien, & Winn, 1990; Insel, 1992). There is a host of neuroimaging evidence indicating anomalous activation of prefrontal brain areas in individuals with autism during so-called cognitive control or executive tasks. The specific prefrontal regions affected and the direction of changes are heterogeneous across studies and related to the specific cognitive tasks utilized, supporting the widely held view that executive functions include a number of distinct cognitive processes. Hyperactivation in the left middle and inferior frontal gyri and orbitofrontal cortex has been reported during a go/no-go (i.e., motor inhibition) task, whereas hyperactivation of the left insula was observed in the same participants during a spatial Stroop (i.e., interference inhibition) task (Schmitz et al., 2006). Hyperactivation in the right superior, middle and inferior prefrontal cortex and the left inferior parietal cortex has been reported during an auditory novelty detection task (Gomot et al., 2008). Rostral anterior cingulate cortex hyperactivation during an antisaccade that predicted the magnitude of repetitive behaviors was reported by Thakkar and colleagues (2008). Finally, hypoactivation bilaterally in middle frontal, right superior frontal, and left inferior frontal regions has been reported during a Tower of London (i.e., problem solving) task (Just, Cherkassky, Keller, Kana, & Minshew, 2007).

Shafritz et al. (2008) reported hypoactivation in the striatum, as well as in the middle and inferior frontal gyri and

anterior cingulate cortex (ACC) in autism during a standard visual target detection (i.e., oddball) task. Furthermore, the magnitude of ACC activation inversely correlated with repetitive behaviors in the autism sample. The anterior cingulate circuit is one of five parallel circuits that link the frontal lobes with subcortical structures. The anterior cingulate circuit projects to the ventral striatum, then to the ventral and rostrolateral globus pallidus and rostrodorsal substantia nigra, which, in turn, project to the medial dorsal nucleus of the thalamus, and then the circuit is completed via projections to the anterior cingulate (for a review, see Cummings, 1993). Injury to this circuit produces deficits on response inhibition tasks (Drewe, 1975), and other repetitive behavior disorders, such as Tourette's syndrome and obsessive compulsive disorder, are characterized by dysfunction within this circuit (Singer, Hahn, & Moran, 1991; Baxter, Phelps, Mazziotta, Guze, Schwartz, & Selin, 1987). To date, no fMRI studies have examined potential links between specific neurocognitive functions and discrete subtypes of repetitive behavior, and thus critical extensions of the neurobiologic study of specific types of repetitive behavior in autism remain to be explored.

Intervention

Behavioral and Psychosocial Intervention

An important distinction that can be made in the autism intervention literature is the differentiation of comprehensive treatment models (CTMs) from focused intervention practices (FIPs) (Odom, Boyd, Hall, & Hume, 2009). CTMs (e.g., Denver Model, LEAP, Lovaas Institute, TEACCH) are conceptually organized treatment packages to address a broad array of skills for children with autism. FIPs (e.g., prompting, reinforcement, PEC, visual supports, response interruption/redirection) are individual instructional practices that are used to address specific targeted skills or presenting symptoms. Seminal work by Odom, Rogers, and colleagues has involved the examination of both CTMs (Odom et al., 2009; Rogers & Vismara, 2008) and FIPs (Odom, Klingenberg, & Rogers, in press) in relation to accepted evidentiary criteria. As a result of this work, subsets of both CTMs and FIPs can be designated as "evidenced-based practices" for autism intervention. In this context, an important question is: what is the evidence base for CTMs and FIPs with respect to the treatment of repetitive behaviors in autism?

Although definitive evidence (e.g., multiple, independent, methodologically sound RCTs) for the efficacy of both CTMs and FIPs in autism is lacking, it is now clear that (1) specific evidenced-based practices for autism intervention can be identified, and (2) the development of young children with autism can be significantly improved by the delivery of these evidenced based CTMs and FIPs. While the bulk of this evidence for efficacy for specific CTMs and FIPs is in the area of specific targeted instruction in the areas of communication,

social skills, play, cognition, and independence, there is evidence that specific FIPs (e.g., behavioral teaching strategies such as prompting, differential reinforcement, interruption/redirection; functional analysis based strategies such as the Positive Behavior Supports approach) can effectively reduce the occurrence of some types of repetitive behavior and the types of problem behaviors that can be associated with repetitive behaviors in autism such as aggression, noncompliance, and self-injury (Odom, et al., in press; Horner, Carr, Strain, Todd, & Reed, 2002).

Two gaps do exist however in this literature on evidenced-based behavioral and psychosocial intervention practices for repetitive behaviors in autism. First, given that there are a variety of discrete types of repetitive behaviors, virtually all of the behavioral/psychosocial intervention research has focused on the lower-order forms of repetitive behavior (stereotyped movements, self-injury) and as a result there are no established evidenced-based practices for treating the quintessential autistic repetitive behaviors like rituals, insistence on sameness/difficulty with change, and intense preoccupations, attachments, and interests (Bodfish, 2004). Second, existing studies and their resultant intervention practices have focused entirely on the frequency of occurrence of repetitive behaviors as outcomes and as a result fail to address the underlying aspect of behavioral inflexibility that is so characteristic of autism. This trait is evident perhaps most clearly in the "higher-order" or cognitive aspects of repetitive behaviors such as sameness behaviors, and restricted interests, which as noted have not been the focus of intervention research to date.

Evidenced-based forms of treatment for other neuropsychiatric disorders characterized by repetitive behaviors may be worthy of consideration in the search for novel forms of intervention to treat the higher-order types of repetitive behaviors and overarching behavioral inflexibility in autism. There is a consensus that cognitive behavioral therapy (CBT) is an effective treatment for child, adolescent, and adult neuropsychiatric disorders characterized by prominent repetitive behavior symptoms such as OCD (Abramowitz et al., 2005; March et al., 1997; Piacentini et al., 2002; POTS, 2004), Tourette's syndrome (Piacentini & Chang, 2005; Carr & Chong, 2005), stereotyped movement disorder (Miller, Singer, Bridges, & Waranch, 2006; Teng, Woods, & Twohig, 2006), and a variety of other repetitive behavior disorders (Woods & Miltenberger, 2001; Deckersbasch, Wilhelm, Keuthen, Baer, & Jenike, 2002; Byrd, Richards, Hove, & Friman, 2002; Wilner, 2006; Wilner & Goodey, 2006). Although a variety of CBT protocols exist (e.g., Exposure Response-Prevention, Habit Reversal Therapy [HRT]), each consists of three similar components: exposure (placing the patient in situations that elicit repetitive behavior symptoms); response prevention (deterring the stereotyped, ritualistic, or compulsive behaviors); and cognitive or behavioral therapy (training the patient or his family to identify and redirect to an alternative/competing response). In two previously reported case studies of an ERP-based intervention for children with autism (Lehmkuhl, Storch, Bodfish, & Geffen, in press; Reaven & Hepburn, 2003),

the intervention was used to treat comorbid OCD symptoms (e.g., contamination thoughts or hand-washing rituals). To date, no studies have addressed the modification of ERP for the treatment of more autism-typical subtypes of repetitive behavior (e.g., insistence on sameness, complex rituals/routines, unusual and intense interests and preoccupations).

Medication Intervention

For persons with autism, symptoms of repetitive behaviors are common, and frequently form a source of significant interference in adapting to educational and social settings. These repetitive behaviors are commonly associated with emotional distress, tension, or dysphoria. While such behaviors can be responsive to behavioral treatments, in their severe forms of expression they are often difficult to manage by psychosocial efforts alone, and lead clinicians to attempt trials of treatment with medications.

Given the evidence linking dopamine functioning and the expression of repetitive behaviors, dopamine-blockade medications have been used for a long time clinically to target interfering repetitive behaviors and their associated mood and behavior problems. The older, high-potency neuroleptic haloperidol was studied extensively in autism in the 1970s and 1980s, and several controlled studies showed evidence of efficacy over placebo among young children treated with relatively low doses (e.g., 1–2 mg/day) (Campbell et al., 1978; Perry et al., 1989). However, the frequent emergence of harmful extrapyramidal symptoms (e.g., dyskinesia, akathisia) significantly limited the use of haloperidol. Older neuroleptics have now been replaced with atypical antipsychotics that combine dopamine and serotonin receptor antagonism. Considerable evidence now exists for the efficacy of these atypical neuroleptics in the treatment of mood and behavior problems in autism (Bryson, Rogers, & Fombonne, 2003), including a large multicenter randomized controlled trial comparing risperidone to placebo in 1010 children with autism aged 5–17 years presenting with clinically significant levels of irritability, tantrums, aggression, and self-injury (McCracken et al., 2002). In this trial, improvements were also found for stereotyped and ritualistic behaviors. While atypical neuroleptics are now established as viable interventions for at least some of the repetitive behaviors associated with autism and their clinical sequelae, they produce adverse effects such as tachycardia, sedation, and weight gain with metabolic symptoms in a significant minority of patients treated.

Because of the success of drug treatment for the management of repetitive behaviors in obsessive compulsive disorder (OCD), and evidence supporting abnormalities in the serotonin system in autism, there has been considerable interest in exploring the possible benefits of serotonergic-acting medications for the control of these repetitive movements associated with autism and other PDDs. Interest in serotonergic mechanisms in the manifestation of symptoms in autism has led to several prior clinical drug trials, with mixed results. Extant data suggest that adolescents and adults with autism may

experience improvements in repetitive behaviors, anxiety, and other related symptoms (Bryson, Rogers, & Fombonne, 2003; Lewis & Bodfish, 2000; McDougle et al., 1997). A large-scale, multisite double-blind randomized controlled trial (n = 149) of children with autism spectrum disorders (age range 5 to 17 years) with clinical levels of repetitive behaviors found that the serotonergic antidepressant citalopram did not differ from placebo in terms of efficacy for repetitive behaviors but did produce significantly more adverse events (e.g., activation, impulsiveness) (King et al., 2009). Thus, while serotonergic antidepressants may be effective in adults with autism, in spite of their widespread use in children with autism, the existing evidence base on the efficacy and safety of serotonergic medications for children with autism is poor.

Conclusion

Understanding autism requires an appreciation of the various types of repetitive behaviors displayed by children and adults with autism, understanding how this variety of repetitive behaviors can affect the course of the disorder, and understanding how the putative neurobiology of repetitive behaviors can be conceptualized in a way that can inform treatment decisions. Although repetitive behaviors in autism are frequently conceptualized as being a single, unitary symptom domain in autism, it is now clear that this aspect of the autism phenotype involves multiple, distinct subtypes of repetitive behavior. This conceptualization of repetitive behavior subtypes is consistent with the reigning notion that autism is not a unitary entity in itself and that efforts to disaggregate the autism phenotype are needed to help identify the multiple pathogenic factors involved in the etiology and development of the disorder. While our understanding of the phenomenology, course, and pathophysiology of repetitive behaviors in autism is growing, evidence on safe, effective, and practical forms of intervention to manage the sequelae of repetitive behaviors still lags far behind what we know about treating other aspects of autism. Closing this gap will involve translating newly emerging evidence on repetitive behavior subtypes and potential subtype-specific pathogenesis into efforts to develop focused forms of behavioral, developmental, and pharmacologic forms of intervention for specific repetitive behavior subtypes.

Challenges and Future Directions

- The emerging discrete subtypes of repetitive behavior seen in ASD offer promise for helping parse the considerable clinical heterogeneity of ASD. It will be important to validate these subtypes by determining if discrete subtypes are associated with differences in developmental course, pathogenesis, and response to established treatments.

- The functional significance of the different forms of repetitive behavior in autism has not been established and this is an important step for guiding treatment decisions in other neurodevelopmental disorders characterized by repetitive behaviors (e.g., OCD, TS). Comparative studies of repetitive behaviors across conditions (ASD, OCD, TS, etc.) are needed to begin to determine the functional significance of the variety of repetitive behaviors in ASD.

- There are currently no evidenced-based focused treatments for repetitive behaviors in ASD despite the fact that in at least a significant subset of cases repetitive behaviors are associated with considerable functional impairment. Research is overdue on both psychosocial and psychopharmacological treatment development focusing on clinically significant repetitive behaviors in ASD.

Developmental Features and Trajectories Associated with Autism Spectrum Disorders in Infants and Toddlers

Points of Interest

- Developmental trajectory in the first 2 years of life may vary across different children with ASD, and across different aspects of development.
- The earlier that a parent becomes concerned about a child with autism, the more likely that the child will have more severe autism symptoms later.
- By the time children with autism reach the second birthday, 80% of parents have become concerned about the child's development.
- Some children with autism exhibit developmental regression, usually affecting social and/or language development, in the first two years of life.
- Early diagnosis of autism is quite stable, especially when made by a professional with expertise in early diagnosis of this disorder.

Over the course of the last decade, there has been a major emphasis on earlier detection of autism spectrum disorders (ASD) by researchers (e.g., Landa, 2008; Zwaigenbaum et al., 2007), public health agencies (Centers for Disease Control and Prevention; 2008), professional health care organizations (American Academy of Pediatrics [AAP]; Johnson et al., 2007), advocacy groups (Autism Speaks, 2007), and clinical providers. The primary reason for this emphasis on earlier detection is to permit earlier access to intervention, which is expected to improve outcomes for children with ASD (Harris & Handleman, 2000; Howard, Sparkman, Cohen, Green, & Stanislaw, 2005; Sallows & Graupner, 2005). Another reason for earlier detection is parents' need for accurate information about their children. Parents of children with ASD often recognize disruptions in their child's behavior or development well before the diagnosis of ASD is given. Recent studies have indicated that parents wish to be informed as early as possible about the presence of ASD in their young child (Johnson, Myers, & the Council on

Children with Disabilities, 2007; Glascoe, 2005). All too often, parents are given inaccurate information about their child's well-being early in the child's life, which may lead to frustration and long-lasting mistrust of professionals. The reduction in familial stress (Goin & Meyers, 2004) and improved child outcomes that result from earlier detection of ASD lead to improved quality of life within families, and quite possibly reduced educational and long-term-care costs. Thus, efforts to detect ASD earlier in life have inestimable benefit for children with ASD, their families, and the community at large.

In the absence of a medical test for autism, research aimed at early detection of ASD has focused on behavioral signs of ASD. Both retrospective and prospective research approaches have been employed. Retrospective approaches involve obtaining past data about a child who has been diagnosed with ASD. Such data may come from medical records, interviewing or surveying parents about their memories of the child's earlier development (often many years in the past), and/or coding (e.g., counting frequency of occurrence and number of different types) behaviors exhibited by a child from home videos recorded earlier in the child's life. Prospective research may involve studies of community-based samples of children who received early developmental screening, studies of infants or toddlers who received assessment within a clinical setting, or studies of infants at high risk for ASD, as is the case for infants who have an older sibling with ASD (Landa, Holman, & Garrett-Mayer, 2007).

Both retrospective and prospective studies have provided insights into the earliest signs of ASD and about the process of early development in infants and toddlers who will later obtain a diagnosis of ASD. For example, studies employing both types of research strategies have indicated that development may be disrupted during the first year of life in some infants later diagnosed with ASD, and that the nature of the earliest signs of developmental disruption may be subtle or nonspecific to ASD. However, by the time of the first birthday, the social and communication characteristics that define autism in older

children are observable in some children with ASD and differentiate those children from age peers with non-ASD developmental delay and typical development. The specific nature of the symptoms and the timing of their onset may differ from child to child. Longitudinal prospective studies indicate that trajectory of development over the first years of life may differ across children having an ASD diagnosis. These issues will be addressed within this chapter as the literature is reviewed on developmental features, diagnosis, and developmental trajectory associated with ASD in the first 3 years of life.

Parents' Early Concerns About Children Diagnosed with ASD

Parents of children with ASD are often the first to observe the signs of developmental disruption. These concerns may arise early, even in the first year of a child's life (Howlin & Asgharian, 1999). When concerns do arise so early, the later diagnosis is more likely to be autism than Pervasive Developmental Disorder Not-Otherwise-Specified (Chawarska et al., 2007a). Similarly, when parents recognized developmental disruption prior to 18 months of age, the child with autism was more likely to have more severe autism symptoms and greater speech delay, lower level of developmental functioning, lower adaptive skills, and a specific neurological disorder (e.g., epilepsy, cerebral palsy, meningitis) (Baghdadli, Picot, Pascal, Pry, & Aussilloux, 2003).

Parents of children later diagnosed with ASD first become concerned about their child at mean age 18 months (Howlin & Asgharian, 1999), with increasing numbers of parents expressing concerns as children approach their second birthday (Wetherby, Bronson-Maddox, Peace, & Newton, 2008). Less than half of the parents of children with ASD younger than 15 months of age expressed concerns about communication development on a communication checklist (Wetherby, Bronson-Maddox, Peace, & Newton, 2008). By the time of the second birthday, 80% of parents of children later diagnosed with ASD recall having been concerned about their child's development (De Giacomo & Fombonne, 1998). Parents' concerns most often focus on speech and language delays (De Giacomo & Fombonne, 1998; Hess & Landa, in press), and less often, concerns involved social, play, sensory, motor (Charman et al., 2000; Hess & Landa, in press) or medical or regulatory problems related to sleep, eating, and attention (De Giacomo & Fombonne, 1998). Parent concerns, as elicited by a structured questionnaire, have not been found to distinguish infants and toddlers later diagnosed with ASD from those later diagnosed with other developmental delay (Wetherby et al., 2008). These concerns are typically reported to a professional when the child is between 18 and 24 months of age (Rogers & DiLalla, 1990; Young, Brewer, & Pattison, 2003). Yet a diagnosis of ASD occurs considerably later, usually not until 4 years of age. The age at first diagnosis tends to be even later for urban, low SES (socioeconomic status) children

(Fombonne, Simmons, Ford, Meltzer, & Goodman, 2001; Gray, Tonge & Brereton, 2006; Howlin & Asgharian, 1999; Mandell et al., 2002; Shattuck, Durkin, Maenner, Newschaffer, Mandell, Wiggins, et al., 2009; Wiggins, Baio, & Rice, 2006; Williams & Brayne, 2006).

What is Known about Signs of ASD in the First Year of Life?

Very little is known about ASD in the first year of life. Most information about developmental features of infants with ASD comes from retrospective studies. Prospective studies have provided only preliminary insights into the developmental features of infants later diagnosed with autism. This is because most studies have not yet followed these infants through the third birthday, the time when diagnosis becomes reliable (Ventola et al., 2006). Information about differences in infants (under 12 months of age) later diagnosed with ASD is reviewed below, with reference made to retrospective and prospective findings.

Attention

Evidence is accumulating that the attention system may be disrupted by 6–12 months of age in infants later diagnosed with ASD. In infants between the ages of 6 and 12 months, the literature describes two types of disruption in attention: difficulty with attention disengagement (Adrien et al., 1992; Maestro et al., 2002; Zwaigenbaum et al., 2005) and diminished attention to faces relative to objects (Baranek, 1999; Maestro et al., 2002; Osterling et al., 2002; Chawarska, Volkmar, & Klin, 2010; Pierce, Conant, Hazin, Stoner, & Desmond, 2011). The latter feature was noted to distinguish infants later diagnosed with ASD from those with non-ASD developmental delay as well as from those with typical development (Baranek, 1999; Maestro et al., 2002). The ability to direct attention to objects or to sustain the focus of attention on objects does not appear to be impaired in infants later diagnosed with ASD (Maestro et al., 2002).

Sensory and Motor Systems

Evidence for disruption in the sensory and motor systems in infants with ASD has emerged from retrospective and prospective studies. Sensory features may include hyposensitivity or hypersensitivity to sound and touch (Adrien et al., 1992; Baranek 1999) and excessive mouthing (Baranek, 1999; Maestro et al., 2002), which, in combination with other variables, distinguished infants with ASD from those with non-ASD developmental delay and those with typical development. Some of the motor abnormalities observed in this author's study of infant siblings of children with autism, such as head lag in older infants, may be related to an abnormality within the sensory system, including proprioception and feed-forward

systems (Flanagan & Landa, 2007). Motor system disruption may involve gross or fine motor delays (Flanagan & Landa, 2007; Ozonoff et al., 2008a), atypical movements (including tremulousness, posturing, or persistent repetition of an age-appropriate behavior such as raspberries; Flanagan & Landa, 2007; Sparling, 1991), or hypotonicity or rigidity of limbs (Flanagan & Landa, 2007; Sparling, 1991). Diminished range of facial expressions and abnormalities related to vocalization or babbling (Maestro et al., 2002) could also be related to disruption in the motor system. It should be noted that motor system abnormalities are not likely to be specific to ASD (Ozonoff et al., 2008a), but may be predictive of social and communication impairments, including autism (Flanagan & Landa, 2007).

Social and Communication Systems

The two most frequently reported aspects of developmental disruption involving the social and/or communication systems involve decreased attention to faces (in infants as young as 6 months of age) and diminished response to name (beginning at 8 months of age; Baranek, 1999; Werner et al., 2000). In Baranek's (1999) study of 9- to 12-month-olds, response to name reliably distinguished infants with autism from those with mental retardation or typical development. Diminished affective responsiveness has also been reported in a retrospective study involving analysis of videotapes of infants (6 months and younger) who had outcomes of ASD versus typical development (Maestro et al., 2002). Social and communication initiation may also be diminished in infants with ASD (Adrien et al., 1993; Flanagan & Landa, 2007; Maestro et al., 2005; Maestro et al., 2002). There is conflicting evidence regarding abnormality of eye contact in infants with ASD (not different from typically developing age peers in a study of 8- to 10-month-olds; versus limited eye contact in case reports by Dawson, Osterling, Meltzoff, & Kuhl, 2000; Klin et al., 2004, and Sparling, 1991). Further evidence for social abnormalities in the first year of life comes from parents' report that their preschoolers with autism had never performed certain social behaviors that typically emerge in the first year of life, including showing anticipation of being lifted, showing affection toward others, showing interest in children other than siblings, reaching for a familiar person, and playing simple interaction games with others (Klin, Volkmar, & Sparrow, 1992).

What is Known about Signs of ASD in the Second Year of Life?

The literature provides more substantial information about predictors of ASD for children in the 1- to 2-year age range. The developmental features associated with ASD become increasingly clear with increasing chronological age (Landa, Holman, & Garrett-Mayer, 2007). Even the passage of a few months may permit recognition of an ASD clinical picture that was previously unclear. The nature of the developmental disruptions in 1-year-olds with ASD will vary from child to child in number, severity, and nature, as well as in the timing of onset and pattern of developmental trajectory. Nevertheless, the guiding principle that social impairment must be present for a diagnosis of ASD holds true even for children at this young age.

Retrospective Studies: 12 to 24 Months of Age

Retrospective studies indicate that at around the time of the first birthday, some children later diagnosed with ASD can be distinguished from their typically developing peers as well as from age peers with other types of developmental delays. In a retrospective study involving analysis of first birthday videotapes, Osterling and colleagues (2002) reported that 12-month-olds later diagnosed with ASD differed from those with intellectual disability and typical development in the frequency and duration of orienting to name and looking at people. There were other behaviors that failed to distinguish children with ASD from those with intellectual disability, but that distinguished both groups of impaired children from typically developing age peers. Such behaviors involved the use of gestures, looking at objects held by others, and the presence of repetitive actions. This supported findings from Osterling and Dawson's (1994) earlier retrospective study that children with ASD differed from 1-year-olds with typical development in the frequency with which they looked at others, showed or pointed to objects, and responded to their name. In addition to the social, communication, and play abnormalities, atypical patterns of sensory responsivity have also been identified in retrospective studies that reviewed home videos taken at about the time of the first birthday (Adrien et al., 1993; Baranek, 1999). Disruption in self-regulation has also been identified in 1-year-olds with ASD (Gomez & Baird, 2005). This finding emerged from a study in which parents completed a standardized temperament questionnaire (the Temperament and Atypical Behavior Scale (TABS) (Bagnato, Neisworth, Salvia, & Hunt, 1999). Based on TABS norms, parents' responses would have resulted in 86% of the children meeting criteria for regulatory disorder (Gomez & Baird, 2005).

In the latter half of the first year of life, multiple retrospective studies indicate that development of children with ASD diverges to a greater degree from typical patterns of development, qualitatively and/or quantitatively. For example, in a small longitudinal, retrospective study, Losche (1990) examined play behavior of children with ASD and typical development using videotapes taken between 4 and 42 months of age. No differences in presymbolic play behavior were noted between the groups until 22 months of age. At that age, however, the children with ASD exhibited a plateau in the frequency of goal-oriented object exploration. In contrast, children with typical development at that age displayed growth in play development, exhibiting greater diversity of play acts with objects and an increase in the frequency of those acts.

This timing of the plateau in children with ASD parallels the mean age at which parents become concerned about their children with ASD (Howlin & Asgharian, 1999), the mean age at which regression occurs (Luyster et al., 2005), and the timing of developmental slowing identified in prospective, longitudinal studies (Landa & Garrett-Mayer, 2006; Landa et al., 2007). Prior to this time (18 to 22 months of age), symptoms of ASD may be absent or too subtle to raise parents' concern. Support for this notion comes from Baird and colleagues' (2000) study of parents' responses on an autism screening questionnaire. Parents of 18-month-olds later diagnosed with ASD did not report that their children showed abnormality in protodeclarative pointing or gaze monitoring (Baird et al., 2000).

Prospective Studies: 12 to 18 Months of Age

Like retrospective studies, prospective studies suggest that, at around the time of the first birthday, some behavioral features are predictive of later developmental disruption, including a later diagnosis of ASD. The behavioral features represent all three of the diagnostic symptom domains for pervasive developmental disorders as defined in the *Diagnostic and Statistical Manual-IV* (American Psychiatric Association [APA], 1994): qualitative impairment in social behavior, qualitative impairment in communication behavior, and repetitive and stereotyped patterns of behavior and interest. Qualitative and quantitative differences in social development are characterized by decreased social responsivity, social initiation, and affective expression. Examples of disruption in social responsivity include poor response to name (Nadig et al., 2007), poor monitoring of others' gaze (Landa et al., 2007), and poor response to others' bids for joint attention (Sullivan et al., 2007). Difficulty with social initiation involves infrequent initiation of joint attention through pointing or showing (Landa et al., 2007), infrequent directing of play acts toward others (Landa et al., 2007), and infrequent initiation of social communication bids (Landa et al., 2007). Response to others' joint attention cues (shifts in gaze, head turn, pointing gesture) occurs less frequently and has a longer period of instability in 1-year-olds with ASD than in age peers without ASD (Sullivan et al., 2007). Young children with ASD also share positive affect with others less often than their non-ASD age peers (Landa et al., 2007). Qualitative and quantitative differences in communication are represented by receptive and expressive language delay (Landa & Garrett-Mayer, 2006) and decreased frequency of communicative bids directed toward others. Communication is characterized by a restricted repertoire of communicative forms, affecting gesture use and production of consonants compared to age peers with typical development or language delays (Landa et al., 2007). Play behavior in children with an early diagnosis of ASD was distinguished from children with typical development and language or social delays; action schema on toys was less diverse and fewer sequences of play acts on toys were exhibited (Landa et al., 2007). In addition, repetitive and stereotyped patterns of behavior and interests are also represented. Repetitive behavior and sensory preoccupation were reported in some 12-month-olds later diagnosed with ASD (Loh et al., 2007; Ozonoff et al., 2008b), especially involving the use of the arms compared to children with other developmental delays and typical development (Loh et al., 2007).

Prospective Studies: 18–24 Months of Age

The studies reviewed below focused on 18- to 24-month-olds with ASD and included a comparison group involving children with non-ASD delays.

An increased number of studies are available to shed light on behavioral abnormalities associated with ASD in 18- to 24-month-olds with ASD. As discussed in the review of retrospective studies above, ASD symptoms become more prominent or persistent in this timeframe, and thus become clearer indicators for concern about the presence of ASD. One illustration of this comes from Cox and colleagues' (1999) follow-up of children with ASD who were originally assessed at 20 months of age. At both the original assessment at 20 months and the follow-up assessment at 42 months of age, the Autism Diagnostic Interview-Revised (ADI-R; Lord, Rutter, & Le Couteur, 1994) was conducted to systematically elicit parents' memories and report of past and current autism-related behavior. Two ADI-R items, "Point for Interest" and "Use of Conventional Gestures" differentiated the ASD group at 20 and 42 months of age from children with language delay and typical development. But with increasing age, an increased number of ADI-R items differentiated children with ASD from other children. At 42 months of age, the items newly endorsed by parents of children with ASD included: "Seeking to Share Enjoyment," "Offering Comfort," "Nodding and Imaginative Play." As with Losche's (1990) report about play development, children with ASD are failing to exhibit the more complex and sophisticated social and play behavior that is expected at more advanced chronological ages. Cox and colleagues (1999) did not find any variables from the Repetitive Behaviors and Stereotyped Interests section of the ADI-R to differentiate the groups at either age. However, the ADI-R is based on parent report. Studies involving direct measurement of children's repetitive behaviors have yielded different results (see references to Wetherby's work below).

Studies involving direct assessment of 18- to 24-month-olds contribute additional insights into the early characteristics of ASD. One of the first such studies focused on children who had failed an autism screening (CHAT; Baron-Cohen, Allen, & Gillberg, 1992) at 18 months of age, and were thus considered at high risk for autism or other developmental delay. This sample of children was assessed extensively at 20 months of age (reviewed below). The children who were later diagnosed with ASD differed in multiple ways from those later diagnosed with a language delay. The children with ASD looked less at adults during play (Swettenham et al., 1998), exhibited decreased frequency of gaze shifts between objects and people (Charman et al., 1997; Swettenham et al., 1998),

were less likely to look at the face of an adult expressing distress (Charman et al., 1997), and imitated less often (Charman et al., 1997). As noted above, Cox and colleagues (1999) found that, per concurrent parent report, 20-month-olds with ASD less often used conventional gestures, including the use of pointing for sharing interest, compared to language delayed and typically developing age peers. Thus, prior to the second birthday, children with ASD displayed abnormality in interpersonal synchrony. They provided few cues to their interaction partner to indicate their interest in being engaged.

Using a similar screening strategy to identify children at high risk for ASD, Wetherby and colleagues (2004) compared 50 children with ASD to 25 children with non-ASD developmental delay and 50 children with typical development at age 18 to 24 months. The children with ASD differed from the non-ASD group in that they less frequently displayed eye contact, coordinated gaze with nonverbal communicative behaviors (e.g., gestures), initiated joint attention, and responded to their name. In addition, the children with ASD exhibited unusual prosody, and more repetitive body movements and repetitive use of objects. The authors then rated videotaped lab-based behavior samples of the children using the Systematic Observation of Red Flags (SORF) for ASD (Wetherby & Woods, 2002). The ASD group differed from the Developmental Delay and Typically Developing groups on nine items, representing impaired social interaction, impaired communication, and repetitive behavior and restricted interests. These included lack of appropriate gaze; lack of warm, joyful expressions; lack of sharing interest or enjoyment; lack of response to name; lack of showing; lack of coordination of nonverbal communication; unusual prosody; repetitive movements with objects; and repetitive movements or posturing of body. Four behaviors differentiated the ASD and developmentally delayed (DD) groups from the typically developing (TD) group, but did not differentiate the ASD and DD groups from each other. These behaviors fall within the domain of communication, and could be considered early signs of nonspecific delay. They include: lack of pointing; lack of playing with a variety of toys; lack of response to contextual cues; and lack of communicative vocalizations with consonants. In later work, Wetherby and colleagues reported finding higher rates and a larger inventory of repetitive and stereotyped body movements and movements with objects in children with ASD than in age peers with developmental delay or typical development (Morgan, Wetherby, & Barber, 2008; Watt, Wetherby, Barber, & Morgan, 2008).

Wetherby, Watt, Morgan, and Shumway (2007) examined children who were first assessed between the ages of 18 and 24 months, and at 30 months of age received an "outcome" diagnosis of ASD, Developmental Delay, or Typically Developing. Based on data obtained via the Communication and Symbolic Behavior Scales Developmental Profile (Wetherby & Prizant, 2002) at the first assessment, the ASD and TD groups were found to differ on all social, communication, and play variables. The ASD and DD groups differed on frequency of gaze shifts between objects and people, response to pointing gestures, rate of communicating, frequency of initiation of joint attention, and variety of conventional gestures used communicatively. This parallels Landa and colleague's finding in early diagnosed 14-month-olds with ASD, but does not entirely parallel the findings involving later diagnosed 24-month-olds with ASD. In Landa and colleagues' (2007) study, the later diagnosed group of children with ASD did not differ from the language and/or social delayed group on the communication or play variables, nor on frequency of triadic gaze. Likewise, they did not differ from nondelayed controls in play behavior.

Early predictors of later ASD severity were examined by Wetherby and colleagues (2007). The following behaviors were predictive of later severity: frequency of behavior regulatory acts and rate of communicating; variety of conventional gestures and consonants; and variety of conventional actions on objects during play as well as variety of pretend play acts. Interestingly, frequency of shared positive affect and gaze shifts did not differentiate the DD and ASD groups, nor did these variables predict ASD severity. One explanation for this may be the coding protocol used by Wetherby's group. For shared positive affect and gaze shifts, the coding protocol required scorers to indicate whether or not the child exhibited that particular behavior within each of the six sampling conditions rather than coding frequency of occurrence of these behaviors. Since young children with ASD do produce some such behaviors (Landa et al., 2007; Charman et al., 1998), a more continuous variable involving frequency of occurrence of such events may be necessary to capture differences between toddlers with ASD and those with other types of developmental delays.

Another important finding emerged from Wetherby and colleagues' (2007) report: response to others' pointing gestures (response to joint attention cues) and initiation of joint attention were highly correlated with language comprehension. Wetherby and colleagues (2007) suggested that joint attention behavior in 18- to 24-month-olds may reflect representational skills rather than just social cognition. This is an interesting notion. Although one prospective, longitudinal study reported that the developmental trajectory of joint attention in the second year of life does not parallel that of word inventory, word combinations, or representational play (Landa et al., 2007; Sullivan et al., 2007), there appears to be a relationship between the developmental trajectories of initiation of joint attention and diversity of gestures produced between 14 and 24 months of age. Landa and colleagues (2007) reported that frequency of initiating joint attention through the use of showing or pointing gesture declines or plateaus between 14 and 24 months of age, much like that of gesture inventory. More research is needed to reveal the relationships between different types of communicative intents, responses to others' communicative bids, gestures, and other forms of communication. Understanding such relationships would have implications for intervention, where treatment focused on some of these aspects of development may result in collateral changes in other aspects.

Implications of the Presence of Early Signs of ASD

The retrospective and prospective literatures indicate that there are a number of different systems in which developmental processes may be disrupted in some younger siblings of children with ASD, even if they are not ultimately diagnosed with ASD. The same is true for children later diagnosed with ASD, whether or not they have a known family history of ASD. Affected aspects of development may involve motor (including muscle tone), attention, motivation and initiative, arousal and self-regulation, expression of emotion, social reciprocity, patterns of social orienting, and coordination and integration of movement/affect/vocalization/gaze. In some infants and toddlers, repetitive body movements and actions on objects are also observed. The behavioral features described above in infants and toddlers with ASD culminate in an abnormal ability to engage in flexible, adaptive, appropriate and well-synchronized social and communicative engagement with others. Although early disruption in these aspects of development does not always predict ASD, they signal the need for monitoring development, at least through the preschool years. Each of the systems mentioned above (attention, motor, affective, self-regulatory, social orienting, etc.) contribute substantially to children's ability to detect relevant saliency, orient to and anticipate social and communicative events, respond contingently and synchronously to the dynamic changes in others' facial and vocal behaviors, and initiate engagement with others in "readable" and predictable ways. For these children, adaptations to environmental input, particularly social input, may be beneficial. Such adaptations in input may include, for example, simplifying the movements required to successfully grasp toys, providing toys that provide rewarding sensory input to the child and that can be easily grasped and held, making social stimuli more salient and consistent in form, introducing highly predictable routines that are presented slowly and with the amount of sensory input that is satisfying to the child, and so forth. The next section of this chapter focuses on guidelines that may facilitate the early identification of children who may be in need of such adapted input, or who may be at high risk for a developmental disorder such as ASD.

Implications for Detecting ASD Prior to the First Birthday

As indicated above, the literature is populated with few studies, all involving small numbers of children, on which to base guidance for clinicians and parents in their efforts to identify infants who will later manifest the full complex of autism symptoms. The early signs of developmental disruption in infants with ASD are subtle, and may not involve the expected social impairments that are so clear in older children with ASD. Furthermore, standardized test scores may fall well within normal limits (Landa & Garrett-Mayer, 2006). Despite such quantitative scores, qualitative behavioral abnormalities or extremes may be present (Landa & Garrett-Mayer, 2006). During infancy, behavioral signs of disrupted development vary in number, nature, and severity (or intensity) from child to child. In addition, identifying infants who will later receive a diagnosis of developmental delay is complicated by the variation that characterizes typical development. Thus, there is a "gray zone" in which the boundaries between "typical" and "atypical" development are unclear. To address this challenge guidelines have been published for primary health providers (Johnson, Myers, & the Council on Children with Disabilities, 2007) for use beginning at age 9 months. These guidelines call for developmental surveillance at well visits conducted at 9, 18, and 24 months of age. During these visits, health care professionals are advised to: (1) elicit and attend to parents' concerns about their child's development; (2) document and maintain a developmental history; (3) make accurate observations of the child; (4) identify risk and protective factors; and (5) maintain an accurate record of documenting the process and findings. Since parents of children with developmental delays may not have initial concerns about their child (Hess & Landa, in press; King et al., 2005; Wetherby, Brosnan-Maddox, Peace, & Newton, 2008), the role of the health care provider is considerable in the early detection of developmental disorders, including ASD. Alternatively, parents' concerns may be more sensitive than developmental measures in some cases (Hess & Landa, in press).

Since guidelines for primary health care providers do not address infants younger than 9 months of age, providers may feel poorly equipped to recognize the earliest signs of developmental disruption or to know when to refer infants for developmental assessment. Since early signs of developmental disruption may be subtle, and there are no clear predictors of ASD from infancy, a prudent guideline for referring younger infants for a developmental assessment may be as follows: (1) refer if there is mild concern (expressed by parent or professional) and one or more risk factors exist (e.g., family history of language impairment or ASD, preterm birth, low birth weight); or (2) refer if there is at least moderate concern, regardless of presence of risk factors. Of course, regardless of risk factors, parents must always make the final decision about seeking a nonmedical developmental assessment. A developmental checklist is provided below (Table 12-1) to assist health care providers and other clinicians to systematically consider aspects of development that may be disrupted in infants at risk for ASD. When possible indicators of risk for ASD are observed or reported, the professional should inquire about the frequency, duration, and intensity of the display of the concerning behaviors. Determining the age at which the concerning behavior began to be exhibited is also important. Referral to an expert in infant development will clarify level of risk, and yield recommendations about how parents may stimulate, regulate, and engage their infants in ways that optimize the infant's development. Obtaining a medical evaluation

Table 12–1.
Developmental features to consider in infant developmental screening for 6- to 9-month-olds

Developmental Domain	Features to Observe or About Which to Query the Parent	Indicators of Possible Risk for ASD
Communication	__ Babbling (frequency, variety of sounds) __Infant watches the face of the person talking to him/her __Vocal turn-taking during engagement with parent __Quality of vocal tone	• Absent or rare occurrence of babbling • Reduced variety of sounds in babbling • No attention to face of speaker • Absence of vocal response to caregiver vocalization • Unusual high pitched squeals
Social Responsivity, Duration of Engagement, and Active Participation During Engagement	__Eye contact __Reciprocal smiling __Orients to name being called __Exhibits a range of facial expressions __Sustains attention to social input __ Initiative with toys and people __Social anticipation	• Gaze aversion, infrequent or brief duration eye contact • Absence of reciprocal smiling, or smiling occurs only when infant is touched, or a robust stimulus is needed to elicit a smile; infrequent social smiles • No response to name being called • Neutral affect • Brief duration of gaze during caregiver engagement with infant • Passivity, rarely reaches for objects without extra assistance from caregiver • Poor anticipation of being picked up or of social games (as in peek-a-boo)
Motor and Sensory	__Muscle tone __Coordinated movements __Motor milestones (sitting, crawling, rolling, supporting self on arms when prone) __Response to touch or other sensory experience __Feeding __Quality of body movements	• Hypotonicity • Poor coordination of hands together • Delay in milestone acquisition; head lag when pulled to sit from supine position • Hyper- or hyposensitive to touch or other sensory experience • Feeding difficulties (e.g., refusing categories of foods) • Unusual posturing or excessive repetition of movements
Play	__Variety of ways of exploring toys __ Variety of toys explored __Nature of object exploration	• Atypically intense focus on specific objects or parts of objects (e.g., wheels on a car) • Repetitive action on a particular object or class of objects (e.g., trying to make lids wobble) • Absence of object exploration or atypical patterns or intensity of exploration (e.g., holding toy close to eyes or in peripheral vision, excessive mouthing)
Self-regulatory	__Temperament __Soothe-ability	• Extreme temperament (including passivity, high reactivity, underresponsive) • Not easily soothed when upset; may be inconsolable

also may be appropriate to rule out known etiologies for the behavioral indicators of developmental disruption (Filipek et al., 1999).

Stability of Early Diagnosis of ASD

The age at which a diagnosis of ASD is made will depend on a variety of factors. There is consensus among autism clinical researchers that by the age of 3 years, a diagnosis of ASD can be made reliably, and that the stability of the diagnosis after this age is high. Two studies have focused on stability of ASD diagnosis in children younger than 2 years of age (Chawarska et al.,

2007b; Cox et al., 1999). Chawarska and colleagues (2007b) studied short-term stability (from just under 24 months of age to 3 years of age) of the diagnosis of autism and Pervasive Developmental Disorder Not-Otherwise-Specified (PDD-NOS) in 31 children referred to a clinic for evaluation to rule out ASD. All children initially diagnosed with ASD remained on the spectrum, however two children shifted diagnosis from autism to PDD-NOS. In another study, Cox and colleagues (1999) reported high levels of stability of ASD diagnosis from 20 months of age to 42–46 months of age in children who had screened positive at 18 months of age an autism screening instrument (CHAT, Baron-Cohen, Allen, & Gillberg, 1992).

Several studies have examined stability of diagnosis of ASD in 2-year-olds. In studies where 2-year-olds diagnosed with

autism or PDD-NOS were followed for at least 5 years, the stability of diagnosis ranged from 85 to 89% (Charman et al., 2005; Lord et al., 2006; Turner, Stone, Pozdol, & Coonrod, 2006). However, one study examining short-term stability of ASD diagnosis in 2-year-olds suggests that, under certain circumstances, early diagnosis of ASD may be unstable (Turner & Stone, 2007). One factor related to diagnostic instability was being younger than 30 months at the time of diagnosis. Stability of ASD diagnosis was 52% in children younger than 30 months of age compared to 87% in children 30 months or older. Two other factors related to diagnostic instability involved milder symptoms, especially social functioning, and higher cognitive test scores (Turner & Stone, 2007). These factors are similar to the predictors of improvement in 2-year-olds with ASD as reported by others (Charman et al., 2003; Lord, 1995). In general, stability of diagnosis in 2-year-olds is associated with experience of the diagnostician (Stone et al., 1999) and severity or pervasiveness of symptoms (Eaves & Ho, 2004; Lord et al., 2006; Moore & Goodson, 2003; Stone et al., 1999; Turner et al., 2006). Stability of diagnosis is greatest when the diagnostic "gold standard" is clinical judgment as opposed to diagnostic classification based on the scores of an autism diagnostic measure, such as the ADI-R (Chawarska et al., 2007b; Kleinman et al., 2008). For children whose diagnostic status shifts from ASD to non-ASD, lingering developmental delays often persist (Fein, Dixon, Paul, & Levin, 2005; Kleinman et al., 2008; Landa, Holman, & Garrett-Mayer, 2007; Turner & Stone, 2007). At present, predicting the children who will improve substantially and, thus, lose the ASD diagnosis is quite difficult. Sutera and colleagues (2007) found only one variable, motor functioning at age 2 years, was associated with optimal outcome (defined as losing the ASD diagnosis). With increasing age, diagnosis becomes more stable (Charman et al., 2005). The findings summarized above have implications for clinical practice. First, diagnosis of children younger than 3 years of age should be made only by clinicians with expertise in autism and in early child development. Second, when a diagnosis of ASD is made, parents should be informed that their child's diagnostic status or severity of symptoms could possibly change when assessed at an older age. Third, follow-up assessments are advised when risk for ASD is considered high, or when an ASD diagnosis is made, in a child younger than 3 years of age.

A word about false negatives is worthwhile. With the extensive media coverage about early signs of ASD, some parents begin to suspect that their child is showing signs of ASD and seek expert advice. Many times the expert who sees the child is a physician. If the physician conducts a screening (e.g., using the M-CHAT, a brief behavioral screening questionnaire, or some combination of formal or informal screening questionnaire and observation) and does not see clear signs of ASD, parents may be informed that their child is "normal." This is probably an accurate conclusion for many children. However, studies (Cox et al., 1999; Landa et al., 2007; Werner & Dawson, 2005) are showing that some children with ASD may exhibit few signs of early developmental disruption, with subsequent change in developmental trajectory (e.g., slowing, plateauing, or regression in development; see "Progression of ASD," below). Indeed, 9 children evaluated at 42 months of age had been judged to have typical development or language delay at 20 months of age (Cox et al., 1999), but were later diagnosed with ASD. In a prospective study of infant siblings of children with autism, Landa and colleagues (2007) reported that nearly half of the children diagnosed with ASD at 3 years of age had not been judged by an expert clinician to have ASD at 14 months of age, though all had been noted to have disruptions in one or more aspects of development. The possibility of "false negatives" may be heightened for toddlers having a positive family history of ASD, or in other high risk populations (e.g., preterm infants), but this author advises professionals to monitor development of toddlers when parents have early developmental concerns, regardless of the medical risk status of the child. The 8-step surveillance guidelines proposed by members of the American Academy of Pediatrics' Council on Children with Disabilities (Johnson et al., 2007) for early detection of ASD within pediatric offices, and the associated decision tree are supported by prospective and retrospective studies. As children approach their third birthday, the likelihood of false negatives diminishes and becomes less of a concern. The likely exception here is children with ASD who have no cognitive or language delays. These children tend to be identified once they are in school and begin to show difficulty in peer interactions.

Issues Related to Threshold for Diagnosing ASD in Children Younger Than 30 Months of Age

Determining the degree to which a young child must vary from typical development, qualitatively and quantitatively, in order to qualify for a diagnosis of ASD is a complex matter. It involves defining the boundaries between "typical" and disordered development, particularly in communication and social behavior. For children younger than 3 years of age, defining these boundaries can be quite difficult. In this author's longitudinal study of infant siblings of children with ASD, where children are tested at 6, 14, 18, 24, 30, and 36 months of age, expert clinicians indicate, at each assessment from 14 to 36 months of age, whether a child displays the signs of ASD, and if so, whether a clinical impression of ASD is warranted. For some children, this is quite difficult because the younger siblings of children with ASD present with a continuum of "typical" to abnormal or delayed functioning in one or more aspects of development, and positive symptoms may not be present or robust in early development (e.g., there can be no echolalia before spoken language begins to emerge). Thus, the research setting mimics community-based health centers, where professionals are faced with difficult decisions about whether to refer a child for developmental assessment, or for children who have received such assessment, whether to diagnose the child with ASD. In this author's lab, the concept of a continuum of risk for ASD is integrated into the process of

establishing clinical impressions. We think of this continuum as beginning with typical development, where expected language, social, motor, cognitive, and behavioral milestones are met and displayed in contextually appropriate ways, with appropriate levels of flexibility and consistency. At the other end of the continuum is clear delay or impairment, where children fail to meet expected milestones, score abnormally on multiple standardized measures of different domains of development, and where clinical judgment of experts from different professional disciplines agree on the diagnosis of ASD. In Figure 12-1 below, this continuum is illustrated.

A behavior sampling guide is provided in Table 12-2. With little extra time or effort, this sample may be collected in a primary health care setting, as well as in a developmental screening center. It is entirely possible that a young child with ASD may perform "normally" in assessment contexts that involve familiar routines and tasks, especially if these do not require the child to integrate multiple aspects of development, as in a peek-a-boo task. Thus, parent report of behavior in different contexts and their sense of the level of "impairment" caused by their child's behavior or responsivity is important to elicit.

Progression of ASD

New insights into developmental trajectories associated with autism are emerging from the prospective, longitudinal studies of infant siblings of children with autism. As discussed above, most such studies are revealing that infants later diagnosed with ASD show only subtle, if any, signs of developmental disruption (Zwaigenbaum et al., 2005; Landa & Garrett-Mayer, 2006). The aspects of development that are disrupted may involve non-ASD specific domains, such as motor development (Bryson et al., 2007; Flanagan & Landa, 2007; Ozonoff et al., 2008a). Near the time of the first birthday, some children with ASD manifest sufficiently robust signs of impairment that ASD can be diagnosed by an expert (Landa, Holman, & Garrett-Mayer, 2007). Other children with ASD, however, do not exhibit clear symptomatology until sometime closer to the third birthday (Landa et al., 2007). This suggests that ASD has a progressive nature during the first few years of life in some, perhaps many, children affected with this disorder. Progression is conceptualized here as a "worsening," involving a shift from rather typical to atypical quality of behavior, a slowing of developmental trajectory or even a plateau in development, or intensification of behaviors that previously were considered subclinical (e.g., increase in repetitive behavior, poor eye contact), and/or there is a loss or attenuation in frequency of occurrence or diversity of previously exhibited behaviors or skills. Using this definition, toddlers with early diagnosis (as in the Landa et al., 2007, paper) may "worsen," as do toddlers with later onset ASD.

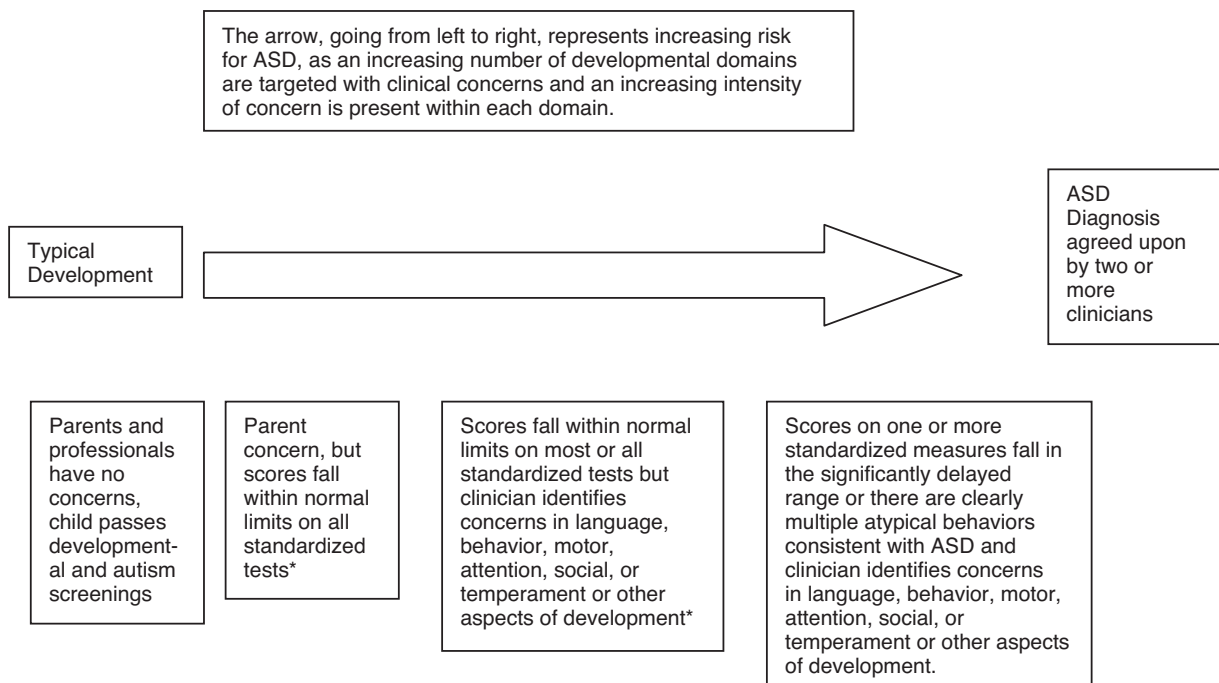
In the past, the nuances of trajectory in children with ASD were not easily defined because of the necessary reliance on retrospective research designs. Retrospective studies, primarily involving parents' recall of their now older child's early


Figure 12–1. ASD risk continuum based on developmental features and parent concern for young children. * Increased weighting is given if the child is "at risk" based on medical or environmental factors (e.g., family history, preterm birth, low birth weight, health history, history of neglect, etc.).

Table 12–2.

Brief procedure for sampling ASD symptoms for children aged 9 to 30 months

Behavior to be Sampled*	Brief Sampling Procedure	Red Flag for ASD
Shared positive affect (looking at a person and smiling)	After playing with the child with some toys for a few minutes as a "warm up," comment on the child's activity or something else about the child and smile. Ask the parents how they elicit a smile from the child at home.	• The child does not smile back at you, and the parent reports that the child does not do so at home except within familiar routines or when anticipating a "tickle" or other physical contact.
Eye contact (looking directly into the eyes of another person)	Throughout the time you are with the child, note whether the child exhibits eye contact with you or their parent.	• The child rarely or never gives eye contact to the parent or to you when you speak to him or her, and the parent confirms that this pattern of behavior is characteristic of the child at home.
Initiation of joint attention (pointing something out for the purpose of sharing, not to ask for something)	Have a remote control toy set up in the room. Without drawing the child's attention to the toy, activate the toy. Remain quiet for a moment or so, watching to see whether the child will look back and forth from the toy to the parent or you, and whether the child will point the toy out to his or her parent.	• The child does not attempt to direct others' attention to the toy by pointing to it and the parents report that the child does not (or rarely will) point to show objects or events of interest to him or her.
Sustained engagement (at an early developmental level, this would involve remaining attentive to the other person, but taking a passive role; at a more mature developmental level, it would involve taking an active role in the interaction)	Ask the parent to engage the child in a familiar routine. Observe the child's reaction. Ask the parent if the child's engagement may also be sustained during less familiar activities or in activities that are not "favorites" of the child.	• The child is difficult to engage, shows only brief or no interest in the routine and the parents report that they are only successful at getting brief moments of engagement with their child. • The parent reports that the child only responds and stays engaged during favorite or familiar routines or activities, or in high affect activities.
Spontaneous imitation of others' actions	Present the parent with two sets of toys. For example, you may have two plastic toy drumsticks, two plastic plates, two forks, and a baby doll. Give one set to the parent and the other set to the child. Ask the parent to tap on the plate gently with the drumstick and to smile at their child as they do it, without telling their child what to do. They should pause, smiling at their child, and then repeat the action. Do this several times.	• The child does not attempt to imitate the parent's action and the parent reports that the child does not imitate without being asked to (or at all) at home.
Response to others' joint attention bids	Place a colorful appliqué on the wall at the child's eye level, 90° to the child's right or left. Place yourself directly opposite the child and point to the appliqué, keeping your finger close to your body (otherwise the child will simply track the movement of your arm movement and look in the direction of the appliqué). As you do this, say "Look *child's name*."	• The child does not look in the direction of your pointing gesture and the parents report that the child does not look where others point, unless they are pointing to an object immediately in front of the child.

Behavior to be Sampled*	Brief Sampling Procedure	Red Flag for ASD
Response to name	Standing 45º to 90º from the child's midline, call the child's name in normal tone of voice. If the child does not respond immediately, pause briefly and repeat two more times. If the child does not respond, ask the parent if this is typical for the child and, if so, what the parents do at home to get the child's attention.	• The child does not respond to their name by looking directly at you when you call the child, and the parents confirm that the child inconsistently responds to their name (or does not respond to their name at all) at home.
Variety of consonants used communicatively	Create a situation in which the child is likely to be highly motivated to communicate. For example, show the child a bottle of bubbles and then blow a few bubbles. Wait and watch to see whether the child requests more bubbles by vocalizing (and what consonants are produced). Throughout the time spent with the child, observe whether the child attempts to communicate, and note number of different consonants used during these communicative bids (e.g., b, p, t, d, m, n, k).	• The child produces fewer than 5 consonants and the parent reports that the child's consonant repertoire (when communicating) is limited to five or fewer consonants at home. (This criterion is applied only to children age 12 months and older.)
*A typical behaviors***		
Posturing of hand, arm, or mouth	Throughout the time spent with the child, note the child's body movements.	• The child holds arm, hand, fingers, mouth, or head in an unusual position. If there is tension in the muscles of the body part being positioned oddly, this is additional basis for concern. If the parent reports that the child shows such behaviors in the home, there is more evidence for concern.
Repetitive or unusual play with toys	Give the child the following toys and allow him or her to play with each one for a brief period: • Toy car • Doll with eyes that open and close, plate, fork, cup • Tin can and lid with wooden alphabet blocks (be sure the child is placed on a hard surface).	• Intense focus on the wheels of the car, flicking the doll's eyes for more than 5 seconds, attempting to make the lid wobble or roll, visual inspection of the letters on the blocks, lining up the blocks.
Motor	Throughout the time spent with the child, note the child's body movements.	• Low muscle tone, poor motor coordination, motor delays.
Unusual squealing	Observe the tonal quality of the child's vocalizations.	• Unusual tonal quality or squealing.
Echoing	Observe the child's verbalizations.	• Repeating segments of movies or television programs, echoing back part of all of what is said to him or her.

*Absence of these behaviors may be red flags for ASD; ** Presence of these behaviors are red flags for ASD.*

development, revealed an important phenomenon involving "worsening" in children with ASD, which was conceptualized as regression. The precise definition of regression has been difficult to bring to consensus among experts beyond the general agreement that the loss of skills occurs mainly in the domains of language and/or social development. Definitions of language regression have focused mainly on the loss of spoken words, since regression usually occurs before children progress to more complex levels of language development (Kurita, 1996; Kurita, Kita, & Miyake, 1992; Kurita, 1985). Regression of social skills has been more difficult to quantify, especially when relying on parent memory of behavior that occurred many years ago.

The challenge of coming to consensus on the definition of regression in ASD is complicated by the variation in the nature of regression as reported by parents. Regression may occur in children whose parents reported previously typical development (constituting 49% of regression cases, per Wilson et al., [2003]). Alternatively, regression may occur in children whose development was previously recognized as delayed. In contrast to Wilson and colleagues (2003), a large collaborative database involving children with parental report of regression indicated that this is the more common phenomenon (Luyster et al., 2005). Some children lost only language skills, some lost only social skills, and others lost skills across multiple aspects of development (Luyster et al., 2005). Most children with regression (77%), however, reportedly lost skills in multiple aspects of development (Luyster et al., 2005). Age of regression varies from child to child, occurring at the mean age of 19 months (Luyster et al., 2005). Regardless of the nuances, however, regression of language and/or social skills rarely occurs in children with typical development or in children with non-ASD developmental delays (Burack & Volkmar, 1992; Lord, Shulman, & DiLavore, 2004; Luyster et al., 2005). Regression is estimated to occur in 20 to 33 percent of children with ASD (Goldberg et al., 2003; Rapin & Katzman, 1998; Rutter & Lord, 1987). Regression appears to occur with similar likelihood in children with or without a history of epilepsy (Luyster et al., 2005).

Prospective, longitudinal studies indicate that the onset of ASD symptoms may occur gradually, often without an accompanying parental report of regression. Our group (Landa, Holman, & Garrett-Mayer, 2007) identified this developmental pattern in about half of the children with ASD. These children were classified as "not ASD" at 14 months of age, with gradual emergence of autism symptoms culminating in a diagnosis of ASD at age 3 years. This group of children with "later ASD onset" had subtle developmental disruption, noted by an expert clinician at 14 months of age, but their social, communication, and play behavior at 14 months of age did not differ significantly from children without ASD. By 24 months of age, their social, communication, and play behavior paralleled that of the children with early onset ASD, and they were clearly distinguishable from the non-ASD groups. In some of the children with early ASD onset, and in all the children with later ASD onset, progressive worsening

could be observed. Since the children diagnosed with ASD in this study (Landa et al., 2007) had an older sibling with autism, they were by definition from multiplex families. It is possible that the nature of regression in children from multiplex families is different from that observed within children from families having only one member with autism, where the genetic mechanism may be different (Sebat, Lakshmi, Malhotra, Troge, Lese-Martin, Walsh, Yamrom, et al., 2007). Despite this possibility, the phenomenon of progressive worsening was illustrated in Cox et al.'s (1999) prospective study of ASD as described above (see "False Negatives," above). Additional evidence for an increase in severity of ASD symptoms is provided by Stone and colleagues' (1999) study of diagnostic stability of ASD. In that study, 37 children diagnosed with ASD were assessed at mean age 31.4 months and again at mean age 45 months. Half of the 12 children initially diagnosed with PDD-NOS were judged by a secondary clinician to have a diagnosis of autism at the follow-up assessment. One longitudinal retrospective study involving videotape analysis of children with ASD at three age periods (10–12 months, 16–18 months, 24–26 months) highlighted what the prospective studies are showing: deficits in interaction and imitation become more prominent with increasing age (Receveur et al., 2005). Outcomes, as measured using standardized tests of verbal and nonverbal IQ and observational measures of severity of autism, were not significantly different for children with ASD whose parents did and did not report a history of regression (Werner, Dawson, Munson, & Osterling, 2005).

Conclusions

This chapter reviewed the literature on developmental features observed in children with ASD in the first 2 years of life. The matter of recognizing early signs of developmental disruption is a critical one, as it opens the door to early intervention. Parents and professionals contribute important insights to the early detection process. Early detection of ASD is usually a process, involving suspicion that something is amiss with the child's development, obtaining validation about concern, and discerning whether the diagnosis of ASD is appropriate. Given that the trajectory of development, such as slowing, plateau, or regression, may be a key factor in determining whether development is truly divergent from the typical path, a single point-in-time assessment for a very young child may not conclusively determine whether a diagnosis of ASD is appropriate. For some children, development will be sufficiently divergent from typical, and the signs of ASD may be clearly present at an early age. In such cases, a diagnosis of ASD may be made with some degree of confidence some time after the first birthday. Professionals are encouraged to become familiar with the early signs of ASD as well as common trajectories associated with this set of developmental disorders. In addition, they are encouraged to seek a clear understanding of parents' concerns and insights into their children throughout childhood, and especially during the

first 3 years of life. Screening for developmental disorders, including an autism-specific screening, is a critical component of well-child visits to pediatricians. Once a diagnosis has been made, the early intervention community of professionals may join together with families to develop an individualized intervention program that draws from the empirical literature of instructional strategies and addresses developmentally appropriate goals, strategically targeting core deficits of ASD within the comprehensive program.

Challenges and Future Directions

- Research is needed to define biomarkers of autism that may help with preclinical identification of autism.
- Assessment protocols and tools for identifying subtle developmental disruption early in life are needed to aid in the design of efficacious early intervention or enrichment programs for infants and toddlers at risk for autism.
- A system is needed to ensure that all children are screened for autism in the first and second years of life.

Development from Preschool Through School Age

Points of Interest

- Do we know if diagnosis from age 2 is reliable and stable?
- What features are associated with better social and communication outcomes?
- When do associated features such as mental health problems begin to emerge?

Over the past decade there has been remarkable progress in our understanding of the early development of children with autism spectrum disorders. Until the 1990s it was rare for children to receive a diagnosis of autism until the age of 3 or 4 years. Therefore, much of the historical literature in both the clinical and research fields starts with descriptions of children with autism at age 4 to 5 years or older. Several factors have driven this change, including efforts to improve earlier identification with the recognition that earlier-delivered intervention may improve outcomes and prevent "secondary" neurodevelopmental disturbances (Dawson, 2008; Mundy, 2003), the development of prospective screening instruments to identify possible cases of autism from the first few years of life (Charman & Baron-Cohen, 2006; Zwaigenbaum & Stone, 2006), and the use of the genetic high-risk research design of prospectively studying younger siblings of children with a diagnosis of autism from the first year of life (Yirmiya & Ozonoff, 2007). This decade of work has uncovered important evidence regarding the developmental trajectory of autism spectrum disorder from toddlerhood, through the preschool years into school age and beyond. An even more recent development has been the application of modern neuroimaging and neuroscientific experimental approaches to infants, toddlers, and young preschool children with autism spectrum disorders (Courchesne et al., 2007). While many of the insights gained from these clinical and experimental studies have proved clinically useful—in particular with respect to questions about when autism can be diagnosed reliably and how

stable the diagnosis is over the course of the preschool years as well as the ability to predict (at least at a group level) outcomes many years later—they have also raised considerable challenges. Among the most notable challenges are the substantial variability in early development trajectory in children with autism and our difficulty in disentangling the extent to which these variable trajectories for individual children are due to intrinsic versus extrinsic factors. This chapter will summarize the state of our current knowledge of these issues and identify challenges for future research and clinical studies.

Diagnosis and Developmental Trajectory Through the Preschool Years

There is a degree of irony that while both psychiatric classification systems are clear that, at least to meet criteria for the core disorder of childhood autism (ICD-10; World Health Organization, 1993) or autistic disorder (DSM-IV-TR; American Psychiatric Association, 2000), symptoms of autism are usually present in the first 3 years of life as evidenced by abnormalities in social interaction, language as used in social communication, and early play skills, until the 1990s few studies had been conducted with samples under the age of 3 years. This is not to challenge the notion that in many if not most cases of autism spectrum disorder, excepting perhaps those with very high IQ or those who meet criteria for Asperger's syndrome, there is some developmental anomaly within the first 3 years. Some recent evidence suggests that, at least in the case of childhood autism, early developmental perturbation that in some but not all cases meets recognized criteria for regression might occur for the majority as opposed to the minority of cases (Landa et al., 2007; Pickles et al., 2009). It may well be that parents do not always notice or pick up on more subtle changes in their children's social and communicative development from infancy to toddlerhood unless there is frank regression, most typically

evidenced in a loss of expressive language skills. Rather, it is to point out that apart from rare exceptions (Gillberg et al., 1990) until the mid-1990s the majority of information about development from toddlerhood through the preschool years came from retrospectively reported information from parents. The growth in our knowledge base regarding the presentation of autism in the preschool years over the past decade is demonstrated by a simple experiment. In August 2008 entering the search terms "autism" and "toddlers" into PudMed identified 88 articles. Seventy-seven of these were published *after* 2000, 57 of which were dated from 2005.

One of the most significant challenges and concerns of this new era of prospectively studying children with autism spectrum disorders from the age of 2 and 3 years concerned diagnosis. Given the relative lack of experience of applying the diagnostic criteria to children of this age, even among the relatively expert clinical teams conducting such studies, one critical question quickly arose: Was the diagnosis accurate and stable when applied at this age? Fortunately, many research teams were studying cohorts of toddlers by the mid-1990s, and evidence regarding the issues of diagnostic accuracy and stability began to emerge as the cohorts were followed into preschool and in the mid-2000s into the school-age years. What emerged from these programs of work were some clear messages (autism *can* be accurately diagnosed in 2-year-olds) but also some areas of uncertainty that will take continued study to resolve (in some cases diagnosis appears less stable). This research will be reviewed next.

Table 13-1 summarizes the diagnostic outcome studies that have followed cohorts of children from initial diagnostic assessments around the age of 2 years into the preschool years and, in several of the more recent studies (Charman et al., 2005; Lord et al., 2006; Turner et al., 2006), into the school-age years. The first series of studies (Cox et al., 1999; Lord, 1995; Moore & Goodson, 2003; Stone et al., 1999) all showed high stability of diagnosis in particular for "core" autism, with somewhat lower stability for broader autism spectrum disorder (ASD) and Pervasive Developmental Disorder Not-Otherwise-Specified (PDD-NOS). The movement across the ASD/PDD-NOS diagnostic category boundary was somewhat different in the different studies, with Stone et al. (1999) finding that 4 out of 12 children who met broader ASD criteria at the initial assessment did not meet criteria for an autism spectrum disorder at follow-up, whereas Cox et al. (1999) found that 7 from 31 children who did not receive an autism spectrum diagnosis at the initial assessment met criteria for broader ASD at follow-up. Several of the studies (Cox et al., 1999; Lord, 1995; Stone et al., 1999) concluded that, for 2-year-olds, expert clinical judgment is more reliable than the standard diagnostic instruments—the Autism Diagnostic Interview-Revised (ADI-R; Lord et al., 1994) and the Autism Diagnostic Observation Schedule-Generic (ADOS-G; Lord et al., 2000). Several studies also found that behaviors from the third symptom cluster that defines autism—restricted and repetitive behaviors and activities—were less evident at 2 years of age than at 3 to 5 years of age (Cox et al., 1999; Moore & Goodson, 2003;

Stone et al., 1999). The samples in these early studies differ in a number of characteristics, including how and for what purposes they were ascertained (for example, prospectively using the CHAT screening instrument in the Cox et al. study vs. following clinical referral for possible autism in the Lord, Moore and Goodson, and Stone et al. studies), IQ, language ability, and the different use and implementation both of standard diagnostic instruments but also of DSM-IV and ICD-10 diagnostic criteria, and these differences might account for the differences found.

The more recent studies differ from the earlier ones in a number of features, most notably considerably larger sample sizes (N = 172, Lord et al., 2006; N = 77, Kleinman et al., 2008) and follow-up periods that extend to age 7 years in the Charman et al. (2005) study and age 9 years in the Lord et al. (2006) and Turner et al. (2006) studies. Broadly, the lessons learned are the same—that the diagnosis of autism is highly stable in these samples but that of broader ASD is less so. Lord et al. (2006) found that age 2 scores on measures of repetitive and restricted behaviors and activities predicted an autism diagnosis at age 9 years. In some of these more recent studies there was greater movement from having an ASD diagnosis at age 2 years to a nonspectrum diagnosis at age 4 (Kleinman et al., 2008; Turner & Stone, 2007). While the authors report the factors associated with these "good outcomes"—mainly higher IQ and better language competency—it is important to remain cautious regarding predictors of poorer or better outcomes. However, the general pattern is of high stability of diagnosis for autism, replicating the earlier pioneering longitudinal work of Sigman and colleagues, who found high stability of diagnosis of children from 4 years of age through to mid-childhood (13 years) and young adulthood (19 years) (McGovern & Sigman, 2005; Sigman & Ruskin, 1999).

For clinicians the lesson is to accept that autism is a *developmental* disorder and at a very young age there may be less certainty regarding the pattern of behavior that a child is showing and the likelihood of their continuing to meet diagnostic criteria into the future. Charman and Baird (2002) discuss the importance of understanding the diagnostic process as an iterative process to be worked out between clinician teams and parents over time and that concepts such as a "working diagnosis" can be helpful. However, at the same time, clinical teams need to be aware of the need to provide sufficient certainty regarding the child's condition that they are not refused appropriate services following assessment. One other important clinical reminder is that while the trajectory of early emerging impairments in social and communication development accompanied by rigid and repetitive behaviors and interests characterizes many children on the autism spectrum, there is a subgroup of particularly verbal and able children who go onto to receive a diagnosis of autism (sometimes called "high functioning autism") or Asperger's syndrome who may not receive a diagnosis in the preschool years. There is also another group who might meet diagnostic criteria for an autism spectrum disorder who do

Table 13–1.
Studies of diagnostic stability from preschool into the school-age years

Reference	Age Time 1	Age Time 2	Diagnoses at Time 1	Findings
Lord (1995)	31 months	50 months	16 CA, 14 NS	Diagnosis largely stable; Clinical judgment more reliable than ADI-R
Stone et al. (1999)	31 months	45 months	25 CA, 12 ASD, 8 NS	CA diagnosis largely stable; ASD less so (4 out of 12 moved to NS at Time 2); Fewer repetitive symptoms at Time 1
Cox et al. (1999)	21 months	45 months	9 CA, 3 ASD, 31 NS	CA diagnosis largely stable; NS less so (7 out of 31 moved to ASD at Time 2); Fewer repetitive symptoms at Time 1; Clinical judgment more reliable than ADI-R
Moore & Goodwin (2003)	34 months	53 months	16 CA, 3 ASD, 1 NS	Diagnosis stable (slight movement between CA and ASD only)
Charman et al. (2005)	25 months	85 months	26 CA	Diagnosis largely stable (3 moved to ASD and 1 to NS at Time 2)
Turner et al. (2006)	31 months	109 months	18 CA, 7 ASD	Diagnosis largely stable (2 CA moved to NS and 1 ASD moved to NS at Time 2)
Lord et al. (2006)	29 months	112 months	84 CA, 46 ASD, 42 NS	Diagnosis of CA largely stable (12 from 84 moved to ASD and 1 to NS at Time 2); ASD less so (27 of 46 moved to CA and 5 to NS at Time 2); NS less so (2 from 42 moved to CA and 9 to ASD at Time 2)
Chawarska et al. (2007)	22 months	36 months	19 CA, 9 ASD	Diagnosis of ASD stable (2 of 19 CA cases moved to ASD at Time 2); Clinical judgment more reliable than ADI-R and ADOS-G
Turner & Stone (2007)	29 months	53 months	38 CA, 10 ASD	Diagnosis stability moderate only (6 of 38 CA cases moved to ASD and 13 moved to NS at Time 2; 6 of 10 cases of ASD moved to NS at Time 2)
Kleinman et al. (2008)	27 months	53 months	46 CA, 15 ASD, 16 NS	Diagnosis stability moderate only (15 of 61 ASD cases moved to NS at Time 2)

CA = ICD-10 childhood autism/DSM-IV autistic disorder; ASD = PDD-NOS, atypical autism; NS = nonspectrum.

not receive an explicit diagnosis—those individuals with moderate to severe intellectual disability or those with an already identified preexisting associated medical condition, such as Fragile X or Down syndrome. In a recent epidemiological study Baird et al. (2006) found that, for cases meeting research diagnostic criteria for an autism spectrum disorder following in-depth assessment, low IQ predicted those who had not received a clinical diagnosis by local clinical services by age 10 years. One final caveat is that the studies summarized in Table 13-1 largely come from expert research clinical centers specifically studying young cohorts of children. In community settings in many countries there is evidence including from recent studies that for many children and their families a diagnosis is not confirmed until children are well into the school-age years (Howlin & Asgharian, 1999; Wiggins et al., 2006).

One final feature that emerges from these longitudinal studies is that, aside from the issue of diagnostic or categorical stability, the developmental trajectory of symptoms measured using a continuous or dimensional (as opposed to a categorical) metric changes over time (see also Honey et al., 2008). For example, Charman et al. (2005) described how the trajectories of the social, communication, and repetitive domain scores on the ADI-R had different developmental trajectories over time, consistent with the notion that the various aspects that make up the autism phenotype might not be tied together as closely as suggested by the current classification systems. This notion has also received support from a twin study demonstrating that, while each component of the autism phenotype is highly heritable, there is only very modest commonality in the heritability of the three components (Ronald et al., 2006). The recognition that autism is a complex

neurodevelopmental condition and that the presentation changes (in different ways in different individuals) over time presents considerable challenges to genetic and neuroscientific investigations (Happé et al., 2006). Longitudinal studies tracing the behavioral autism phenotype will therefore be important not only for informing clinicians regarding diagnostic practice but also for answering basic science questions regarding influences on the etiology and course of the disorder.

Language and Communication Development from Toddlerhood to the School-Age Years

Delayed language milestones are common in many preschool children with autism spectrum disorders, and the diagnostic criteria include both a delay in the emergence of language and the atypical use of nonverbal social-communication abilities including joint attention behaviors, social imitation, and pretend play abilities. However, while it is not uncommon for 2- and 3-year-olds with core autism (as opposed to those with Asperger's syndrome) to be nonverbal, language and nonverbal communication abilities typically do begin to develop throughout the preschool period as children enter kindergarten and school (Charman, Drew, et al., 2003; Luyster et al., 2007). Previously, the prognosis in terms of the proportion of children with autism who go on to develop functional language was considered poor, with papers from the 1970s and 1980s suggesting that perhaps only 50% of children develop functional speech (DeMyer et al., 1973; Freeman et al., 1985)—a reflection of the severely autistic and intellectually delayed cohorts who were first studied longitudinally. However, more recently it has become clear that language onset and outcomes are very variable, but generally more positive, for children with the spectrum of autism disorders. For example, in the large clinical cohort recently described by Hus and colleagues (N = 983; mean age 8 years, SD 5 years, range 4 to 52 years; Hus et al., 2007) only 9.8% had no single words (using the ADI-R criteria of 5 or more words used on a daily basis excluding "mama," "papa," etc.), 41.0% had delay in single word onset (> 24 months) but had single words when assessed, and half were not delayed in single word onset (49.2%; data from Hus et al., 2007, Table 5, p. 443). For phrase speech, the comparable figures were 24.0% of individuals with no phrase speech when assessed, 51.3% with delayed phrase speech onset (>33 months) but with phrased speech when assessed, and one quarter were not delayed in phrase speech (24.7%; data from Hus et al., 2007, Table 5, p. 443). A longitudinal study with a subgroup (N = 206) of the same cohort measured language ability at age 2, 3, 5, and 9 years (Anderson et al., 2007). This allowed sophisticated statistical modeling using growth curves to plot the trajectory of language development through the preschool years into school age. At a group level, the trajectory of growth in language abilities was slower for the children with a diagnosis of autism than for the children with

PDD-NOS or a nonspectrum developmental disorder. However, within each diagnostic group language growth and outcomes were very variable—and this variability increased over time—with some children in each group making such good progress that their language abilities were at the expected level at age 9 years, whereas other children in each group, in particular a subset of the children with "core" autism, made very little progress at all (see Figure 13-1). Age 2 symptom severity, nonverbal cognitive abilities, and joint attention skills were significant predictors of language outcomes at age 9 years. Anderson et al. (2007) conclude that their study "offers messages of both hope and realism" (p. 602) regarding the language outcomes of children receiving an early diagnosis of autism spectrum disorder.

There is also increasing recognition that while expressive language competencies might be the most evident delay for some preschool children with autism spectrum disorders, receptive abilities can be relatively more delayed (Charman, Drew, et al., 2003; Hudry et al., 2008; Luyster et al., 2007). This is clinically important but requires sensitive handling to explain that what parents sometimes take as "understanding" is often understanding of familiar routines and contextual cues rather than language comprehension per se. However, this finding is important as it is related to the appropriate focus of development, psycholinguistic approaches to communication intervention for preschool children with autism (see below).

Over the past 20 years there has been increasing interest in delineating the emergence of language competencies in children with autism spectrum disorder from toddlerhood through the preschool years. In part, this is to aid the clinical ability to determine likely prognosis—clinicians will recognize how parents understandably desire to be told if their child will talk and when. However, it has also helped develop our theoretical understanding of how (albeit sometimes delayed) language develops in autism. This is important both to understand if the mechanisms underpinning (delayed) language development are the same as or different from those in typically developing infants—about which a great deal is known (Bloom, 2000)—and to inform communication-based approaches to early intervention (see below).

Many studies over the past 20 years have demonstrated the perhaps unsurprising fact that over time individual variability is relatively stable in cohorts of preschoolers with autism—that is, early language competence predicts later language competence—including in some studies that followed children into the school-age period (e.g. Charman et al., 2005; Lord & Schopler, 1989; Mundy et al., 1990; Sigman & Ruskin, 1999; Venter et al., 1992). However, theoretically more interesting has been the question of whether earlier-emerging social communication abilities predict later language development. A strong psycholinguistic tradition from the study of normative language development has shown that this is the case for typically developing infants and toddlers (Bates et al., 1989; Carpenter et al., 1998; Morales et al., 2000; Mundy & Gomes, 1998). Given that many preschoolers with autism spectrum

disorders are impaired in their development of language ability *and* of early social communication abilities, the question of whether such associations also hold for toddlers and preschoolers with autism is both of clinical but also of theoretical interest. Demonstrating that the same association holds between early social communication abilities and later language development might suggest that similar developmental mechanisms are operating—albeit at a slower rate than in the typical case. Mundy et al. (1990) were the first to provide evidence to support this position, finding that joint attention behaviors (alternating gaze, pointing, showing, and gaze following) measured at 45 months were associated with language outcomes 13 months later. Sigman and Ruskin (1999) extended this finding by demonstrating associations from the preschool years to later language ability at 12 years of age. Stone and colleagues have also demonstrated longitudinal associations between various aspects of imitation and play as well as joint attention abilities at 2 years of age and language abilities measured at 4 years of age. This pattern has now been replicated in several other studies (e.g. Toth et al., 2006), including one that followed children with autism spectrum disorders from toddlerhood (20 months) into the preschool years (42 months; Charman, Baron-Cohen, et al., 2003).

These findings are both of theoretical and practical importance. Theoretically they suggest that since some of the associations seen in preschoolers with autism spectrum disorders are similar to that seen in typical development it might be the case that the mechanisms that operate are similar too. This is relevant to informing approaches to communication-based approaches to intervention. Although individual stability of skills (language to language) or of one "precursor" skill to another later emerging skill (joint attention to language; Charman et al., 2000) may tell us something about intrinsic

characteristics of the child, they may also suggest routes to intervention. Evidence consistent with this proposition was provided by Siller and Sigman (2002), who demonstrated that individual differences in maternal synchronicity (sometimes called "sensitivity") measured in joint play interactions was associated with later language outcomes even over many years. The circle is squared, so to speak, by several recent randomized controlled intervention trials. These have used a variety of social-communication strategies, including the promotion of joint attention, imitation, and joint social engagement skills both directly delivered by therapists (Kasari et al., 2006, 2008; Yoder & Stone, 2006) and delivered by training parents in these methods (Aldred et al., 2004; Drew et al., 2002), and found that language outcomes (and in the case of the Aldred et al. study social outcomes) can be improved. For developmentalists, this convergence of evidence that for preschool children with autism spectrum disorders there are both naturalistic associations over time between early social communication skills and later language outcomes and that these can be altered by targeted intervention in controlled studies is as close to evidence for a development mechanism as it is possible to get (Bradley & Bryant, 1983).

Social Development and Adaptive Behavior Development into the School-Age Years

While the development of language and communication abilities has understandably been the focus of much research interest in delineating the developmental trajectory of children with autism spectrum disorders from preschool to the school-age years, it is also of considerable importance to measure and

understand the influences on social development. This reflects not only the central place that social development—both the characteristic social impairments that are the primary feature of the diagnostic criteria but also the continuing emergence of positive social interests and competencies—has in our understanding of autism but also the changing social environment that children encounter as they emerge from the preschool period. When children enter kindergarten or preschool and then school their social milieu and the challenges they face in terms of forming friendships and social relationships changes considerably. Several studies have looked at the trajectory of social development in autism—both in terms of symptom measures but also in terms of everyday socially adaptive behavior, as measured by instrument such as the Vineland Adaptive Behavior Scales (VABS; Sparrow et al., 1984, 2006).

Initial studies used retrospective designs to document the changes in autism symptoms, including social behaviors, comparing current to past symptoms by parent report on the ADI-R. Piven et al. (1996) studied 38 adolescents and adults and found reductions on all 3 symptom domains compared to retrospective report at age 4 to 5 years. Fecteau et al. (2003) compared parent current report of symptoms at a mean age of 13 years with retrospective report at age 4 to 5 years in a sample of 28 children and adolescents and found significant reduction in symptoms on each of the 3 ADI-R domain scores, with most improvement shown in social symptoms. Interestingly, both studies reported fewest improvements in the repetitive behaviors and restricted interests domains. Piven et al. (1996) caution against the reliability of retrospective parental report that can be subject to biases in both directions (remembering things as "much worse" than they were in the light more recent improved behaviors and skills; and underreporting current symptoms as they are an improvement on the past) and also that the particular items included in the ADI-R algorithm that was developed to capture a lifetime diagnosis with age 4 to 5 years being considered the prototypical age at which autism symptoms are fully emerged and the presence at any point in a child's past (ADI-R "ever" ratings) might underestimate current social and communication difficulties in school-age children, adolescents, and adults.

A prospective longitudinal study by Szatmari and colleagues (Starr et al., 2003; Szatmari et al., 2003) has followed a group of high-IQ children and adolescents with autism (N = 41) and Asperger's syndrome (N = 17) from their initial diagnostic assessment at age 4 to 6 years over two years to age 6 to 8 years (Starr et al., 2003) and then to young adolescence (10 to 13 years; Szatmari et al., 2003). They found somewhat different patterns for the diagnostic groups with slight increases in social and communication symptoms on the ADI-R for the Asperger's group but reductions in social symptoms, but not communication symptoms, for the "high functioning" autism group (Starr et al., 2003). For neither group did scores on the repetitive and rigid behaviors change over time. The Szatmari et al. (2003) report focused on predictors of later outcomes and found that early language and nonverbal abilities were the strongest predictors but also reported lower adaptive behavior

on the VABS in adolescence compared to childhood. As summarized above, in their diagnostic outcome study Charman et al. (2005) also reported ADI-R symptom domain scores and found that from 2 to 7 years of age social and communication symptoms diminished (while those in the repetitive behavior domain initially increased and then decreased. One striking finding from this study was the increasing variability of the level of social symptoms over time and also among the general trends to diminished social impairment different children made progress across different timepoints as measured at age 2, 3, 4, to 5 (this timepoint only was retrospective) and 7 years. What this study does not answer is the underlying explanation for why some children, for example, make considerable progress between age 3 and age 4–5 years, while for others the most gains are made between 5 and 7 years. This pattern of individual variability is illustrated in Figure 13-2. While longitudinal studies are valuable, only randomized trials have the power to indicate likely causative effects of extrinsic factors, and only larger cohort studies (such as the Anderson et al. (2007) language study described above) the power to model different subgroup trajectories. Moss et al. (2008) reported ADI-R scores in a cohort of 35 children assessed at age 4 years and again at age 11 years and found that social and nonverbal communication domain scores were significantly reduced over time but repetitive behavior domain scores did not change. Lord et al. (2006) also presented ADI-R and ADOS scores at age 2 and age 9 years but found a somewhat different pattern. On the ADI-R, scores increased in each of the 3 domains (Lord et al., 2006, Table 2). On the ADOS-G the pattern was somewhat different, with a reduction in social domain scores and repetitive behavior domain scores for both children with an age-2 diagnosis of autism and PDD-NOS but little change in communication domain scores. Comparing findings across these different studies is not possible due to differences in the child characteristics, measures used and timepoints of the assessments, as well as extrinsic factors (such as interventions; likely differing etiologies) that were not controlled and often not measured. However, in line with our current conception of autism spectrum disorders as developmental disorders there is change in social symptoms as children enter the school-age years, and at a group level the most consistent finding is that social symptoms diminish. However, what is notable in line with the data presented on language above is that variability increases over time. At a clinical level this can be frustrating for clinicians and for parents alike—what parents want to know is what the future holds for their own child. From the clinician's perspective extrapolating from group data to an individual child is not possible. This high-lights the need for continuing longitudinal and controlled intervention trials in order to better inform prognosis and also to identify those individuals most in need of the most intensive interventions.

The above studies examined the trajectories of social impairments as measured by the diagnostic instruments the ADI-R and ADOS, but there are other facets of social development that are not always well captured by such instruments, in particular everyday social, communication, and daily living
Figure 13–2. ADI-R Reciprocal Social Interaction Domain scores from Charman, T., Taylor, E., Drew, A., Cockerill, H., Brown, J. A., & Baird, G. (2005). Outcome at 7 years of children diagnosed with autism at age 2: Predictive validity of assessments conducted at 2 and 3 years of age and pattern of symptom change over time. *Journal of Child Psychology and Psychiatry, 46,* 500–513.

adaptive skills. Several studies have shown that early social communication behaviors such as joint attention, imitation, and play are predictive of later language and social outcomes (Charman et al., 2003; Toth et al., 2006). Recent, more experimental studies have indicated that individual differences in key brain regions such as the amygdala are also associated with behavioral outcomes, reflecting the fact that autism is a neurobiobehavioral disorder (Munson et al., 2006; Mosconi et al., 2009).

Several cross-sectional studies have used the VABS (Sparrow et al., 1984) with samples of school-age children with an autism spectrum disorder. At least 2 findings have a high degree of consistency across samples. The first is that overall adaptive outcome is significantly lower than IQ, and the second is that, perhaps unsurprisingly, socialization skills are most delayed in comparison to communication and especially daily living skills (Carpentieri & Morgan, 1996; Freeman et al., 1999; Klin et al., 2007; Liss et al., 2001; Saulnier & Klin, 2007; although see Klin et al, 2007, Figure 1, for a example in the Michigan sample where daily livings skills are as depressed compared to IQ as socialization skills).

These findings are clinically important for several reasons. First, even for individuals who perform at or above age expectations within the adult-directed and relatively contained and predictable psychometric test situation their everyday "street smarts" (Klin et al., 2007) coping behavior can be significantly impaired. Indeed, the discrepancy between IQ scores and adaptive functioning is often most notable in individuals with high IQs, and Klin and colleagues found that socialization and daily living skills standard scores were 2 to 3 standard deviations below Full Scale IQ scores in 2 independent samples. This study also found that adaptive skills (in terms of standard scores) decreased with age, suggesting that the "lag" between measured intelligence and everyday coping widened between the early school years and late adolescence (see Szatmari et al, 2003; summarized above). Note however, that other studies have found no association between age and adaptive ability (e.g. Schatz & Hamden-Allen, 1995), and one study even found a positive association (Freeman et al., 1999). Further longitudinal studies are required to understand which developmental pattern is most representative. Both Klin et al. and Szatmari et al. found only marginal associations between autistic social and communication impairments and adaptive skills, suggesting that everyday adaptive behavior needs to be the target of intervention studies, alongside social understanding and skills and language and communication skills.

Alongside the discrepancy between a child's intellectual ability and his/her adaptive functioning, many children with autism spectrum disorders, including those with average or above average IQ, have significant difficulties with self-help and self-organization. This is related to their problems with the components of executive function, including set-shifting, generating ideas, and planning (Russo et al., 2007). Instruments such as the Behavioural Assessment of Dysexecutive Syndrome for Children (BADS-C; Emslie et al., 2003) can be helpful when used in conjunction with a structured parents and teacher rating scale, (e.g. the Adaptive Behaviour Assessment System-Second Edition [ABAS-II; Harrison & Oakland, 2003] or the Vineland Adaptive Behaviour Scale-II [Sparrow et al., 2006]) for determining whether executive functioning difficulties are affecting daily functioning (Bolte & Poustka, 2002). Gilotty et al. (2002) found negative associations between executive dysfunctions, including the ability to initiate behaviors and working memory, as measured by the Behavior Rating

Inventory of Executive Function (BRIEF; Gioia et al., 2000) and adaptive skills as measured by the VABS. One clinical lesson from these findings is that in particular as the social and organizational challenges of the school environment increase as children enter high school and teaching moves from a one-teacher, one-classroom environment to a many-teachers, many-classrooms environment, children with autism may need support to manage this more challenging environment (see Ozonoff, 1998; for examples of everyday strategies to overcome executive difficulties). Executive difficulties also impact on a child's ability to learn in the classroom environment, and a detailed psychometric assessment can identify specific executive difficulties that can inform approaches to remediation (see Box 13-1).

Box 13–1

Case description of a girl with specific executive difficulties.

Reprinted with permission from Charman, et al. (2008).

Case description
Lucy is an 8-year-old girl. Observed behavior in class: Lucy is distractible, daydreams, misunderstands the teacher's instructions, loses her possessions, and is always in the wrong place; her math and literacy skills are very weak. Her teacher believes she has poor attention and that her behavior is attention-seeking as, when an adult works with her, she is able to perform much better. Initial observations, using time-sampling, indicate that Lucy is off-task 70% of the time. An age matched peer is only off-task 22% of the time in the same lesson.

Assessment results
Assessments show that Lucy has average intellectual ability (Full Scale IQ: 90) but very poor executive skills (e.g. D-KEFS Colour-Word Interference, Scaled score: 3. Tower, Scaled Score: 3. BADS-C, Standard Score: 55). She finds it hard to plan her work although she can follow individually given instructions well; she does nothing when given open-ended tasks; cannot organize herself unless following a repetitive and learned routine; cannot hold instructions in her head or generate an understanding of what the instructions mean in practical terms, and does not know when to apply rules.

Intervention
Interventions need to focus on providing a model or framework within which Lucy can operate. At the beginning of every task she should be shown each step that she will need to take; she should be shown the end-point of what she is trying to achieve, and she should be taken through the steps needed to achieve this goal. By following this process and achieving success on several occasions, she will be able to learn how to apply the same series of steps to similar situations—i.e., she will develop a template to use in the future. When faced with changes to the task, she will need support to adapt her learned system. She should be provided with a visual timetable of the day's events and the things she needs for each session so that she can begin to learn to organize herself and see the sequence of events ahead of her.

A number of recently developed standardized instruments exist that test a range of cognitive abilities that make up the executive system (Delis-Kaplan Executive Function System [D–KEFS]; Delis et al., 2001; NEPSY; Korkman et al., 1997). Alongside routine psychometric assessment of IQ and language and communication skills, psychometric assessment of executive abilities, as well as attention and memory abilities (e.g. Working Memory Test Battery for Children (WMTB-C; Pickering & Gathercole, 2001); Test of Everyday Attention in Children (TEA-Ch; Manly et al., 1998)) can be helpful in identifying why a seemingly bright child is struggling either with learning or with managing the complex school environment. Based on a detailed psychometric assessment of executive, memory and attention difficulties bespoke approaches to intervention to bootstrap executive or memory difficulties can then be implemented to help a child fulfill their learning potential within the school environment and at home.

The Emergence of Comorbid Psychiatric Disorders in the School Age-Years

It is common for preschool children with an autism spectrum disorder to manifest behavior problems, and advice on management should form part of the postdiagnostic support provided by clinical services (Herring et al., 2006). However, several recent studies using questionnaire measures have reported high rates of psychiatric problems in school-age children and adolescents with autism spectrum disorders (Steinhausen & Metzke, 2004; Sukhodolsky et al., 2008). Two recent studies have used structured parental interviews that assess psychiatric disorder "caseness" and also found high rates. Leyfer et al. (2006) described rates of lifetime psychiatric disorder in 5- to 17-year-old children with autism, using a new interview, the Autism Comorbidity Interview-Parent and Lifetime Version (ACI-PL), modified from the KSADS (Chambers et al., 1985). Just less than three quarters met criteria for one or more DSM-IV disorders, with the most commonly reported disorders being specific phobia (44%), obsessive compulsive disorder (36%), and ADHD (30%). Studying a population-derived sample of 10- to 14-year-olds with autism or a broader autism spectrum disorder, Simonoff et al. (2008) found that 70% of participants had at least one comorbid disorder and 41% had 2 or more. The most common diagnoses were social anxiety disorder (29%), attention-deficit/hyperactivity disorder (28%) and oppositional-defiant disorder (28%). Simonoff and colleagues systematically examined whether the presence of psychiatric disorders was systematically associated with child (e.g., low IQ), parental (e.g., parent mental health difficulties), or contextual (e.g., deprivation) factors, but found few associations. Simonoff et al. (2008) suggest that the presence of an autism spectrum disorder "trumps" other risk factors that are commonly associated with childhood psychiatric disorders. They conclude that "Psychiatric disorders are common and frequently multiple in children with autism spectrum disorders. They may provide targets for intervention and should be routinely evaluated in the clinical

assessment of this group" (Simonoff et al., 2008, p. 921). There are issues regarding the extent to which these disorders should be considered truly "comorbid"—an independently occurring disorder unrelated to the primary symptoms of autism itself— or whether psychiatric symptom scales are endorsed by parents on the basis of autistic symptoms (see also Pine et al., 2008). While further research including direct assessments of mental state in school-age children is warranted to help determine the answer to this conundrum, the challenges of interviewing children with low IQ and the veracity and representativeness of self-report in children (and indeed adults) with autism spectrum disorders are considerable. It might be that in the future advances in genetics or neuroimaging experimental methods will help disentangle these issues, although for now clinicians, educators, and parents need to be aware that cognitive and behavioral manifestations that resemble those seen in children and adolescents without autism but with psychiatric disorders are common in autism spectrum disorders.

Conclusions

It is now widely recognized that there is very large heterogeneity in the children for whom a clinical diagnosis of "autism spectrum disorder" is clinically appropriate and that etiology will differ from case to case, moving some researchers from the biological fields of science to coin the term "the autisms" (Geschwind & Levitt, 2007). However, autism remains quintessentially a *developmental* disorder and heterogeneity in many, if not most, domains of functioning increases with age. Thus, predicting outcomes into the school years for children seen as toddlers and preschoolers can be very difficult. Determining the influence of intrinsic and extrinsic factors—and the interplay between the two (see Dawson, 2008)—remains a significant challenge but one in which the pace of research is at last beginning to catch up with the questions that parents understandably ask of clinicians ("How will my child do in school?"; "Will they go to college and be able to live independently?") (see Howlin et al., 2009; Rogers & Visnara, 2008; for reviews). The evidence base for interventions for preschool and school-age children has, until recent years, been woefully inadequate (see chapters by Green; Kasari; Rogers; Schreibman and Smith; for reviews). However, there are an increasing number of published studies including randomized controlled trials that provide evidence for the benefit of interventions, including those that focus on areas of core deficit such as communication (Aldred et al., 2004; Howlin et al., 2007; Kasari et al., 2008; Yoder & Stone, 2006).

The findings of the longitudinal studies summarized earlier and those of intervention trials offer both hope but also caution. Hope because some children with autism make significant progress as they enter the school-age years. Caution because in all cohort and intervention studies some children make little progress and because development can bring with it new challenges and problems such as mental health difficulties. Over the past decade there has understandably been a great focus on toddlers and preschoolers with autism spectrum disorders, with great advances in knowledge and clinical practice about early risk signs and early detection and diagnosis. The challenges faced by school-age children with autism spectrum disorders differ from those of the toddler, whose parents or caregivers structure much of their everyday world. An increasing emphasis on social group activities, self-organized behavior, and formal learning as children enter school can be a very challenging change for many children with autism spectrum disorders and much work remains to be done for us to understand how to help children with autism, their families, and educators to meet these challenges.

Challenges and Future Directions

- We need to integrate information on behavioral developmental trajectories with emerging developmental neurobiological accounts.
- The developmental trajectory of individual children differs significantly, and we do not know how much individual trajectories are influenced by intrinsic versus extrinsic factors.
- Better-controlled studies on the effects of intervention and schooling are needed.

Adolescents and Adults with Autism Spectrum Disorders

Points of Interest

- Improvement in autism symptoms and behavior problems is evident during adolescence and adulthood, although the majority of individuals with ASD remain significantly affected and dependent at least partially on the support of others.
- Comorbid psychiatric disorders affect approximately half of adolescents and adults with ASD. The majority is prescribed psychotropic medications; and once beginning medications the probability of discontinuing such medications is very low.
- Almost one quarter of adults continue in some type of postsecondary education once leaving high school, and about 20% achieve competitive or supported employment in the community. However, nearly half of adults attend day activity centers or sheltered workshops, and fewer than 10% have no structured day activity.
- Relationships between adolescents and adults with ASD and their parents and siblings are largely positive, although behavior problems interfere with close family relationships at these stages of life.
- High levels of maternal warmth and low levels of maternal criticism are longitudinally predictive of reduced behavior problems and autism symptoms in adolescents and adults, suggesting possible avenues for intervention.

Autism Spectrum Disorders (ASDs) are often conceptualized as disorders of childhood. However, for most affected individuals, autism lasts throughout the life course, although the severity of symptoms often declines with advancing age (for a review, see Seltzer, Shattuck, Abbeduto, & Greenberg, 2004). As most individuals with ASD live a full lifespan, many more years are spent in adolescence and adulthood than in childhood. Nevertheless, the bulk of research and clinical knowledge is focused on early identification of ASD, the early years after the diagnosis, and the response to early intervention.

In this chapter, we focus on autism during adolescence and adulthood. We summarize the available research and provide an in-depth report of the findings from our ongoing longitudinal study, "Adolescents and Adults with Autism (AAA)." Our focus in this chapter is on (1) the developmental course of autism symptoms and behavior problems during adolescence and adulthood, (2) physical and psychiatric comorbidities during these life stages, (3) the transition from school to adult life, and (4) family relations. Our goal is to present a multidimensional description of ASD during adolescence and adulthood.

Overview of the AAA Study

Our longitudinal study began in 1998 and it will extend through 2012, encompassing 12 years in the lives of each participating family during the 14-year study period. The inclusion criteria were as follows: the son or daughter was age 10 or older when the study began, had received an ASD diagnosis (autistic disorder, Asperger's disorder, or PDD-NOS) from an independent health or educational professional, and had a research-administered Autism Diagnostic Interview-Revised (ADI-R, Lord et al., 1994) profile consistent with the specific ASD diagnosis. Nearly all (94.6%) of the 406 sample members met ADI-R lifetime criteria for a diagnosis of autistic disorder. Case-by-case review of the other sample members (5.4%) determined that their ADI-R profile was consistent with their autism spectrum diagnosis (either Asperger's or PDD-NOS). Many sample members (44.2%) had been given multiple diagnoses on the autism spectrum; 37.2% have received two diagnoses (most commonly autistic disorder and PDD-NOS in 28.3% of the

sample), and 5.3% received all three diagnoses on the autism spectrum. For this reason, we refer to our sample members as having ASD, even though nearly all qualify for a diagnosis of autistic disorder.

Half of the families were from Wisconsin (n = 202), and half from Massachusetts (n = 204). We used identical recruitment (distributing information through service agencies, schools, clinics) and data collection methods in both states. When the study began, two thirds of the probands (65.1%) were living in the parental home. Currently (in 2009), the proportion who are coresiding is lower (41.6%), reflecting out-of-home placement during the past decade. Additionally, some sample members made educational transitions into (n = 61) and out of (n = 92) high school during the study period.

At Time 1, the probands ranged in age from 10 to 52 (mean = 21.91, SD = 9.41). Two thirds (63.8%) were under age 22. Their characteristics are consistent with what we would expect based on epidemiological studies of autism (Fombonne, 2003). Three fourths (73.2%) were male. One quarter (24.4%) had a seizure disorder, and a similar number (25.6%) were nonverbal or only spoke in single words. The majority (70.2%) had intellectual disability (ID).

We chose to include a wide age range of individuals with ASD for two reasons. First, the behavioral manifestations of developmental disabilities often change with age (Hodapp, 2004). Age-related change in the behavioral phenotype has been examined in adults with Down syndrome, Fragile X syndrome, Williams syndrome, and Prader-Willi syndrome (Dykens, 2004; Hodapp & Ricci, 2002; Jerrold et al., 2001; Wright-Talamante et al., 1996), but less is known about the life course trajectory of ASD. By examining behavioral change longitudinally across a broad range of ages, it is possible to describe the life course trajectory of autism symptoms and related behavior problems.

Our second rationale for including a broad age range is to be able to examine a number of age-related transitions. As noted above, our study includes adolescents and adults who transitioned into and out of high school, and moved out of the family home (and sometimes back). Once our study is completed, we will have collected pre- and posttransition measures on individuals who experience each of these transitions, and we will thus be able to examine their impacts on the unfolding lives of individuals with ASD in adolescence and adulthood.

We collect data from the families every 18 months. Thus far (between 1998 and 2009), we have conducted six repeated in-depth interviews with mothers, conducted a Daily Diary Study with the mothers, collected saliva from mothers to measure cortisol as a biomarker of daily stress, administered questionnaires to fathers and both adolescent and adult siblings, and administered cognitive assessments and interviews with the adolescents and adults with ASD.

More detailed descriptions of our methodology and findings can be found in publications from our research group (e.g., Greenberg, Seltzer, Hong, & Orsmond, 2006; Lounds,

Greenberg, Seltzer, & Shattuck, 2007; Orsmond & Seltzer, 2009; Shattuck et al., 2007; and Seltzer et al., 2003).

Developmental Course of Autism Symptoms and Behavior Problems

Only a few studies have examined the developmental course of autism during adolescence and adulthood, and these studies agree that although there is a gradual pattern of improvement, residual levels of impairment remain clinically significant and continue to limit quality of life (Billstedt et al., 2005; Fombonne, 2003; Howlin et al., 2000, 2004; Kobayashi & Murata, 1998; Mawhood et al., 2000; Nordin & Gillberg, 1998; Piven et al., 1996; Rutter et al., 1967). Furthermore, development may be "splintered," with improvement evident in only some of behaviors and symptoms and with different timing of improvements across behaviors (Seltzer et al., 2003). Additionally, there can be plateaus, and for some individuals, symptoms may even worsen (Gillberg & Steffenberg, 1987). Behavior problems are often exhibited by people with ASD (Aman et al., 2003; Hollander et al., 2003; Lecavalier, 2005; Shea et al., 2004; Tonge & Enfield, 2003). However, our research (Shattuck et al., 2007) was the first prospective study to have examined change in behavior problems among adolescents and adults with ASD.

Our retrospective and prospective analyses indicated that improvement in symptoms and behavior problems is evident during adolescence and adulthood. Although 95% of our sample qualified for a diagnosis of autistic disorder during childhood (using the ADI-R), by the time our study began, only about half (54.8%) currently showed symptoms severe enough to qualify for this diagnosis (Seltzer et al., 2003). Building on this pattern of improvement, our prospective analyses (Shattuck et al., 2007) indicated that between Times 1 and 4 of our study (spanning a 4.5-year period), the sample members improved significantly on 57% of the ADI-R algorithm items that rated current functioning, most prominently in the domain of restricted, repetitive behaviors and interests.[1] No item assessing current functioning worsened significantly, on average, over this 4.5-year period. These prospective analyses also revealed that internalizing, externalizing, and asocial behavior problems were significantly less frequent at Time 4 than Time 1. The subgroup who did not have ID and who had better language ability at Time 1 improved the most (Shattuck et al., 2007).

A similar pattern of improvement was evident in a life course analysis of restricted repetitive behaviors (RRBs) in individuals with ASD ranging from 2 to 62 years of age, combining data from seven studies including ours (Esbensen, Seltzer, Lam, & Bodfish, 2009). Over 700 individuals with ASD were rated on the Repetitive Behavior Scale-Revised (Bodfish, Symons, Parker & Lewis, 2000; Lam & Aman, 2007). In cross-sectional cohort comparisons, RRBs were found to be less frequent and less severe among older than younger individuals,

corroborating that autism symptoms abate with age. Further, we found that discrete types of RRBs had unique age-related patterns. For example, restricted interests were the most prevalent RRB across most ages, although they were markedly less prevalent among older individuals with ASD than younger individuals in these cohort comparisons and showed the steepest slope of age-related differences. Self-injurious repetitive behaviors were the least prevalent RRB across all ages. Stereotyped movements were common among young children with ASD, more so than rituals and compulsions, but became less prevalent than these other RRBs in adulthood. These unique patterns of age-related differences suggest that RRBs are a heterogeneous group of behaviors, and further confirm the findings reported in Lam and Aman (2007) that RRBs are not uniform in their age-related patterns.

On a less optimistic note, our sample members with ASD continued to struggle with social isolation in adolescence and adulthood. Overall, we found that fewer than 10% had reciprocal friendships with age peers, and nearly half had no peer relationships (Orsmond, Krauss, & Seltzer, 2004). Those who had peer relationships were more likely to be adolescents than adults, and had less impairment in reciprocal social interaction, as measured by current ratings on the ADI-R, than those who did not have friends. Although friendships were rare, the sample members more frequently engaged in recreational activities, including exercise (74.5% exercised at least once a week), working on a hobby (41.3% at least weekly), participating in group recreational activities (35.3% at least weekly), attending religious services (30.6% at least weekly), and socializing with relatives, neighbors, or people they knew from school or work (22.6%, 20.9%, and 13.2%, respectively, at least once a week).

In summary, past research suggests, and our findings confirm that, unlike some other developmental disabilities (e.g., Down syndrome, Fragile X syndrome) that evidence flat or declining patterns of functioning during adulthood, ASD shows a gradually improving pattern with respect to autism symptoms and behavior problems, on average. Nevertheless, the majority of the adolescents and adults in our sample remain significantly impaired and, as described below, at least partially dependent on the assistance of others.

Physical and Psychiatric Comorbidities

Fully 25–50% of individuals with ASD have comorbid health problems (Billstedt et al., 2005; Bryson & Smith, 1998). Up to 12% have disorders of known or suspected genetic origin (Kielinen et al., 2004). Lifetime rates of epilepsy are high (up to 40%), especially among those with ID, with seizures often developing during adolescence (Billstedt et al., 2005; Fombonne, 2003). Disrupted sleep is reported in 40–80% of children with ASD (Richdale, 1999).

In our sample of adolescents and adults, health problems were common. Only 29% were rated by their mothers as being in excellent health. According to maternal report, disrupted sleep was frequent (70% of adolescents and adults had disrupted sleep, with 35% having disrupted sleep once a week or more often). Also, many reported that their son or daughter had gastrointestinal (GI) problems (58%, with 22% having GI problems once a week or more often). One quarter (25%) had seizures. Of those who had seizures, most reported tonic-clonic (63%), absence (31%), or complex partial (26%) seizures, and some had multiple types of seizures. Fully 12% of the sample had at least one emergency room visit in the past year, with some reporting more than 50 visits.

Studies of children with ASD find consistently high rates of comorbid psychiatric disorders. Studies have shown that approximately three fourths of children with autism, PDD, and Asperger's syndrome met symptom criteria for at least one other comorbid psychiatric disorder (de Bruin, 2007; Ghaziuddin et al., 1998, Leyfer et al., 2006). Other studies report that children with ASD have higher rates of a variety of psychiatric disorders than typically developing children, including mood disorders, anxiety disorders, and oppositional defiant disorder (Gadow, Devincent, Pomeroy & Azizian, 2004, 2005; Kim et al., 2000).

Rates of comorbid psychiatric disorders remain high as individuals with ASD enter adolescence and adulthood. Ghaziuddin et al. (1998) reported that about 50% of adolescents and adults with Asperger's syndrome met diagnostic criteria for a comorbid psychiatric disorder. Bradley et al. (2004) found that 67% of adolescents and adults diagnosed with both autism and severe intellectual disability met at least one clinical cutoff for a psychiatric disorder. Tsakanikos and colleagues (2006) reported somewhat lower rates in their large community-based study of adults who had both autism and intellectual disability, with 36% of the sample having a psychiatric disorder.

We examined this issue in our sample of adolescents and adults with ASD (Kring, Greenberg, & Seltzer, 2008) and found that approximately half (52%) of the sample members had at least one comorbid psychiatric diagnosis, according to maternal report. Anxiety disorders were the most prevalent, with over 40% of the individuals with ASD in our sample having received an anxiety disorder diagnosis, of which a large subgroup had obsessive-compulsive disorder. Depression also was quite prevalent among these adolescents and adults (23.9%). We do not have data about whether the probability of receiving diagnoses of anxiety and depression increases for children with ASD during adolescence, whether anxiety and depressive symptoms increase in severity, or whether these comorbid conditions increase in individuals with ASD at any greater rate than in the general population during adolescence. These all remain important questions for future research.

There remains considerable debate about the prevalence of psychotic disorders among individuals with ASD. Some reports indicate higher rates of schizophrenia and bipolar disorder in individuals with ASD (e.g., Billstedt et al., 2005), but other investigations have shown rates comparable to individuals with other types of DDs (Tsakinikos et al., 2006) and to the general population (Kobayashi & Murata, 1998; Lainhart &

Folstein, 1994; Morgan et al., 2003). In our study, 5.9% of the adolescents and adults with ASD had a diagnosis of bipolar disorder and 2.6% had a diagnosis of schizophrenia (Kring et al., 2008), which is substantially higher than in the general population (estimated at 0.4%–1.6% for bipolar disorder and 0.5%–1.5% for schizophrenia; APA, 2000).

Relatively little is known about the extent to which individuals with ASD and comorbid psychiatric disorders have more severe symptoms of autism, elevated behavior problems, and more physical health problems than those with autism and no comorbid psychiatric disorders. Kim et al. (2000) found evidence that children with ASD who also had anxiety or depression had elevated levels of behavior problems (Kim et al., 2000). In our study of adolescents and adults, those with ASD and a comorbid psychiatric diagnosis had significantly more repetitive behaviors, higher levels of asocial behaviors, poorer overall health, more frequent GI problems, and more difficulty sleeping than those with ASD only (Kring et al., 2008).

Adolescents and adults with ASD are frequently prescribed medications for psychiatric and health problems. There is some evidence supporting the efficacy of psychotropic medications in reducing behavior problems (Anderson et al., 1989; Gordon et al., 1993; Hellings et al., 2006; McDougle et al., 1996; Research Units on Pediatric Psychopharmacology Autism Network, 2002). However, these medications carry the risk of side effects (Aman, Lam & Von Bourgondien, 2005; Tsai, 1999), which may adversely affect health (Law, 2007).

We conducted a longitudinal analysis of medications taken by the adolescents and adults with ASD in our sample, spanning the 4.5 years between Times 1 and Time 4 of our study (Esbensen, Greenberg, Seltzer & Aman, 2009). We found that a total of 57% of our sample members were taking at least one prescription psychotropic medication, and 37% were taking at least one prescription nonpsychotropic medication at the beginning of the study (with 70% taking at least one prescription medication of either type at Time 1). The proportion of individuals taking these medications increased significantly over time, with 81% taking at least one medication 4.5 years later (64% taking at least one psychotropic medication and 50% taking at least one nonpsychotropic medication at Time 4). We calculated the conditional probabilities of continuing or altering medication status over the 4.5-year study period, and the findings were highly informative about medication practices over time. Our data showed that once adolescents and adults with ASD are prescribed medications, they are highly likely to stay medicated. This pattern was more pronounced for psychotropic medications (approximately 11 times more likely to remain on psychotropic medications than to *stop* taking them) than for nonpsychotropic medications (nearly five times more likely to stay on nonpsychotropic medications than to stop during the 4.5 year study period). Thus, a considerable number of individuals with ASD are being prescribed psychotropic medications, and once prescribed it is likely that they will remain on these medications for many years.

To summarize, our data confirm past research that adolescents and adults with ASD have a high rate of comorbidities at these stages of life, particularly psychiatric diagnoses. Not surprisingly, this is a highly medicated population. Juxtaposed against this pattern of multiple diagnoses and high rates of psychotropic medications is the pattern of improvement in autism symptoms and behavior problems, reported above. An unanswered question is whether the increasing use of psychotropic medication may account for some of the behavioral and symptomatic improvements evident in our sample members, or whether the trajectory of improvement reflects the natural course of ASD in adolescence and adulthood.

The Transition from School to Adult Life

Change is often extremely stressful for individuals with ASD, but they must face many age-related transitions. The transition out of high school signifies the end of the entitlement to educational services mandated by federal law. Moving to one's own home is a daunting challenge for many individuals with ASD, and lack of independence results in continued family caregiving. Residence in a group home or supported living also continues to challenge parents who must provide oversight in a service system marked by very high staff turnover and questionable quality of services. Over time, there is an increasing risk of parental marital disruption, health decline, and death, which in turn may have consequences for the timing of other transitions for individuals with ASD. Each transition has its own ecology, but the timing, antecedents, and consequences are poorly understood.

In 2006, there were nearly 224,000 children and adolescents in the primary and secondary school systems with an ASD diagnosis; the number of students served with an ASD diagnosis increased 650% between 1996 and 2006, and 34% between 2004 and 2006 (IDEA, 2008). The number of children diagnosed with ASD began rising rapidly in the early 1990s (Gurney et al., 2003), and children from that generation are now exiting the school system, putting an extreme burden on an already overtaxed adult service system (Howlin, Alcock, & Burkin, 2005). Although this increase in the prevalence of ASD may be due in part to diagnostic substitution (Shattuck, 2006), nevertheless many of these adolescents and young adults are in need of formal and informal supports during and after transition.

There is considerable variability in the age when individuals with ASD exit the educational system. Some higher-functioning individuals graduate from high school with their similarly aged peers. Others take advantage of IDEA and continue in school until age 22. Once they leave school and lose entitlement to services, there is an increase in parental responsibility. Leaving high school does not necessarily imply the receipt of a diploma. Howlin et al. (2004) reported that 78% of their sample left high school without a formal diploma,

fewer than one third were working, and the majority of jobs did not require a skill and were poorly paid (Howlin et al., 2005), all of which are stressful for the individual and the family.

We conducted preliminary analyses examining the post-secondary educational and employment activities in which individuals with ASD participated during their first 18 months after exiting the secondary school system. Nearly one quarter of our sample members (23%) went on to some type of post-secondary education; the majority of these (70%) were in school more than 10 hours a week. Another 22% did not pursue postsecondary education, but obtained a competitive or supported job in the community. However, the most prevalent activity for our sample members after exiting high school was participation in day activity centers or sheltered workshops (46%). The remaining 9% had no employment activities. Although the proportion of adults with ASD who had no regular daytime activities is cause for concern, our data suggest that most are able to find some type of regular day activity after leaving high school. Nevertheless, the fact that approximately half of the sample members were in segregated day programs or workshops for individuals with developmental disabilities points to the challenge of finding community employment for these adults.

An increasing number of adults with ASD live apart from their parents. Rumsey et al. (1985) reported that 36% of the adults in their sample lived away from their parents. Gillberg and Steffenberg (1987), reporting on the birth cohort with autism born in Goteburg, Sweden, between 1961 and 1968, found an even split between those who lived with their parents and those in nonfamily settings. In other studies, the proportion of adults living away from parents was about two thirds (Howlin et al., 2004; Wolf & Goldberg, 1986). Therefore, although some adults with ASD continue to live with their parents, a substantial number move into nonfamily settings. No recent study has described the living arrangements of adults with ASD, with the exception of Howlin et al. (2004), which reported on a British sample.

We examined the percentage of adults with ASD who were living with their families at our most recent wave of data collection. Results were similar to what was found by Gillberg and Steffenberg (1987); fewer than half of the individuals with ASD were living with parents or other relatives (41.6%). Of those who were not living with family, 62% were living in a community residence or foster home, and 34% were living in semi-independent or independent housing. Narrowing the sample to those who were between the ages of 10 and 22 years at the start of the study, we found that over 82% were residing with parents at the first time point (in 1998). At the most recent time point, 10 years later, the percentage living with family dropped to 61%. Just over one half of those who moved out of the family home went to live in semi-independent or independent settings, while the other half lived in community residences, foster homes, or institutionalized settings. In sum, the percentage of adolescents and adults with ASD living with family in our sample was slightly higher than Howlin et al.'s

(2004) British sample, with younger adults more likely to live with family than older adults.

In another analysis, we profiled adult lives of individuals with ASD and contrasted them with another well-defined group of adults with ID, namely adults with Down syndrome (DS; Esbensen, Bishop, Seltzer, Greenberg, & Taylor, 2010). Using data from a linked longitudinal study of adults with DS (Krauss & Seltzer, 1999), analyses included 70 adults with ASD, and 70 adults with DS who were matched on age and ID (all had ID). Dependent variables included residential arrangements, social contact with friends, vocational activities, and an overall composite of adult success that combined these three domains.

Our analyses revealed significant differences between the adults with ASD and the adults with DS in residential independence and social contact with friends. On average, adults with ASD lived in less independent residential settings than did adults with DS. Furthermore, only 8% of these adults with ASD visited with friends several times a week, compared to 25% of adults with DS. Given these differences, it was not surprising that adults with ASD scored lower on the composite measure of adult success than did adults with DS. Our findings suggest that the difficulties in attaining adult independence that have been reported in other studies of individuals with ASD (Ballaban-Gil, Rapin, Tuchman, & Shinnar, 1996; Eaves & Ho, 2008; Howlin et al., 2004; Kobayashi, Murata, & Yoshinaga, 1992) cannot be accounted for only by impairments in cognitive abilities, as ID was controlled in our study. Instead, there are characteristics or behaviors associated with the ASD phenotype that place adults with ASD at an elevated risk for poorer adult outcomes.

We also examined the role of adult services (occupational therapy, psychiatric services, or transportation services) in promoting adult success, and found that the number of services received was related to greater adult success for adults with DS, but was unrelated to adult success for those who had ASD (Esbensen et al., 2010). This finding points to the need to develop new, more effective methods of service delivery targeted specifically to meet the needs of adults with ASD.

In summary, the transition from adolescence to adulthood brings many changes to the lives of individuals with ASD. About one quarter pursue some type of postsecondary education after leaving high school, and about one fifth had obtained supported or independent jobs in the community. However, nearly half were in segregated vocational settings and a few had no day activity, which is cause for concern. Regarding residential transitions, it is common for individuals to move out of the family home once they reach adulthood, and about half of those who move away from home live either independently or in semi-independent settings. Their lifestyles are considerably more restricted than counterparts with Down syndrome. Finally, the receipt of formal services is associated with greater adult success for those with DS but not for those with ASD, suggesting a need for the development of more effective services for persons with ASD in adulthood.

Family Relationships

Although adulthood signifies a time of increasing independence from the family, for individuals with disabilities, the role of the family remains predominant throughout the life course and critical to maintaining a high quality of life (Seltzer, Krauss, Orsmond, & Vestal, 2000). Our study provided the opportunity to assess parent-child relationships during adolescence and adulthood and also the relationships between the individual with ASD and his or her unaffected siblings. These are reported in this section, along with findings about how the family environment is associated with changes in the symptoms of autism and behavior problems during these stages of life.

Parent-Child Relationships in Adolescence and Adulthood

Research on young children with ASD has shown that, despite the communication and social challenges associated with this disorder, strong bonds of attachment are formed, and interactions between parents and the child are positive (see Rutgers, Bakermans-Kranenburg, van Ijendoorn, & van Berckelaer-Onnes, 2004, for a review). Nevertheless, mothers may experience the relationship as quite different from their relationships with their other (unaffected) children.

These patterns characterizing the mother-child relationship tend to persist into adolescence and adulthood. In our study, we assessed the degree of positive affect felt by mothers toward their son or daughter with ASD and the mother's perception of reciprocated positive affect from the adult child to her (Orsmond, Seltzer, Greenberg, & Krauss, 2006). The Positive Affect Index (Bengtson & Roberts, 1991) assessed the dimensions of affection, respect, fairness, understanding, and trust in the parent-child relationship, each rated on a 6-point scale, with scores of 5 or 6 signifying a high degree of positive affect with respect to the particular dimension. We found a strong pattern of positive affect felt by the mother for the son or daughter. Fully 90.1% of the mothers gave ratings of either a 5 or a 6 for the degree of affection she felt toward her son or daughter with ASD and more than three fourths of the mothers (78.2%) gave rates of either 5 or 6 with respect to the degree to which she respects her son or daughter with ASD. About half of the mothers rated their feelings of fairness toward (57.9%) and understanding of (53.0%) their son or daughter with ASD at the high end of the scale (i.e., a rating of 5 or 6), but only about one third (38.1%) of the mothers felt that they trusted their adolescent or adult child to this degree.

There were lower ratings of reciprocated positive affect from the adolescent or adult with ASD, as perceived by the mother. Just under two thirds of the mothers perceived the highest levels (i.e., a rating of 5 or 6) of affection from their son or daughter, and about two fifths (39.6%) felt that their adolescent or adult child had the highest levels of respect for them. Only about one quarter of the mothers perceived a high

level of reciprocated feelings of fairness (27.7%) and understanding (29.2%) from their son or daughter. However, three fourths (74.3%) felt that their adolescent or adult child with ASD trusted them at the highest levels.

We also rated mothers' expression of warmth toward their adolescent or adult son or daughter with ASD, using standardized and independent ratings of the Five Minute Speech Sample (Magana, Goldstein, Karno, Miklowitz, Jenkins, & Falloon, 1986). Consistent with the data on positive affect, over one third (35.6%) of mothers were rated as expressing moderately high to high degrees of warmth when describing their child with ASD, half (50.5%) expressed some to moderate degrees of warmth, and only 10.4% were rated as expressing no or very little warmth in the relationship (Orsmond et al., 2006).

Thus, the descriptive data suggest that relationships between mothers and their adolescent or adult child with ASD are positive during these stages of life, with the most positive aspects being the exchange of affection between the mother and her adolescent or adult child. Contrary to historical characterizations of mothers of individuals with autism (Bettelheim, 1967), the majority of mothers in our sample had warm and positive relationships with their adolescent son or daughter.

Sibling Relationships in Adolescence and Adulthood

The sibling relationship is one of the most important family relationships, as it typically lasts the longest. Siblings of individuals with an ASD often become the guardians when their parents are no longer able to provide care, due to illness or death. Thus, maintaining a positive sibling relationship and sibling psychological well-being is crucial to the long-term quality of life of individuals with an ASD. Moreover, sibling well-being has the potential to impact maternal well-being. We have found that mothers who have a child with an ASD and another child with a diagnosed disability report higher levels of depressive symptoms and anxiety and lower levels of family adaptability and cohesion, compared to mothers whose only child with a disability has an ASD (Orsmond, Lin, & Seltzer, 2007). These differences were observed when the children were adolescents and adults, suggesting that the effects of such caregiving experiences continue beyond childhood.

Our research has been among the first to examine sibling well-being and sibling relationships specifically during the life stages of adolescence and adulthood. Prior research has focused on childhood (e.g., Knott et al., 1995; Rivers & Stoneman, 2003) or included siblings in broad age ranges that span childhood through adolescence and young adulthood (e.g. Bägenholm & Gillberg, 1991; Kaminsky & Dewey, 2001; Ross & Cuskelly, 2006). Taking a developmental perspective will help us understand the unique challenges to siblings and the family at different life stages (Orsmond & Seltzer, 2007).

As siblings during adulthood are establishing their independent lives, we observed fewer shared activities between adult siblings than was reported for adolescent siblings (Orsmond, Kuo, & Seltzer, 2009). However, feelings of

closeness in the sibling relationship did not differ between the samples of adolescent and adult siblings, suggesting fewer changes in the quality of sibling relationships across these life stages. For both age groups, behavior problems manifested by the brother or sister with an ASD were associated with fewer shared sibling activities and a more distant sibling relationship. Interestingly, support from parents was particularly important to adult siblings, wherein adult siblings who reported greater support from their parents reported a closer sibling relationship (Orsmond et al., 2009).

We also examined the extent to which sibling relationships in adulthood, when one sibling has an ASD, are distinct from sibling relationships in adulthood when one sibling has Down syndrome (Orsmond & Seltzer, 2007). Using data from the same linked longitudinal study on adults with DS as mentioned above (Krauss & Seltzer, 1999), we found that siblings of adults with an ASD have less contact with their brother or sister, and report lower levels of closeness in the sibling relationship and more pessimism about their brother or sister's future, than do siblings of adults with DS (Orsmond & Seltzer, 2007).

Comparing sibling well-being among adolescent and adult siblings of individuals with ASD, we did not find a significant age-related difference in their report of depressive symptoms (Orsmond et al., 2009), suggesting stability in the risk of depression among siblings of individuals with ASD from adolescence to adulthood. Focusing on the adolescent sample, we found that one third reported depressive symptoms on the Center for Epidemiological Studies Depression Scale (CES-D) above the clinical cutoff score of 16. Compared to community samples of adolescents, this rate is not elevated, but there was considerable variability within our sample, and sisters reported significantly higher rates of depressive and anxiety symptoms than brothers (Orsmond & Seltzer, 2009). Realizing that siblings are at risk of negative outcomes both because of family stress (such as maternal distress or behavior problems manifested by the brother or sister with an ASD) and because of genetic vulnerabilities, we have examined the variability in depressive symptoms in these siblings from a diathesis-stress perspective (e.g., Bauminger & Yirmiya, 2001). We found support for this model, in that the siblings with the highest level of depressive symptoms were those who experienced a greater number of stressful life events in the past year and also were rated by their mothers as showing more subclinical symptoms of the autism phenotype (Orsmond & Seltzer, 2009).

Taken together, our research findings on siblings suggest an altered path of sibling relationships that may put individuals with an ASD at risk of limited support after their parents are deceased. At the same time, we have identified some factors that might put siblings themselves at risk of adverse outcomes (e.g., the experience of stressful life events), and these could serve as screening factors to identify siblings who might need additional individual supports to help promote their well-being into adulthood. Nevertheless, the majority of siblings remain involved with their adult brother or sister with ASD and function in the nonclinical range psychologically.

The Family Environment and Expressed Emotion

One aspect of the family environment that has been receiving increasing attention for families of individuals with disabilities is *expressed emotion* (EE). EE is a measure of emotional intensity in the family and specifically refers to criticism or emotional overinvolvement of one family member toward another. In individuals with mental health problems such as schizophrenia and bipolar disorder, EE has been a strong predictor of outcomes including relapse (Butzlaff & Hooley, 1998; Lopez et al., 2004). Concomitantly, in studies of families of individuals with developmental disabilities, EE, particularly criticism, has consistently be related to elevated behavior problems in both children and adults (Chadwick, Kusel, & Cuddy, 2008; Hastings, Daley, Burns, & Beck, 2006; Hastings & Lloyd, 2007). When considering the association between EE and the behavioral functioning of individuals with developmental disabilities, it is important to consider that these relationships are likely bidirectional. Behavior problems have been repeatedly documented as a significant source of stress for parents (Hastings et al., 2005; Herring et al., 2006; Lounds et al., 2007), which may in turn relate to elevated levels of EE in the home. Conversely, high levels of EE may serve to maintain or even exacerbate children's behavior problems (Hastings & Lloyd, 2007).

> **Expressed Emotion** is a qualitative measure of the amount or degree of emotion displayed. The measure is usually applied to caretakers or to family members in a home setting.

In our research, we have examined the bidirectional associations between aspects of the family environment and the behavior problems and autism symptoms in adolescents and adults with ASD. Before discussing our findings, it is particularly important to note that although the family environment may have an impact on the behavioral functioning of the individuals with ASD, this does not imply that the child's ASD is *caused* by the family. In the past, mothers of children with ASD were wrongly accused of causing their child's autism by being emotionally cold and distant. In contrast with this inaccurate and stigmatizing early belief, research subsequently has shown that parents of children with ASD interact with their children in ways that are just as sensitive and responsive as parents of children with other developmental disabilities and parents of typically developing children (Siller & Sigman, 2002; van IJzendoorn et al., 2007). Furthermore, there is clear consensus that ASD is a complex neurodevelopmental disorder that is strongly genetic in origin (Folstein & Rosen-Sheidley, 2001). Despite the genetic etiology of ASD, however, it is still possible to explore ways in which the phenotypic expression of ASD may be influenced by family factors. This has been our focus in several studies.

In one set of analyses, we explored the bidirectional effects of maternal EE, specifically criticism and emotional overinvolvement, on the behavior problems and autism symptoms of adolescents and adults with ASD. Using a subsample of

coresiding mothers and children at Time 2 and Time 3 of our study, cross-lagged panel analyses revealed that high levels of EE were associated with increases in internalizing, externalizing, and asocial behavior in the adolescents and adults with ASD over an 18-month period. A high level of EE was also related to increasingly severe autism symptoms (Greenberg et al., 2006). Of note, most families in our study did not have abnormally elevated levels of EE, perhaps reflecting successful coping and adaptation by these families (Greenberg et al., 2006). These findings also underscore that, even in the absence of extreme levels of EE, the family environment is still an important influence on development in adolescents and adults with ASD.

In a separate set of analyses (Smith, Greenberg, Seltzer, & Hong, 2008), we examined the bidirectional impact of prosocial family processes such as warmth, praise, and relationship quality on behavior problems and autism symptoms, using the same longitudinal design. We found that high levels of warmth and praise were associated with the abatement of repetitive behaviors over time. Additionally, a positive mother-child relationship quality was associated with reductions in internalizing and externalizing problems, repetitive behaviors, and impairments in social reciprocity 18 months later in our sample of adolescents and adults with ASD.

Interestingly, in these analyses, the majority of effects flowed from parent to child, although we did find some evidence of reciprocal child-to-mother effects in a few instances. Overall, we found that the majority of mothers in our sample expressed low levels of criticism and high levels of warmth toward their son or daughter with ASD and that positive aspects of the family emotional climate were associated with improvements in behavior problems and autism symptoms during adolescence and adulthood. These findings highlight how a positive family environment can act as a mechanism for improving the quality of life for individuals with ASD.

Taken together, the findings from our investigations of EE and warmth in families of adolescents and adults with ASD suggest that some aspects of the family environment may be useful targets for future interventions. Specifically, reducing criticism and increasing warmth, praise, and relationship quality may serve not only to improve the family emotional climate but also to reduce behavior problems and alleviate autism symptoms during adolescence and adulthood. In families of individuals with mental health problems, family psychoeducation programs have been shown to be very effective for reducing levels of EE, leading to reductions in family burden and better outcomes for the individuals with a mental health condition (Hogarty et al., 1991; Klaus & Fristad, 2005; Lopez, Toprac, Crismon, Boemer, & Baumgartner, 2005; Miklowitz et al., 2004). These interventions typically involve weekly group sessions wherein multiple family members are provided with education on the nature, course, and management of the condition as well as activities to practice problem-solving. Although the challenges associated with parenting an adolescent or adult with ASD are distinct from those faced by families coping with psychiatric conditions, some aspects are similar, such as managing difficult behaviors and navigating the service system. As such, a family psychoeducation intervention may be one potentially promising model that could be effectively adapted for families of individuals with ASD during adolescence and adulthood.

Conclusion

Much remains to be learned about individuals with ASD during adolescence and adulthood. Studies of those who become symptom-free and who lead normative adult lives will have great importance for informing our understanding of ASD across the life course. In addition, it will be profitable to examine the cohort of individuals with ASD who remain supported by their families or by the formal service system in order to identify the constellation of services, employment opportunities, and living arrangements that promote a high quality of life. In particular, the identification of factors that ease the transition out of high school will be valuable.

Challenges and Future Directions

- Other research is needed to reveal more about the health of individuals with ASD, especially as they reach midlife and old age. The many comorbid physical and psychiatric conditions that characterize this population, and their heavy prescription medication use, make it important to determine the long-range consequences of health problems and medication practices that often begin in childhood.
- Behavior problems continue during adolescence and adulthood in individuals with ASD and remain major risk factors for disrupted family relationships and a limited quality of life. Therefore, more research is needed to develop and evaluate interventions aimed at reducing behavior problems during adolescence and adulthood, as they represent risk factors throughout the life course.
- The young children who receive an ASD diagnosis today may have a very different life course than the cohort that has been followed in the AAA study. Changing diagnostic patterns, improved early detection and diagnosis, more widespread early intervention, and more supportive societal attitudes might signal a more promising life course for those who reach adolescence and adulthood in the future. Yet it is only by studying this population longitudinally, extending into the adolescent and adult years, that we will be able to disentangle cohort differences from the true developmental course of the behavioral phenotype of autism and related disorders.

Commentary ⊞ Katherine A. Loveland

Issues in Defining the Core Features of Autism Through the Lifespan

The quest to define autism in terms of its central characteristics has evolved greatly over the past fifty years, as evidenced both by changing descriptions of the syndrome in the Diagnostic and Statistical Manual (DSM) of the American Psychiatric Association, and by changes in the topics most researched by investigators in the field. In this commentary I discuss some of the outstanding issues that must be confronted if we are to attain a better understanding and definition of autism (hereafter referred to as Autism Spectrum Disorder or ASD, for simplicity) and move beyond the limitations of present diagnostic models.

Since the syndrome was first identified, the core characteristics of ASD have been a source of controversy (see Mundy, chapter 8, this volume). Much ink has been expended in the battle to secure the high ground in this controversy, with adherents to various positions claiming to have identified the "real" underlying deficit in ASD, from which all else proceeds. As in the ancient Indian parable of the blind men and the elephant, however, scholars have naturally tended to interpret ASD according to the conceptual and methodological lenses through which they have viewed it. Thus, for example, over the decades psychodynamic models gave way to those involving language, perception and cognition, emotion, social cognition, or neuropsychological differences, reflecting the models and approaches current in the behavioral and medical sciences at the time. Why should ASD pose such problems to our attempts to define its essential characteristics?

Clinicians and researchers have long recognized that difficulties and disagreements in specifying the core characteristics of ASD stem in part from the wide heterogeneity among individuals with this type of disorder. Individuals vary not only in the severity of autistic behaviors, but also in other characteristics such as intellectual ability, level of language development, motor skills and behaviors, sensory differences, early social communication as well as emotional behavior and responsivity (see Loveland & Tunali, 2005, for review). This wide range of presentations has led to the currently accepted practice of

referring to "Autism Spectrum Disorders," a term that embraces all forms of the disorder and suggests the image of a vector along which individuals can be located according to their severity.

Although the concept of the spectrum is in many ways an improvement over a model that does not recognize degrees of severity, it too is incomplete as a characterization of a developmental disorder such as ASD, since the spectrum concept does not necessarily encompass the idea of change with development. The task of specifying the core characteristics of ASD is further complicated when we consider the implications of a lifespan perspective. For example, Lord et al. (2006) and others have found that a consequence of the move to greater inclusiveness in the definition of ASD is that children on the margins of the definition, i.e., those with less classical presentations, are less likely to exhibit stability of diagnosis with increasing age. Charman (chapter 13, this volume) also emphasizes that heterogeneity among individuals with ASD actually increases as they become older, with various "core characteristics" progressing and skills developing at different rates. Thus, the fact that ASD is developmental in nature becomes critical to our consideration of the autism spectrum and the question of core characteristics: ASD must be conceptualized not as a discrete and static disorder presenting at a particular point in time, but as a *complex developmental process or pathway* that differs from the typical and that extends across the lifespan of the individual. An implication of this view is that over the life of the individual, ASD will present differently at different chronological ages, as a function of a complex combination of influences both within and outside the person. Among these are the genotype of the individual, maturational stage, family resources and functioning, social experiences with peers, the individual's own actions, changing social expectations of the individual as he or she matures, and many others. Current efforts to specify the earliest observable behavioral markers for high risk of ASD in infants (e.g., Brian et al., 2008; see also chapter 12, this volume)

demonstrate that many of the characteristics we regard as essential to the syndrome of ASD emerge over time rather than being fully manifested when development first departs from a typical pathway. Thus, we can expect that ASD, far from being a discrete constellation of clinical signs that once it arrives remains fixed in its manifestations over time, is instead a moving target—a target moreover that moves with the child, developing as she or he develops, being constantly shaped by factors both within the individual and originating in the environment.

It is no wonder then, that there remains controversy about what unifies this disorder, with its changing manifestations over the lifespan of the individual. In the face of such frustrating complexity one might reasonably look for a way to characterize ASD that does not depend on behavioral characteristics of the phenotype to unify our concept of ASD across the lifespan. The tremendous growth in basic biomedical research on ASD that has occurred in the past 15 years represents in part a search for a way to find order amid chaos.

At the present time scientific and methodological advances in the biomedical sciences, particularly in imaging and genetics, have led to a widely accepted goal of characterizing ASD according to its basis in biological differences. This goal has been adopted in part because of the overwhelming evidence that biological differences from the typical population are present, and also because their discovery has the potential to lead to medical treatments or even prevention. Therefore, the search for the essentials of the syndrome has moved conceptually from the behavioral to the biological level. In recent years the study of the autism phenotype has become less a focus of the attempt to pin down the true nature of the syndrome, and more an adjunct to studies of genetics, neurobiology, and other biomedical approaches that fit within the reductionist program and that have the potential to lead to specific medical treatments. Although a detailed discussion of such research efforts is beyond the scope of this chapter, it is safe to say that as interesting and promising as such studies are, they have as yet not resulted in an improved specification of the core characteristics of autism. Numerous genetic discoveries have pointed to the involvement of a variety of genes, but it has become clear that the phenotype of ASD is multiply determined and that the genetic picture is likely to remain complex (see for review Geschwind, 2009; also see Section VI, this chapter). Similarly, some exciting findings resulting from neuroimaging of children and adults with ASD, for example evidence of differences in functional connectivity among brain regions (e.g., Just, Cherkassky, Keller, Kana, & Minshew, 2007), have opened new vistas in the ways we think about the brain and how it develops in ASD. However, rather than pointing to clear and specific markers that could simplify the early diagnosis of autism, the findings of biomedical studies have continued instead to reveal the great complexity of the disorder. As a consequence of this inherent complexity, a model of ASD across the lifespan of the individual that is both comprehensive and realistic will by necessity include the effects of many influences beyond those of genotype and brain

maturation and will suggest mechanisms by means of which these influences lead to particular outcomes.

We can illustrate in a simplified way, using the metaphor of a snowball that grows larger as it rolls downhill, how secondary psychopathologies comorbid with ASD might arise, and worsen, over the life of an individual. If ASD is considered as a developmental pathway, then factors affecting development either supportively or adversely have their effects not only at a single time point but continuously and cumulatively over time. Just as the snowball grows larger as it rolls downhill accumulating more snow, an individual's developmental pathway will tend to depart from the typical to a greater and greater degree over time if the supportive influences are not sufficient to mitigate the effects of those that are adverse. A key feature of this model is that influences are not one-way, but transactional, such that a child's actions on the environment help to determine the feedback that the child receives, shaping not only future behaviors but ultimately the child him- or herself. If unusual or maladaptive behaviors are met with negative feedback from the child's environment (chiefly, the social environment), the child with ASD will be very likely to experience stress and anxiety. The result is that the child with ASD is exposed to frequent episodes of negative, highly stressful experiences.

The cumulative effects of negative experiences throughout life can have a profound effect on the well-being of the individual with ASD. These experiences, whether minor (e.g., frustration at being made to change activities) or major in nature (e.g., a lengthy and very upsetting experience with a large crowd of noisy people; being socially rejected for acting differently) might arguably affect individuals with ASD more severely than would be typical, in part because of the difficulty in emotional self-regulation associated with ASD, which renders them less able to regain equilibrium after an upset (see Loveland, 2005, for further discussion), and because of underlying genetic susceptibilities. Consequently, as families, educators, and clinicians well know, periods of emotional upset may be lengthy and exhausting for both the individual and others. Such episodes may constitute repeated stressors to the developing brain that have as their longer-term outcome psychiatric comorbidities such as anxiety disorders, depression, and other mood disorders, as well as other behavioral problems. A number of studies have documented the developmental pathway toward anxiety disorders in children who are by temperament highly reactive, showing that such a mechanism is not limited to ASD but is generally applicable to human neurodevelopment (see Bradley, 2000, for an excellent discussion of this topic; see also Schore, 1996, 1997). Given that verbal persons with ASD frequently struggle painfully with social relationships and learning to behave appropriately, it is not surprising that in adulthood many of them are more troubled by accumulated psychiatric disorders than by the symptoms of ASD itself.

Even if we accept the complexity that comes with a truly developmental way of viewing ASD, we are still left with the question of heterogeneity among individuals on the spectrum,

and the consequent difficulties in both clinical diagnosis and research. If the heterogeneity of phenotype in the autism spectrum is as great as research suggests; if the neurobiological and biomedical correlates of ASD, including genetics, are not only exceedingly complex but also highly variable among individuals; if the characteristics of individuals with ASD become more, not less, heterogeneous with development; if linking genotypes to the categorical phenotype of ASD has proven increasingly complex; then can we in fact expect to define core characteristics that are common to all persons with ASD regardless of age, sex, developmental level, severity, genotype, etc.?

Perhaps we have been asking the wrong question.

Perhaps it is time to move away from the traditional scheme of psychiatric classification that depends on identifying a number of specific symptoms in order to determine whether an individual does or does not meet the criteria for a particular diagnostic category. The dichotomous (yes or no) approach to clinical classification has utility from a practical standpoint, of course, in that it is easier to determine a patient's eligibility for treatments, services, insurance coverage, educational programs, etc., if he or she can be said to fall within a particular category. On the other hand, for reasons discussed above, the dichotomous, categorical approach is a poor model to use as a basis for understanding a developmental disorder such as ASD. In the clinical realm, it encourages the clinician, the educator, and the family to think of ASD as a distinct and reified entity, that one either has or does not have. In the realm of research, the dichotomous classification scheme encourages investigators to classify together under the same diagnostic umbrella, as it were, individuals who though technically meeting the same diagnostic criteria, are nonetheless widely different in numerous ways.

A number of authors have in the past few years argued in favor of adopting a new approach to psychiatric classification, not only of ASD but of other psychiatric disorders as well (e.g., Craddock, O'Donovan, & Owen, 2009; Geschwind, 2009; O'Donovan, Craddock, & Owen, 2009). In addition to the increasingly obvious shortcomings of the dichotomous classification scheme as noted above, there are other reasons to revise the approach we use to guide our clinical practice and research. We now know that psychopathologies long conceptualized as separate and discrete are in fact overlapping in both behavioral and biological characteristics. For example, Craddock et al. (2009) in their recent discussion of relationships among schizophrenia, bipolar disorder, and mixed psychoses argued that current genetic findings are not compatible with dichotomous methods of classification. They further suggested that we must use methods of classification that capture phenotypic variability within and among individuals of the same diagnostic category and must link this variability to its biological substrates.

An approach that holds much promise for overcoming some of the limitations of the current diagnostic scheme grows out of the search for genotype/phenotype relationships in behavioral genetics. The concept of the *endophenotype* refers to quantifiable component characteristics that lie between a complex genotype and phenotype (see DeGeus & Boomsma, 2001; Gottesman & Gould, 2003; and Viding & Blakemore, 2007, for reviews and discussion of this topic). Endophenotypes may be behavioral or biological in nature. Ideally, a behavioral or biological marker should meet the following criteria to be selected as an endophenotype (Viding & Blakemore, 2007): (1) It should be reliably measurable; (2) It should be to some extent heritable; (3) Some association between the behavioral or cognitive phenotype and the proposed endophenotype should be demonstrated; (4) There should be evidence that the proposed endophenotype and the behavioral or cognitive phenotype have some shared genetic basis; (5) There should be evidence of a causal relationship such that the phenotype would not be realized without the presence of the endophenotype. Some possible behavioral/cognitive endophenotypes relevant to developmental psychopathology are self-regulation of emotions, behaviors, and choices; inhibition; ability to sustain attention; ability to manage attention flexibly and appropriately (e.g., to switch attention as needed, to selectively attend, etc.); motivational differences (e.g., readiness to initiate, response to rewards); temperament of the individual; motor skills; executive functions (e.g., planning and organizing), and others. Endophenotypes may also be biological, as in specific neuroanatomical or neurofunctional, physiological or biochemical characteristics of the individual. Because they are simpler components of complex disorders, endophenotypes presumably have much greater potential for being linked to a specific genetic or neurobiological basis. Because they do not constitute in themselves whole syndromes, but rather elements, it is also possible to imagine that different complex syndromes may share certain endophenotypes. If so, comparative studies of disorders that apparently share certain endophenotypes (e.g., Craddock et al., 2009) may shed light on the processes that lead to expression of these endophenotypes as well as of broad phenotypes such as ASD.

In fact, there is growing evidence from both clinical observation and scientific investigations that ASD has many overlaps with other disorders, not only in behavioral symptoms but in definable brain abnormalities and in its genetic basis. Increasingly, investigators have begun to identify these areas of overlap, and to consider possible relationships among the syndromes as they are currently defined. Clinical experience as well as a growing literature suggests that there is an unusually high prevalence of comorbid psychiatric disorders with ASD (although cf. Melville et al., 2008, who found that the rate of such disorders was not greater than that in a general sample of comparable persons with intellectual disability). For example it is very common for individuals with ASD, particularly those with greater intellectual ability and language skills, to show prominent symptoms of anxiety (Groden, Cautela, Prince, & Berryman, 1994; Kim, Szatmari, Bryson, Streiner, & Wilson, 2000; Leyfer et al., 2006; Loveland, 2005; Mazefsky, Folstein, & Lainhart, 2008; Russell & Sofronoff, 2005) as well as major mood disorders including depression and bipolar disorder (Ghaziuddin & Zafar, 2008). Also commonly found in individuals with ASD are symptoms of attention-deficit/hyperactivity

disorder (ADHD; Pearson et al., 2006; Ryden & Bejerot, 2008) and obsessive-compulsive disorder (OCD; Rossi, 2006). Some investigators have also found evidence that these psychopathologies are more common among parents of individuals with ASD than in the typical population (e.g., Mazefsky, Folstein & Lainhart, 2008), suggesting that there may be a heritable risk factor involved. These findings support the idea that the relationship between ASD and other psychopathologies is a fertile ground in which to seek potential endophenotypes.

As an example, the possible overlap of obsessive-compulsive disorder (OCD) and ASD has been explored in a number of recent studies. The question of overlap between OCD and ASD has long been the subject of controversy, since both disorders involve repetitive behaviors (see chapter 17, this volume). Although there are qualitative differences between the compulsive behaviors and obsessive thoughts that typically occur in OCD and repetitive, stereotyped behaviors typically observed in ASD, it is nonetheless possible that there is underlying commonality. Russell, Mataix-Cols, Anson, and Murphy (2005), studying adults with a primary diagnosis of OCD and those with a diagnosis of ASD, concluded that up to 50% of their sample with ASD had obsessions and compulsions that were similar to those of the patients with OCD and were not accounted for by stereotyped and repetitive behaviors characteristic of ASD. Bejerot and Mortberg (2009) found that adults with OCD were much more likely (50% of the sample) to have been bullied at school as children than were those with social phobia (20%) or a reference group (27%). The investigators argued that this finding was due to overlap between the characteristics of OCD and ASD, since their sample with OCD also had more signs of low social skills. Obsessive-compulsive symptoms in parents have also been found to be positively associated with measures of restricted interests and repetitive behavior in their child with ASD (Abramson et al., 2005; Hollander, King, Delaney, Smith, & Silverman, 2003; Kano, Ohta, Nagai, Pauls, & Leckman, 2004), suggesting that an endophenotype for repetitive behaviors may exist as a heritable trait that could be linked to a genetic basis. In fact, a number of studies have identified genes that are associated with the risk of both OCD and ASD (e.g., McDougle, Epperson, Price, & Gelernter, 1998; Wendland et al., 2008). Executive dysfunction has also been found in the first-degree relatives of individuals with OCD as well as the relatives of individuals with ASD (Delorme et al., 2007) and has been suggested as an endophenotype common to both disorders.

Behavioral or biological evidence of possible endophenotypes has been gathered from comparisons of ASD with other disorders as well. Recent evidence that schizophrenia, like ASD, is a disorder of neurodevelopment has led to reopening the question of overlap between the two disorders (Nylander, Lugnegard, & Hallerback, 2008). Genetic studies of schizophrenia and bipolar disorder (BPD) indicate that some loci confer risk of both disorders and risk of ASD as well (see Craddock et al., 2009, for review). Genes in the chromosomal 8p region may confer risk of disorders including schizophrenia,

BPD, ASD, and depression, as well as some nonpsychiatric diseases (Tabarés-Seisdedos & Rubenstein, 2009). Deletion of 15q13.3 has been found to be associated with risks of both ASD and BPD (Ben-Shachar et al., 2009). Findings such as these lend weight to the argument that ASD shares endophenotypes with other disorders, and that further research to specify these endophenotypes will lead to a better understanding of how such disorders develop, and how development leads to expression of different clinical outcomes in different individuals.

A wide variety of possible endophenotypes relevant to ASD and related disorders have been proposed. If borne out by subsequent research, these candidate endophenotypes may be used to reduce the heterogeneity that results from using clinical classifications to form study samples. Among these are response monitoring (linked to abnormalities of anterior cingulate cortex) (Thakkar et al., 2008); inattention and hyperactivity (Tani et al., 2006); problems in executive functioning and motor skills (Rommelse et al., 2009); style of face-processing (Adolphs, Spezio, Parlier, & Piven, 2008); response variability (shared with ADHD and Tourette's syndrome; Geurts et al., 2008); a local bias in visual information processing (Wang, Mottron, Peng, Berthiaume, & Dawson, 2007); diminishment of a cingulate cortex "self" response when deciding what to do next or imagining oneself doing so (Chiu et al., 2008); a quantitative measure of ASD symptomatology particularly social relatedness (Social Responsiveness Scale) linked to loci on chromosomes 11 and 17 (Duvall et al., 2007); a metabolic endophenotype related to oxidative stress and linked to a genetic basis (James et al., 2006); and language delay (Spence et al., 2006). In addition some studies have begun to rule out potential endophenotypes for ASD, such as visual motor reconstruction (Block Design task) (de Jonge, Kemner, Naber, & van Engeland, 2009); and TPH2 alleles and haplotypes and GLO1 alleles (Sacco et al., 2007). Thus, the tools are beginning to be available to develop a way of classifying the characteristics of individuals with ASD (and other disorders) according to endophenotypes, which are measurable, linked to both genotype and phenotype, and can be assorted differently for different individuals. Such an approach would not dispel the heterogeneity present in ASD; rather, it would acknowledge variation among individuals while providing a more potentially useful way to characterize them.

The Core Characteristics of ASD Reconsidered

I have argued that despite many years of productive research on ASD, we have continued to try to classify individuals using a method that does not reflect what we have learned about this complex disorder. Neither the developmental nature of ASD nor the heterogeneity of expression it finds in different individuals is captured by the current categorical classification system. Not surprisingly, the current system has proven to be a poor basis for forming samples for research, particularly genetic

research, and it has failed to shed much light on the ways individuals with ASD change over the course of their lives. The question of core characteristics reflects the current diagnostic system, and thus it too may need to be reconsidered.

Devising a way to characterize ASD that will address the issues I have discussed is neither simple nor straightforward. At this time we have few established endophenotypes for ASD that meet the criteria mentioned above (see Viding & Blakemore, 2007). Moreover there is much we do not know about development in ASD, particularly in those individuals who may be described as within the "Broader Autism Phenotype." With this in mind, I offer the following suggested directions for future investigation.

Researchers should embrace the study of individual differences in the ASD phenotype. The great majority of studies on ASD have been nomothetic in approach, seeking to find commonalities among persons with ASD in order to determine standards for diagnosis, education, treatment, neural basis, etc. However, variations among individuals may be informative in ways that cannot be achieved using a nomothetic approach, in which variations are typically regarded as "noise" to be controlled or eliminated through matching. Towgood, Meuwese, Gilbert, Turner, and Burgess (2009) recommended that investigators consider using the multiple case series approach often used in neuropsychology, because it permits the investigator to identify variability that may be lost in a typical group comparisons approach and that may be important to understanding the disorder(s) under study. Such studies may add to our ability to isolate relationships between genotype and phenotypes in ASD and establish whether they do or do not meet the criteria for an endophenotype.

More research should be focused on adults with ASD, including the ways the manifestations of the disorder have changed over time. At present we know much less about adults with ASD than we do about children. In particular the factors that lead to more- and less-desirable outcomes is deserving of study. Fortunately in Western countries many individuals with ASD do receive services and supports that lead to improvements in their functioning over time, at least in some areas. As the large prospective study by Seltzer et al. (chapter 14, this volume) demonstrates, development continues in adulthood in persons with ASD, just as it does in typical persons. Overt symptoms of ASD tend to become less pronounced as the individual reaches adulthood, particularly in those with higher intellectual functioning and those who have received remediation. One can speculate, as do Seltzer et al. in their chapter, that thanks to better identification and more available early intervention, those who are children now can look forward to a still better outcome in adulthood than those of the earlier cohorts who are now adults. However there remain major gaps in our knowledge. For example, we are only beginning to observe the lives of persons with ASD over 50 years of age; how their behavioral and cognitive symptoms change with aging remains largely unexplored.

Researchers should continue to identify endophenotypes that contribute to the larger ASD phenotype and its variations as well as commonalities between ASD and other disorders.

The constellation of endophenotypes we call ASD is not so distinct from other disorders as was once thought (ADHD, OCD, schizophrenia, BPD, etc.). Not only do such disorders seem to co-occur frequently, but there is evidence that they overlap in both phenotypes and genotypes. It should be possible, then, to use comparisons among these disorders to help clarify the relationship of genotype to endophenotype, and endophenotype to phenotype. Indeed studies of this nature are already taking place at an accelerating rate, and it seems likely that this type of research will play a very important role in advancing our knowledge of how and why ASD occurs.

Researchers should work toward creating a "lexicon" of endophenotypes that is not applicable only to a single disorder, but to multiple disorders, and that may become the basis for a new clinical classification system. Under such a system the emphasis might be on specifying the endophenotypes expressed in that individual, their severity, and their implications for treatment, rather than classifying the individual as a whole. Ultimately, a more fine-grained and precise description of an individual with ASD might resemble not a point along a single spectrum (vector) for ASD severity, but a cloud of points in an n-dimensional space where n represents the number of relevant quantifiable endophenotypes considered. Such a hypothetical system of classification would offer the advantage of avoiding the necessity of using categories labeled "Not Otherwise Specified," which as currently used are by nature heterogeneous and vague. It would also provide more specific and quantifiable ways of dealing with the heterogeneity of the "Broader Autism Phenotype" (BAP) in research.

Finally, the approach I have sketched in this commentary, though as yet far from being realized, offers both the researcher and the clinician one further advantage over the present categorical method. By removing the necessity of dichotomous classification for psychopathologies, it serves to emphasize that in the human population there is no clear, sharp line between the normal and the abnormal but instead, the concept of the spectrum applies to everyone.

15 Intellectual Disabilities and Autism Spectrum Disorder: A Cautionary Note

Elisabeth M. Dykens, Miriam Lense

Points of Interest

- Approximately two thirds of children with autism spectrum disorders have co-occurring intellectual disabilities, and autism is also associated with several genetic syndromes that involve intellectual disabilities.
- Persons with intellectual disabilities, including those with specific genetic etiologies, are underrepresented in autism research, often due to specific exclusionary criteria.
- Research findings from studies of individuals with autism and high IQ may not necessarily extend to lower functioning individuals with autism spectrum disorders.
- Researchers must more explicitly justify their reasoning for excluding individuals with low IQ from their research programs.
- Many research designs could be adapted to also include people with intellectual disabilities, as exemplified in phenotypic studies of persons with genetic syndromes with or without intellectual disabilities.
- Individuals with autism and low IQ or with specific genetic syndromes need to be included in research to further our understanding of the causes and mechanisms associated with autism.

This chapter presents a cautionary tale about the impact of the broader definition of autism on how investigators are conducting their research. Diagnostically, the autism spectrum has expanded to include milder types of autism that are not necessarily associated with intellectual disabilities. At the same time, the inclusionary criteria for autism studies have narrowed to primarily include persons with high IQs, to the exclusion of those with autism and low IQs or with co-occurring syndromes or neurological disorders.

In considering this broader diagnostic scope and more narrow focus on higher IQ individuals, it is important to note that intellectual disabilities (previously termed mental retardation) have long been associated with autism spectrum disorders. The DSM-IV-TR (APA, 2000) notes that up to 75% of children with ASD have co-occurring intellectual disabilities, but for many reasons, this estimate may no longer be accurate. This chapter provides a brief review of the prevalence of intellectual disabilities in ASD, and although not exhaustive, the review highlights the co-occurrence of ASD and intellectual disabilities, and factors that complicate these prevalence studies.

Beyond intellectual disabilities per se, autism is also associated with specific genetic etiologies, and many of these syndromes also involve intellectual disabilities. A growing body of literature now describes how autism spectrum disorder (ASD) is manifest in people with such diagnoses as tuberous sclerosis, Fragile X, Prader-Willi, Angelman, and other syndromes. Syndromes that involve both ASD and intellectual disabilities provide unique windows into genetic and neurobiological factors associated with autism (Dykens, Sutcliffe, & Levitt, 2004). Even so, having a known etiology is typically an exclusionary criterion for most autism studies.

Indeed, despite the robust associations between intellectual disabilities and ASD, persons with low IQ or with genetic syndromes are increasingly excluded from research in ASD. We provide data in support of this disquieting research trend, as reflected in a review we conducted of published, peer-reviewed studies. Why are children or adults with ASD and intellectual disabilities, with or without a co-occurring genetic syndrome, increasingly excluded from published ASD research?

Decades ago, studies in autism relied primarily on those with intellectual disabilities, as this reflected the conceptual framework of autism at that time. The pendulum now appears to have swung in the opposite direction, whereby persons with intellectual disabilities are routinely excluded from study protocols. The chapter discusses several possible reasons for this trend, including arguments both for and against including those with low IQs in autism research. The chapter concludes with recommendations that facilitate the inclusion of those with intellectual disabilities into future research in ASD.

Prevalence of Intellectual Disabilities in ASD

Intellectual disabilities affects from 1.5% to 3% of the population, and although the term "mental retardation" was previously used in the United States, a name change to "intellectual disabilities" occurred across the major disability research and service organizations approximately 3 years ago. Beyond a change in terms, there is general agreement across several diagnostic systems that intellectual disabilities consist of: (1) an IQ score of 70 or less as determined on standardized testing; (2) co-occurring deficits in adaptive functioning (in 3 or more areas); and (3) an onset that begins in the developmental years, before age 18 (APA, 2000).

Beyond these general similarities, the major diagnostic schemas differ somewhat in their approaches. The DSM-IV-TR and ICD-10 require standardized IQ and adaptive behavior testing in order to classify persons into traditional levels of delay (mild, moderate, severe, profound). The American Association of Intellectual and Developmental Disabilities (AAIDD) rejects these classifications, as they suggest inherent deficits within people. Instead, the AAIDD adopts an approach based on the intensity of environmental supports that people need to function their best (Luckasson et al., 2002). While there is considerable merit to this perspective, the AAIDD system has not been widely adopted, and the majority of researchers continue to use traditional diagnostic systems.

Given such definitions of intellectual disabilities, how often do intellectual disabilities occur in ASDs? Based on findings to date, no one knows for certain, and estimates vary widely. Table 15-1 summarizes selected prevalence studies on ASD that included IQ data. These epidemiological studies were international in scope, based in the UK, United States, China, Australia, Japan, Portugal, Finland, and Iceland.

As Table 15-1 reveals, the prevalence estimates of intellectual disabilities in ASD range from a low of 34% to a high of 84%, with a median of 65% across the 14 studies. This estimate of intellectual disabilities in ASD is lower than the 75% noted in DSM-IV-TR, but remains impressively high. Indeed, based on these studies, the majority of children with ASD have co-occurring intellectual disabilities.

Even so, several caveats are in order, as the same challenges for epidemiological studies of ASD in general hold true for studies that report intellectual disabilities as a co-occurring or secondary condition of ASD. These methodological concerns include: variable sample sizes and age ranges of participants across studies, with low sample sizes having less reliable estimates; and different diagnostic criteria for ASD across studies and over time.

Diagnostic criteria for autism ranges from rating scales or checklists, typically seen in earlier work, to more rigorous and contemporary diagnoses based on DSM or ICD criteria, or such diagnostic interviews as the ADOS and ADI-R. Comparing rates over time is also complicated by the broadening of the autism diagnostic criteria to include milder forms of ASD, as reflected in the DSM-IV-TR (APA, 2000). An additional

Table 15–1.

ASD prevalence studies from 2000 to 2008 that included DSM-IV or ICD-10 ASD diagnostic criteria and IQ data

Lead Author	Dx Criteria	Study N	N with ASD	% ASD with ID
Baird et al., 2000	ICD-10	16,235	50	40%
Baird et al., 2006	ICD-10	56,946	81	53%
Bertrand, 2001	DSM-IV	8,896	36	63%
Chakrabarti & Fombonne, 2001	ICD-10, DSM-IV	15,500	26	71%
Chakrabarti & Fombonne, 2005	ICD-10, DSM-IV	10,903	24	67%
Fombonne, 2001	DSM-IV, ICD-10	10,438	27	44%
Honda, 2005	ICD-10	32,791	123	75%
Icasiano, 2004	DSM-IV	54,000	177	47%
Kawamura, 2008	DSM-IV	12,589	288	34%
Kielinen et al., 2000	ICD-10	152,732	187	50%
Magnússon et al., 2001	ICD-10	43,153	57	84%
Oliveira, 2007	DSM-IV	67,795	115	83%
Wong, 2008	DSM-IV	4,247,206	682	70%
Yeargin-Allsopp, 2003	DSM-IV	289,456	987	68%

Note: ID = Intellectual disabilities (formerly mental retardation).

source of variance relates to different methods used to identify mental retardation or intellectual disabilities across studies. For these reasons, Table 15-1 only includes studies that: were published after 2000; used well-accepted diagnostic criteria for autism; and included participants' IQ scores as opposed to their levels of delay (e.g., mild intellectual disabilities).

IQ levels do, however, differ substantially across diagnoses included under the umbrella of autism spectrum disorders. By definition, those with Asperger's disorder do not have clinically significant delays in language or cognitive development, but share the qualitative impairments in social interaction and restricted stereotypes or repetitive interests and activities that characterize autism in general. In pervasive developmental disorder not-otherwise-specified (PDD-NOS), intellectual disabilities may or may not be present, as this term is used to describe children with social impairments along with the presence of either restricted interests or impairment in cognitive or communicative skills. PDD-NOS is often a default diagnosis used to describe children who have mild or absent symptoms in one of the three core domains of autism. Children with autistic disorder have impairments in all three core domains of autism, and are more likely to have co-occurring intellectual disabilities. Even so, the term "high-functioning autism" is often used to describe persons with relatively high IQs, or those in the average range or higher.

Examining subtypes of ASD, Witwer and Lecavalier (2008) reviewed 22 studies that compared clinical differences between two of more groups of children with reliably-established diagnoses of autism, Asperger's disorder, or PDD-NOS. For studies in this review that reported IQ scores, we calculated the mean IQ for each subtype of ASD. As expected, the average IQ of persons with Asperger's disorder was 103.1, based on 12 studies that included a group with this disorder. Eleven studies in the Witwer and LeCavalier (2008) review included a group with PDD-NOS, and their average IQ was 86.1. Surprisingly, however, the average IQ of children with autistic disorder was 82.3, with just two of the 13 studies that included a group with autism reporting an average IQ of less than 70. Many of the studies stipulated low IQ as an exclusionary criteria, and we return to this trend later in the chapter.

Genetic Syndromes Associated with ASD and Intellectual Disabilities

A second, related issue concerns genetic syndromes. Recent estimates suggest that approximately 10% or less of the population of persons with ASD have a known co-occurring genetic syndrome (Herman et al., 2007; Muhle, Trentascoste, & Rapin, 2004; see also the chapters by State, Lamb, and Geschwind in this book). So called "syndromic autism" varies in prevalence and core autism features across different syndromes, but collectively are not believed to represent a major proportion of the population of persons with ASD. Table 15-2 summarizes the estimated occurrence rates of ASD in selected genetic syndromes. While this review is not exhaustive, it aptly demonstrates that autism is reasonably prevalent in certain genetic syndromes.

Table 15–2.

Selected genetic intellectual disability syndromes associated with ASD

Lead Author	Syndrome	% Estimate ASD
Chahrour, 2007	Rett, MCEP2 mutations	80–100%
Cook, 2001	15q11-q13 duplications	80–100%
Moss, 2008	Cornelia de Lange syndrome	62%
Peters, 2004	Angelman syndrome	42% (primarily class I deletions)
Rogers, 2001	Fragile X syndrome	30%
Sikora, 2006	Smith-Lemi-Opitz	75%
Smalley, 1998	Tuberous sclerosis	25%
Veltman, 2005	Prader-Willi syndrome	25% (38% UPD; 18% deletions)
Vorstman, 2006	22q11.2 deletion (VCFS)	50%

Note: UPD = uniparental disomy; VCFS = Velocardiofacial syndrome.

Given the heterogeneity of ASD, these genetic syndromes provide important perspectives that can fast-track candidate gene discoveries in ASD (see Muhle et al., 2004 for a thoughtful review). Examining two syndromes with high rates of co-occurring ASD, for example, Nishimura et al. (2007) identified several common genes that were dysregulated in subjects with autism and Fragile X syndrome, and autism due to 15q11-q13 duplications. Beyond their promising findings of shared molecular pathways in ASD, this study demonstrates the utility of syndromic-based research in autism.

Our purpose here is not to justify the scientific merit of examining "syndromic autism," but to highlight a research practice that may not serve the field well. On the one hand, for researchers who examine behavior in people with syndromes, the syndrome is the focus of study, and phenotypic studies may or may not include assessments of ASD along with other syndrome characteristics. Thus, one might assess autism in Prader-Willi syndrome (Veltman et al., 2005), along with other salient characteristics of this syndrome such as hyperphagia (Dykens et al., 2007), jigsaw puzzle skills (Verdine et al., 2008), or associations between the behavioral phenotype and genetic subtypes and age (Dykens et al., 2008). Phenotypic studies are not rooted in the autism field, but will include ASD assessments to the extent needed to accurately depict the syndrome's phenotypic expression.

In contrast, researchers rooted in the autism field, who focus exclusively on ASD, generally exclude participants with known etiologies or intellectual disabilities. Instead, these researchers examine individuals with what some refer to as "pure autism," or idiopathic, primary, or nonsyndromic autism. While these studies are essential, such syndromic versus nonsyndromic research practices have led to a growing separation of research and disability communities. Such separation is reflected in different professional conferences and journals that cater to each of these groups, as well as in separate, national efforts to develop ASD versus syndrome-based databanks, biobanks, or patient registries. Thus, persons with Fragile X, Down, Prader-Willi, or other syndromes are either excluded from or not well represented in databases connected to the Autism Treatment Network or Simons Simplex or Sibling Studies. Though the Autism Genetic Resource Exchange (AGRE) includes representative proportions of individuals with genetic syndromes and autism, the overall numbers of these individuals are too low for meaningful analyses.

At the same time, many syndrome-specific advocacy or parent groups are now developing their own data repositories, biobanks, or research registries. On the one hand, this separation seems logical, as not all parents or researchers who study syndromes need be concerned with autism, especially in syndromes where autism is relatively infrequent. But to the extent that persons with genetic syndromes also have ASD or brush up against issues related to ASD, then sharing data, registries, and resources would accelerate the pace of discoveries and of more effective treatments for persons with (or without) syndromic autism.

A Year in the Life of an Autism Journal

What are the current practices regarding intellectual disabilities for researchers who publish studies pertaining to ASD? Are the IQs of participants routinely reported? How many studies include or exclude those with low IQs? To address these questions, we selected a long-standing and highly regarded autism journal, the *Journal of Autism and Developmental Disorders* (*JADD*), and reviewed all studies published in 2008. Although not an exhaustive review of ASD work, we reasoned that studies published in 2008 would likely be representative of other recent years, and that a leading journal in autism would pull for quality submissions that included such methodological details as IQ scores. For the journal review we identified how IQ was reported (as an average, range, or not at all) in child versus adult participants, and when possible, we tallied or extracted mean IQ scores from each study.

As shown in Table 15-3, the vast majority of publications for both children and adults with ASD included participants with high IQs. Regarding children, 60 studies used either high IQ *or* low IQ children, with 77% of articles including children with high IQs only. Typically these studies had a required IQ score of greater than 75, 80, or 90 as an inclusionary criterion. In contrast, 23% of articles included children with low IQs only. Examining the actual numbers of participants enrolled in these 60 articles, 83% of research subjects had high IQs, and 17% low IQs.

Some studies of children with ASD included those with both low *and* high IQs: 19 studies included children with IQs less than 70 along with children with higher IQs. Of the 16 studies using low and high IQ children that reported actual IQ data, 10 reported a mean IQ greater than 70, and the mean IQ across these 10 studies was 77.80. Six studies reported mean IQs less than 70, with an overall average IQ of 66. Thus, while these 16 studies included some low IQ participants, on average most had IQs greater than 70, suggesting that the majority of participants were relatively high functioning.

Our review of 2008 *JADD* articles also indicates that adults are less often studied than children, and that the vast majority of adult studies only include high-functioning individuals. Of the 30 studies on adults with ASD, just 3 included persons with low IQs, and 27 with high IQs—the average IQ of these adults was 106.4. Thus, 9 times as many studies were published on high IQ adults than low IQ adults with ASD.

Examining the actual numbers of adult participants, 73% had high IQs, and surprisingly, the three studies of lower IQ adults represented over one quarter (27%) of adult subjects. This relatively high percentage is due to the fact that 2 of the 3 studies were based in large institutions for persons with intellectual disabilities. While such settings offer increased numbers of participants, they may not be representative of persons with ASD growing into adulthood today.

A final observation stemming from our 2008 *JADD* review is that the majority of studies (70%) included IQ data of some sort. Of the 47 articles that did not do so, 28% were parent

Table 15–3.

Data on low versus high IQ in children and adults with ASD as published in the 2008 volume of *JADD*

	Number of Studies	Number of Participants	Mean IQ, other IQ data
Low-IQ Children	14	380	*M* IQ = 58.21 (based on 9 studies)
			2 studies noted "profound or severe" ID
			3 studies stipulated IQ < 70
High-IQ Children	46	1,861	*M* IQ = 102.10 (based on 35 studies)
			6 studies stipulated IQ > 70 or 75
			4 studies stipulated IQ > 80 or 90
			1 study noted IQ range (85–115)
Low- & High-IQ Children	19	690	*M* IQ = 72.73 (based on 16 studies)
			2 studies noted IQ range (53–124; 52–85)
			1 study noted % no ID, mild, moderate, severe ID
Low-IQ Adults	3	210	% noted for mild, moderate, severe, profound ID
High-IQ Adults	27	572	*M* IQ = 106.4 (based on 22 studies)
			4 studies stipulated IQ > 70, 80, or 90
			1 study noted IQ range (73 to 129)

surveys; 21% were case studies or single-subject interventions that may or may not have included formal developmental testing; 19% were genetic, medical, or physiological studies; 17% used large-scale or population-based datasets; and 15% sampled teachers or educators about their students with ASD. While there is room for improvement, the majority of articles that focused on children or adults with ASD included some index of intellectual functioning.

In summary, this "year in the life of an autism journal" confirms that published studies in ASD primarily include children and adults with relatively high IQs. While one could argue that 2008 may not be representative, there are no glaring or obvious cohort differences to suggest that 2008 differs dramatically from 2007 or 2009. As well, relative to other journals focused on autism, there is no reason to suspect that *JADD* is more or less likely to pull for submissions on high versus low functioning autism.

Based on studies summarized in Table 15-1, approximately 65% of persons with ASD also have an intellectual disability. Yet our journal review suggests that only 10% to 23% of published articles are focused on persons with ASD and intellectual disabilities. In contrast, from 77% to 90% of studies we sampled in 2008 were restricted to persons with high IQs. Assuming that studies on all persons on the autism spectrum are critically important steps toward discovery, why are those with lower IQs not well represented in today's research landscape?

Reasons for Excluding Those with Intellectual Disabilities from ASD Research

Researchers present several explanations about why those with intellectual disabilities are often excluded from contemporary autism work. Some suggest that with the broadening of the autism diagnostic criteria, the field is now "catching up" or balancing out work based on a previous conceptual model of autism that primarily included lower functioning individuals. If this is indeed the case, we would expect to see an eventual shift toward a middle ground, with approximately equal numbers of studies that focus on low or high IQ participants, or that include a wider range of IQ in the same study.

A common explanation for excluding those with intellectual disabilities is that the demands of a particular research task or protocol are too difficult for those with low IQ. Tasks that require, for example, a high cognitive load, higher-order or abstract reasoning, or insight into one's thoughts or emotions are all better suited for those with higher IQs. In addition, some methodologies, such as functional neuroimaging, require that participants comply, remain still, and respond to various button presses or stimuli while in the scanner, and these are more challenging for those with lower IQs. By virtue of their better-developed cognitive and communicative skills, higher-functioning persons with ASD have provided novel insights into the phenomenology of ASD, as well as on neural functioning and basic mechanisms associated with the wider autism spectrum.

Even so, generations of biobehavioral scientists have specialized in the field of intellectual disabilities, and used a variety of methodologies that assess cognitive, neural, social, emotional, and adaptive functioning. Further, functional and structural neuroimaging studies have now been conducted in persons with intellectual disabilities and with Fragile X, Prader-Willi, Williams, and other syndromes. Techniques to enhance valid imaging data from persons with intellectual disabilities include behavioral interventions to decrease movement in the scanner and increase compliance, the use of mock scanners, and new methods of acquiring imaging data. These approaches hold much promise for imaging work in persons with intellectual disabilities and ASD.

Some experimental tasks can also be adapted to those with low IQ, while other experimental tasks can simply be used "as is" in persons with intellectual disabilities. Examples of specific methodologies or tasks gleaned from the 2008 *JADD* review that were limited to high-functioning persons but could easily be used across the IQ spectrum include: wearing actigraphy watches; playing cards with a peer; deciding if a speaker was male or female; taking a hearing test; providing saliva samples for cortisol assays; and identifying moods on feeling thermometers. The inclusion of those with low IQs may not necessarily be methodologically challenging for these or other ASD studies.

A second issue, however, is that some researchers are understandably striving to recruit a homogeneous sample of high-functioning persons with ASD. Presumably, their hypotheses and research questions demand that they focus exclusively on this high-IQ subgroup. Surprisingly few investigators, however, specify why their questions pertain only to high-functioning individuals, nor do their publications necessarily explain the scientific rationale for excluding those with lower IQs. Without a well-articulated rationale for using IQ cutoffs, excluding those with intellectual disabilities seems arbitrary; over the long term, this practice may not reflect well on the broader ASD field.

A third point is that because autism is a spectrum disorder, some investigators assume that findings from high IQ individuals will automatically apply to those with lower IQs. By definition, findings from ASD in its more "pure" form must apply to those with ASD and intellectual disabilities. Given the heterogeneity of ASDs, however, it seems shaky at best to assume that processes in high IQ individuals will simply extend to those with ASD and intellectual disabilities. Actually, this is an empirical question, and data are needed from both low- and high-IQ persons with ASD to determine if findings from individuals with high IQ are applicable to those with intellectual disabilities. Of concern, however, is that most researchers do not seem to be tackling this question, and are increasingly shying away from studies that include individuals with both low and high IQ.

Ideas for ASD Research That Includes Intellectual Disabilities

Table 15-1 suggests that approximately 65% or more of persons with ASD also have an intellectual disability, yet these individuals are not well represented in national ASD research networks, data repositories, or in published articles on ASD. Although far from comprehensive, our journal review suggests that a minority of published articles (from 10% to 23%) focus on persons with ASD and intellectual disabilities. A further concern applies to IQ across autism spectrum diagnoses. Calculating means IQs from Witwer and Lecavalier's (2008) review of ASD diagnoses, we found the expected high IQ in those with Asperger's disorder (M = 103.1), a lower IQ in those with PDD-NOS (M = 86.1), and a surprisingly high average IQ in participants with autistic disorder (M = 82.3). Although autistic disorder often

includes those with intellectual disabilities, the reliably diagnosed participants in this review were relatively high functioning. Although further work is needed to explore these trends, it appears that those with lower IQs are not well represented in published research. As this imbalance may impede new insights into ASD, how can we increase the inclusion of those with intellectual disabilities into current ASD research?

A first step is for investigators to ask if their study hypotheses only apply to those with ASD and high IQs. Do investigators know for certain that their data will be compromised by adding those with intellectual disabilities to their study? Or are preliminary data needed on how those with low IQs might perform on a given task in order to make an informed decision about IQ inclusionary criteria and data integrity?

Perhaps intellectual disabilities should be a human subject characteristic that investigators are required to address in IRB and grant applications. Just as investigators must specify their rationale for the inclusion or exclusion of children, women, and ethnic/minority participants, maybe they should also specify the scientific rationale for excluding those with low IQs. Although this idea is not likely to be formally adopted, being asked to justify the exclusion of those with intellectual disabilities could sharpen investigators thinking about the role of IQ in their design.

Assuming that study hypotheses could be extended to those with low IQs, a second step is for investigators to think creatively about their methodology. How could tasks or experimental manipulations be adapted in order to glean meaningful data from participants with ASD and intellectual disabilities? Are extra supports, costs, or accommodations needed in order to include those with intellectual disabilities? Specific ways of examining persons with a broad range of IQs may be extracted from research on the behavioral phenotypes of persons with genetic etiologies of intellectual disabilities. In this work, IQ is rarely used to truncate samples, and all persons with a given genetic syndrome are included in research, regardless of their IQ. IQ effects are assessed in phenotypic data, which then inform links between underlying molecular genetics of syndromes, neurological functioning, and behavioral phenotypes.

Recent recommendations for dimensional assessments of cognitive, linguistic, adaptive, and social functioning in ASDs (Volkmar, State, & Klin, 2009) are similar to approaches taken in most phenotypic studies, and hint at the idea of moving away from low IQ as an exclusionary criterion in ASD research. Instead, IQ could be cast as a continuous variable that informs the broad autism phenotype.

Conclusion

Intellectual disabilities remain a highly prevalent co-occurrence with ASD. Our review of recent, well-conducted ASD epidemiology studies suggests that approximately 65% of those with an ASD have intellectual disabilities. As well, certain genetic intellectual disability syndromes are characterized by relatively

high rates of ASD. Even so, persons with ASD and intellectual disabilities or with specific genetic etiologies, are not well represented in today's ASD research landscape. The exclusion, or relatively poor representation, of those with low IQs or genetic syndromes is reflected in large-scale databases, biobanks, and participant registries, as well as in published, peer-reviewed articles. Our admittedly limited sampling of "a year in the life of an autism journal" revealed that only 23% of articles on children, and 10% on adults, included persons with intellectual disabilities. Examining the numbers of children enrolled in these studies, 83% were high functioning, and 17% had intellectual disabilities.

The current research practice of truncating IQ and focusing primarily on those with high IQs does not represent the full scope of autism as a spectrum disorder, limits generalizability of findings, and does not represent the majority of persons who have autism spectrum disorder. This chapter describes several ideas for increasing the representation of those with intellectual disabilities into future ASD research.

This chapter sounds a strong cautionary note about research practices. It does not aim to detract from the critical importance of studies of "pure" autism, or those with high IQs, idiopathic autism, or no known genetic etiology. These samples are essential for ongoing, multisite efforts aimed at candidate gene discovery, or linking ASD candidate genes to specific aspects of the ASD phenotype. Similarly, the cautionary note does not aim to promote research focused exclusively on those with low IQs or with syndromic autism. Rather, a more equitable or balanced inclusion of individuals with low and high IQs is essential for future discoveries about the etiologies, mechanisms, and treatments of ASD.

Future Directions and Challenges

- Researchers should aim to increase numbers of individuals with lower IQ or syndromic autism in autism research programs and large-scale databases and biobanks. Studies of individuals with differing types of syndromic autism may provide information on common genetic or molecular pathways.
- Instead of setting IQ cutpoints, researchers should examine IQ as a continuous variable that can affect other areas of the phenotype.
- If researchers choose to exclude individuals with intellectual disability or syndromic autism, they should provide rationalizations for why these exclusions are necessary for their research question and should address whether or not their findings would extend to the broader phenotype.
- Researchers will need to think creatively about how to adapt research paradigms (if necessary) to include lower functioning individuals, which may include specific supports, accommodations, or additional costs. Researchers in the field of autism can look to the field of behavioral phenotypes in genetic syndromes for how these adaptations have been put into practice to successfully include lower functioning individuals in research.

Comorbid Obsessive-Compulsive Disorders

Points of Interest

- Converging research suggests substantial overlap in phenomenology, comorbidity, course, family and genetic findings, neurobiology, cognitive functioning, and treatment response, across ASD and putative OCSDs. These data support the existence of a valid repetitive behavior domain that cuts across traditional diagnostic boundaries.
- The overlap in repetitive behaviors across nosological categories can also be conceptualized as a symptom-based dimension, or continuum, that encompasses "normal" behavior and extends beyond in degree and/or severity.
- Grouping the diverse repetitive behaviors into homogeneous, independent subfactors (i.e., dimensions) will allow future research to reveal unique neurobiological underpinnings associated with each, which will provide insight into the development of new treatment approaches.
- Accumulating empirical research across academic disciplines is supporting the conceptualization of higher-and lower-order dimensions of repetitive behaviors across OCD spectrum diagnostic categories.
- Recent findings are emerging that suggest a familial link and genetic vulnerability for the higher-order repetitive behaviors in autism and OCD, which may represent an underlying endophenotype. Neuroimaging data supports these findings.

Restricted and repetitive behavior is a core symptom domain of autism spectrum disorder (ASD). Behaviors categorized within this symptom domain range, however, both in form and severity. Moreover, repetitive behaviors are not unique to ASD, and in fact, they are recognized across various DSM-IV diagnostic categories. This overlap of repetitive behaviors across various disorders was studied by the Research Planning Agenda for the DSM-V Work Group on Obsessive-Compulsive Disorders and Related Disorders (OCDRD), which proposed a putative Obsessive-Compulsive Spectrum Disorders (OCSDs) grouping.

A variety of disparate disorders have been conceptualized as being a part of the OCSDs category (Hollander, Kim, Braun, Simeon, & Zohar, 2009; Hollander, Wang, Braun, & Marsh, 2009). While autism might fit into such a category, given the importance of childhood specialists (e.g., pediatricians, pediatric neurologists) and childhood history in the diagnosis and ongoing treatment of ASD, it is unlikely that autism will be a part of the final consideration (Hollander, Kim, Braun, Simeon, & Zohar, 2009). The other disorders being considered as part of the OCSDs span across various traditional DSM-IV diagnostic categories, potentially including anxiety disorders (e.g., obsessive-compulsive disorder [OCD]), impulse control disorders (e.g., trichotillomania [TTM]), personality disorders (e.g., obsessive-compulsive personality disorder [OCPD]), somatoform disorders (e.g., body dysmorphic disorder [BDD]), Tourette's and other tic disorders, stereotyped movement disorders, and Sydenham's and other Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections (PANDAS) (Hollander, Kim, et al., 2009). Converging data is emerging that suggests that, in addition to sharing the core symptom of repetitive thoughts and behaviors, these seemingly distinct disorders may also exhibit a similar course, comorbidity, familial and genetic features, brain circuitry, and treatment response profile (Hollander, Kim, et al., 2009; Hollander, Wang, Braun, & Marsh, 2009).

An alternative way to conceptualize repetitive behaviors across disorders is to identify and examine "symptom dimensions" that are empirically derived from factor analytic studies. These dimensions encompass "normal behavior" and extend beyond in degree and/or severity. As will be discussed later in the chapter, such factors may each be related to a distinct genetic contribution, neurobiological underpinnings, comorbidity, treatment response profile, and course of illness.

Regardless of whether this overlap is conceptualized from a "spectrum" or "dimensional" standpoint, the relevance is of interest both heuristically and clinically. Heuristically, these commonalities may suggest a common underlying neuropathological mechanism for this core symptom domain across autism and other putative OCD spectrum disorders. This knowledge, in turn, can provide insight into the development of new treatment approaches.

Chapter 11 of this book details more fully the types and the range of repetitive behaviors that are specific to ASD. The relationship between ASD and other OCSDs, including autoimmune disorders, stereotyped movement disorders, and Tourette's and other tic disorders will be detailed elsewhere in this book. This chapter will therefore focus primarily on the overlap of repetitive, restricted, and/or stereotyped patterns of behavior, interests, and/or activities that characterize both ASD and related OCD spectrum disorders including OCD, OCPD, BDD, and TTM. This chapter will be organized into the following sections: First, the symptomatic commonalities in repetitive behaviors between ASD and other OCSDs will be outlined. Next, research findings related to the frequent comorbidity, similar course, and potentially overlapping genetic, neurobiological, and neuropsychological correlates across these disorders will be summarized. Finally, different approaches to subtyping the diverse symptoms that comprise the repetitive behavior domain will be presented. This is important because the identification of homogeneous subgroups will arm investigators with more power to uncover the unique pathogenesis that underlies each repetitive phenotype.

Commonalities in Repetitive Behaviors in Autism and Other OCSDs

Autism

The term "repetitive behavior" in autism encompasses a wide range of heterogeneous symptoms and activities, each characterized by nonfunctional repetition, rigidity, and/or inflexibility. The DSM-IV describes repetitive behaviors in autistic disorders as an abnormally circumscribed interest or preoccupation (e.g., focus on subway maps), an unreasonable insistence on sameness, inflexible persistence in following non-functional routines or rituals (e.g., eating the same food for lunch, everyday, at exactly 12:00 noon), and/or stereotyped and repetitive motor mannerisms (e.g., hand flapping and body rocking). Individuals with ASD may also engage in repetitive behaviors such as lining up objects, ensuring symmetry, ritualistic behavior, and repetitive language. Clinically, other repetitive behaviors are commonly observed in individuals with ASD, but are either not mentioned in the DSM-IV, or are referred to as "associated symptoms." These include repetitive self-injurious behaviors (e.g., head banging and wrist biting), pathological repetitive grooming (e.g., hair

pulling, skin-picking, nail biting), hoarding, Pica, dyskinesias, and unusual sensory interests such as repetitive sniffing and/or mouthing objects.

Traditionally, the repetitive behaviors in autism have been conceptualized as a single, unitary symptom domain. More recently, however, research findings are supporting the existence of multiple, distinct subtypes of repetitive behavior, which have been subcategorized into higher- and lower-order behaviors (Hollander et al., 1998). Briefly, higher-order behaviors, which are cognitively mediated, include complex behaviors such as circumscribed interests, repetitive language, and object attachments. Lower-order behaviors are thought to involve the more primitive brain, and include repetitive sensory and motor behaviors such as stereotyped movements, repetitive manipulations of objects, body rocking, finger flicking, and repetitive touching. As will be discusses later in this chapter, growing empirical research supports the existence of higher- and lower-order subtypes of repetitive behaviors not only in ASD, but also across diagnostic categories within the putative OCSDs.

Obsessive Compulsive Disorder (OCD)

OCD is classified in the DSM-IV as an anxiety disorder; however, it is primarily characterized by repetitive thoughts and behaviors, and irresistible impulses and urges, not by anxiety per se. In fact, the *International Statistical Classification of Diseases and Related Health Problems-10th Revision* (ICD-10; World Health Organization, 2003), which is the classification of diseases by the World Health Organization, does not classify OCD as an anxiety disorder. Rather, the ICD-10 categorizes OCD under the umbrella "Neurotic, stress-related and somatoform disorders." Although anxiety is mentioned as regularly being present, it is not the defining feature of OCD in the ICD-10. Along these lines, a redefining of the OCSDs as being a separate chapter within the anxiety disorders, or a separate category altogether, is currently being discussed for DSM-V (Bartz & Hollander, 2006).

Repetitive behaviors in OCD are manifested as obsessions and compulsions. The DSM-IV describes an obsession as a repetitive thought or impulse that is subjectively experienced as intrusive and/or inappropriate, and thereby causes anxiety and distress. A compulsion is characterized as the engagement in a repetitive action, aimed at avoiding or relieving the anxiety that is caused by the obsession. These symptoms parallel the complex higher-order repetitive behaviors displayed in ASD, such as ritualistic behaviors, preoccupations, and a desire to maintain sameness.

Obsessive-Compulsive Personality Disorder (OCPD)

Since its conception, the distinction between OCPD and OCD has been controversial. Adding to the confusion, the symptomatic profile of OCPD has changed over the past few decades. For example, DSM-II characterized "obsessive-compulsive

personality" as an inflexible adherence to standards, severe introversion, and rigidity. DSM-III (American Psychiatric Association [APA], 1980) added affective constriction, perfectionism, and a lack of awareness of how one's behavior affects others. In 1987, the DSM-III-R (APA, 1987) minimized focus on affective restriction and added excessive preoccupation and hoarding. Today, OCPD is classified in DSM-IV (APA, 2000) as a Cluster C Personality Disorder, and is characterized by a pervasive preoccupation with organization (e.g., details, rules, lists, order, schedules), perfectionism, excessive devotion to work, inflexible morality, insistence that other's follow their rules, hoarding, miserly spending, and/or rigidity and stubbornness.

It is at once apparent that many of these symptoms substantially overlap with both the obsessions and compulsions in OCD, and the repetitive behaviors exhibited in ASD. Furthermore, written descriptions of OCPD in the DSM-IV, including language such as "prone to repetition," "inflexible," "rigid," and "difficulty acknowledging the viewpoints of others," further highlight the observable commonalities between OCPD, ASD and OCD.

Importantly, *hoarding,* a compulsion to excessively collect things without discarding, traverses ASD, OCD, and OCPD. For example, hoarding is included as part of the diagnostic criteria of OCPD; it is considered a compulsion in OCD; and it not uncommonly co-occurs with ASD (McDougle, Kresch, et al., 1995; Russell, Mataix-Cols, Anson, & Murphy, 2005).

Trichotillomania (TTM)

Trichotillomania (TTM) is characterized by the recurrent pulling out of one's hair in the scalp, eyelashes, face, nose, pubic area, eyebrow, etc., often resulting in noticeable bald patches. In the DSM-IV, TTM is classified as an impulse disorder, although, it has an indisputable compulsive quality to it. Moreover, similar to the function of compulsions in OCD, hair pulling is thought to reduce anxiety in individuals with TTM (Woods et al., 2006). A preoccupation with symmetry, which is also exhibited in autism and OCD, has also been suggested to trigger TTM.

Body Dysmorphic Disorder (BDD)

Body dysmorphic disorder (BDD) is classified as a somatoform disorder in the DSM-IV, and is characterized by a recurrent and intense preoccupation with imagined ugliness and/or a physical defect. In order to mitigate these obsessions, individuals with BDD engage in repetitive mirror-checking, camouflaging, frequent requests for reassurance, and/or skin-picking (Frare, Perugi, Ruffolo, & Toni, 2004; Hollander, Neville, Frenkel, Josephson, & Liebowitz, 1992; Phillips, 1996). These repetitive behaviors clearly resemble compulsions in OCD. The focus of the obsession, however, may differ between BDD and OCD: in BDD the preoccupation is centered on a perceived physical defect, whereas in OCD, the preoccupation may encompass a broad range of content.

It is readily apparent from the descriptions above that there is substantial overlap in the repetitive thoughts and behaviors that manifest in ASD, OCD, and other OCD spectrum disorders such as OCPD, TTM, and BDD. Additional support for the existence of a valid repetitive behavior domain, which cuts across traditional diagnostic boundaries, is rapidly accumulating from diverse disciplines. These findings will be discussed below, highlighting similarities in the comorbidity, course, family and genetic research, neurobiology, neuropsychology, and treatment response profile across OCSDs.

Comorbidity

The co-occurrence of two disorders, referred to as comorbidity, is one piece of evidence that suggests a common underlying pathophysiology between the co-existing diseases. Several obstacles hamper investigations of disorders that may be comorbid with ASD. First, to date, there are no standard, reliable measures of assessing comorbidity in ASD (Ghaziuddin, Ghaziuddin, & Greden, 2002; Matson, Smiroldo, & Hastings, 1998). Further, individuals with ASD frequently present with intellectual disability (Matson et al., 1998), which in itself is associated with the stereotypies and other repetitive behaviors displayed in idiopathic autism (Matson et al., 1997). As such, it is sometimes difficult to disentangle the origin of these repetitive behaviors.

In spite of the aforementioned assessment difficulties, recent studies have attempted to estimate comorbidity with ASD. For example, a 2.7% lifetime prevalence of Asperger's syndrome was found in individuals diagnosed with OCD (LaSalle et al., 2004). This is well above current estimates of Asperger's disorder in the general population (Fombonne & Tidmarsh, 2003). Conversely, approximately 25% of adults with Asperger's syndrome were found to have comorbid OCD (Russell et al., 2005).

The occurrence of other OCD spectrum disorders with each other has frequently been reported. For example, patients with BDD have a 30% lifetime prevalence of OCD (Gunstad & Phillips, 2003). Further, a high incidence of OCD has been reported in patients with TTM (Ferrao, Miguel, & Stein, 2009) and OCPD (Gunderson et al., 2000; Skodol et al., 1995) Similarly, patients with a current diagnosis of OCD have a higher lifetime prevalence rate for BDD and pathological grooming conditions compared to controls (i.e., 16% vs. 3%, and 41% vs. 17%, respectively) (Bienvenu et al., 2000).

Recent studies have estimated that hoarding and saving compulsions occur in 15–40% of OCD patients (Hanna, 1995; Mataix-Cols, Nakatani, Micali, & Heyman, 2008; Rasmussen & Eisen, 1992). Hoarding has also been reported in up to 30% of individuals with autism (McDougle, Kresch, et al., 1995; Russell et al., 2005). Hoarding, in turn, has been associated with other OCSDs, including pathological repetitive grooming such as TTM (9%), skin picking (39%), and nail biting (39%) (Samuels et al., 2002).

In summary, comorbidity has been reported among OCD, ASD, and hoarding, as well as between TTM, BDD, and OCD. This co-occurrence is one piece of evidence in favor of a common etiology across the disorders.

Course

In addition to the similarities in symptoms and comorbidity discussed above, autism and OCD spectrum disorders have parallels relating to the course of illness (see Figure 16-1). With regard to the course of ASD, abnormalities are thought to be present from birth, but must be present prior to the age of three to meet formal DSM-IV criteria. Autism is a chronic and lifelong illness, though some improvement may be seen in symptom domains over time (Fecteau, Mottron, Berthiaume, & Burack, 2003; Piven, Harper, Palmer, & Arndt, 1996). In terms of gender, males are affected with autism significantly more often than females, as evidenced by the approximately 4 to 1 male to female ratio (Fombonne, 2005).

OCD, in contrast, has a bimodal age of onset, with peaks during puberty, and then again during early adulthood (Zohar, 1999). It has been suggested that early-onset OCD is most similar to the course of autism, as it is also more prevalent in males than females (Tukel et al., 2005), and follows a chronic course (Fontenelle, Mendlowicz, Marques, & Versiani, 2003; Sobin, Blundell, & Karayiorgou, 2000). When hoarding is accompanied with symptoms of OCD, the hoarding symptoms appear to have an earlier age of onset (Pertusa et al., 2008).

Less is known regarding the course of BDD, TTM, and OCDPD. Demographic data, and illness duration of BDD appears to be similar to that of OCD (Phillips et al., 2007). TTM has a mean age of onset between 9 and 13 years of age, and is widely viewed to have a persistent course. Males may have a later age of onset than females. (Lochner, Seedat, & Stein, 2009). According to the DSM-IV (APA, 2000), OCPD is typically diagnosed in late adolescence or young adulthood, and it occurs almost twice as frequently in males than females.

With specific regard to the developmental course of repetitive behaviors, recent findings suggest that they are one of the earliest signs to appear in autism, occurring during the first and second year of life (Ozonoff et al., 2008; Watt, Wetherby, Barber, & Morgan, 2008). Significant repetitive behaviors continue to be reported by adolescents and adults with ASD (Esbensen, Seltzer, Lam, & Bodfish, 2009; Fecteau et al., 2003). Some studies suggest that the developmental trajectory differs for different repetitive behaviors in ASD. For example, motor and sensory repetitive behaviors have been found to occur more frequently in younger children (aged 2–4), with the repetitive behaviors becoming more complex by age 7–11 (Bishop, Richler, & Lord, 2006; Militerni, Bravaccio, Falco, Fico, & Palermo, 2002). Similarly, a recent study by Esbensen et al. (2009) found that stereotyped movements were more frequent in young children than in adults. Some studies have reported that whereas restricted interests, unusual preoccupations, and complex stereotypy may decrease with age (Esbensen et al., 2009; Seltzer et al., 2003), ritualistic behavior and a need for sameness appear to be frequent in older individuals with autism (Esbensen et al., 2009). Retrospective data have also suggested some improvement in repetitive behavior with age, but not as pronounced as improvements in the social and language domains (Fecteau et al., 2003; Piven et al., 1996) that together define autism.

In terms of the course of repetitive behaviors across the OCD spectrum, Hollander theorized that over time, the lower-order symptom dimension of repetitive behaviors, which serve to mediate arousal, progress into higher order, cognitively mediated repetitive behaviors (Hollander, personal communication). For example, as previously mentioned, young children with autism often engage in perseverative, self-stimulatory behaviors including hand flapping, rocking, lining objects up, and opening and closing doors. Similarly, young children with other OCD spectrum disorders may engage in comorbid, self-stimulatory trichotillomania. In older children with autism, these lower-order behaviors may be supplemented and/or substituted by higher order OCD spectrum behaviors such as checking, washing, counting, repetitive requesting, and repetitive asking for reassurance. Comorbid OCD spectrum
Figure 16–1. Timeline of average age of onset of disorders with a core repetitive behavior domain. Horizontal gray bands represent the approximate age range of onset for each corresponding disorder, with the bolder, middle color signifying the average. Vertical gray lines each represent one year.

disorders at this age might include BDD, as well as grooming and checking rituals.

Taken together, there is some overlap in the course of ASD and OCD spectrum disorders. Most notably, there is a greater male to female ratio in ASD, OCD, OCDPD, and hoarding, and the course is similar as well. Developmental research is beginning to depict a possible age-related trend for repetitive behaviors, with the earlier years being characterized by motor and sensory-related repetitive behaviors (e.g., stereotypy, TTM) that are later accompanied and/or replaced with higher-order repetitive thoughts and behaviors (e.g., obsessions, rituals). This is interesting given the earlier average age of onset for disorders characterized by motor-sensory related repetitive behaviors (e.g., autism and TTM) compared to the later onset for the more cognitively mediated repetitive behaviors (see Figure 16-1.) Clearly, more research is needed to determine the validity of this age-related trajectory.

Family Studies

Family studies, which demonstrate a high occurrence of OCD spectrum disorders in relatives of probands with OCD spectrum disorders, suggest a possible genetic link across them. For example, OCD has been found to be more prevalent in relatives of autistic probands compared to relatives of Down syndrome probands (Bolton, Pickles, Murphy, & Rutter, 1998) and control probands (Micali, Chakrabarti, & Fombonne, 2004).

In terms of other OCSDs, compared to first-degree relatives of control probands, first-degree relatives of probands with OCD have been reported to have a greater frequency of OCPD (5.8% vs.11.5%, respectively) and pathological grooming symptoms (10% vs.17%, respectively) (Samuels et al., 2000). Relatives of probands with early-onset OCD have a particularly high prevalence of OCD compared to control relatives (22.7% vs. 0.9%) (do Rosario-Campos et al., 2005), which is of particular interest given the observation that early-onset OCD is similar in course and gender ratio to that of autism. A familial link has similarly been reported in TTM, with relatives of probands with TTM approximately 20% more likely to exhibit OCD and TTM compared to control probands (Christenson, Mackenzie, & Reeve, 1992; Lenane et al., 1992).

With regard to a family history related to repetitive behaviors per se, Hollander et al. (2003) found that autistic probands who engaged in high levels of repetitive behaviors were more likely to have parents with OCD compared to autistic probands who exhibited few repetitive behaviors (15% vs. 4%, respectively). More recent studies have utilized quantitative symptoms dimensions to examine familial linkage. For example, Abramson et al. (2005) reported a positive correlation between the "Insistence on Sameness" factor on the Autism Diagnostic Interview-Revised (ADI-R) in subjects with autism and obsessive-compulsive behaviors in parents.

Studies that examined sibling-pair correlations similarly found a significant familial relationship for the "Insistence on Sameness," as well as for the "Circumscribed Interest" factor, on the ADI (Lam, Bodfish, & Piven, 2008; Szatmari et al., 2006). Interestingly, neither of these studies found a familial relationship for the lower-order "Repetitive Sensory and Motor" factor. Along these lines, a multiplex family study also reported a familial pattern for higher-, but not lower-, order repetitive behaviors in first-degree relatives of individuals with ASD (Silverman et al., 2002). Higher-order repetitive behavior in idiopathic OCD has also been linked to a family history of OCD spectrum disorders. More specifically, OCD probands whose obsessions and compulsions included ordering and symmetry were more likely to have a relative with OCD (Alsobrook, Leckman, Goodman, Rasmussen, & Pauls, 1999; Hanna, Fischer, Chadha, Himle, & Van Etten, 2005).

In summary, family studies typically show that relatives of probands with OCD spectrum disorders have an increased risk of also having an OCD spectrum disorder. Further, research is emerging that is making a strong case for a familial link for higher-order repetitive behaviors in autism and OCD, which may represent an underlying endophenotype.

Genetics

Genetic linkage and association studies have reported genetic relationships between OCD and some OCD spectrum disorders. For example, linkage analysis has revealed that individuals with more severe OCD displayed an autism susceptibility gene on chromosomes 1, 6, and 19 (Buxbaum et al., 2004). The chromosome 15q11-q13, in particular, has been implicated in repetitive behaviors in autism. Moreover, families sharing high scores on the "Insistence on Sameness" factor of the ADI showed increased linkage at the GABRB3 locus in 15q11-q13 (Shao et al., 2003).

As with OCD, the serotonin transporter (5-HTT) is considered to be a candidate gene for autism. Investigations have isolated a genetic linkage of autism to the chromosome 17q11.2 region that harbors the serotonin transporter gene (SLC6A4) (Cantor et al., 2005; McCauley et al., 2004; Risch et al., 1999). Moreover, Brune, et al. (2006) reported an association between 5HTTLPR long/long genotype of the SLC6A4 and repetitive sensory-motor behaviors. Similarly, a link has been reported between novel variants at the serotonin transporter locus and rigid compulsive behavior (Sutcliffe et al., 2005). Associations with the 5-HTTLPR polymorphism, have, however, been mixed (Conroy et al., 2004; Devlin et al., 2005; Kim et al., 2002; Yirmiya et al., 2001). Nevertheless, a link between the 5-HT transporter and repetitive behaviors is consistent with the abundance of 5-HT receptors housed in the basal ganglia, which, as will be discussed in the following section, has been implicated in the expression of repetitive behaviors (Di Giovanni, Di Matteo, Pierucci, Benigno, & Esposito, 2006).

Other genes have also been implicated in repetitive behaviors. More specifically, studies show that dopamine transporter knockout mice exhibit a greater insistence on fixed patterns of action (Berridge, Aldridge, Houchard, & Zhuang, 2005). Other studies have found that a mitochondrial aspartate/glutamate carrier polymorphism on chromosome 2 was associated with routines and rituals in individuals with autism (Silverman et al., 2006). In addition, a significant allele sharing for hoarding phenotypes has been found for markers at 4q34–35, 5q35.2–35.3, and 17q2 (Zhang et al., 2002).

Neuroimaging

Current neuroimaging and cognitive findings across OCD spectrum disorders provides further evidence of a common underlying pathophysiology. More specifically, neuroimaging research has tended to show dysfunction in the cortico-striatal-thalamo-cortical circuit (sometimes referred to as the "OCD circuit"), which includes the basal ganglia, anterior cingulate, dorsolateral and orbitofrontal cortex, and the thalamus. As will be discussed in the next section, abnormalities in this pathway are supported by reduced performance on cognitive tasks that are mediated by these brain regions.

In terms of aberrant functioning within structures of the basal ganglia, recent MRI studies have revealed enlarged bilateral (Herbert et al., 2003; Sears et al., 1999) and right (Hollander, Anagnostou, et al., 2005) caudate volume in patients with autism compared to controls. The variability in findings may be a result of the positive correlation between right caudate volumes and higher order repetitive behaviors (Hollander, Anagnostou, et al., 2005). This hypothesis is consistent with increased right caudate volume reported in patients with OCD (Scarone et al., 1992), who also exhibit higher order repetitive behaviors. These data suggest a possible common underlying neural pathway associated with the higher order, cognitive mediated repetitive behaviors across both ASD and OCD.

In subjects with trichotillomania, smaller left putamen volume and increased grey matter density in the left stratum has been reported relative to normal controls (Chamberlain et al., 2008; O'Sullivan et al., 1997). Furthermore, a negative correlation has found between TTM severity and striatal activity, in that, more severe hair pulling was associated with a greater reduction in striatal activity (Stein et al., 2002).

Abnormalities in the anterior cingulate cortex have also been frequently reported across OCD-related disorders. For example, reduced metabolism and volume in the anterior cingulate have been observed in individuals with ASD relative to healthy controls (Haznedar et al., 1997; Haznedar et al., 2000; Ohnishi et al., 2000). Further, white matter disruption in the anterior cingulate has been reported in autism (Barnea-Goraly et al., 2004), as well as in OCD (Szeszko et al., 2005).

A differential pattern of cingulate activity has been shown for OCD patients with and without hoarding symptoms (Saxena et al., 2004). More specifically, OCD patients who also exhibit hoarding symptoms displayed reduced metabolism in the posterior cingulate gyrus compared to controls, and in the dorsal anterior cingulate compared to nonhoarding OCD patients. These data, together with findings of an earlier age of onset for hoarding with OCD versus hoarding without OCD, distinct susceptibility genes for hoarding, as well as, as will be discussed later in the chapter, an empirically derived hoarding factor in OCD, suggest that compulsive hoarding may be an independent subtype of repetitive behaviors.

Few studies have specifically investigated the neural structures involved in repetitive behaviors. Hollander et al. (2005) found a positive correlation between the severity of repetitive behaviors and right caudate and putamen volumes in patients with autism. This association was particularly strong for the higher-order OCD spectrum repetitive behaviors, such as insistence on sameness/resistance to change. Sears et al. (1999) similarly reported that enlarged caudate volume in autism was correlated with difficulties with minor change in routine, compulsions and rituals, and complex motor mannerisms.

Taken together, replicated neuroimaging findings have revealed a link between higher-order repetitive behaviors and structures in the basal ganglia, and the anterior cingulate cortex. This finding suggests that dysfunction in this circuitry may lead to the expression of higher-order repetitive behaviors across OCD spectrum disorders. Alternatively, subtle structural and/or functional alterations along the corticostriatal pathway may be associated with different symptom presentations of repetitive behavior. More research is needed linking brain imaging findings to distinct repetitive behaviors.

Neuropsychology

Structures within the corticostriatal neural pathway, which as discussed above, have been found abnormal in neuroimaging studies of OCSDs, play a prominent role in the mediation of executive functions. As such, one would expect executive dysfunction to be significant in the neuropsychological literature of OCD spectrum disorders.

Executive function is an umbrella term used to describe cognitive functions involved in planning and executing complex behavior such as organization, inhibition, initiation of action, self-monitoring, cognitive flexibility and set-shifting. Many of these functions are characteristic of ASD and OCD spectrum disorders. For example, in autism, difficulty inhibiting behavior may lead to repetitive verbalizations and/or actions, and in OCSDs, it may manifest as difficulty repressing unwanted obsessions, and/or controlling compulsions such as hair pulling.

Neuropsychological studies have in fact demonstrated deficits in response inhibition in individuals with OCSDs, albeit with variable results. Bohne et al. (2008) reported poor motor inhibition in patients with TTM, but not in patients

with OCD. In contrast, Chamberlain et al. (2006) found that both patients with TTM and patients with OCD showed impaired motor inhibition, though the impairment was more significant in patients with TTM. Variable findings have also been reported regarding inhibition in autistic samples (Ozonoff, Strayer, McMahon, & Filloux, 1994; Shafritz, Dichter, Baranek, & Belger, 2008). However, it is of considerable interest that during a response inhibition task, functional brain imaging studies have correlated reduced inhibitory control with hypometabolism in the anterior cingulate in individuals with ASD (Anagnostou, 2006; Kana, Keller, Minshew, & Just, 2007). This is consistent with dysfunction in the anterior cingulate, which, as previously discussed, has frequently been reported across OCD spectrum disorders.

Another executive function that is often impaired in individuals with OCDRS is cognitive flexibility. Poor flexibility can manifest in preservative, stereotyped behavior, rigidity, and inflexibility. A recent study compared cognitive set shifting between subjects with TTM, OCD, and controls. Deficits in cognitive flexibility were demonstrated only in patients with OCD relative to controls (Chamberlain et al., 2006). In contrast other studies have found impaired cognitive set-shifting in subjects with TTM compared to controls (Stanley, Hannay, & Breckenridge, 1997). In samples of autistic individuals, executive deficits have been found in set-shifting (Ozonoff et al., 2004) as well as in an increased rate of perseverative responding compared to controls (Turner, 1999).

Few studies have explored the relationship between performance on tests of executive functioning and repetitive behavior. Turner (1999) reported that poorer performance on tasks that measure initiation and inhibition of response were associated with higher levels of repetitive behavior, in both high- and low-functioning patients with autism. In contrast, Ozonoff et al. (2004) reported no relationship between performance on tasks of executive functioning and repetitive behavior. More recently, Lopez et al. (2005) found that repetitive behaviors are associated with some, but not other executive functions. More specifically, in adults with autistic disorder, repetitive behavior was correlated with cognitive flexibility, response inhibition, and working memory, but not with planning or fluency.

In summary, executive dysfunction in response inhibition, cognitive flexibility, and perseveration has been demonstrated in OCSDs, albeit with some inconsistency. Variable findings in studies of executive function are not surprising, however, as these functions each comprise of a range of independent processes, and different research measures tap into different functional components. It is interesting, however, that an fMRI study that examined neural activity during an executive task demonstrated a relationship between executive function impairment, repetitive behavior, and frontostriatal circuitry. Similar interdisciplinary research will help to relate executive functioning to the expression of repetitive behaviors and the integrity of brain structures in OCD related disorders.

Pharmacology/Treatment Response

Common neurotransmitter systems, and a similar response profile to psychopharmacological treatments, have been found across some OCD spectrum disorders. For example, treatment with clomipramine has been reported to be more effective than desipramine for patients with OCD (Hollander & Kahn, 2003; Leonard et al., 1989), ASD (Gordon, State, Nelson, Hamburger, & Rapoport, 1993), BDD (Hollander et al., 1999), and TTM (Swedo et al., 1989). In addition, selective serotonin reuptake inhibitors (SSRIs) are the first-line treatment for OCD and BDD.

Treatment with SSRIs has similarly been efficacious in reducing repetitive behaviors in ASD in some but not all studies. For example, in randomized controlled clinical trials of children, adolescents, and adults treated with fluoxetine (Buchsbaum et al., 2001; Hollander, Phillips, et al., 2005) and fluvoxamine (McDougle, et al., 1996), significant improvements in repetitive symptoms were demonstrated compared to placebo. A recent study, however, that compared citalopram to placebo, found no difference in outcome between the treatment conditions (King et al., 2009). The discrepancy in findings may be the result of differences in methodology between studies (e.g., dosing, age of sample, etc.), as well as individual variability. Alternatively, since SSRIs effectively reduce anxiety in samples with autism (Buchsbaum et al., 2001; Hollander, Phillips, et al., 2005) (Steingard, Zimnitzky, DeMaso, Bauman, & Bucci, 1997), which is likely to be associated with reduced rigidity in adherence to routines and rituals (Soorya, Kiarashi, & Hollander, 2008), SSRIs may exert their effect on the higher-order repetitive behaviors. Future outcome studies with SSRIs may benefit by examining the relationship between treatment response, higher- vs. lower-order repetitive behaviors, and anxiety.

Nevertheless, there is strong evidence that implicates serotonin in playing a role in the expression of repetitive symptoms. For example, Hollander et al. (2000) found that the sensitivity of the 5HT1d receptor was associated with the severity of repetitive behaviors in adults with autism. Further, as previously reported, the serotonin transporter (5-HTT) has been studied as a possible candidate gene for autism.

Dopaminergic abnormalities have also been implicated in both ASD and OCD (Denys, Zohar, & Westenberg, 2004; Hollander, Baldini Rossi, Sood, & Pallanti, 2003; McCracken et al., 2002). For instance, children treated with the antipsychotic risperidone showed reductions in stereotypy, hyperactivity, and aggressive symptoms compared to those on placebo. Significant improvement in repetitive behaviors in children with ASD has also been associated with divalproex treatment (Hollander et al., 2006). Other support for dopamine's role in OCD spectrum disorders is the common use of dopamine blockers as augmentative treatment in individuals with treatment-resistant OCD (Pallanti, Bernardi, Antonini, Singh, & Hollander, 2009). Moreover, dopaminergic neurotransmission plays a significant role in mediating the

function of structures in the basal ganglia, which as previously discussed are associated with the expression of repetitive behaviors, and are aberrant in many OCD spectrum disorders.

Phenotypes of ASD and OCSDs

As discussed throughout this chapter, the repetitive behaviors that are displayed in ASD and other OCD spectrum disorders lie across a broad spectrum that ranges from repetitive body movements to more cognitively mediated symptoms, such as circumscribed interests and obsessions. Several approaches have attempted to reduce the heterogeneity of repetitive behaviors into meaningful categories. The traditional method has been to consider whether or not the symptoms are *egodystonic*, that is, whether the individual perceives them as irrational and/or unreasonable. Importantly, when symptoms are egodystonic, they provoke significant mental distress (e.g., anxiety). In attempt to diminish that stress and anxiety, compulsions and rituals are performed, for example in OCD and BDD. With regard to TTM, tension is thought to mount immediately before, or during, attempts to avoid hair-pulling, followed by a sense of relief and pleasure during hair-pulling.

In contrast, repetitive behaviors exhibited in ASD and OCPD are not subjectively recognized as excessive or senseless, and do not provoke anxiety. Thus, they are *egosyntonic*. For example, many individuals with Asperger's disorder derive satisfaction and comfort from their preoccupations. Assessment of perceived rationality in ASD, however, is difficult due to impaired introspection that is inherent in the disorder. For patients with OCPD, obsessions and compulsions are also viewed as enjoyable, and, in fact, these patients will readily explain why their behaviors are rational.

One drawback of the egodystonic, egosyntonic classification of repetitive behaviors is that the same behavior may be subjectively experienced differently. As such, it becomes unclear as to whether the behavior is functioning as an anxiolytic in one individual relative to another. For example, one patient may engage in excessive list-making to reduce the significant subjective distress created by an egodystonic obsession. Alternatively, list making may be related to a preoccupation with detail, as in OCPD, and in this case, it is likely to be enjoyable, not resisted, and therefore, egosyntonic. Another shortcoming of this distinction stems from the discovery that there is a continuum of insight (i.e., degree of understanding of the problematic or irrational nature of the symptoms) into a patient's OCD-like symptoms. For example, Foa et al. (1995) conducted a field study for the DSM-IV and found that of 432 individuals with OCD, only 8% currently lacked insight, and 5% reported that they never had insight. This study propelled the DSM-IV to replace the egodystonic attribute of repetitive behaviors in OCD, and add a "poor insight" specifier. Poor insight is characterized as not realizing that obsessions and actions are excessive and unreasonable, and significantly interfere with daily life.

In contrast to egodystonicity, poor insight in OCD has been associated with treatment outcome, as well as with specific types of obsessions. For example, Tolin, Abramowitz, Kozak, and Foa (2001) found that poor insight was associated with religious obsessions, fears of making mistakes, and unwanted obsessional impulses to act aggressively. Other studies have found that poor insight was found more often in individuals with somatic obsessions (e.g., physical appearance, fears of illness), compared to other OCD symptoms (Abramowitz, Franklin, Schwartz, & Furr, 2003; McKay, Neziroglu, & Yaryura-Tobias, 1997; Neziroglu, Pinto, Yaryura-Tobias, & McKay, 2004). This is consistent with a finding in BDD, which also involves somatic symptoms, which reported a negative correlation between insight and symptoms severity (Eisen, Phillips, Coles, & Rasmussen, 2004). Poor insight in OCD has also been associated with poor psychopharmacological and behavioral treatment outcome (Raffin, Guimaraes Fachel, Ferrao, Pasquoto de Souza, & Cordioli, 2009; Shetti et al., 2005) and an earlier age of onset (Catapano et al., 2009).

With advances in theory and research, greater specificity of the structure of the repetitive behavior domain of OCD spectrum disorders has been conceptualized. In particular, various research groups have utilized factor analytic methods to mathematically derive independent underlying dimensions (also called factors or subtypes) of repetitive symptoms. Importantly, each of these homogeneous subtypes may be associated with a unique etiology and treatment response profile.

Using this technique, the most established factors that have emerged in the autism literature are the "lower order" and the "higher order" subtypes of repetitive behaviors. More recently, however, the structure of the repetitive behaviors has become even more specific, as additional distinct factors have been identified. In the earlier research (Cuccaro et al., 2003; Szatmari et al., 2006) factor analyses were performed on the symptoms items of the Autism Diagnostic Interview-Revised (ADI-R), a clinical assessment that focuses on the three main autism symptom domains (i.e., reciprocal social interaction; communication and language; and restricted and repetitive, stereotyped interests and behaviors). The results of these factor analyses yielded "lower-" and "higher-" order factors, in both children and adults. As previously mentioned, the lower-order factor, also referred to as "Repetitive Sensory and Motor Behaviors," includes symptoms such as hand and finger mannerisms, repetitive use of objects or parts of objects, unusual sensory interests, stereotyped body movements, and rocking. These repetitive behaviors are thought to be self-stimulatory and serve to modulate the level of arousal. The higher-order repetitive domain, called "Insistence on Sameness," comprises symptoms such as resistance to trivial changes in routine and environment, compulsions, and rituals. These repetitive thoughts and behaviors are thought to be mediated by higher cognitive processes.

Several groups have, in fact, demonstrated that the higher- and lower-order repetitive domains are correlated with level of cognitive functioning. More specifically, whereas higher-order repetitive symptoms have been associated with higher

intellectual functioning (Militerni et al., 2002), lower-order repetitive behaviors have been linked with intellectual disability (Bishop et al., 2006; Militerni et al., 2002). Consistent with this, symptoms that comprise the lower-order domain, such as stereotyped motor movements, have also been linked to neurological dysfunction (Peterson et al., 2003; Sears et al., 1999), and as such, are also manifested in neurological-based OCSDs such as Tourette's syndrome (TS), Sydenham's chorea, as well as ASD.

More recently, a distinct third repetitive behavior factor in autism has been identified, also derived from the items on the ADI-R (Lam et al., 2008). This factor materialized because, in contrast to the earlier research, ADI-R items that did not load on either the "Repetitive Sensory and Motor Behaviors" or "Insistence on Sameness" factor were not excluded from the analysis. This third factor, described as "Circumscribed Interests" includes circumscribed interests, unusual preoccupations, and unusual attachment to objects.

In attempt to provide even more definition and structure to the repetitive domain, recent investigations have utilized instruments that more explicitly delineate repetitive behaviors. For example, a factor analysis using the items on the Repetitive Behavior Scale-Revised (RBS-R), conducted by Lam and Anon (2007), derived 5 subscales in children and adults with ASD. They included "Ritualistic/Sameness Behavior" (repetitive performance of activities of daily living, resistance to change, need for sameness), "Stereotypic Behavior" (repeated, purposeless body movements), "Self-injurious Behavior,"

"Compulsive Behavior" (repetitive behavior performed according to a rule, or until its "just right"), and "Restricted Interests" (limited range of interest, focus or activity). In contrast, Anagnostou et al. investigated the structure of the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) in individuals with autism (unpublished data). Results yielded four empirically derived distinct factors, which comprised higher-order repetitive behaviors (e.g., ordering, washing, repeating, checking, ritualistic eating and rituals), lower-order repetitive behaviors (self-injurious behaviors, touching, rubbing), hoarding, and obsessions.

If the overlap of symptoms between ASD and other OCD spectrum disorders is meaningful, then repetitive symptoms within disorders should share a similar underlying factor structure, or should overlap with one or more established repetitive factor domains. Bloch et al. (2008) recently conducted a large-scale meta-analysis to validate the factor structure of the Y-BOCS in OCD. This study yielded 4 factors, including "Forbidden Thoughts" (obsessions involving aggression, sexual, religious, and somatic content, as well as checking compulsions), "Symmetry" (symmetry obsessions, and repeating, ordering, and counting compulsions), "Cleaning" (cleaning and contamination), and "Hoarding" (hoarding obsessions and compulsions).

Examination of the factor structure of repetitive behaviors on the Y-BOCS between ASD and OCD samples is notable for interesting similarities and differences (see Figure 16-2). For example, the repetitive symptoms intrinsic to each disorder

	Distinct					Overlapping	
	Lower-Order	Higher-Order					Hoarding
Factor	Repetitive sensory and motor	Sameness	Circumscribed interest	Cleaning	Forbidden thoughts	Symmetry	Hoarding
Symptoms	Touching • Rubbing • Stereotyped body movements • Repetitive use of objects • Unusual sensory interests • Self-Injurious behaviors	Need for sameness • Resistance to change • Repetitive performance of activities of daily living	Restricted interests • Unusual preoccupations • Unusual attachments to objects	Cleaning • Contamination	Aggression: Sexual • Religious • Somatic	Symmetry • Repeating • Ordering • Counting • Checking • Rituals	Hoarding obsession and compulsions
Diagnosis	ASD	ASD	ASD	OCD	OCD	ASD & OCD	ASD & OCD

Figure 16–2. Summary of distinct and overlapping repetitive factors in autism spectrum disorder (ASD) and obsessive-compulsive disorder (OCD). Distinct repetitive factors found only in ASD include the lower order "Repetitive Sensory and Motor" factor and the higher order "Sameness" and "Circumscribed Interest" factors. Distinct factors found in OCD include the higher order repetitive factors of "Cleaning" and "Forbidden Thoughts." Overlapping factors, which have been derived in both samples of ASD and OCD, include the higher order "Symmetry" factor, and a "Hoarding" factor.

loaded similarly to yield 2 analogous factors. The first, characterized as a distinct hoarding subtype, was derived in both the ASD and OCD samples. The validity of hoarding as a discrete subtype is supported by previous research, which suggests that hoarding is associated with a distinct biological and genetic profile, poor insight, and resistance to psychological and pharmacological treatments (Abramowitz et al., 2003; Lochner et al., 2005).

The second repetitive dimension uncovered in both samples involves repeating, ordering, symmetry, counting, and rituals. This is referred to as the "Symmetry" factor in OCD, and the "Higher-order" repetitive factor in ASD. Strong support for a distinct higher-order, cognitively mediated repetitive factor comes from family and genetic studies. As previously discussed, family studies have demonstrated a familial link for the "Insistence on Sameness" and "Circumscribed Interests" factors of the RRBS, as well as the "Insistence on Sameness" factor of ADI-R (Abramson et al., 2005; Lam et al., 2008; Silverman et al., 2002; Szatmari et al., 2006). Furthermore families sharing high scores on the "Insistence on Sameness" factor of the ADI showed increased linkage at the GABRB3 locus in 15q11-q13 (Shao et al., 2003). In contrast, no familial or genetic link has been reported for the lower-order sensory motor repetitive behaviors. Neuroimaging findings, which suggest a positive correlation between higher-order repetitive behaviors and caudate and putamen volumes (Hollander, Anagnostou, et al., 2005; Sears et al., 1999), also point in the direction of a unique etiology for this repetitive domain.

A distinction in the underling factor structure of repetitive behaviors between the ASD and OCD sample is that the lower-order repetitive factor, which is consistently yielded in studies of ASD, was not reported in the OCD sample. This lack of finding supports previous research that suggests lower-order repetitive behavior is in fact a homogeneous neurologically based factor (Peterson et al., 2003; Sears et al., 1999), associated with intellectual disability (Bishop et al., 2006; Militerni et al., 2002) but not common in OCD (McDougle, Kresch, et al., 1995). In contrast, a subtype of "Forbidden Thoughts" was identified in OCD, but not ASD, samples. This concurs with a study that directly compared the Y-BOCS in adults with OCD and ASD, and found that patients with OCD were significantly more likely to experience aggressive, sexual, religious, and somatic obsessions compared to patients with ASD (McDougle, Krystal, Price, Heninger, & Charney, 1995). It is also of interest to note that aggressive, religious, and somatic obsessions have been associated with an unfavorable treatment response (Erzegovesi et al., 2001; Ferrao et al., 2006; Mataix-Cols, Marks, Greist, Kobak, & Baer, 2002) and with poor insight (Catapano et al., 2009; Erzegovesi et al., 2001; Raffin et al., 2009), thus mounting further support to the validity of this subtype.

To the authors' knowledge, no studies have been performed looking at the structure of repetitive symptoms in BDD, OCPD, or TTM. Within the framework of the empirically validated repetitive symptom dimensions described above, however, it is not difficult to conceptualize where they

may fit in. For example, as the content of obsessions in BDD are somatic in nature, they would seemingly load with the "Forbidden Thoughts" factor that also includes somatic preoccupations. Similarly, the repetitive behaviors exhibited in TTM, stereotypic movement disorder, skin picking, and Tourette's syndrome should effectively superimpose on the lower-order repetitive cluster found in ASD.

As can be seen, the heterogeneous repetitive behaviors across OCD spectrum disorders can be reduced and more specifically categorized into discrete repetitive domains. Individuals with these disorders, in turn, could be subgrouped accordingly. For example, one individual diagnosed with ASD may predominately engage in self-stimulatory behavior whereas another may primarily experience extreme resistance to trivial changes. The former patient in this example could be reclassified into the lower-order repetitive behaviors subtype, and the latter could be categorized within the higher-order domain. Alternatively, another individual with autism may display symptoms within both dimensions, or may even have a combination of symptoms across dimensions. This is also the case for individuals with other OCD spectrum disorders, who would be classified within the same repetitive clusters. Grouping the diverse repetitive behaviors into homogeneous domains will provide future research with more statistical power to reveal the unique neurobiological underpinnings associated with each dimension. This will, in turn, inform the development of new treatment approaches, with the ultimate goal of offering patients personalized treatment that will match their unique pattern of symptom dimensions to specific and targeted treatments.

Conclusions

Evidence is converging across multiple disciplines to support the conceptualization of discrete dimensions of repetitive behaviors across OCD spectrum disorders. Importantly, this subtyping appears to reduce heterogeneity in research studies to allow for the identification of OCD spectrum endophenotypes. For example, recent findings have demonstrated that higher-order repetitive behaviors across disorders have familial and genetic linkage, as well as similar neurobiological findings. In contrast, lower-order repetitive behaviors appear not to be influenced by genetics, but rather by neurological insult, including intellectual disability. Hoarding has also manifested as a distinct repetitive dimension across OCD spectrum disorders, with a unique underlying neuropathophysiology.

Challenges and Future Directions

- Future studies that examine repetitive behaviors in OCD spectrum disorders would benefit by using measures that assess the full range of thoughts, actions, and behaviors

within this domain. This would allow for a more the precise identification of homogeneous dimensions within the core repetitive behavior domain.

- More interdisciplinary studies are needed to delineate the unique neurobiological underpinnings associated with each repetitive symptom dimension.
- Studies are needed to examine the possibility of a differential treatment response between patients with symptoms that load primarily on one repetitive symptom dimension versus another.

Interface Between Autism Spectrum Disorders and Obsessive-Compulsive Behaviors: A Genetic and Developmental Perspective

Points of Interest

- Autism Spectrum Disorders (ASD) include obsessive-compulsive behaviors (OCB) that partially overlap with obsessive-compulsive disorder (OCD).
- The symptoms that most closely resemble the repetitive behaviors seen in ASD include:
  - Ordering and arranging, counting, doing and redoing often prompted by sensory phenomena urges, or a need to have things feel, look, or sound "just right";
  - Rituals associated with sleep-wake transitions, separation from attachment figures, as well as habits associated with dressing and grooming; and
  - Collecting or hoarding.
- OCB associated with ASD are partially independent of genetic associations with the social disabilities of ASD, suggesting that a different set of genes influence OCB versus social behavioral deficits.
- Several family-genetic studies have indicated that OCD itself may be part of a broader autism disorder phenotype, because there is increased risk of OCD or traits in close family relatives of individuals with autism.
- Many typically developing children display OCB as toddlers and in the preschool age range. These behaviors are also frequently persistent in individuals with genetically determined intellectual disabilities including Fragile X syndrome, Prader-Willi syndrome, and Smith-Magenis syndrome.
- Specific vulnerability genes associated with OCB in ASD have not been identified. Like ASD, OCB are likely to prove to be multidimensional and polygenic. Some of the vulnerability genes may prove to be generalist genes influencing the phenotypic expression of both ASD and OCD, while others will be specific to subcomponents of the ASD phenotype.

Autism Spectrum Disorders (ASD) are severe neurodevelopmental disorders characterized by impairments in reciprocal communication and social interactions, accompanied by restricted interests and/or stereotyped patterns of behaviors (Lord, Cook, et al., 2000; Lord, Leventhal, et al., 2001). The prevalence of ASD is currently estimated to be at least 6 per 1000 children (Yeargin-Allsopp, Rice, et al., 2003; Fombonne, 2005). Family and twin studies indicate that ASD have a strong genetic component (Folstein & Rutter, 1977; Bailey, Le Couteur, et al., 1995; Folstein & Rosen-Sheidley, 2001; Veenstra-VanderWeele & Cook, 2004; Gupta & State, 2007). It is also clear that ASD are etiologically heterogeneous. This heterogeneity can markedly reduce the power of gene-localization methods, including linkage analysis (Zhang & Risch, 1996; Gu, Province, et al., 1998; Alcais & Abel, 1999). Some of the core features of ASD (e.g. phrase speech delay and repetitive behaviors) may themselves be familial traits (Silverman, Smith, et al., 2002; Kolevzon, Smith, et al., 2004; Ronald, Happe, et al., 2006a; Ronald, Viding, et al., 2006b; Freitag, 2007; Yrigollen, Han, et al., 2008) and may thus be useful phenotypes for identifying ASD-related genes.

Obsessive-compulsive behaviors (OCB) are one of the behavioral phenotypes that have shown the greatest promise for identifying different ASD-related phenotypes based on cross-sectional and family-genetic, linkage, and association studies (Bolton, Pickles, et al., 1998; Bejerot, Nylander, et al., 2001; Buxbaum, Silverman, et al., 2004; Bejerot, 2007; Cath, Ran, et al., 2008; Cullen, Samuels, et al., 2008; Ivarsson & Melin, 2008). At the surface, this would naturally lead to questions concerning the heritability of obsessive-compulsive disorder (OCD) and the possibility that some of these behaviors might be shared in common across OCD and ASD. It is clear that twin and family-genetic studies suggest that genetic factors play a role in the transmission and expression of OCD (Pauls, 2008). Although earlier studies have indicated that the vertical transmission of OCD in families is consistent with the effects of a single major autosomal gene (Cavallini, Pasquale, et al., 1999), it is likely that there are a number of vulnerability genes involved. Similar to ASD, etiologic

heterogeneity may be reflected in phenotypic variability, making it highly desirable to dissect the OCD, at the level of the phenotype, into valid quantitative heritable components.

Questions are increasingly being raised concerning the degree to which the OCB seen in many individuals with ASD are related to their social difficulties (Mandy & Skuse, 2008). Nevertheless major questions remain concerning the precise nature of the OCB seen in ASD and whether and how closely these behaviors resemble those seen in OCD. We undertake this review with the firm belief that identifying genetic risk factors for ASD, OCB, and related phenotypes and characterizing their role in early brain development will be important in understanding the molecular pathogenesis of ASD, as well as for defining methods for better diagnostics, and developing therapeutic approaches (Abrahams & Geschwind, 2008). In order to achieve this goal, common phenotypic measurements are needed. Consequently, the question of "what phenotype is being evaluated" will be a key focus as we review the available data concerning the broader autism phenotype (Piven, Palmer, et al., 1997; Bolton, Pickles, et al., 1998; Cath, Ran, et al., 2008).

Clinical Phenotypes

A major issue in considering the phenotypic overlap between ASD and OCD concerns the degree to which the behaviors and mental states described as "compulsive" or "obsessional" are really the same across the two sets of disorders. Terms used to describe the OCB seen in ASD include repetitive interests, behaviors, and activities (RIBAs) (Bodfish, Symons, et al., 2000; Charman & Swettenham, 2001; Mandy & Skuse, 2008). Questionnaire, interview, and direct observation data all point to the presence of a range of OCB in ASD that, to some extent, are dependent on the individual's mental age (Table 17-1; Esbensen, Seltzer, et al., 2009). While there are a few overlapping items such as ordering/arranging, collecting, and the need for things to be "just right," it is also clear that the range of repetitive behaviors include some seen in young typically developing children that may persist for a longer period of time in individuals with ASD and OCD.

From the ASD perspective, information collected during formal evaluations using the Autism Diagnostic Interview, Revised (ADI-R), (Lord, Rutter, et al., 1994) provides a sense of what behaviors are typical of some individuals with ASD. For example, Frazier and colleagues (Frazier, Youngstrom, et al., 2008) recently reported the results of both exploratory and confirmatory factor analysis of the ADI-R and confirmed the existence of a Stereotyped Behavior and Restricted Interests factor that includes each of the ratings on the repetitive behavior domain of the ADI-R (R1: circumscribed interests; R2: compulsive routines; R3: stereotyped motor mannerisms; and R4 preoccupation with objects; Table 17-1). A number of other questionnaires and direct observation measures contain similar constructs (Berument, Rutter, et al., 1999; Bodfish, Symons,

et al., 2000; Wetherby, Watt, et al., 2007). At present, the most detailed of these scales is the Repetitive Behavior Scale-Revised, which includes 43 items divided into 5 domains (Table 17-1). Of interest, scores in each of these domains are sensitive to both chronological and mental age. The scores in each domain decrease with advancing chronological age and are higher in the presence of intellectual disability (Esbensen, Seltzer, et al., 2009). The slope of the decline with chronological age was steepest for the stereotyped repetitive behaviors and the ritualistic/sameness repetitive behaviors domains.

However, typically developing young children beginning around the second year of life develop a variety of rituals, habits, routines, and preferences, some of which resemble the behaviors associated with ASD and OCD (Evans, Leckman, et al., 1997; Zohar & Felz, 2001). The idea that compulsive ritualistic behaviors may be normative in young children is not new. Gesell and his colleagues (Gesell, 1928; Gesell & Llg, 1943) were among the first to recognize that young children—particularly those around the age of two and a half—begin to establish rigid routines that Gesell termed the "ritualisms of the ritualist." Rather than addressing emotional needs, Gesell believed children engage in rituals to master the tasks of a specific developmental epoch, for instance, matters of feeding, toileting, and dressing. More than 80% of parents report the presence of a bedtime ritual for children by the age of three years. It is less well known that these compulsive ritualistic behaviors manifest in most typically developing children in a regular sequence. After the emergence of a bedtime ritual, the need to arrange things "just right" or in a symmetrical pattern appears, followed by the child's being very concerned with dirt and germs, and finally, the need to collect and store objects. With the exception of hoarding, each of these behaviors peaks at the age of three years. (Evans, Leckman, et al., 1997) Hoarding, in contrast, shows a monotonic increase, at least until the age of six years, when more than 60% of normal children display this trait (Evans, Leckman, et al., 1997; Zohar & Felz, 2001). The earlier the age at which these compulsive behaviors appear, the more advanced the child's developmental level. It is also striking that children with severe intellectual disabilities, including many children with ASD whose mental age remains in the low range, show a persistence of many of these obsessive-compulsive behaviors (Evans & Gray, 2000; Greaves, Prince, et al., 2006). From this perspective, one could ask whether the repetitive behaviors seen in some children with ASD are little more than the persistence or increase in severity or frequency of these "normal" repetitive behaviors.

The complex clinical presentation of OCD can be summarized using a few consistent and temporally stable symptom dimensions (Mataix-Cols, Rosario-Campos, et al., 2005). These can be understood as a spectrum of potentially overlapping features that are likely to be continuous with "normal" worries and extend beyond the traditional nosological boundaries of OCD. Although the understanding of the dimensional structure of obsessive-compulsive (OC) symptoms is still imperfect, recent large-scale meta-analysis of data from more than 5,000 individuals provides the clearest picture of the

Table 17–1.

Overlapping phenotypes and assessment tools

Class	Description	Measurement
DSM-IV-TR criteria #3 for Autistic Disorder	Restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following: - Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus - Apparently inflexible adherence to specific, nonfunctional routines or rituals - Stereotyped and repetitive motor manners (e.g., hand or finger flapping or twisting, or complex whole-body movements) Persistent preoccupation with parts of objects	*Autism Diagnostic Interview-Revised* (Lord et al., 1994) R1. Encompassing preoccupation or circumscribed pattern of interest: circumscribed interests and unusual preoccupations R2. Apparently compulsive adherences to nonfunctional routines or rituals including verbal rituals and compulsions/rituals R3: Stereotyped and repetitive motor mannerisms including hand and finger mannerisms as well as other complex mannerisms R4: Preoccupations with part-objects or nonfunctional elements of materials including the repetitive use of objects and unusual sensory interests *Autism Screening Questionnaire* (Berument et al., 1999): Eight items loaded on a single factor: Repetitive used objects; Unusual sensory interests; Compulsions and rituals; Unusual preoccupations; Use of other's body to communicate; Complex body mannerisms; Unusual attachment to objects; and Circumscribed interests. *Repetitive and Stereotyped Movement (RSM) Scales* (Wetherby & Morgan, 2007) Direct observation: RSM with Body: Flaps; Rubs body; Pats body; and/or Stiffens body parts and postures; RSM with Objects; Restricted preoccupation in intensity or focus with restricted interest; Swipes; Rubs/Squeezes; Rolls/Knocks Over; Rocks/Flips; Spins/Wobbles; insists on sameness or difficulty with change in activity; Collects; Moves/Places; Lines up/Stacks and/or Clutches *Repetitive Behavior Scale-Revised* (RBS-R, Bodfish et al., 2000) Questionnaire completed by parent, teacher, or caregiver, five empirical derived subscales: Stereotyped behavior; Self-injurious behavior; Compulsive "just-right" behavior; Ritualistic/sameness; and Restricted interests
Obsessive-Compulsive Behaviors Within Pervasive Developmental Disorders	Beginning from an obsessive-compulsive symptom perspective, investigators have adapted the "compulsions" portion of the Y-BOCS symptom checklist. The symptoms that most closely resemble the repetitive behaviors seen in ASD include ordering and arranging, counting, doing and redoing often prompted by sensory phenomena urges, and rituals associated with sleep-wake transitions, separation from attachment figures, as well as habits associated with dressing and grooming, ordering and arranging, and collecting	*Children's Yale-Brown Obsessive Compulsive Scale for Pervasive Developmental Disorders* (CY-BOCS-PDD, Scahill et al., 2006) 9 classes of compulsions are included in the CY-BOCS-PDD checklist. The same nine categories are present in the CY-BOCS symptom checklist: Washing/cleaning; Checking; Repeating rituals; Counting compulsions; Ordering/arranging; Hoarding/saving compulsions; Excessive games/superstitious behaviors; Rituals involving other persons; and Miscellaneous compulsions. The content of only two of the CY-BOCS categories were modified for this scale: repeating rituals for the CY-BOCS-PDD includes: "touching in patterns; rocking; Spinning, twirling, pacing; spinning objects; and Echolalia." Likewise, the Miscellaneous Compulsions category for the CY-BOCS-PDD includes: "Repetitive sexual behavior (masturbation, grabbing at crotch)."

(*Continued*)

Table 17–1. (*Contd.*)

Class	Description	Measurement
Classic Obsessive-Compulsive Disorder Behaviors	Obsessive-compulsive disorder is clinically heterogeneous. There are a variety of obsessive-compulsive dimensions that are usually prompted by anxious intrusive thoughts or images or sensory phenomena.	*Children's Yale-Brown Obsessive Compulsive Scale for Pervasive Developmental Disorders* (CY-BOCS-PDD, Scahill1 et al., 1997): This scale is modeled on the original Yale-Brown Obsessive Compulsive Scale (Y-BOCS, Goodman et al., 1989) with 8 categories of obsessions (Contamination obsessions; Aggressive obsessions; Sexual obsessions; Hoarding/saving obsessions; Magical thoughts/superstitious obsessions; Somatic obsessions; Religious obsessions; and Miscellaneous obsessions) and 9 categories of compulsions (see above). *Dimensional Yale-Brown Obsessive Compulsive Scale* (DY-BOCS, Rosario-Campos et al., 2006): This scale specifically rates the severity of obsessive-compulsive (OC) symptoms within multiple symptom dimensions. Although the understanding of the dimensional structure of (OC) symptoms is still imperfect, recent large-scale meta-analysis of data from more than 5,000 individuals provides the clearest picture of data of the interrelationship of these symptom dimensions (Bloch3 et al., in press). The four factors validated by this meta-analysis are included in the DY-BOCS: (Factor I) FORBIDDEN THOUGHTS—Aggressive, sexual, religious, and somatic obsessions and checking compulsions; (Factor II) SYMMETRY—Symmetry obsessions and repeating, ordering, and counting compulsions; (Factor III) CLEANING—Cleaning and contamination; and (Factor IV); HOARDING—Hoarding obsessions and compulsions. The Miscellaneous obsessions and compulsions were not included in these analyses.
Normative Repetitive Behaviors	Mental age–dependent multidimensional rituals associated with sleep-wake transitions, separation from attachment figures, as well as habits associated with dressing and grooming,; ordering and arranging, and collecting. The content of many of these items resembles the symptom dimensions that are commonplace in pediatric-onset as well as adult-onset OCD: worries about harm and separation; ordering and arranging; contamination worries and collecting.	*Childhood Routine Inventory*: (CRI, Evans et al., 1997): 19 items, parental report: Prefer to have things done in a particular order or in a certain way (i.e., is he/she a "perfectionist"?); Very attached to one favorite object? Very concerned with dirt, cleanliness, or nearness? Arrange objects, or perform certain behaviors until they seem "just right" to him/her? Have persistent habits? Line up objects in straight lines or symmetrical patterns? Prefer the same household schedule or routine every day? Act out the same thing over and over in pretend play? Insist on having certain belongings around the house "in their place"? Repeat certain actions over and over? Have strong preferences for certain foods? Like to eat food in a particular way? Seem very aware of, or sensitive to how certain clothes feel? Has a strong preference for wearing (or not wearing) certain articles of clothing? Collect or store objects? Seem very aware of certain details at home (such as flecks of dirt on the floor, imperfections in toys and clothes)? Strongly prefer to stick to one game or activity rather than change to a new one? Make requests or excuses that would enable him/her to postpone going to bed? Prepare for bedtime by engaging in a special activity or routine, or by doing or saying things in a certain order or certain way?

interrelationship of these symptom dimensions (Bloch, Landeros-Weisenberger, Rosario, et al., 2008). The four factors that emerged from this systematic analysis were: (Factor I) Forbidden thoughts—Aggression, sexual, religious, and somatic obsessions and checking compulsions; (Factor II) Symmetry—Symmetry obsessions and repeating, ordering, and counting compulsions; (Factor III) Cleaning—Cleaning and contamination; and (Factor IV) Hoarding—Hoarding obsessions and compulsions. While any of these may be present in individuals with ASD, Factor II is particularly common. This symptom dimension is also one where various sensory phenomena are commonplace. These sensory elements often occur prior to the repetitive movement and include localized tactile and muscle-skeletal sensations that are associated with an urge to perform certain repetitive behaviors; "just-right" perceptions associated with sensory stimuli such as visual, tactile, or auditory; as well as a feeling of incompleteness, which refers to an inner sense of discomfort that can only be relieved by performing the repetitive behaviors (Prado, Rosario, et al., 2008).

Efforts to use the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) in assessing the OCB in ASD began with the work of McDougle and colleagues (McDougle, Kresch, et al., 1995). They recruited 50 ASD subjects (with or without significant intellectual disability) and compared them to 50 age- and sex-matched individuals with OCD. They reported that compared to the OCD group, the ASD patients were significantly less likely to experience thoughts with aggressive, contamination, sexual, religious, or somatic content. With regard to compulsions, cleaning behaviors were less common in the ASD group. However, other compulsions including repetitive ordering; hoarding; touching, tapping, or rubbing; as well as self-damaging or self-mutilating behavior occurred significantly more frequently in the ASD patients.

More recently, Russell and colleagues (Russell, Mataix-Cols, et al., 2005) studied 40 individuals with high-functioning ASD and compared them to a matched group of individuals with OCD. Although the OCD group had higher OC symptom severity ratings, up to 50% of the ASD group reported at least moderate levels of interference with daily functioning from their OC symptoms. Some of the most frequent OC symptoms reported from the Y-BOCS symptom checklist in the high-functioning ASD group included: obsessions of contamination (60%), symmetry (55%), aggressive content (50%), and hoarding (43%); as well as compulsions of checking (60%), cleaning (55%), and repeating (43%). In addition, Cath and colleagues (Cath, Ran, et al., 2008) also used the Y-BOCS to compare a group of individuals with high-functioning ASD with either comorbid OCD or comorbid social anxiety disorder (SAD) to individuals with either OCD or SAD alone and to a group of normal controls. Twelve subjects were in each of the four groups of comorbid ASD, OCD, SAD or control. The factor scores for the four OC symptom dimensions were then compared across the four groups. Although few significant differences were observed, the mean values for all of the OC symptom dimensions were higher in the OCD group and in the ASD

comorbid group compared to the SAD and the normal control groups. While this study needs to be replicated with a larger number of subjects in each group and with the addition of a pure ASD contrast group, these findings bring to mind a recent report by Pine and colleagues (Pine, Guyer, et al., 2008) that found that pediatric patients with mood disorders exhibit higher scores on ASD symptom scales than healthy children or children with non-OCD anxiety disorders.

There has also been an effort to adjust the available OCD severity rating scales such as the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) for use in children with ASD (Scahill, McDougle, et al., 2006). This has led to the creation of CY-BOCS modified for pervasive developmental disorders (CY-BOCS-PDD; Table 17-1). Scores on the CYBOCS-PDD only modestly correlated with the repetitive behavior domain of the ADI-R and they also failed to discriminate between measures of repetitive behavior and maladaptive behavior (Scahill, McDougle, et al., 2006). This suggests that these two scales may be measuring partially distinctive traits. Another approach would be to use the Dimensional Yale-Brown Obsessive Compulsive Scale (DY-BOCS; Rosario-Campos, Miguel, et al., 2006). The DY-BOCS separately assesses the clinical severity associated with each OC symptom dimension. The use of this scale in family-genetic, twin, linkage, and association studies would allow investigators to better characterize the nature of the OC traits seen in the relatives of ASD probands.

Neuropsychological Endophenotypes

Yet another approach is to identify potentially informative endophenotypes based on neuropsychological test performance or on brain imaging findings. Ideally, traits identified in this manner would be evident in unaffected family members as well as the probands. One example of this approach is reported by Delorme and his colleagues (Delorme, Gousse, et al., 2007). They administered five tests assessing executive functions (Tower of London, verbal fluency, design fluency, trail making, and association fluency) to 58 unaffected first-degree relatives (parents and siblings) of probands with ASD and 64 unaffected first-degree relatives of individuals with OCD. Only the Tower of London results showed similarities between the ASD relatives and the OCD relatives, suggesting shared executive dysfunction in this domain. There are several endophenotypes of this sort that have recently emerged in OCD. For example, Chamberlain and colleagues (Chamberlain, Menzies, et al., 2008) identified reduced activation of several cortical regions, including the lateral orbitofrontal cortex, in both OCD patients and a matched group of unaffected first-degree relatives, during a reversal learning task. It would be useful to know if a similar result would be seen in the first-degree relatives of ASD probands.

Recently, Bloch and colleagues (Bloch, Landeros-Weisenbergerm, et al., 2008) discovered that as many as half of

the pediatric OCD cases have a marked discrepancy between verbal and performance IQ scores. This association of verbal-performance IQ discrepancy and OCD was still significant after adjusting for full-scale IQ, age, and gender and excluding OCD subjects with comorbid ADHD or a tic disorder. This finding is of potential interest given that Williams, Goldstein, et al. (2008) also found a similar profile of lower performance IQ scores relative to verbal IQ scores in 18% to 32% of children with high-functioning ASD.

Evidence for a Familial Relationship Between Autism Spectrum Disorders and Obsessive-Compulsive Behaviors

The advantages and disadvantages to specific approaches to studying the role of genetic factors in ASD are presented in Table 17-2. Figure 17-1 presents the range of genetic and environmental factors that interact over the course of brain development that lead to the emergence of autistic disorder and related OCB phenotypes.

Twin and Family Studies

In 1977, Folstein and Rutter found that while many of the nonautistic co-twins in their ASD twin study did not meet the criteria for autism, they showed ASD traits which in turn sparked a renewed interest in identifying heritable "lesser variants." This finding led, in part, to the initiation of two large studies done more or less in parallel (Bolton, Macdonald, et al., 1994; Piven, Palmer, et al., 1997). The results taken together indicate that the first-degree relatives of individuals with ASD have an increased tendency to show social reticence and communication difficulties as well as an insistence on sameness.

Subsequently, there have been at least three family-genetic studies that have indicated that OCD itself may be part of the "broader autism phenotype." There are data to suggest that the association between ASD and OCD may be strongest in families of individuals on the more severe end of the autism spectrum disorder (i.e., those with autistic disorder), especially those with prominent repetitive behaviors (Bolton, Pickles, et al., 1998; Hollander, King, et al., 2003; Wilcox,

Table 17–2.

Overview of approaches in studying genetics of obsessive-compulsive behaviors and autism spectrum disorders

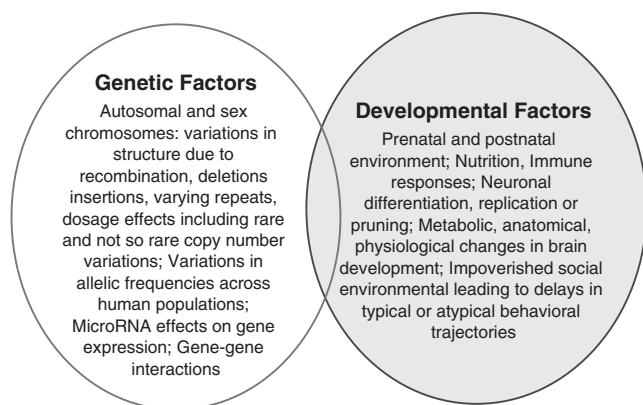
Study Design & Methods	Advantages	Disadvantages
Family-Twin	Study role of genetic effects (concordance of identical vs. fraternal twin pairs) as well as the shared vs. unique environmental effects	**Rare disorders are harder because more efforts to access large sample sizes**
Family-Trio	Reduces genotyping errors because parents of probands are included, so that maternal vs. paternal transmission can be studied	More laborious for ascertainment; difficult to obtain specimens from parents, especially for later onset disorders
Case-Control	Easy and less expensive to perform with access to larger sample sizes	Matching for many variables is challenging, especially ethnic variation in large or combined samples
Quantitative	May be used for polygenetic disorders and to estimate heritability or strength of genetic influences on particular traits	Limited by assumptions underlying specific modes of inheritance and analytic methods for evaluating multiple genes with small effect sizes
Linkage	Linkage recombination maps allow researchers to locate novel regions or genes by testing for genetic linkage of the already known markers	For complex traits, poor reproducibility (improves with larger samples and a larger number of studies); often there are broad peaks with low resolution (never improves)
Candidate Gene	Testing direct hypotheses for specific genes; focused, less expensive	Limited by known pathophysiologic differences or candidates based on treatment responses. Difficult to find novel genes (given many unknown genes in multigenetic disorders)
Array technology	Can provide information on thousands of targets in a single experiment (e.g., genes, mRNA, CNV, etc.) The possibility of inducing neural pluripotent stem cells from individuals with ASD is particularly exciting	Large numbers of targets relate to computational and statistical challenges
Epigenetic	May provide insight into heritable traits with limited or unclear evidence for DNA sequence variation	Many nongenetic factors may cause the organism's genes to behave differently; limited by studying one of many mechanisms at a time (e.g., methylation)


Figure 17–1. Developmental and genetic variables and their interaction influence the emergence of obsessive-compulsive behaviors in individuals with autism spectrum disorders. Both genes and events affecting the course of brain development can influence the emergence of autism spectrum disorders (ASD) and obsessive-compulsive behaviors (OCB). Some genes may also influence an individual's exposure to risk (and protective) environments. There is also a growing body of evidence on the importance of gene–environment interactions (G × E) in relation to ASD and obsessive-compulsive disorder such that even adverse experiences might have a negligible effect in the absence of relevant susceptibility genes and yet have a very large effect in the presence of such genes.

Tsuang, et al., 2003). Specifically, Bolton and colleagues (Bolton, Pickles, et al., 1998) studied the pattern of familial aggregation of psychiatric disorders in relatives of 99 autistic and 36 Down syndrome probands and found that motor tics, OCD, and affective disorders were significantly more common in relatives of autistic probands. Those relatives with OCD were also more likely to exhibit autistic-like social and communication impairments. Subsequently, Wilcox, Tsuang, et al. (2003) interviewed 300 family members of autistic probands (120 first-degree, 150 second-degree, and 30 third-degree relatives). In addition, they interviewed 290 family members of probands with more broadly defined pervasive developmental disorders (PDD; 121 first-degree, 139 second-degree, and 30 third-degree relatives) and 310 family members of a healthy control group (123 first-degree, 149 second-degree, and 38 third-degree relatives). They found a significant concentration of psychiatric disorders, primarily OCD and other anxiety disorders, in just the relatives of the autistic probands. The degree of mental illness in the families of autistic probands was more than five times higher than in either the PDD contrast group ($x^2 = 8.45$, p < 0.001) or the healthy control group ($x^2 = 9.58$, p < 0.001).

The finding that OCD was largely seen in the families of probands with autistic disorder is striking and requires replication, particularly in light of the following findings reported by Hollander and colleagues (Hollander, King, et al., 2003). They evaluated the parents of autistic disorder probands with high vs. low rates of repetitive behaviors as measured by scores

on R1 and R2 subscales of the ADI-R (Table 17-1). They found that children who had high total scores on the repetitive behavior domain of the ADI-R were significantly more likely, by a factor greater than 3, to have one or both parents with OC traits or OCD compared with children who had low total scores in this domain ($x^2 = 4.70$, p = 0.03). This was especially true of the fathers, 27% of whom met criteria for OCD as opposed to just 7% of the mothers. In future studies, it will be of interest to examine the OC symptom dimensions that are the most prominent in these fathers. Our prediction is that OC symptoms associated with ordering, symmetry, counting, doing and redoing, and the need for things to be "just right" would be particularly common. It will also be important to determine if this association was more common among the fathers of children with autism compared to the fathers of children with a development disorder that is not autism.

Quantitative Genetics

Quantitative genetic studies are designed to evaluate the relative strength of genetic and environmental influences on variations of particular traits within a population. In human research, this is most commonly studied using twin and adoptee designs. They are highly dependent on the assumptions underlying the models being used to evaluate the available data and as such, cannot "prove" that a particular model is true. The most that can be said is that a particular model is "consistent with the available data." Another challenge for quantitative genetic studies in autism is that analytic methods for evaluating multiple genes of small effect size, as found in autism, are still in their early stages of development.

In relation to ASD, several quantitative genetic studies have sought to estimate the heritability of ASD-related OCB. Using items from the ADI-R, in a large sample (N = 457) of individuals within 212 multiple affected sibships, Silverman and colleagues (Silverman, Smith, et al., 2002) found evidence that the severity of an autistic person's ASD-related OCB were largely unrelated to their level of social-communication impairment. This finding was supported by a subsequent study from the same group (Kolevzon, Smith, et al., 2004), which compared intrafamilial to interfamilial trait variability to estimate familiality. In a sample of 15 pairs of identical twins and one set of quadruplets, they found no evidence supporting the view that ASD-related OCB were related to their level of social-communication impairment.

Subsequently, investigators (Ronald, Happe, et al., 2005; Ronald, Happe, et al., 2006a) completed two twin studies that yielded a similar conclusion. First, they gave a questionnaire to parents and teachers of over 3,000 twins, who were part of the Twins Early Development Study, a cohort of twins born in the UK between 1994 and 1996. This questionnaire had 10 items designed to measure possible "social impairments" (social and communication deficits typical of ASD) and six items addressing "nonsocial behaviors relevant to autism."

Only modest correlations between these two scales were found using either the parent data or the teacher data ($n = 3{,}090$). In the formal twin analyses looking at additive genetic variance vs. shared and unshared environmental factors, they reported that both traits were highly heritable (62% to 76%), but that the genetic correlation between social impairments and nonsocial behaviors relevant to autism was quite low. This led the authors to predict that "over half of the genes found to be associated with quantitative variation in social behaviors will not be found to be associated with nonsocial behaviors associated with autism." In sum, the available quantitative genetic literature is consistent with the view that the OCB associated with ASD are partially genetically independent of those associated with the social disabilities of ASD.

Linkage Analyses

Although there is considerable evidence for a strong genetic component to the intergenerational vulnerability to develop ASD, several genome-wide screens for susceptibility genes have been carried out with limited success in consistently identifying specific loci. This is likely to reflect the presence of a multiplicity of genes of modest effect as well as phenotypic, genetic, and population diversity. Among the available genome-wide studies, Alarcon and colleagues (2002) were the first to explore the OCB subphenotype. In addition to finding strong quantitative trait locus evidence for age-of-first-word on chromosome 7q, they also reported a smaller broad peak on 7q for restrictive-repetitive behavior phenotype that is considered a distinct locus.

Subsequently, Buxbaum and colleagues (Buxbaum, Silverman, et al., 2004) systematically assessed the value of severe OCB in order to define a more homogeneous subset of individuals with autism. OCB were assessed using the ADI-R (Table 17-1). In the sample with more severe OCB, the strongest evidence for linkage was at the marker D1S1656 (Chromosome 1: 245.1cM) where the multipoint nonparametric linkage (NPL) score was just above 3.00. The authors concluded that their data supported the presence of an ASD susceptibility gene associated with OCB on chromosome 1 and provided modest support for the presence of OCB-related ASD susceptibility genes on chromosomes 6 and 19.

Another study that explicitly sought to identify genetic loci associated with the OCB of ASD was reported by Shao and colleagues (Shao, Cuccaro, et al., 2003). They limited their focus to a specific region on chromosome 15q11-13 and utilized a novel technique called ordered subset analysis (OSA) to ensure a greater degree of sample homogeneity with regard to the OCB associated with ASD ("insistence on sameness" = IS). Individual IS scores were computed by summing a subset of the total items in the "restricted, repetitive, and stereotyped behaviors and interests" domain of the ADI-R items designed to measure this type of OCB. Their analysis of families sharing

high scores on the IS factor increased the probability for linkage evidence in the 15q11-q13 region from a logarithm of odds (LOD) score of 1.45 to a LOD score of 4.71. While their results support the hypothesis that the analysis of phenotypicly homogeneous subtypes may be a powerful tool in mapping the disease-susceptibility genes of complex traits, it is notable that this chromosomal region was not one of the chromosomal regions identified in the Buxbaum et al. (2004) study. This is probably explained by the fact that Buxbaum's group used very severe OCB to define a homogeneous subset of families; and Shao focused on subjects with IS to create homogeneity.

Several autism linkage studies have pointed to the 17q region near the serotonin transporter gene (SERT; Stone et al., 2004; Sutcliffe et al., 2005). The highest LOD score for a linkage peak in the 17q11.2 region (where SERT is located) was found when all male affected sibling pairs were considered (Stone et al., 2004), but no similar peak in this region was present when sibling pairs had at least one affected female (Sutcliffe et al., 2005). This suggests that sex differences also need to be considered in studying genetic risk for OCB-related subphenotype.

Candidate Gene Studies

Serotonin Genes

Serotonergic pathways have been consistently implicated in the pathobiology of both ASD and OCD (Pardo & Eberhart, 2007; Goddard, Shekhar, et al., 2008). Several serotonergic genes have been evaluated as candidate genes in both ASD and OCD including SERT (*SLC6A4*), tryphophan hydroxylase (TH2), and *SLC6A4*, the serotonin 5-HT(2B) receptor gene.

SERT, *SLC6A4*

The SERT gene is located on 17q11.1–q12 and is called *SLC6A4* because it belongs to the monoamine transporter family. SERT has 13-14 exons with alternate splicing of exon 1B. It also has a well-characterized functional polymorphism upstream of the coding sequence. The promoter region of SERT contains a polymorphism with "short" and "long" repeats that leads to variation in the levels of gene transcription (McDougle, Epperson, et al., 1998). The long (L) allele consists of 16 copies of a 20-23 base pair repeat unit and the short (S) allele contains 14 copies. In addition to these length variants, there is a single nucleotide polymorphism (SNP) (rs25531, A→G) that changes the functional status of the L allele (Hu, Frank, et al., 2006). Another SNP (rs25532, C→T) also affects gene expression suggesting further categorization of functional variants (Wendland, DeGuzman, et al., 2008). Unrecognized SNP variability related to functional expression may explain some of the contradictory results with combined subgroups when examining disorder association.

Initially, OCD studies reported a family-based association with the L allele in European-American families (McDougle et al., 1998) and that OCD probands were more likely to carry two copies of the long allele or L/L (48% vs. 32%; Bengel, Greenberg, et al., 1999). However, L allele associations were not found with OCD patients of Afrikaner, Mexican, Jewish, German, French, or other descent (Frisch, Michaelovsky, et al., 2000; Camarena, Rinetti, et al., 2001; Di Bella, Erzegovesi, et al., 2002; Chabane, Millet, et al., 2004; Walitza, Wewetzer, et al., 2004; Bloch, Landeros-Weisenberger, Sen, et al., 2008). There was no overall association in a Korean sample, but there was a very low percentage of L/L genotypes, and the L/L group combined with the S/L group had higher scores for religious/somatic-related symptoms on the Y-BOCS (Kim, Lee, et al., 2005). Population differences of polymorphism frequencies, SNP variability, how polymorphisms are grouped or combined, and sample ascertainment or phenotype variability contribute to the complexity of the possible association of SERT polymorphisms and OCD.

SERT polymorphism studies in ASD have also yielded complex and mixed results that are likely due to phenotypic and ethnic heterogeneity. There have been reports of increased occurrence of the S allele variant in an American ASD sample (Cook, Courchesne, et al., 1997) and the tendency for the L variant in a German sample (Klauck, Poustka, et al., 1997). Although there are some population specific replications (Devlin et al., 2005), the range of mixed results reported in the literature likely reflects methodological and sample differences.

A few studies have focused on subphenotypes of ASD that include OCB. For example, a Dutch group found that the 12/12 long allele genotype of Intron 2 VNTR had the highest severity of OCB (Mulder, Anderson, et al., 2005). They did not find significant differences between L or S SERT polymorphisms. In an independent American sample (Brune, Kim, et al., 2006), there were no significant subphenotype relationships with the Intron 2 VNTR genotypes but there was an L/L genotype association with the stereotyped and repetitive motor mannerisms subdomain of the ADI-R. Sutcliffe and collaborators reported that the presence of novel SERT variants, including Gly56Ala, Ile425Leu, and Leu550Val, was correlated with high scores on OCB items of the ADI-R scale (Sutcliffe, Delahanty, et al., 2005). This study illustrates the importance of looking for rare versus common variants.

Indeed, it has been suggested that rare gene variants associated with OCD phenotypes may be found in up to 2% of OCD cases (Wendland, DeGuzman, et al., 2008) and as many as 10% of cases of ASD (Freitag, 2007). Examining rare variants is an alternative method to the broader scale genome-wide evaluations which seek to find common variants accounting for common diseases. In both ASD and OCD it seems possible that uncommon, relatively highly penetrant functional variants may more directly contribute to these relatively common diseases.

For example, the SERT Ileu425Val was originally found in six individuals with OCD (two of whom also had Asperger's disorder) within two unrelated families among 112 OCD probands (Ozaki, Goldman, et al., 2003; Wendland, DeGuzman, et al., 2008). The total frequency of SERT Ileu425Val in all populations that have been genotyped (3155 individuals) is 0.61%. It is a hypermorphic mutation, which produces a gain of SERT function (Prasad, Zhu, et al., 2005). SERT Ileu425Val was reported in a male sibling pair, both of whom had ASD (Sutcliffe, Delahanty, et al., 2005). Because it was also present in the probands' unaffected mother and three sisters but not their unaffected brother, Sutcliffe and colleagues suggested that this might be due to a male-biased genetic risk for ASD. This group also reported 19 other SERT variants (four coding, and 15 in 50 and intronic regions) and examined their association with rigid-compulsive traits in their ASD sample (Sutcliffe et al., 2005). Wendland and colleagues summarized that Ileu425Val has been identified in 15 clinically evaluated individuals, including nine with OCD and one with obsessive compulsive personality disorder from five families out of a total OCD sample of 530 probands/families (Wendland, DeGuzman, et al., 2008). Of the 14 cases where SERT was also genotyped, it is important to note that Ileu425Val occurred together with the L allele or LL (or L_AL_A) genotype. Looking over all diagnoses in this rare variant sample, social dysfunction disorders such as ASD and social phobia were present in 5/8 men but only 1/6 women, suggesting sex differences of clinical phenotype.

Tryptophan Hydroxylase *(TPH2)*

The *TPH2* gene has been studied in ASD and OCD because it is the rate-limiting enzyme responsible for 5-HT synthesis in the brain. Coon and colleagues reported a possible association between the *TPH2* gene and two SNP variants (rs4341581 in intron 1 and rs11179000 in intron 4) in ASD, especially in patients reported to have more severe repetitive and stereotyped behaviors (Coon, Dunn, et al., 2005). Similarly, Mössner and colleagues studied *TPH2* and found two common SNPs in a different region of the gene (rs4570625 and rs4565946 in intron 2) to be associated with childhood onset OCD in a family-based sample of 71 trios (Mossner, Walitza, et al., 2006). More recent studies have failed to replicate these initial studies of *TPH2* and OCD association. When rs4341581, rs11179000, and a different set of eight SNPs were selected to cover the 95 kb region of the *TPH2* gene and tested in a large cohort of 352 families with ASD, no significant associations in the overall group or in any clinically defined subsets of families with either severe OCB or self-stimulatory behaviors were found (Ramoz, Cai, et al., 2006). On a larger, independent sample of Italian and American probands with ASD, *TPH2* alleles and haplotypes were not significantly associated with the overall sample, with repetitive and stereotyped behavior measures, and with endophenotypic analyses for 5-HT blood levels, cranial circumference, and urinary peptide excretion rates (Sacco, Papaleo, et al., 2007).

5-HT(2B) Receptor Gene

Given that atypical antipsychotics are sometimes successful in augmenting OCD treatment with SSRIs, the 5HT(2B) receptor

is a potential candidate for involvement in the neurobiology of OCD. 5HT(2B) is located on chromosome 2q36-37.1, and the 2q region was implicated in a genome scan with 56 individuals from seven families with multiplex pediatric probands (Hanna, Veenstra-VanderWeele, et al., 2002). DNA from probands from these seven families, along with 10 unrelated control subjects and 10 unrelated ASD probands, were studied, but no evidence for a functional mutation was found.

Glutamate Genes

The glutamatergic system has been implicated in the neurobiology of both ASD and OCD (Bhattacharyya & Chakraborty, 2007; Pardo & Eberhart, 2007; Pittenger, Kelmendi, et al., 2008). A majority of studies have examined the role of a high affinity glutamate transporter and several of the glutamate receptors.

SLC1A1

The *SLC1A1* gene is located on chromosome 9p24 and belongs to the monoamine transporter family as a neuronal glutamate transporter expressed in the brain. Similar to SERT, the glutamate transporter is important for the excitatory actions of glutamate and for maintaining extracellular concentrations within a normal range. The chromosomal region of *SLC1A1* showed suggestive linkage in a genome-wide scan of seven, large extended pedigrees of probands with early onset OCD (Hanna, Veenstra-VanderWeele, et al., 2002) and linkage in 42 pedigrees with early onset OCD (Willour, Yao Shugart, et al., 2004). In addition, three studies have reported an association between markers at *SLC1A1* and independent OCD samples (Arnold, Sicard, et al., 2006; Dickel, Veenstra-VanderWeele, et al., 2007; Stewart, Fagerness, et al., 2007). In a collaborative autism genome-wide linkage project, *SLC1A1* was identified as a candidate gene because it fell close to the linkage peak at 9p24.1 that occurred in families with female probands with ASD (Szatmari, Paterson, et al., 2007). Brune and colleagues tested three SNPS (rs301430, rs301979, rs301434) previously associated with OCD and looked for haplotype associations in 86 strictly defined trios with ASD (Brune, Kim, et al., 2006). In males only, Family-Based Association Tests showed nominally significant associations between ASD and rs301979 as well as the rs301430–rs301979 haplotype under a recessive model.

Glutamate Receptor Genes

The glutamate receptor 6 gene (*GRIK2* or *GLUR6*) plays a role in synaptic transmission related to learning a memory. It became a candidate gene after studies indicated chromosome 6q21 as a region linked to ASD (Philippe, Martinez, et al., 1999; Jamain, Betancur, et al., 2002). *GRIK2* is a member of the ionotropic kainate receptor family that is expressed during brain development. Although some studies have reported that markers within *GRIK2* are associated with ASD (Jamain, Betancur, et al., 2002; Shuang, Liu, et al., 2004; Kim, Kim, et al., 2007), these same markers do not replicate in all ethnic

populations (Dutta, Das, et al., 2007). In a study of *GRIK2* with 156 OCD probands of European descent, the I867 allele on exon 16 was transmitted less often than expected (Delorme, Krebs, et al., 2004). Future research needs to examine subgroups of ASD with more severe OCB as well as to examine the genetics of other genes within the glutaminergic pathway. For example, mRNA levels of several genes in the glutamate system (including *SLC1A3*, glutamate receptor AMPA1, and glutamate receptor binding proteins) were abnormal in brain samples of 10 individuals with ASD as compared with 23 matched controls (Purcell, Jeon, et al., 2001).

GABA Receptor Genes

GABA is the main inhibitory neurotransmitter in the human brain and it binds to two distinct receptor types: the ionotrophic GABA$_A$ and GABA$_C$ receptors with Cl$^-$ channels and fast synaptic transmission, or the metabotrophic GABA type B (GABA$_B$) G-coupled protein for prolonged inhibitory signals. Three GABA$_A$ receptor genes (*GABRB3*, *GABRA5*, and *GABRG3*) are located in the 15q11-q13 chromosomal region. Several studies have shown linkage to markers near or within *GABRB3* to be associated ASD (Cook, Courchesne, et al., 1997; Philippe, Martinez, et al., 1999; Martin, Menold, et al., 2000; Buxbaum, Silverman, et al., 2002; Shao, Cuccaro, et al., 2003; McCauley, Olson, et al., 2004; Curran, Roberts, et al., 2005; Kim, Kim, et al., 2007), although other studies have failed to replicate this association (Maestrini, Lai, et al., 1999; Salmon, Hallmayer, et al., 1999; Tochigi, Kato, et al., 2007). Recently, Kim and colleagues examined SNPs within the 15q11-q13 for association with specific restrictive-repetitive behavior phenotypes measured on the ADI-R and ADOS (Kim, Kim, et al., 2007). Among 93 SNPs, 5 SNPs showed nominally significant association, three of five were close in proximity to GABA$_A$, and two of the five near GABA$_A$ showed genotype-phenotype interactions with an ADI-R subdomain related to inflexible language behavior. Only one study has examined GABA$_A$ receptor genes in individuals with OCD (Zai, Arnold, et al., 2005). They reported nominally significant trends toward biased transmission of the -7265A allele and associations with elevated Y-BOCS severity.

Chromosomal Abnormalities Associated with Both ASD and OCB

Prevalence of chromosomal abnormalities in individuals with ASD is estimated between 5% to 10% (Zhao, Leotta, et al., 2007). Here we focus on those chromosomal alterations that have been associated with the presence of OCB.

Fragile X and Other X-linked Syndromes

The most prevalent chromosomal abnormality associated with ASD is Fragile X syndrome (FXS). Molecular testing for the FMR-1 gene is recommended in individuals diagnosed

with ASD and probands identified with FXS are excluded from most genetics studies of ASD. The behavioral phenotype of FXS includes OC behaviors as well as stereotypic behavior, gaze aversion, inattention, impulsivity, hyperactivity, hyperarousal, social anxiety, withdrawal, social deficits with peers, abnormalities in communication, and unusual responses to sensory stimuli. The full mutation is described as having more than 200 CGG repeats in the 5' untranslated region of the FMR1 located at Xq27.3 and typically involves an altered pattern of methylation. There is transcriptional silencing of the FMR1 gene and lack of the FMR1 protein called FMRP. Recent studies suggest that some males with the premutation also have social, emotional, and cognitive deficits, although sample sizes are small or clinically referred (Dorn, Mazzocco, et al., 1994; Tassone, Hagerman, et al., 2000; Hagerman & Hagerman, 2002; Aziz, Stathopulu, et al., 2003; Goodlin-Jones, Tassone, et al., 2004; Moore, Daly, et al., 2004).

A study of men and women with the premutation, but without age-related Fragile X–associated tremor/ataxia syndrome (FXTAS), reported higher levels of OC symptoms on the Symptom Checklist-90-R (Hessl, Tassone et al., 2005). In men only, elevated FMR1 mRNA, rather than CGG repeat size or percent of FMRP expression (peripheral lymphocyte immunocytochemistry), was significantly associated with increased OC symptoms and psychotic episodes with and without FXTAS symptoms. An association with elevated FMR1 mRNA and anxiety in women, but only in women with skewed X activation ratio toward active premutation alleles, was also found. Previous studies have shown elevated levels of anxiety and OCB in some females with FXS (Lachiewicz, 1992).

In a recent cytogenetic analysis of 26 patients with OCD, 21% of the peripheral cells of one male patient with OCD were found to have a fragile site at Xq27-q28 (Wang & Kuo, 2003). This was determined to be in the region of FRAXE mutation, a hyperexpansion of the CCG repeat in the 5' untranslated region of the FMR2 gene (Wang & Kuo, 2003). Typically FRAXE is associated with mild or borderline mental retardation (50 < IQ < 85; Gecz, 2000). In this patient's family, expansion of FRAXE CCG repeats and methylation cosegregated with OCD in the proband and a speech impairment in a maternal uncle. Unfortunately, the specific OCD symptom presentation in this individual was not reported.

Hendriksen and Vles (2008) also recently reported on the results of a questionnaire study of 351 males with Duchenne muscular dystrophy (DMD). DMD is characterized by progressive proximal muscular dystrophy and is the result of mutations in a very large gene that encodes dystrophin and is located at Xp21.2. In this study, 11 of the subjects were reported to have ASD and of this number three (27%) also had OCD. Unfortunately, no details were provided concerning either the nature of the ASD or OCD symptomatology.

Finally, several other studies involving individuals with other X-chromosome abnormalities have suggested a link between ASD and OCB. For example, El Abd and colleagues (1999) identified five women with deteriorating social skills as well as attentional problems, impulsive and aggressive behaviors, and prominent OCB. All of these women had a subphenotype of Turner's syndrome with a small, active, early replicating, ring X chromosome and inactive specific transcript (XIST) locus confirmed by fluorescent in situ hybridization. There have been at least eight other cases with similar karyotypes and behavioral-cognitive phenotypes that included intellectual disabilities and developmental delays (El Abd, Patton, et al., 1999). In another case report, a patient with Asperger's syndrome, OCD, and major depression was discovered to have 45X/46XY mosaicism (Fontenelle, Mendlowicz, et al., 2004). An earlier study (Telvi, Lebbar, et al., 1999) reported that two (7%) patients were diagnosed with ASD in a sample of 27 patients with 45X/46XY mosaicism, but the nature and severity of OCB was not assessed.

Prader-Willi Syndrome and Other Disorders Associated with Chromosomal Alterations in the 15q11–q13 Region

Duplications and deletions of genes within this chromosomal region have been associated with both ASD and OCB. Inherited duplications of 15q11-q13 (mostly maternal) have been observed in 1% to 3% of cases of ASD, either as interstitial duplications or supernumerary isodicentric marker chromosomes containing one or two extra copies of this region (Veenstra-VanderWeele & Cook, 2004). If the paternal copy of this region is deleted, Prader-Willi syndrome (PWS) occurs. In contrast, the loss of the maternal copy of this region is associated with Angelman's syndrome. PWS is of interest because the clinical presentation of these individuals frequently includes mild to moderate intellectual disability and social deficits as well as OCB. The OCB include: hoarding of non-food items; ordering/arranging things; requiring symmetry and exactness; preference for daily routines; verbal perseveration or talking too much; the need to know, ask, tell, or rewrite; and repeating rituals with grooming, toileting, or showering (Dykens & Cohen, 1996; Dykens & Roof, 2008). The majority of individuals with PWS have a paternally derived interstitial deletion of 15q11-13, but 25% have maternal uniparental disomy 15 (UPD), and 2% to 5% have imprinting defects (Dykens & Roof, 2008). Recent studies suggest that those with maternal UPD are at greater risk for ASD symptomatology than those with paternal deletions of 15q11-q13 (Milner, Craig, et al., 2005; Dimitropoulos & Schultz, 2007). Although Milner et al. (2005) found no clear differences in OC symptom severity comparing PWS cases due to paternal deletions vs. maternal UPD, Zarcone, Napolitano, et al. (2007) more recently reported that PWS individuals with the long type TI deletion had more compulsions regarding personal cleanliness (i.e., excessive bathing/grooming) while those with the short type TII deletion were more likely to have OC symptoms in the symmetry and ordering domain.

Smith-Magenis Syndrome and Alterations in the Region of 17p11.2

Behavioral issues with patients with duplications of 17(p11.2p11.2) are notable for variable symptoms including

expressive language delay, attention problems, hyperactivity, and intellectual disability. A subset of these patients also displays OCB (Potocki, Chen, et al., 2000; Nakamine, Ouchanov, et al., 2008). For example, Nakamine, Ouchanov, et al. (2008) recently described an individual who inherited a 17p(11.2p11.2) duplication de novo on a paternal chromosome and whose clinical presentation included an expressive language delay, ASD, and OCB, whereas another patient inherited the duplication on a maternal chromosome and presented with hyperactivity and OCB (Potocki, Chen, et al., 2000).

Future Directions for OCB and the Broader Phenotype of ASD

In this final section, we point to the need for greater specification of component ASD and OCB phenotypes over the course of development, and then briefly consider a few of the emerging areas of research including the expanded use of genome-wide association studies, the availability of DNA microarrays, the importance of noncoding RNAs, copy number variation, and epigenetic programming.

Greater Specification of Relevant Phenotypes Over the Course of Development

Currently available data suggest that, with rare exceptions, ASD is typically a multidimensional, polygenic disorder in which the effects of individual genes are much smaller than previously thought. It is likely that certain genes will differentially influence the emergence of specific domains of ASD-related behaviors. At the moment, a number of scales have been developed to measure restricted repetitive and stereotyped patterns of behavior. One additional scale, the DY-BOCS, has been developed for use in studies of individuals with OCD. The value of this scale for ASD has not been evaluated. Rating the severity of each of the OC or symptom categories, including the symmetry dimension, in ASD family-genetic, twin, linkage, and association studies would allow investigators to determine whether or not this set of OC symptoms predominates in ASD probands and their relatives.

In any case, additional research is needed to sort out which of the available scales provides the best coverage and how these behaviors correlate, or not, with (1) the social and communicative deficits seen in ASD and/or (2) repetitive behaviors seen in other disorders such as OCD as well as with the repetitive behaviors that are normally seen in typically developing children; as well as to what extent these phenotypes change with advancing chronological age and are influenced by the individual's mental age. When examining subgroupings of OCB in ASD, it has recently been reported that circumscribed interests or insistence on sameness may have a stronger familial relationship whereas stereotypies/repetitive motor behaviors may be related to severity or intellectual disability (Lam et al., 2008). It is important to note that that there were no significant differences in OCB overall and in subgroupings except

for repetitive sensory behaviors when 33 pairs of sex-, IQ-, and age-matched children with Asperger's or high-functioning autism were compared (Cuccaro et al., 2007). In addition to questionnaire and interview data, future studies need to collect data acquired by direct observation. Performance on standardized neuropsychological tasks (and perhaps on the associated patterns of brain activation) may also provide valuable endophenotypes for future studies, but this will require testing unaffected (or less affected) family members (Chamberlain, Menzies, et al., 2008).

Gene Array Studies

Given the sequencing of the human genome, it is now possible to monitor expression levels of thousands of genes simultaneously using DNA microarrays. Gene expression profiling of peripheral blood of a small number of ASD patients has led to the preliminary identification of a subset of genes relating to glutamatergic neurotransmission (Purcell, Jeon, et al., 2001). Nishimura and colleagues used microarray analyses to study males with autism with known Fragile X mutation (FMR1-FM) or duplication of 15q11-13 (dup-15q) (Nishimura, Martin, et al., 2007). By comparing mRNA expression profiles in lymphoblastoid cells, they identified 68 genes dysregulated in both groups with genetically known causes related to autism phenotype. In search of common molecular pathways, they discovered that the cytoplasmic FMR1 interacting protein 1 (CYFIP1) was upregulated in dup-15q individuals. Using animal neural tissue models, they also showed common regulation of downstream genes JAKMIP1 and GRP155. In addition, they demonstrated that lymphoblastoid expression in humans can mirror these animal neural expressions by showing differential expression of JAKMIP1 and GRP155 in male sibling pairs discordant for idiopathic ASD. Thus far, only one of these gene expression studies (Hu, Sarachana, et al., 2009) has incorporated the OCB associated with ASD as a subtype to study (Baron, Tepper, et al., 2006; Hu, Frank, et al., 2006; Gregg, Frank, et al., 2008; Hu, Sarachana, et al., 2009).

Work using DNA microarrays in ASD has begun, but in the future it will permit investigators to use hundreds, or perhaps thousands of genes to assess an individual's genetic vulnerability and to use these sets of genes in research that explores developmental change and continuity, comorbidity with other disorders, as well as gene-gene and gene-environment interactions. We also anticipate that the use of gene expression data will increase as sample sizes grow, and that gene expression information will be better integrated with a greater specification of the relevant phenotypes including OCB associated with ASD.

Perhaps the most exciting development is the capacity to induce pluripotent "stem" cells by reprogramming somatic cells from patients with ASD. This will permit investigators to recapitulate neuronal development in vitro by differentiating neuronal progenitors of various CNS lineages and compare patterns of expression in ASD cell lines vs. those seen in typically developing individuals as well as OCD patients (Gurdon & Melton, 2008).

Noncoding RNAs

Another discovery with far-reaching implications for future genetic research is the importance of noncoding RNAs. MicroRNAs (miRNAs) are short, 20-22 bases, noncoding RNAs that typically suppress translation and destabilize messenger RNAs that bear complementary target sequences. Many miRNAs are expressed in a tissue-specific manner and may contribute to the maintenance of cellular identity. Remarkably, recent studies suggest that tissue-specific miRNAs may function at multiple hierarchical stages within gene regulatory networks, from targeting hundreds of effector genes to controlling the levels of key transcription factors (Makeyev & Maniatis, 2008). This multilevel regulation may permit individual miRNAs to profoundly affect the gene expression program of differentiated cells. It is also possible that specific miRNAs could alter cellular identities.

Copy Number Variation

Genomic microduplications and microdeletions, also known as copy number variants (CNVs) refer to differences in the number of copies of a particular region of DNA within the genome of an individual. Recent reports have suggested the possibility that CNVs play a role in the development of complex disorders including ASD and schizophrenia (Sebat, Lakshmi, et al., 2007). Genomic structural variation is not entirely new to the field of ASD genetics, as chromosomal disorders were among the earliest identified genetic abnormalities associated with ASD phenotypes. The increased resolution of array-based approaches suggests that the proportion of cases attributable to structural variants will be considerably higher than the 6% to 7% identified by standard cytogenetic techniques. CNVs with a potentially large impact on ASD susceptibility include maternal duplication(15)q11-q13, deletion(22)q13-SHANK3, deletion(16)p.11.2, deletion(X)p22-NLGN4, deletion(X)q13-NLGN3, homodeletion(4)q28.3, and PCDH10, and there are more than a dozen CNVs with moderate or mild effects that probably require other genetic (or nongenetic) factors to take the phenotype across the ASD threshold (Cook & Scherer, 2008). Again, it will be critical for investigators to consider the relevant ASD subphenotypes including OCBs as they analyze these formidable data sets.

Epigenetic Programming

Epigenetics is another emerging field of potential promise for understanding the origins of ASD. Epigenetics is a fundamental part of eukaryotic biology. Epigenetic programming involves the modification of DNA and the chromatin proteins that associate with it during key periods of development. Frequently these modifications have enduring effects on gene expression in key brain regions. In addition, some epigenetic alterations can be passed from one generation to the next. For example, there is now compelling data for the presence of developmental windows during which the genetically determined microcircuitry of key limbic–hypothalamic–midbrain structures are

susceptible to early environmental influences and that these influences powerfully shape an individual's responsivity to psychosocial stressors and their capacity to parent the next generation (Kaffman & Meaney, 2007). These early environmental influences have been shown to alter the pattern of methylation of the promoter region of the glucocortoid receptor gene in the hippocampus. This epigenetic change stably alters the level of glucocortoid receptor gene expression and hypothalamic-pituitary-adrenal responses to stress. Imprinted genes expressed in the brain are numerous, and it is clear that they play an important role in nervous system development and function. Epigenetic modulations, mediated in part by DNA methylation, RNA-associated silencing, and histone modification, can transform dynamic environmental experiences into altered genomic function and the emergence of stable alterations in phenotypic outcome. Behavioral analyses of rare imprinted disorders, such as Rett syndrome, FXS, PWS, and Angelman's syndrome, will continue to provide insight regarding the phenotypic impact of imprinted genes in the brain, and can be used to guide the study of normal behavior as well as more common, but genetically complex, disorders such as ASD (Zhao, Pak, et al., 2007; Goos & Ragsdale, 2008).

Conclusion

The last three decades of research have demonstrated that ASD is more genetically heterogeneous than initially thought. Important progress toward the understanding of genetic influences in ASD has been made by the combination of family and twin studies, segregation analyses, parametric and nonparametric linkage analyses, and association studies, as well as the study of rare genetic variants. The currently available data suggest that, with few exceptions, ASD is typically a multidimensional, polygenic disorder in which the effects of individual genes are much smaller than previously thought. This implies that in a majority of cases, ASD vulnerability is determined by a multiplicity of genes interacting with specific environmental risk factors over the course of development. One of the relevant phenotypes within the broader ASD phenotype is OCB. Like ASD itself, the etiologies of OCB are likely to prove to be multidimensional and polygenic, and significant progress is being made in assessing the relevant symptom domains (and neuropsychological endophenotypes) and their interrelationship with the family of vulnerability genes that underlie OCD and related disorders.

Challenges and Future Directions

- Challenges include the marked clinical heterogeneity of the autism spectrum disorders (ASD) and the frequent occurrence of obsessive compulsive behaviors (OCB) in very young (2–6 years) typically developing individuals.
- OCB may be an important clinical phenotype within the broader ASD nosological categorization. Like ASD, OCB

may be related to a broad set of disorders and have its own polygenic liability. This highlights the challenge of identifying multiple etiologies across the spectrum of a diagnostic category.

- Methodological challenges of imprecise or varying phenotypic definitions, insufficient power, varying designs, genotyping inconsistencies, and different modes of analyses contribute as well.
- In order to discover molecular and genetic mechanisms, collaborative approaches need to generate shared samples, resources, and novel genomic technologies, as well as more refined phenotypes and innovative statistical approaches.
- At present the most promising area is the induction of pluripotent "stem" cells by reprogramming somatic cells from patients with ASD. This will permit investigators to recapitulate neuronal development in vitro by differentiating neuronal progenitors of various CNS lineages and comparing patterns of expression in ASD cell lines, stratified by the presence and degree of OCB, versus those seen in typically developing individuals.
- There is a growing need to identify the range of molecular pathways involved in OCB related to ASD in order to develop novel treatment interventions. Recent advances in treatment trials with known genetic disorders like Fragile X illustrate the promise of such translational research.

Attention-Deficit/Hyperactivity Disorder (ADHD)

This chapter is dedicated to Dr. Richard Todd, who died prior to the publication of this book (for further comment, see acknowledgment at end of chapter).

Points of Interest

- ADHD symptoms are common in ASD, yet DSM-IV-TR does not allow codiagnosis of ADHD and ASD.
- Among individuals with ASD, the presence of ADHD is associated with more severe impairment and higher likelihood of additional comorbid psychopathology.
- Recent evidence suggests some of the same genetic influences affect the development of both ASD and ADHD.
- ADHD symptoms in ASD often respond to standard ADHD medications such as stimulants, atomoxetine, and alpha adrenergic agents. Neuroleptics can also reduce ADHD symptoms in ASD.
- Distinguishing between ASD-related and ADHD-related social impairments may be helpful when planning nonpharmacologic interventions such as social skills training.
- Revision of diagnostic criteria to allow a diagnosis of ADHD for individuals with ASD may facilitate identification and treatment of ADHD symptoms.

Introduction

Attention-deficit/hyperactivity disorder (ADHD) is one of the most common childhood-onset neurodevelopmental disorders. The DSM-IV ADHD symptom criterion lists nine inattentive and nine hyperactive-impulsive symptoms. ADHD subtypes are defined as predominantly inattentive, predominantly hyperactive-impulsive, or combined type, depending on whether there are at least six symptoms in one or both of the two symptom categories. Some of the symptoms and behaviors commonly seen in autism spectrum disorders (ASD) could fit the description of ADHD symptoms, but may

have an entirely different underlying mechanism when they occur in ASD. For example, an individual with autism may exhibit the DSM-IV ADHD inattentive symptom of not listening, but this may be due to specific deficits in the areas of communication and joint attention rather than general difficulty in paying attention. Also, some individuals with autism may have excessive motor activity due to frequent repetitive/stereotyped movements, but this may have a different quality than the restlessness and excessive movement that is typical of hyperactivity in ADHD. Social anxiety may lead to fidgeting in social situations, which could also be misinterpreted as a hyperactive symptom of ADHD. If one considers DSM diagnoses in terms of a diagnostic hierarchy, then it can be argued that ADHD-like symptoms (particularly those that could be explained by decreased social attention) are always present in severe forms of ASD, and an additional diagnosis of ADHD may seem redundant. However, if ADHD symptoms in ASD are associated with more severe impairment or altered response to treatment, then it may be important to diagnose and treat ADHD when it co-occurs with an ASD. This chapter reviews the existing literature on co-occurrence of ASD and ADHD in clinical and epidemiological samples, discusses genetic and other biological mechanisms that may contribute to the co-occurrence of these symptoms, briefly discusses the treatment of ADHD symptoms in ASD, and provides some general comments on diagnostic nosology and areas in need of further research.

ADHD in ASD: Prevalence and Clinical Significance

DSM-IV-TR prohibits the diagnosis of both ADHD and ASD in the same individual (APA, 2000). In part due to this exclusion criterion, many studies of ASD or ADHD exclude individuals who show signs of the other diagnosis. However,

ADHD symptoms are very common in ASD, and in some cases these ADHD symptoms may be of very high clinical and etiological relevance.

Several studies have investigated the prevalence of ADHD symptoms and diagnoses among individuals with ASD (DeVincent, Gadow, Delosh, & Geller, 2007; Gadow & DeVincent, 2005; Gadow, DeVincent, & Pomeroy, 2006; Gadow, DeVincent, Pomeroy, & Azizian, 2004, 2005; Goldstein & Schwebach, 2004; Hattori et al., 2006; Lecavalier, Gadow, Devincent, & Edwards, 2009; Ogino et al., 2005; Sturm, Fernell, & Gillberg, 2004; Yoshida & Uchiyama, 2004). Results of clinic-based studies are described in Table 18-1. In summary, these studies indicate that if the DSM exclusion criterion prohibiting co-diagnosis of ASD and ADHD is ignored, about 40–80% of clinically ascertained individuals with ASD meet criteria for an ADHD diagnosis. Some investigators of the relationship between ADHD and ASD suggest these two disorders may actually belong in the same diagnostic spectrum (Hattori et al., 2006). Others describe evidence that the presence of ADHD symptoms in a subset of children with ASD represents a co-occurring psychiatric syndrome that presents very similarly in children with ASD as it does in those without ASD (Gadow et al., 2006; Lecavalier et al., 2009).

Through a small retrospective chart review of 27 children with autism or Pervasive Developmental Disorder Not-Otherwise-Specified (PDD-NOS), Goldstein and Schwebach found that 26% of these children met symptom criteria for combined type ADHD, 33% met criteria for the inattentive

Table 18–1.

Studies of attention-deficit/hyperactivity disorder in patients with autism spectrum disorders

Study Authors, Year	Number of Subjects, Diagnoses	Percent of ASD Subjects Meeting Criteria for ADHD	Other Key Findings
Goldstein & Schwebach, 2004	N = 27, autism or PDD-NOS	59% of all ASD subjects	26% had combined type ADHD 33% had inattentive ADHD
Yoshida & Uchiyama, 2004	N = 53, high functioning ASD	68% of all ASD subjects	23% had combined type ADHD 38% had inattentive ADHD 8% had hyperactive-impulsive ADHD
Sturm, Fernell, & Gillberg, 2004	N = 101, 90% Asperger's, 9% PDD-NOS, 1% high-functioning autism	75% of all ASD subjects	95% had attention problems 56% had hyperactivity 50% had impulsivity
Hattori et al., 2006	N = 15 ASD subjects N = 20 ADHD subjects N = 40 controls	Following the DSM-IV exclusion criterion, Subjects with PDD were excluded from the ADHD group in this study.	ASD and ADHD groups both had higher ASD and ADHD symptom ratings than controls. ADHD symptom ratings were similar between ASD and ADHD groups. The authors questioned whether ASD and ADHD are distinct disorders.
Gadow et al., 2006	N = 449 with parent ADHD ratings, N = 441 with teacher ADHD ratings. 35% Autism, 22% Asperger's, 43% PDD-NOS	53% of all 3–12 year old ASD subjects had ADHD (same overall percentage whether by parent or teacher rating).	ASD subjects with combined type ADHD had more oppositional, aggressive, and autistic symptoms than those with inattentive ADHD. Inattentive subtype was the most common. ADHD subtypes and associated comorbidity patterns were similar in ASD subjects and non-ASD control subjects. Some analyses were first reported separately for preschool and elementary school age groups (Gadow et al., 2004, 2005).
Lee & Ousley, 2006	N = 58 autistic disorder, N = 12 Asperger's, N = 13 PDD-NOS	78% of all ASD subjects 83% of autism subjects 58% of Asperger's disorder subjects 77% of PDD-NOS subjects	Combined type ADHD was the most common subtype in autistic disorder, but inattentive type was the most common in Asperger's disorder and PDD-NOS.
Holtmann, Bolte, & Poustka, 2007	N = 182 ASD subjects, split into high and low ADHD groups for comparison on CBCL measures.		ASD subjects with ADHD had higher internalizing and externalizing symptoms. They also had higher impairment on the social interaction subscale of the ADI-R.

type, and 41% did not meet symptom criteria for ADHD (Goldstein & Schwebach, 2004). Sturm, Fernell, and Gillberg performed a larger chart review of 101 Swedish children with pervasive developmental disorders (90% Asperger's disorder, 9% PDD-NOS, 1% high-functioning autism), and found that 95% had "attentional problems," 56% had "hyperactivity," and 50% had "impulsiveness." They also reported that 75% had symptoms consistent with an ADHD diagnosis (Sturm et al., 2004). Yoshida and Uchiyama evaluated 53 Japanese children with high-functioning pervasive developmental disorders, and found that 68% met criteria for ADHD: 38% had the inattentive type, 23% had combined type, and about 8% had the hyperactive-impulsive type (Yoshida & Uchiyama, 2004). Hattori and colleagues compared ratings of ADHD and ASD symptoms in 20 children with ADHD, 15 children with ASD, and 40 normal controls. They found that the ASD and ADHD groups both had higher ratings of ASD and ADHD symptoms than controls. Based on their findings, they questioned whether ADHD and autism spectrum disorders are truly distinct (Hattori et al., 2006).

Lee and Ousley also investigated ADHD symptoms in a clinical sample of 83 children and adolescents with ASD, and found that 78% had symptoms consistent with an ADHD diagnosis (Lee & Ousley, 2006). They found that while the combined subtype was most common in autistic disorder, the inattentive subtype was the most common subtype in Asperger's disorder and PDD-NOS.

Kenneth Gadow and colleagues have published a number of studies investigating the validity of ADHD diagnoses in ASD (DeVincent et al., 2007; Gadow, Devincent, & Schneider, 2008; Gadow & DeVincent, 2005; Gadow, Devincent, & Drabick, 2008; Gadow et al., 2006; Gadow et al., 2004, 2005; Lecavalier et al., 2009). In a group of 6- to 12-year-old clinic-referred patients with ASD (38% with autism), they found that 59% of ASD males and 67% of ASD females had ADHD. In this study, the inattentive subtype was the most common form of ADHD among children with ASD, just as it was among non-ASD clinical and nonreferred community comparison groups (Gadow et al., 2005). Findings were similar in a study of preschoolers (Gadow et al., 2004). The same research group reported that children with the combination of ASD and combined type ADHD had more oppositional, aggressive, and autistic symptoms than those with the combination of ASD plus inattentive type ADHD (Gadow et al., 2006). Another analysis found that children with ASD who have the combination of ADHD and tics have particularly high levels of psychopathology, suggesting that the combination of ADHD and tics may be an indicator of a more complex psychiatric disorder (Gadow & DeVincent, 2005). This group also reported an association between sleep problems and increased ADHD symptoms among children with ASD (DeVincent et al., 2007). Another study found that ADHD symptom severity was associated with higher rates of medication treatment and current use of special education services among children with ASD (Gadow, Devincent, & Schneider, 2008). In ASD children, the combination of oppositional-defiant disorder (ODD) plus ADHD was associated with particularly high rates of medication use, co-occurring psychiatric symptoms, and adverse environmental factors indicative of disadvantage (Gadow, Devincent, & Drabick, 2008). In one of their most recent papers, this group of investigators concludes that ADHD and several other DSM psychiatric diagnoses are valid constructs in children with ASD (Lecavalier et al., 2009).

Holtmann, Bolte, and Poustka also explored the association of ADHD symptoms with autistic behavior domains and co-occurring psychopathology. In children with ASD, they found that ADHD symptoms were associated with more impairment on the social interaction subscale of the Autism Diagnostic Interview-Revised (ADI-R) as well as higher levels of internalizing and externalizing symptoms measured using the Child Behavior Checklist (Holtmann, Bolte, & Poustka, 2007).

Population-based studies are also important in determining the prevalence of ADHD among individuals with ASD. Simonoff and colleagues have reported the presence of ADHD in 28% of 112 10- to 14-year-old children with ASD from a population-derived cohort. They also found that those with ADHD had very high rates of additional comorbidity, with a second comorbid psychiatric diagnosis in 84% of ASD subjects who had ADHD (Simonoff et al., 2008). Of note, the prevalence of ADHD among ASD subjects from this population-based sample is somewhat lower than reported in the clinic-based studies shown in Table 18-1, and this difference may be due to referral bias. Since individuals with the combination of ASD plus ADHD have higher rates of additional comorbidity and impairment, the ASD subjects with ADHD (and higher comorbidity) may be more likely to present to clinics for treatment.

Social Impairment in ADHD

There are also a few studies of autistic symptoms in children and adolescents whose primary diagnosis is ADHD. In order to distinguish this from social impairment that may be due to ADHD itself, it is helpful to have an awareness of the typical social deficits that are very common in ADHD. It has long been recognized that children with ADHD are often socially impaired, and many published papers have described the phenomenology and treatment of social difficulties that are frequently present in ADHD (de Boo & Prins, 2007; Reiersen & Todd, 2008). Sociometric studies requiring children within a group to comment on their relationships with specific peers indicate that children with ADHD are often rejected by their peers (Blachman & Hinshaw, 2002; Hoza, Gerdes, et al., 2005; Hoza, Mrug, et al., 2005). Some of the social impairment can be attributed to the direct effects of ADHD symptoms on social behaviors. For example, impulsive and intrusive behaviors may lead to difficulties in making and keeping friends if peers are annoyed by such behaviors. Co-occurring psychopathology such as social anxiety and oppositional behaviors (Jensen et al., 2001), and cognitive

impairments such as working memory and executive deficits (Diamantopoulou, Rydell, Thorell, & Bohlin, 2007) may also contribute to the social deficits seen in ADHD. A conceptual framework for social deficits in ADHD is presented in Table 18-2. The extent of overlap between mechanisms of social impairment in ADHD and autism remains unclear.

In addition to some of the social difficulties that have been classically described in ADHD, several recent clinic- and population-based studies indicate that children with a primary diagnosis of ADHD often have additional deficits in the areas of social reciprocity, communication impairment, and repetitive/stereotyped behaviors that suggest the presence of

mild ASD symptoms or diagnoses (Clark, Feehan, Tinline, & Vostanis, 1999; Hattori et al., 2006; Reiersen, Constantino, & Todd, 2008; Reiersen, Constantino, Volk, & Todd, 2007; Santosh & Mijovic, 2004; Mulligan et al., 2009; Nijmeijer et al., 2009; Grzadzinski et al., 2010).

Clark and colleagues studied autistic symptoms using the Autism Criteria Checklist in a clinical sample of 49 children with ADHD and estimated that 65–85% had difficulties in social interaction and communication (Clark et al., 1999).

Santosh and Mijovic examined evidence of autistic-like symptoms through a chart review of 309 child and adolescent patients with ICD-10 Hyperkinetic Disorder (HKD),

Table 18–2.
A conceptual framework for social deficits in ADHD

Social Deficit Category	Specific Behaviors/Problems/Perceptions that may Lead to Social Impairment/ Relationship Difficulties/Rejection by Peers
Social Deficits Directly Resulting from ADHD Symptoms:	
1. Inattention	-Fails to notice/attend to social cues. -Forgets social plans/promises. -Loses others' things. -Appears disorganized. -Fails to focus on conversations. -Unable to persist in prolonged games. -Unable to attend to and learn appropriate social protocols.
2. Hyperactivity	-Moves quickly between peer activities. -Has increased energy that tires others out. -Talks too much/monopolizes the conversation. -Unable to sit still for a game or conversation with peers.
3. Impulsivity	-Rapidly/unexpectedly changes plans based on impulses. -Shows impulsive aggressive behaviors. -Impulsively makes comments that offend others. -Impulsively intrudes on others' space. -Insists on being first. -Poor at taking turns.
Social Deficits Resulting from Co-Occurring Problems:	
1. Poor emotional regulation	-Has emotional outbursts that disrupt activities and annoy others. -Unpleasant mood makes social interactions unpleasant for peers. -Social anxiety leads to social avoidance.
2. Oppositional Behavior	-Unwilling to go with others' plans or consider others' opinions. -Argumentative with peers.
3. Autistic symptoms	-Decreased desire for close friendships leads to social avoidance. -Decreased ability to read/understand social cues. -Decreased empathy with failure to respond appropriately to peer emotions. -Odd/repetitive behaviors that annoy peers. -Poor reciprocal communication/conversation skills. -Insistence on playing games related to own unusual or hyperfocused interests. -Rigid/stereotyped play behaviors. -Few shared interests with peers.
Social Deficits Resulting from Specific Cognitive or Language Deficits:	
1. Low overall IQ	-Perceived by others as "not smart." -Unable to logically solve social problems. -Failure to notice when being taken advantage of by peers. -Difficulty learning social skills

(Continued)

Table 18–2. (*Contd.*)

Social Deficit Category	Specific Behaviors/Problems/Perceptions that may Lead to Social Impairment/ Relationship Difficulties/Rejection by Peers
2. Poor executive function	-Difficulty planning social responses. -Difficulty adjusting behavior appropriately for social context. -Difficulty distinguishing between appropriate vs. inappropriate social behaviors. -Difficulty deciding when to use specific social skills.
3. Poor working memory	-Unable to process complex social situations. -Difficulty holding in mind social context information. -Trouble keeping in mind topic of game/conversation. -Difficulty remembering steps necessary to play a game. -Difficulty remembering promises to peers. -Difficulty interacting/conversing with more than one peer at a time.
4. Language impairment	-Has odd speech patterns that peers find strange or difficult to understand. -Difficulty communicating leads to decreased ability to confide in peers, converse, or develop meaningful friendships.

a diagnosis similar to DSM-IV combined type ADHD. Compared to 2048 psychiatric controls without HKD, ASD, or obsessive-compulsive disorder diagnoses, the patients with HKD were more likely to exhibit the "autistic symptom triad" of impaired social interaction, impaired communication, and repetitive/stereotyped behaviors. Santosh and Mijovic found evidence of two types of social impairment in their HKD subjects, which they named relationship difficulty and social communication difficulty. Those with evidence of social communication difficulty had more developmental delays and autistic-like symptoms such as repetitive/stereotyped behaviors and language problems. On the other hand, those with relationship difficulty had more conduct problems, mood symptoms, and environmental stressors. The authors suggested children with relationship difficulty may benefit from more family interventions, while those with social communication difficulty may require more social skills training (Santosh & Mijovic, 2004).

Grzadzinski and colleagues (2010) recently found evidence of autistic traits in a clinical sample of 75 children with DSM-IV-TR ADHD who did not have any history of an ASD diagnosis. They found that 32% of these children had elevated autistic traits based on a Social Responsiveness Scale (SRS) T-score ≥ 60. Those with elevated SRS scores showed evidence of non-structural language abnormalities on the Children's Communication Checklist-2 and greater oppositional behaviors, but did not show greater anxiety or ADHD symptoms.

Because clinic-based studies are prone to referral bias, it is also important to examine the relationship between ADHD and autistic symptoms in subjects ascertained through population-based samples. In our own population-based studies of ADHD, we have used the Social Responsiveness Scale (SRS) as a measure of autistic traits. This 65-item parent- or teacher-rated scale focuses on deficits in reciprocal social behavior, but also includes items assessing the other two autism symptom

domains of communication impairment and stereotyped/ repetitive behaviors (Constantino & Gruber, 2005; Constantino, Przybeck, Friesen, & Todd, 2000). Elevated SRS scores correlate highly with Autism Diagnostic Interview-Revised (ADI-R) algorithm scores (Constantino et al., 2003). In a population-based sample of Missouri twins, we found statistically significant SRS score elevations in children and adolescents with DSM-IV ADHD. SRS scores were highest in children with DSM-IV combined type ADHD or a severe combined subtype of ADHD defined using latent class analysis of DSM-IV ADHD symptoms (Reiersen et al., 2007). We also found that among children with ADHD, those with parent-reported motor coordination problems on the Child Behavior Checklist (CBCL) were more likely to have elevated autistic symptoms than those without parent-reported motor problems (Reiersen, Constantino, et al., 2008). This is consistent with a Scandinavian concept of Deficits in Attention, Motor Control, and Perception (DAMP), a syndrome that has recently been redefined as a combination of ADHD plus Developmental Coordination Disorder (DCD). Children with DAMP frequently show evidence of ASD in addition to their ADHD and DCD symptoms (Gillberg, 2003).

Examination of the ADHD-enriched International Multi-center ADHD Genetics (IMAGE) study sample has also revealed evidence of elevated ASD symptoms in subjects with ADHD. The Social Communication Questionnaire (SCQ) and Children's Social Behavior Questionnaire (CSBQ) were used as measures of autistic traits in this study. Analyses using the SCQ suggested autistic symptoms in ADHD are familial and associated with neurodevelopmental and oppositional-defiant disorders (Mulligan et al., 2009). Additional analyses using the CSBQ in Dutch participants within the IMAGE sample also showed elevated levels of autistic traits in ADHD probands and their siblings compared to controls, but weak and nonsignificant cross-sibling cross-trait correlations

suggested the familiality of ASD symptoms may be largely independent from ADHD familiality (Nijmeijer et al., 2009).

Underlying Biology and Genetics

Evidence for Genetic Overlap

Based on studies described above, it is apparent that ASD and ADHD symptoms frequently co-occur. The biological mechanisms underlying the co-occurrence of these two types of symptoms remains to be elucidated. Some recent studies suggest that some of the same genetic influences may affect both ASD and ADHD symptoms. Smalley and colleagues found statistically significant overlap between genetic linkage peaks on review of autism and ADHD linkage studies (Smalley, Loo, Yang, & Cantor, 2005). Nijmeijer, Arias-Vasquez, and colleagues (2010) performed a QTL linkage analysis of autistic symptoms in the ADHD-enriched IMAGE sample, and hypothesized that one of their suggestive linkage peaks (at 15q24) may be pleiotropic for ADHD and ASD since the height of this peak was reduced when a measure of ADHD symptoms was included as a covariate. In a recent study of 12,206 8-year-old twins, Ronald and colleagues found evidence for substantial overlap of genetic influences on autistic and ADHD symptoms (Ronald, Simonoff, Kuntsi, Asherson, & Plomin, 2008). They estimated genetic correlation (r_g) for ASD and ADHD traits in the range of 0.54–0.57 and non-shared environmental correlation (r_e) in the range of 0.15–0.35, depending on rater (parent vs. teacher) and sex. Similarly, a study of 674 young adult Australian twins suggested overlapping genetic influences on self-reported autistic and ADHD symptoms (Reiersen et al., 2008), with r_g estimated at 0.72 and r_e estimated at 0.26. While there is evidence of substantial genetic overlap from the above twin studies, both studies estimated that only a small proportion of environmental influences were shared between the two disorders. So, while common genetic factors may underlie both ADHD and ASD, environmental influences may predispose individuals to one disorder or the other. The degree of overlap of genetic and environmental influences on the two disorders may vary depending upon the age of ADHD and ASD symptom assessment. Ronald, Edelson, Asherson, and Saudino (2010) recently reported a study of autistic-like traits and ADHD behaviors in 2-year-old twins which suggested a smaller degree of genetic overlap ($r_g = 0.26$), complete overlap of common environmental influences ($r_c = 1.00$), and the possibility that non-shared environmental influences tend to increase one of the two symptom domains while decreasing the other ($r_e = -0.17$). Additional types of neurodevelopmental disorders may also show genetic overlap with ASD and ADHD. For example, another twin study by Lichtenstein, Carlstrom, Rastrom, Gillberg, and Ankarsater (2010) suggested that ADHD, tic disorders, and developmental coordination disorders are all influenced by genetic and environmental factors that also

contribute to ASD. Perhaps even where the same genetic predispositions toward psychopathology are present, the timing or type of environmental insults may result in different forms of psychopathology. Gene-gene interactions may also influence the specific type of symptoms that develop.

So far, there are few reported examples of specific genetic variations associated with both ADHD and autistic symptoms. In our own Missouri twin sample, we found that among children with severe combined type ADHD, those with the DRD4 7-repeat allele were more likely to have clinically elevated autistic traits as measured by the SRS (Reiersen, Neuman, et al., 2008). Although there was evidence of an interaction between prenatal nicotine exposure and the DRD4 7-repeat allele in producing risk for severe combined type ADHD (Neuman et al., 2007), no main or interaction effects of smoking were found for SRS score (Reiersen, Neuman, et al., 2008). This may be one example where a gene can influence both ADHD and autism symptoms, but environmental interactions with this gene may be different for autism and ADHD symptoms. Another recent study found an association between a Monoamine Oxidase A gene promoter polymorphism and ADHD symptoms in children with ASD (Roohi, DeVincent, Hatchwell, & Gadow, 2009). Children with the 4-repeat allele had higher parent-rated ADHD symptoms than those with the 3-repeat allele. The same research group found lower levels of ADHD symptoms and language deficits but higher levels of tics and social anxiety in ASD subjects homozygous for the DAT1 10-repeat allele (Gadow, Roohi, DeVincent, & Hatchwell, 2008). Using the IMAGE and Tracking Adolescents' Individual Lives (TRAILS) samples, Nijmeijer, Hartman, and colleagues (2010) found evidence that interaction of perinatal risk factors with catechol O-methyltransferase gene (COMT) and the serotonin transporter gene (SLC6A4) may influence ASD symptoms in children with ADHD. These association studies should be considered preliminary, and require replication.

There are also some well-known complex genetic syndromes that can produce both ASD and ADHD. Two examples are 22q11 deletion syndrome (also known as velocardiofacial syndrome or DiGeorge syndrome) (Antshel et al., 2007; Fine et al., 2005; Gothelf et al., 2004; Niklasson, Rasmussen, Oskarsdottir, & Gillberg, 2002; Ousley, Rockers, Dell, Coleman, & Cubells, 2007; Vorstman et al., 2006) and Fragile X premutation (Farzin et al., 2006). In the case of 22q11 deletion syndrome, the proportion of these individuals having ADHD and ASD diagnoses varies by study, and appears affected by whether formal evaluation for ASD was done and whether the researchers adhered to the DSM-IV exclusion prohibiting codiagnosis of ADHD and ASD (Reiersen, 2007). The 22q11 deletion is also associated with increased risk of psychotic disorders such as schizophrenia (Murphy, 2005; Ousley et al., 2007). In addition to the above example, copy number variation (insertions/deletions) in other gene regions have shown evidence of association with autism (Glessner et al., 2009; Hogart, Wu, Lasalle, & Schanen, 2010; Kakinuma & Sato, 2008; Kusenda & Sebat, 2008) and/or

ADHD (Elia et al., 2009), and frequently the regions of duplication/deletion include genes that are thought to be involved in neurodevelopment. As in the example of 22q11 deletion syndrome, some of the same copy number variants that increase risk for ADHD and/or autism may also increase the risk for other psychiatric disorders such as schizophrenia (Cook & Scherer, 2008; Williams, Owen, & O'Donovan, 2009). In a recent review of the shared heritability of ADHD and ASD, Rommelse, Franke, Geurts, Hartman, and Buitelaar (2010) suggest future studies should include family-based designs which obtain data on ADHD symptoms, ASD symptoms, endophenotypic measures, and environmental measures from all family members. They also discuss several potential candidate pleiotropic genes based on existing studies of both disorders.

Potential Biological Mechanisms

A vast number of genes involved in neurodevelopment and/or neurotransmission might theoretically affect both ASD and ADHD symptoms, but genes relevant to the brain's dopaminergic system may be of particular relevance. Stimulant medications used to treat ADHD increase dopaminergic neurotransmission, and many ADHD candidate genes are related to the dopamine system (Faraone et al., 2005; McGough, 2005; Neuman et al., 2007; Todd et al., 2005; Todd & Neuman, 2007). Dopaminergic neurons innervate both the frontal cortical attention regions and midbrain motor control regions (Todd & Botteron, 2001), and dysfunction of the dopaminergic system has been implicated in motor dysfunction, ADHD, and autism (Nieoullon, 2002). Also of note, motor abnormalities have been described in both ADHD and ASD (Mahone et al., 2006; Mostofsky, Burgess, & Gidley Larson, 2007), and the syndrome described as Deficits in Attention, Motor Control, and Perception (DAMP) typically includes autistic features along with ADHD and motor coordination deficits (Gillberg, 2003). Certain aberrant cognitive processes may be relevant to both ASD and ADHD, and these may also be affected by dysfunction in the dopaminergic system. For example, executive function deficits have been found in ADHD, ASD, and in motor coordination disorders (Geurts, Verte, Oosterlaan, Roeyers, & Sergeant, 2004; Goldberg et al., 2005; Livesey, Keen, Rouse, & White, 2006; Pennington & Ozonoff, 1996; Piek, Dyck, Francis, & Conwell, 2007; Piek et al., 2004; Sergeant, Geurts, & Oosterlaan, 2002). Our own research group has proposed a dopaminergic synapse-based model in which interaction between dopamine system gene polymorphisms and prenatal nicotine exposure influences the development of ADHD and/or autistic symptoms (Reiersen, Constantino, et al., 2008; Reiersen, Neuman, et al., 2008; Todd & Neuman, 2007). If individuals with a combination of ASD and ADHD respond to typical stimulant treatments, this would support the hypothesis that the mechanism of ADHD symptoms is similar, whether or not ASD is present. And in fact, individuals with ASD often do respond to typical ADHD treatments as described below. However, different effects of prenatal exposure to nicotine on ADHD versus ASD suggests some differences in the underlying mechanisms that produce ADHD versus ASD.

Treatment of ADHD Symptoms in ASD

A number of studies have evaluated the effects of medication treatment on ADHD-like symptoms in autistic disorder (Hazell, 2007). In his review of this treatment literature, Hazell concluded that methylphenidate, atomoxetine, some anticonvulsants, guanfacine, and donepezil showed evidence of moderate benefit. Atypical neuroleptics such as risperidone and quetiapine also improved ADHD symptoms in autism, but commonly had side effects of weight gain and sedation. Often medication studies for treatment of autism have included outcome measures related to ADHD symptoms, but only a few studies have specifically targeted individuals with the combination of ASD and ADHD symptoms. The use of methylphenidate for treatment of ADHD symptoms in ASD is supported by two placebo-controlled trials and a retrospective and prospective effectiveness study (Handen, Johnson, & Lubetsky, 2000; RUPP, 2005; Santosh, Baird, Pityaratstian, Tavare, & Gringras, 2006). The effectiveness of guanfacine is supported by a chart review, a small open-label trial, and a small double-blind, placebo-controlled, cross-over trial (Handen, Sahl, & Hardan, 2008; Posey, Puntney, Sasher, Kem, & McDougle, 2004; Scahill et al., 2006). The use of atomoxetine is supported by small open-label and placebo-controlled trials (Arnold et al., 2006; Posey et al., 2006; Troost et al., 2006).

One retrospective and prospective effectiveness study by Santosh and colleagues compared treatment responses of children with ADHD only to those with comorbid ADHD and ASD (Santosh et al., 2006). They concluded that stimulants were as effective in children with ASD plus ADHD as they were in children with ADHD alone, but also acknowledged that randomized, controlled trials are needed to further investigate the efficacy of stimulants for treating ADHD symptoms in ASD. They did not find a significant difference in side effects between groups, but they noted a trend toward increased dysphoria and obsessionality in the ASD group (Santosh et al., 2006), so they recommended caution with stimulant dosing and close monitoring for side effects in patients with ASD. Double-blind, randomized trials directly comparing stimulant response between a pure ADHD group and a group presenting with the combination of ASD and ADHD symptoms are needed to further investigate any difference in response rates and side effects.

As mentioned earlier, 22q11 deletion syndrome is a special case of a genetic disorder associated with both ADHD and ASD. Though some experts have been concerned about use of stimulants in these individuals due to their risk for psychotic symptoms, results of an open-label study suggested that stimulants are safe and effective for treating ADHD in 22q11 deletion syndrome (Gothelf et al., 2003).

Nonpharmacological treatments may also be very important in reducing ADHD symptoms in ASD. Educational accommodations for individuals with ASD should take into account the presence of any ADHD-like symptoms. For example, children who have ADHD symptoms may need more help organizing tasks and assignments, may pay attention better if sitting near the front of the classroom, may require instructions to be repeated more than once or written down for the student, and may benefit from extended time for completion of examinations.

Social skills therapies may be helpful for children with ASD and for children with ADHD. However, the type of therapy may be different depending on the nature of the social deficits that are present. Children who mainly have social reciprocity deficits typical of autism spectrum disorders may need more training in the areas of appropriate social communication (pragmatics, etc.) as well as education regarding situationally appropriate behaviors in various contexts. They may also need encouragement to initiate and maintain social interactions. Children with high levels of ADHD symptoms may benefit more from social skills therapies geared toward reducing inappropriate social behaviors that result directly from ADHD symptoms (for example, difficulty waiting turn, intrusiveness, and poor self-control due to impulsivity).

Box 18–1
Optimizing diagnostic nosologies

- Co-occurrence of multiple neurodevelopmental disorders is common, but current diagnostic criteria do not fully take this into account.
- Revision of DSM to allow diagnosis of ASD and ADHD in the same individual may encourage clinicians to assess and treat ADHD symptoms when they occur along with ASD.
- Future studies aimed at disentangling ASD from ADHD symptoms may lead to improved tailoring of treatment according to the symptom variations, strengths, and weaknesses of individual patients.

Conclusions

Given the studies showing frequent co-occurrence of ADHD and autistic symptoms and the evidence that ADHD symptoms in ASD are associated with higher levels of co-occurring psychopathology and impairment, it appears important to assess for ADHD symptoms in ASD. Individuals with the combination of ASD and ADHD may have a more complex neurodevelopmental disorder than those with ASD alone. They may have different comorbidity profiles and a different long-term prognosis. Also, individuals with the combination of ASD and ADHD may benefit from specific treatment of ADHD symptoms (for example, standard ADHD medications

plus social skills interventions that target classic ADHD-type social impairment in addition to ASD-type social impairment). Revision of DSM diagnostic criteria to allow codiagnosis of ASD and ADHD may encourage clinicians to assess and treat ADHD symptoms in patients with ASD. Future studies may address the issues of disentangling ASD from ADHD symptoms and tailoring treatment according to symptom variations, strengths, and weaknesses of individual patients.

Challenges and Future Directions

- Detailed phenotypic studies aimed at disentangling the measurement of ADHD and ASD symptoms may contribute to better diagnostic classification as well as the development of new treatments to specifically target different types of social impairment that are present in ASD and/or ADHD.
- Studies including neurocognitive testing and functional neuroimaging may help to clarify similarities and differences in brain function between ASD and ADHD.
- Further genetic studies considering gene-gene interaction, gene-environment interaction, and timing of environmental insults may further elucidate the mechanisms of abnormal brain development that can lead to ASD, ADHD, or both.
- Future treatment studies should include randomized, double-blind clinical trials directly comparing treatment response between ASD+ADHD and ADHD-only groups.

Specific Language Impairment

Points of Interest

- The deficits in specific language impairment (SLI) extend beyond language.
- The language deficits that are common in SLI involve the meaning (semantics) system and the structural (grammatical) system. Speech sound disorders (phonology) and disorders of language use (pragmatics) are less common.
- The range of severity of language deficits in children with SLI is more limited than that found in children with ASD.
- The nature of the overlap of SLI and ASD within affected children, as well as near family members remains a topic of debate.
- *CNTNAP2* appears to be a liability gene for ASD and SLI.

SLI, also called developmental aphasia, dysphasia, developmental language disorder, or language delay, is a developmental disorder characterized by limitations in language learning. Children with SLI are less capable than their unaffected same-age peers at understanding or expressing language. Any or all domains of language—syntax, morphology, phonology, semantics, and pragmatics—may be affected and, in any given child, one domain of language may be more severely affected than another. The extent to which they are behind their peers varies from mild to severe. The hallmarks of SLI vary with age: toddlers with SLI typically present with late onset of first words (Trauner, Wulfeck, Tallal, & Hesselink, 2000); preschoolers are often late to acquire grammatical inflections and function words (Leonard, 1998; Rice & Wexler, 1996); school children frequently have difficulty with sentence repetition (Conti-Ramsden, Botting, & Faragher, 2001), word finding (Lahey & Edwards, 1999; McGregor, Newman, Reilly, & Capone, 2002), and narrative formulation (Johnston, 2008; Liles, 1985). Learning to read and write is often problematic as well

(Catts, 1993). Some children do seem to "outgrow" SLI early in life, but once children enter school, the severity of their deficits remains relatively stable (Tomblin, Zhang, Buckwalter, & O'Brien, 2003). Older children and young adults present with a broad range of academic difficulties (Young et al., 2002). Follow-ups beyond the late teens are rare, but one study of seventeen 30-year-olds who had severe receptive and expressive SLI as children revealed persistent problems with spoken and written language as well as deficits in phonological processing, verbal short-term memory, and theory of mind (Clegg, Hollis, Mawhood, & Rutter, 2005). Even among adults who seem to have compensated for their SLI, weaknesses emerge in formal assessments that stress the linguistic system (Tomblin, Freese, & Records, 1992).

As the name implies, the clinical manifestations of SLI are limited to language. By definition, there are no broader, clinically significant deficits in cognition or delays in motor, social, or emotional development (American Psychiatric Association, 1994, *Diagnostic and statistical manual of mental disorders*). Nevertheless, it is common for children with SLI to struggle in academic and social settings and to have difficulty with peer relationships (Young et al., 2002; Clegg et al., 2005).

This chapter will summarize the status of research on the nature and etiology of SLI. Because late emergence of language and, in many cases, subsequent limitations in language learning also characterize children with autism spectrum disorders (ASD), we will pay particular attention to similarities and differences that may exist between SLI and autism with regard to symptoms and etiology. At the end of the chapter we will examine models of the relationships between ASD and SLI.

Prevalence

SLI is a common developmental disorder. In the United States, prevalence is estimated at 7.4% (Tomblin, Records,

Buckwalter, et al., 1997). Of course, prevalence estimates are a rather direct function of the test cutoffs used for identification. In the study conducted by Tomblin and colleagues (1997), children randomly sampled from the states of Iowa and Illinois were identified as having SLI if they scored at least 1.25 standard deviations below the mean on at least two of six measures of language. If the distributions of these scores had matched perfectly the distribution of the scores collected from children nationwide during the norming of these tests, one would expect 10% of the children to fall at or below 1.25 standard deviations of the mean (a score of -1.25 standard deviations is equivalent to the 10th percentile). Therefore, it is quite sensible that the prevalence estimate obtained by Tomblin and colleagues was close to 10%. A cutoff of -1 would have yielded a higher estimate of prevalence; -2 a lower one. The logical relationship between rather arbitrary test cutoffs and prevalence does not diminish the validity of the diagnosis. In societies that place high value on articulate language, being among the least articulate 3%, 10%, or even 15%, of the society is nearly certain to limit success and well-being.

Diagnosis

The diagnosis of SLI is based solely on certain patterns of strength and weakness rather than etiology. In this respect, it is similar to many developmental disorders such as autism. A clinician may diagnose SLI in children who have poor language achievement and yet the common causes of slow language development such as mental retardation, autism, or limitations in motor control and hearing acuity can be excluded (Stark & Tallal, 1981). Frank neurological problems are also excluded in cases of SLI; however as we will note later, subtle differences in brain structure are likely. SLI is typically diagnosed in the preschool or early school years (Stanton-Chapman, Chapman, Bainbridge, & Scott, 2002), although diagnoses are possible at both earlier and later points in development. The clinician commonly documents poor performance on a battery of standardized language tests as well as some detriment to the function of the child in familial, social, academic, or professional settings. For example, interviews with the teacher, observations of the child in classroom situations, and curriculum-based assessments may reveal the functional impact on academics (Westby, 2006). Clinicians may also supplement standardized tests and functional assessments with dynamic assessments, tasks that measure the ability to learn aspects of language over time rather than extant knowledge of the language at a single point in time (Pena, Iglesias, & Lidz, 2001).

There is no universally agreed on test battery nor a particular test score that defines SLI. In recent years, tasks that involve repetition of nonwords (1996), sentence repetition (Conti-Ramsden et al., 2001), and marking of tense and agreement in English speakers (Rice & Wexler, 1996) have been proposed as sensitive indicators of SLI; however these markers have not been shown to be specific to SLI, as poor performance on

these is also found in other populations of children with developmental disorders (see, for instance, Eadie et al., 2002; Grant et al., 1997). Tests that are well standardized and appropriately normed for the test-taker and that include measures of comprehension and production in all language domains would be considered best practice (Bishop, 1997). Depending on the age of the test-taker, tests that measure written as well as spoken language may be included. Guidelines set forth in the International Classification of Diseases (World Health Organization, 1993) specify that children diagnosed with SLI score at least 2 standard deviations below age level on standardized measures of language. Bishop and Edmundson (1987) associated severe SLI with scores of at least 2 standard deviations below the mean on any measure and moderate SLI with scores of at least 1.5 standard deviations below the mean on two or more measures. Specific cutoffs vary from lab to lab, clinic to clinic, and school to school (Aram, Morris, & Hall, 1993).

Diagnosis of SLI and ASD Compared

Current standards for the diagnosis of autism require a delay in the development of language and persistent qualitative abnormalities in the social use of language. Subsequent to the delay in language onset, a substantial variation in the use of language form (syntax, morphology, and phonology) and content can been seen among children with ASD. SLI is primarily characterized by deficits in the development of the form and content of language. Thus, whereas children with ASD may or may not have form and content deficits, all children with SLI will have such deficits and these are likely to be persistent through much if not all of childhood. Children with ASD are also required to have impairments in social interactions and the presence of repetitive stereotyped behaviors for diagnosis. In contrast, children with such social and behavioral deficits would be excluded from a diagnosis of SLI (Leonard, 1998). As such, SLI and autism by definition are exclusive of each other because of this exclusionary condition within the construct of SLI. This exclusionary requirement was established to highlight the fact that often language impairment can be found in the absence of other conditions; however, the requirement that SLI be independent of autism must be recognized for what it is—a diagnostic criterion established purely by fiat. We therefore acknowledge that there is certainly a reasonable chance that the developmental conditions that contribute to SLI could also contribute to autism. Therefore, overlap in behavioral characteristics and etiology should be considered as viable and requires empirical consideration.

One way that SLI and ASD might overlap is that SLI could developmentally progress into autism. Two studies recently reported data showing that some children initially diagnosed as language impaired and perhaps SLI as young children were later found to meet diagnostic qualifications for ASD. Conti-Ramsden et al. (2006) reported that approximately 4 percent of adolescents with a history of SLI demonstrated

characteristics necessary for a diagnosis of ASD, as considered by the ADOS and ADI-R; a rate nearly 10 times what would be expected for the general population. These authors concluded that this was due to the developmental progression of SLI into ASD. Bishop et al. (2008) also reported that 21% of adults who had earlier been identified as having specific speech and language impairments in early childhood met criteria for ASD using the ADOS-G and ADI-R. These authors interpreted their data and those of Conti-Ramsden et al. (2006) as indicative of diagnostic substitution in childhood. This substitution of language impairment for autism was considered to be the result of narrower criteria for autism at the time of the initial diagnosis. With changes in diagnostic criteria over time, children who earlier were not viewed as presenting ASD came to meet the criteria for ASD as the criteria shifted.

Behavioral Profile

An early sign of SLI is the late emergence of spoken words during the second year of life (Trauner et al., 1995). (Charman, Drew, Baird, & Baird, 2003; Ellis Weismer, et al., 2008; Luyster, Lopez, & Lord, 2007) Even after the child with SLI has begun to use words, subsequent word learning remains slow relative to same-age peers. For example, preschoolers with SLI require twice the numbers of exposures to new words before they can learn them (Gray, 2003). Once a word has been learned, semantic representation of the word is typically fragile as characterized by word-finding problems in preschoolers and school-age children with SLI, as well as sparse lexical semantic representations and semantic category knowledge (Kail & Leonard, 1986; McGregor et al., 2002). As compared to expression, comprehension of words is an area of relative strength (Thal & Tobias, 1992).

In general, the grammatical development of children with SLI is even more limited than their word learning. In the preschool years, they tend to produce short sentences that lack nonobligatory arguments and grammatical inflections (van der Lely, 1998). Inflections that mark finite tense and agreement on verbs (e.g, he play*s*, he play*ed*) are particularly prone to omission (Rice & Wexler, 1996). Children with SLI continue to lag behind their same-age peers in grammatical development once they have entered school. For example, they rarely use sentences that involve noncanonical word order (e.g., *the dog was kissed by the cat*), auxiliary inversion (e.g., *is he going to the store*?), conjoined clauses (e.g., *he is happy but she is sad*), or embedded clauses (e.g, *we knew he could swim*) (Johnston & Kamhi, 1984; Leonard, 1995). Careful testing reveals that comprehension of these advanced sentence structures is often problematic as well (Bishop, 1997; van der Lely, 1994). Though no longer frequent in their spoken language, omissions of grammatical inflections characterize their written language (Scott & Windsor, 2000).

For many children with SLI, speech sound production is an area of relative strength (Kjelgaard & Tager-Flusberg,

2001; Shriberg, Tomblin, & McSweeny, 1999). Shriberg and colleagues (1999) reported the comorbidity of speech sound deficits and SLI to be less than 2%. Despite this sparing of speech sound production abilities, children with SLI have often been shown to be poorer than typically developing age mates in tasks that place demands on phonological skills such as those requiring repetition of lengthy unfamiliar phonological sequences (nonword repetition) (Bishop et al., 1996; Conti-Ramsden & Botting, 2000), the conscious identification and manipulation of sound units of words (deletion or blending of syllables or phonemes) (Kamhi et al., 1988), and perceptual discriminations of synthetic speech or syllabic words (Coady et al., 2007; Montgomery, 2003).

Pragmatics and the social use of language is generally considered a relative strength for children with SLI: 85% score higher on measures of pragmatic communication than semantics and syntax (Tomblin, Zhang, Weiss, Catts, & Ellis Weismer, 2004). That said, children with SLI present with a variety of pragmatic difficulties including attributing emotions to others and understanding utterances that are not literally true (Botting & Conti-Ramsden, 2008; Farmer, 2000), even after controlling for overall language ability (Botting & Conti-Ramsden, 2008). These children also demonstrate difficulty with basic social tasks. They interact differently than their normally developing peers in classroom contexts, are less preferred by their peers, and experience significantly fewer peer contacts (Bishop & Baird, 2001; Botting & Conti-Ramsden, 2008; Craig, 1993; Fujiki, Brinton, & Todd, 1996). These difficulties may, in part, be attributed to the difficulty that children with SLI demonstrate in their conversational exchanges. Because they have difficulty taking the perspective of their conversational partner (Farrant, Fletcher, & Mayberry, 2006), children with SLI tend to contribute too little or too much information, make irrelevant comments, and/or ask inappropriate questions (Adams & Bishop, 1989; Marton, Abramoff, & Rosenzweig, 2005). These are long-term problems that increase with age, leading to an increased risk of victimization by 11 years of age (Conti-Ramsden & Botting, 2004). Thus, although pragmatics is not a prominent area of difficulty for them, children with SLI are not unscathed in social communication.

A subgroup of children with SLI with pragmatic difficulties that overshadow their grammatical deficits but do not meet the criteria for a diagnosis of ASD have been described (Bishop & Norbury, 2002; Botting & Conti-Ramsden, 1999). This profile has been referred to as semantic-pragmatic language impairment or more recently pragmatic language impairment (PLI; Bishop, 2000; Brook & Bowler, 1992). These children do not represent misdiagnosed cases of ASD, but rather are a group of children who have some features of both autism and SLI. Children with PLI have been described as sociable, talkative children who produce stereotyped language with abnormal prosody, focusing conversation on topics of their own particular interest. However, these same children have good reciprocal interactions and do not show nonverbal repetitive behaviors that are characteristic of ASD (Bishop & Norbury, 2002).

Behavioral Profiles of SLI and ASD Compared

To summarize, children with SLI have widespread deficits in communication development, but with particular difficulties with grammar and phonological working memory along with relative strengths in speech sound production and pragmatics. The language and communication profiles of children with ASD are more completely described in Chapters 9 and 27 in this volume. In those chapters we find that the skills of children with ASD with regard to form and content can vary widely. With regard to those aspects of language most often viewed as "markers of SLI," there are data that show that some, but not all, of the children with ASD show poor grammatical skills (Botting & Conti-Ramsden, 2003; Kjelgaard & Tager-Flusberg, 2001; Roberts et al., 2004) and also poorer phonological short-term memory as shown in their nonword repetition (Botting & Conti-Ramsden, 2003; Kjelgaard & Tager-Flusberg, 2001; Whitehouse et al., 2007). These data have provided the basis for an active debate over the presence or nature of an overlap of SLI and ASD, as will be discuss further at the end of this chapter.

As noted earlier in the diagnostic contrast of SLI and ASD, impaired reciprocal social interactions are grounds for ruling out SLI, whereas such impairments are required of children with ASD. Additionally, the use of language for socially adapted appropriate communication has been well documented to be a prominent feature of ASD. Therefore, an overlap in the full range of pragmatics deficits between SLI and ASD has been essentially prohibited by this exclusionary condition. Also as noted above, children with SLI have been shown to have difficulties with pragmatics, but these deficits are generally less prominent than those seen in ASD. Furthermore, there is some question as to whether the pragmatic difficulties in SLI are a primary part of the communication problems of children with SLI or secondary to the form and content difficulties they experience (Redmond & Rice, 1998). Thus, pragmatics and social communication skills are clearly the developmental domain where there is little overlap between SLI and ASD. It remains unclear, however, as to whether this is evidence that these are naturally different developmental disorders or whether a naturally occurring relationship has been severed by the imposition of exclusionary standards for SLI. Studies concerned with underlying neurological function could shed light on this.

Neurological Findings and SLI

Questions concerning brain function among children with SLI have been informed by theory but limited by the technology that is available. Thus, in concert with research concerned with other developmental disorders such as autism and dyslexia, most of the search for neural anatomical bases of SLI has

focused on whether there are differences in relative brain volumes across different brain regions. In particular, interest has focused on the cortical regions of the inferior frontal cortex including Broca's area and the temporal parietal region often defined as the perisylvian region including Wernicke's area. Within individuals with typical language development these regions are usually larger in the left hemisphere (leftward asymmetry) than the right. Likewise, measures of functional brain activity using fMRI or an intracarodid amobarbitol (Wada) test during language tasks have shown a common left hemispheric dominance for language tasks. This convergence of anatomical and functional asymmetry has supported the viewpoint that anatomical differences in these language areas could contribute to functional outcomes (for a cautionary viewpoint, see Eckert et al., 2006).

Early autopsy findings by Galaburda et al. (1985) suggested that developmental dyslexia and other developmental language disorders such as SLI might be associated with the absence of expected asymmetry of the perisylvian region. Soon after this, a neuropathological study of a deceased child with a diagnosis of developmental dysphasia was reported to have abnormal symmetry of the perisylvian region (Cohen et al., 1989). These findings generated considerable interest in this region as MRI imaging became available. Jernigan et al. (1991) reported that children with SLI had smaller-than-expected left perisylvian volumes, and at the same time Plante and colleagues (Plante et al., 1989; Plante et al., 1991) reported reduced left asymmetry of the perisylvian region. Similar results regarding reduced rates of leftward asymmetry of the perisylvian region in children with SLI were reported by Gauger et al. (1997). Preis et al. however, did not find abnormal symmetry in the perisylvian region (Preis et al., 1998). Gauger et al. also extended the regions of interest for SLI to the inferior frontal cortex, where they also found the volume of the left pars triangularis to be smaller in children with SLI than controls. Evidence that abnormal asymmetries in the perisylvian region were further supported by Leonard and colleagues who found reduced asymmetry in this region differentiated children with SLI from children with dyslexia and normal readers (Leonard et al., 2002). More recently De Fosse et al. (2004) also found a rightward asymmetry in the inferior frontal cortex of children with SLI. Surprisingly, the planum temporale was found to have more leftward asymmetry in the children with SLI than among typically developing children in this study. Herbert et al. (2005) performed a nested hierarchical analysis ranging from whole brain through major anatomical lobes to smaller regions defined as parcellation units with images from children with SLI. Similar to De Fosse et al., they found more rightward asymmetry in the frontal language areas and more leftward asymmetry in the perisylvian language areas.

Most of the research concerning brain structure and SLI has concentrated on the study of brain regions that have long been associated with language functions. Such an approach assumes that there are language-specific brain regions and that language can be viewed as a special cognitive faculty. Under the alternate view that language arises from a widely

distributed nonmodular neural system, Herbert and colleagues (Herbert et al., 2003; Herbert et al., 2005) examined larger-scale brain regions including subcortical structures. From this larger perspective they found little evidence of abnormal asymmetry at these whole brain–level analyses, despite having found such asymmetries at the more local parcellation units. At this larger-scale analysis they did find that children with SLI (and children with ASD) presented larger cortical volume due to greater amounts of white matter, in other words, greater amounts of connectivity via myelinated fiber tracts. Although connectivity is generally considered important for neural networks, excessive connectivity could result in inefficient and noisy processing.

These findings are beginning to reveal replicable differences between brain structure of typically developing children and those with SLI. Those studies concerned with patterns of asymmetry in the two principal language regions support the notion that variations in basic neurodevelopmental processes involving these language regions contribute to the liability for SLI. It seems that this vulnerability is more consistently found in the inferior frontal region than in the perisylvian region, and some evidence of more general abnormalities involving general brain size can be found. Of course these conclusions assume that these differences in asymmetry and volume are laid down during early development and are not themselves the product of poor language learning (Locke, 1994). Furthermore, it is clear that although there appear to be anatomical effects that are robust enough for group differences, there are often cases of either abnormal asymmetry accompanied by normal language or normal patterns of asymmetry accompanied by abnormal language. Thus, as Herbert et al. (2003) note, these anatomic findings do not point to a simple deterministic relationship with language development.

Neurological Findings in SLI and ASD Compared

There have been substantially more structural imaging studies of individuals with autism (see Section II of this book) than SLI. Far more brain regions and brain features have been examined in autism than in SLI, where the focus has largely been on language regions. Among these is a small set of studies that has directly contrasted children with SLI and children with ASD. In addition to reporting on findings concerned with SLI, the De Fosse et al. (2004) study described earlier compared children with SLI with children with ASD who either presented with poor language or had normal language abilities. Patterns of abnormal asymmetry in the inferior frontal cortex were found for the children with SLI and the children with ASD who were also language impaired. Likewise both the SLI and children with ASD and language impairment showed the unexpected exaggerated L > R asymmetry described earlier. The children with normal language but with ASD did not show these abnormal asymmetric relationships.

Herbert et al. (2005) used children with ASD who were described as being high functioning and therefore would be likely to have had normal structural language abilities and may have been similar to De Fosse's normal language ASD group. Despite this, they also found patterns of asymmetry similar to those of the De Fosse study for both anterior and posterior parcellation units involved with language. Thus, they also found the unexpected abnormal exaggerated L > R in both groups. Also, as we noted earlier, this study found larger overall cortical size in both groups. Herbert and Kenet (2007) have concluded from these findings that autism and SLI share many, although not all, neurological features and thus could be viewed as overlapping conditions.

Familial Aggregation of SLI

If SLI and ASD are overlapping conditions, we would expect that they share, in part, etiological origins. One clue to the origins of SLI is that it tends to aggregate in families (Beitchman et al., 1992; Neils & Aram, 1986; Tallal et al., 1989; Tomblin, 1989). Familial aggregation is one piece of evidence in support of a genetic contribution to the etiology of SLI. Of course, as in all cases of complex developmental disorders, the behavioral manifestations of SLI are multidetermined: both genes and the environment participate. Certainly, genes are not the whole story. Three well-documented environmental risks for SLI are low maternal education (Stanton-Chapman et al., 2002; Tomblin, Smith, & Zhang, 1997), higher birth order (Hoff-Ginsberg, 1998; Stanton-Chapman et al., 2002; Tomblin, 1990), and single-parent homes (Stanton-Chapman et al., 2002). These risks pertain to the care-giving environment. Mothers with limited formal education are less knowledgeable about childcare and development than more educated mothers (Furstenberg, Brooks-Gunn, & Chase-Lansdale, 1989). If these mothers are the sole head of household or have many children, the time they can devote to any one child is limited. More siblings and fewer parents obviously make for less opportunity for dyadic interactions between child and adult, interactions known to facilitate language development (Tomasello & Farrar, 1986). Whereas none of these factors alone would cause SLI, a child with a vulnerable genotype faced with these environmental factors is at greater risk.

In any study of familial aggregation, results will vary depending on the phenotype, or behavioral profile, examined. Some studies of familial aggregation of SLI employ a broader phenotype; they include speech, language, and reading problems; whereas others employ a narrower phenotype. In the Tomblin (1989) study the phenotype was limited to specific language and speech sound disorders. Tomblin and Buckwalter (1994) have also found that SLI diagnosed on the basis of direct assessment occurs in 21% of the first-degree relatives of SLI probands and at a rate of 28% in the male relatives of these probands. Rice and colleagues (1998) reported very similar rates of speech/language impairment in the nuclear family

members of probands who were identified by their failure to mark tense in obligatory contexts. More recently, Tallal and colleagues (Tallal et al., 2001) also tested family members of SLI probands and probands with normal language status. They reported a rate of 31% SLI in the families of the SLI probands and 7.1% in the control families. Thus, across a large number of studies using a range of methods of ascertainment and measurement of the language phenotype, support for the familiality of SLI can be found.

Twin studies of specific language impairment have provided evidence that this familial feature to SLI is at least partially genetically influenced. Lewis and Thompson (1992) reported concordance rates of 86% for monozygotic (MZ) and 48% for dizygotic (DZ) twins with speech and language problems. Bishop, North, and Donlan (1995) reported a concordance of .46 and .70 for the DZ and MZ twins, respectively, for twins ascertained for specific speech and language impairments. Later, Tomblin and Buckwalter (1998) looked at twins with a language-impaired proband and found a concordance for the MZ pairs of .96 and .69 for the DZ pairs and obtained a group difference heritability of .45. Dale and colleagues (1998) also have reported group differences heritability in a large-scale twin study. Using delays in vocabulary development of 2-year-olds as a phenotype, these investigators found heritability rates of .73. In the study by Dale and colleagues (1998) heritability was lower, as the cutoff score for language delay was shifted from the 5th percentile upward toward the 16th percentile, suggesting that there may be unique genetic contributions to particularly low language abilities. This research group (Spinath et al., 2004) has reported similar results for a phenotype that included grammar as well as vocabulary. In this study, group differences heritability for children with low language was higher than individual differences heritability (h^2) for a sample of children that included typically developing children. Thus heritability increased with severity; however variation in severity involved both verbal and nonverbal abilities.

In most of the studies up to this point, the phenotype was often one that allowed language, nonverbal IQ, and speech sound status to covary. During the last few years, research has come to focus on the question of which of these aspects of the phenotype are most likely to be genetically influenced. Initially the question focused on the covariance of language and nonverbal IQ. Hayiou-Thomas and colleagues (2005) reported that heritability of poor language accompanied by low nonverbal IQ (nonspecific language impairment; NLI) was much higher than was found for children who had discrepancies between language and nonverbal IQ (SLI). These findings suggested that the heritability of poor language was only found when it occurred with poor nonverbal skills, suggesting that the genetic influence was not limited to language, but perhaps "generalist" genes. DeThorne and colleagues (DeThorne et al., 2005) pointed out that the children with SLI in the Hayiou-Thomas et al. study had less severe language impairment as well as better nonverbal IQ, and the NLI children had more severe language impairment. Thus language severity and

nonverbal IQ were confounded. DeThorne and colleagues examined this question further by controlling for this confound and demonstrated that heritability of language impairment was independent of the child's nonverbal IQ. Consequently, these findings support the contention that poor language is genetically influenced regardless of nonverbal IQ. Collectively, these studies would also seem to be in agreement with Bishop, North, and Donlan (1995), who had earlier concluded that the genetic studies of SLI should dispense with a nonverbal IQ criterion as a part of the phenotype.

In most of the twin studies on SLI, phonological deficits in the form of speech sound disorders were considered as a part of the general specific speech and language disorder phenotype. Bishop and Hayiou-Thomas (2008) reexamined the Hayiou-Thomas et al. (2005) data and reported low heritability of SLI in children with nonverbal IQs above 85, but high heritabilities of speech sound ability in children with similar nonverbal IQs. Likewise, heritability of clinically identified SLI was higher than SLI identified via population sampling. This latter difference was attributed to greater rates of children with SLI and comorbid speech sound disorder in the clinically identified group. These authors argue that the prior reports of substantial heritability of SLI may be due to the confounding of speech sound disorder in several of these studies. This conjecture is given further support by studies showing substantial heritability estimates for speech sound disorder (Bishop et al., 1995; DeThorne et al., 2006; Lewis & Thompson, 1992) and phonological memory (Bishop et al., 1996). These results would suggest that phonological abilities including speech sounds production skills may be, in their own right heritable, and that characterization of these aspects of the broader language phenotype should be employed in genetic studies of children with SLI. Whether all of the heritability of SLI can be attributed to speech sound abilities will require additional research.

Familial Aggregation of SLI and ASD

Earlier we reviewed evidence suggesting that SLI may be comorbid with autism and this comorbid condition may account for a substantial subgroup of individuals with autism. Alternatively, SLI has also been considered to be a milder variant of autism. Each of these accounts implies that autism spectrum disorders and SLI may share a common liability factor. This sharing could be either in a subgroup of children with ASD or it could span all individuals and differ with respect to the strength of the effect. The later view allows the traits that comprise autism and SLI to be dimensional, and thus the familial liability may be expressed in subclinical behavioral levels of some or all of these behavioral dimensions in the near relatives of children with autism or SLI. Thus, a very reasonable place to look for this shared liability is within families. If autism and SLI are related due to a common familial etiology, we should expect to see a co-occurrence of SLI and autism features among near relatives of children with SLI or autism.

The first investigation of this sort can be seen in Folstein and Rutter (1977), who found increased rates of language problems in nonautistic co-twins of autistic probands. More recently, Le Couteur and colleagues (1996) reported additional support for these results in a follow-up of the Folstein and Rutter twin study with a new sample of twins. Similar findings of familial loading of communication deficits in nonautistic family members of probands with autism have been found in studies of the Broader Autism Phenotype (BAP) hypothesis (Bishop et al., 2006; Plumet et al., 1995; Cox et al., 1975; Boutin et al., 1997; Bolton et al., 1994; Le Couteur et al., 1996; Landa et al., 1992; Folstein et al., 1999; Szatmari et al., 2000). In all these studies, near relatives of probands with ASD were evaluated with respect to language related disorders. One study (Tomblin et al., 2003) examined this relationship between ASD and SLI by obtaining evidence for ASD in siblings of probands with SLI. A comparison of the sibling scores from SLI and the ASD probands on the Autism Behavior Checklist (ABC; Krug et al., 1980) did not show a significant difference, however all siblings with scores on the ABC indicative of risk were sibs of probands with low language. Furthermore the rate of diagnosed autism in the siblings of probands with SLI was significantly higher than population estimates for the prevalence of autism at that time. Thus, these data provided partial support for a reciprocal familial relationship between ASD and SLI. Although the studies above found that near relatives of probands with autism were liable for communication deficits, it should be recognized that several studies have not found such evidence (Szatmari et al., 1993; Fombonne & Du Mazaubrun, 1992; Gillberg et al., 1992; Fombonne et al., 1997; Pilowsky et al., 2003; Bishop et al., 2004). Bishop et al. (2006) observed that many of the studies showing a relationship used measures based on history or report from family members regarding communication status, whereas those that did not find an elevated rate of language impairment in family members of probands with autism employed language tests. These language tests were typically focused on language form and meaning rather than communication function; whereas the historical reports could reflect poor communication function. Bishop et al. (2006) predicted that if both communication function and structure were systematically measured in the siblings of children with ASD, it would be likely that the excess deficits would be concentrated in social communication. Bishop et al. (2006) explored this using a structured questionnaire that spanned communication function and structure. Elevated rates of poor communication were found in the relatives of the autism probands; however, this elevated rate was not concentrated in the domain of communication function. These results provided support for a more generalized language impairment to be a part of the BAP, and thus could be considered to suggest that SLI may overlap with ASD. More recently however, Whitehouse, Barry, and Bishop (Whitehouse et al., 2007) tested the language structure and social communication abilities among parents of children with ASD and parents of children with SLI. It is noteworthy in this study that

the parents of the two groups were similar in nonverbal IQ and education. In fact, the parents in this study were well above average on nonverbal IQ. Despite this matching, the parents of the SLI probands were found to have poorer phonological and language skills than the parents of ASD probands. In contrast, the parents of ASD probands had poorer social communication skills than the parents of SLI probands. These data support the view that SLI and ASD do not share common liability factors so long as a distinction is made between the structural aspects of language and the social functional aspects of communication. Thus, currently, the extent to which there is a shared etiology or liability between ASD and SLI remains unclear.

Molecular Genetic Evidence

Linkage Studies

In the past 9 years there have been reports of two genome-wide scans for developmental language disorders. Bartlett and colleagues (Bartlett et al., 2002) reported suggestive linkage of phenotype of receptive language impairment to a locus on 2p in family members from 5 families originally ascertained for schizophrenia. A linkage of reading to 13q (*SLI3*) was also reported in this study. The SLI consortium in England (Newbury, Ishikawa-Brush, et al., 2002) performed a sib-pair genome-wide scan with SLI probands that resulted in linkage to loci at chromosomes 16q (*SLI1*) and 19q. The language trait linked to chromosome 19q (*SLI2*) was one that represented the children's ability to express words and sentences. The chromosome 16q locus was linked to a measure of phonological working memory (PM) requiring remembering and repeating nonsense words. A subsequent study by this same research group was able to replicate the linkage of PM to *SLI1* and *SLI2* in a new sample, but when the samples were combined PM was only linked to *SLI1* (Newbury et al., 2004). Two additional analyses of these data provided further support for the linkage of PM to the SLI1 locus and sentence usage including grammar and vocabulary for *SLI2* (Monaco, 2007; Falcaro et al., 2008). Previous work has shown that phonological memory is a sensitive indicator of SLI and may be an important cognitive skill for language development (Dollaghan & Campbell, 1998; Ellis Weismer et al., 1999; Conti-Ramsden & Hesketh, 2003). To date, no fine mapping results have been published pointing to the possible causal locus for *SLI1*, and it will be important to further replicate these findings in independent samples.

Candidate Gene Studies

To date one gene (FOXP2) has been found to be strongly implicated in language development (Lai et al., 2001). These results came from the study of one family with a point mutation of FOXP2 and high rates of speech and language impairment. However, several studies have not found evidence of

this gene contributing to SLI in the general population (Newbury, Bonora, et al., 2002; Meaburn et al., 2002; O'Brien et al., 2003). Thus, although FOXP2 appears to affect neural systems important for normal speech and language development, it does not appear to be a very common basis for language impairment. This failure to find association or linkage of language impairment to FOXP2 in population samples is consistent with other studies (Bartlett et al., 2002; SLI Consortium, 2004). Our group (O'Brien et al., 2003) did find an association of language impairment to two markers flanking FOXP2 in the region of WNT2, suggesting that a language-related locus other than FOXP2 may reside nearby. One significant association was to a marker within the CFTR gene, and these findings have been replicated by Bartlett (2004). Recently, Tyson and colleagues (2004) reported a microdeletion at 7q31.3 in a child with a complex balanced translocation involving chromosomes 5, 6, and 7. This child presented with language impairment and also cleft palate. These authors concluded that their results supported the O'Brien et al. (2003) results that suggest that a gene concerned with language disorders lies in the 7q31.2-31.3 region.

Bartlett et al. (2004) reported candidate region studies for two additional regions that had been found promising on an initial genome linkage study (Bartlett et al., 2002). In this study significant linkage was again found for a reading phenotype at chromosome 13q (*SLI3*).

Overlaps in Genetic Bases of SLI and ASD

If ASD and SLI co-occur in families, a reasonable hypothesis might be that there is a shared genetic liability for SLI and ASD. Previously, we reviewed the current molecular genetics research on SLI. Far more research has been conducted on the genetics of ASD. There have been at least 18 reported genome-wide linkage scans and now two genome-wide association scans (see, for instance, Freitag, 2007). Strikingly, none of these studies have reported linkage or association to the *SLI1* or *SLI2* regions. The most widely replicated linkage findings have involved a region on chromosome 7q and 2q. The studies concerning the 7q locus in autism has been particularly interesting to those studying the genetics of SLI, because in many cases, these linkage signals have been improved when the phenotype was narrowed to focus on language (Alarcon et al., 2005; Alarcon et al., 2002; Wassink et al., 2001; Alarcon et al., 2005). One gene in this region is *FOXP2*, which as we noted earlier has been implicated in speech and language. The fact that *FOXP2* was in the region where these linkages were found led some research groups to examine *FOXP2* in ASD samples to determine if *FOXP2* might be the source of the linkage. In the majority of these studies no association was found between *FOXP2* and ASD (Newbury, Bonora, et al., 2002; Gauthier et al., 2003; Wassink et al., 2002); however, Gong and colleagues have reported an association of markers within *FOXP2* to autism in a sample of Chinese individuals of Han descent (Gong et al., 2004).

Thus, so far, common genetic variation within *FOXP2* has not been shown to be associated with either SLI or ASD. Recently however, the 7q region has yielded rather robust findings with regard to another gene, *CNTNAP2*. This gene is in the 7q35 region and also lies under the linkage peak found in the earlier linkage studies on autism cited above. The CNTNAP2 protein is a member of the neurexin superfamily that is concerned with cell adhesion and is expressed in brain. Bakkalouglu et al. (2008), Alarcon et al. (2008), and Arking et al. (2008) simultaneously published papers showing that common and rare genetic polymorphisms within *CNTNAP2* were associated with autism. Bakkalouglu et al. reported a case with mental retardation and ASD who had a chromosomal inversion that disrupted *CNTNAP2*. Furthermore, these authors resequenced *CNTNAP2* in 635 individuals with autism and 942 controls and found an elevated but nonsignificant rate of rare variants that yielded changes in the amino acid sequence of CNTNAP2. In both the Bakkalouglu et al. and the Arking et al. studies the phenotype was based on autism diagnosis. In the Alarcon et al. study, the phenotype most strongly associated with *CNTNAP2* was a quantitative trait concerned with the age at which the parents reported the child with ASD acquiring the first word, and therefore these findings implicated CNTNAP2 as a possible genetic cause of language problems with or without autism. Soon after these reports of *CNTNAP2* association, Vernes et al. (2008) reported that *CNTNAP2* was a downstream regulatory target of *FOXP2* and that the same genetic polymorphism reported to be associated with autism by Alarcon et al. (2008) was also associated with phonological short-term memory in a sample of children with SLI. These findings have provided the first strong evidence supporting a shared etiology between autism and SLI.

Two other regions that have been reported to be linked to SLI lie at 13q and 2q. Both these regions were found to be linked to phenotypes associated with SLI by Bartlett and colleagues (Bartlett et al., 2002, Bartlett et al., 2004). The region of linkage on chromosome 13q has also been linked to autism in two studies (Barrett et al., 2001; Bradford et al., 2001). Likewise the region on 2q linked to SLI was found to be linked to autism in one study also by Barrett and colleagues (Barrett et al., 2001).

Thus, out of the 5 regions (*SLI1, SLI2, SLI3*, 2q, and 7q35), three of these fall into regions that have also been implicated in autism. Thus, although the molecular genetics findings are by no means conclusive that there is genetic overlap, these molecular data are consistent with the quantitative genetic findings showing some evidence of shared familial/genetic liability between autism and SLI.

Hypotheses on the Relationship of SLI and Autism

Throughout this chapter we have described the behavioral and etiologic findings concerning SLI and have provided

comparisons and contrasts of these features with ASD. As noted earlier, there has been a long-standing interest in possible ties between autism and SLI. This has resulted in several different hypotheses being proposed.

The first account associating SLI and autism was that of Bartak, Rutter, and Cox (Bartak et al., 1975; Bartak et al., 1977), where it was hypothesized that these conditions represented different points on a single dimension of severity of language impairment (Figure 19-1). At this time, these authors considered the possibility that the social and behavioral features of autism resulted from the language impairment. Therefore this model assumed that ASD and SLI would have common etiologies and the difference was in the severity of expression and the development of secondary abnormal social responses to communication difficulties. Their research, however, provided evidence that clear qualitative differences existed between these two conditions, and thus the model of SLI and autism lying on a single continuum was rejected. Soon, Rutter (1978) introduced a model of autism wherein ASD was formed from deficits in three domains of development (language, social interest, rigidity). Within this conceptualization, ASD was a mixture of these three domains. As a part of this model, some researchers began to report that the nonautistic relatives of autistic individuals were likely to demonstrate milder forms of one or more of the particular components of the full syndrome of autism, and this led to the notion of a broader autism phenotype (BAP: Piven, 1999). This provided a means for SLI to overlap with autism with regard to the language dimension while contrasting with autism on the other two dimensions, as depicted in Figure 19-2.

A feature of the mixture model would be that all children with ASD would present with SLI-like language problems. As we noted earlier, children with SLI often have particular difficulties with the development of grammatical morphology and with the accurate repetition of novel words. Tager-Flusberg (Tager-Flusberg, 2004; Kjelgaard & Tager-Flusberg, 2001) found that indeed a subgroup of children with autism presented a similar profile of deficits. Additionally, they found some children with autism who had normal language ability albeit poor social communication. Thus, Tager-Flusberg proposed that many but not all children with autism presented with comorbid SLI (see Figure 19-3). Thus, like the mixture model, SLI and autism overlap, but unlike the mixture model,

they are considered as distinct, since children could present with ASD and not SLI and obviously SLI but not ASD. As such, SLI and ASD would be viewed as comorbid and therefore likely to have related if not shared etiologies.

Recently, Whitehouse and colleagues (Whitehouse et al., 2007; Whitehouse et al., 2008) have argued against this notion of an overlap between SLI and ASD, claiming that SLI and ASD, although similar in some surface manifestations of language deficits, differ with regard to the underlying bases of these deficits. They suggest that the apparent signs of SLI among children with ASD do not hold on closer inspection and that the overlap in familial risk is likewise weak and not well founded. These authors have concluded that there is no basis for claiming that SLI and ASD are related at the behavioral symptom or etiologic level. They concluded that children with SLI present with a disorder that involves deficits in phonological working memory and grammatical development whereas children with autism have impairments in language use and social interactions as well as restricted interests and behaviors. Even in cases where there appears to be symptom overlap, such as with nonword repetition, the underlying reasons for poor repetition differs between the two groups. Thus, within this viewpoint we should expect that these are independent

Figure 19–1. Autism as a result of severe specific language impairment. As the severity of SLI increases, the odds of social difficulties increase.

SLI and Autism as independent conditions
Figure 19–4. SLI and autism as independent conditions where overlap is no greater than expected by chance.

disorders and that would only co-occur at levels expected by chance (see Figure 19-4).

It should be noted that these conclusions by Whitehouse and Bishop were reached prior to the publication of the data on *CNTNAP2*. As noted earlier, allelic variation in *CNTNAP2* is associated with autism and in particular age of first-word production in these children and it is also associated with phonological memory measured by nonword repetition in children with SLI. If *CNTNAP2* does confer liability for both autism and SLI, it would provide for quite strong support for these two conditions being comorbid. What remains unclear is whether *CNTNAP2* is a gene that influences a wide range of neural developmental phenotypes, or whether it impacts on brain systems that are particularly important for language.

Conclusion

For nearly three decades SLI has served as a model of developmental language disorder that can be examined without the influence of other developmental disorders. As researchers have approached SLI, we can find that some seem to make the assumption that SLI represents a unique form of poor language and thus the etiologic systems that underlie SLI are also unique to SLI and distinct from those that cause poor language development in children with other developmental disorders. Within this vein of thinking a full account of SLI will consist of a set of unique language features (markers) that map onto a unique etiologic system. Plomin once described this type of model for developmental disorders when applied to genetics as One Gene One Disorder (OGOD). In such a case we would also not expect overlap between SLI and other developmental disorders to exceed chance levels. If it does, we would need to consider that this is due to something analogous to phenocopy. The specificity of SLI in this model would also extend to its distinctiveness from individual differences within the normal population. The recent findings of an etiologic overlap in the form of similar risk alleles being shared between autism and SLI challenges this model of SLI.

These findings of overlap between SLI and autism suggest that we need to rethink our basic assumptions about SLI, and this rethinking may also have an impact on views of the language impairments in autism. An alternative perspective may be that that cutting across ability levels (poor, average, or high) and across various disability groups will be a common set of causal factors that account for an important fraction of the individual differences in children's development of language content and structure. This viewpoint was voiced by Leonard (1987), when he concluded that SLI is likely to represent the tail end of the normal distribution of language ability and is fully consistent with the quantitative trait locus model that Plomin (1994) described as an alternative. In this regard, it is quite possible to expect that etiologic factors such as risk variants of *CNTNAP2* will be found in excess in other populations with developmental language problems and indeed even will be found in typically developing children. These etiologies alone are most likely probabilistic rather than deterministic and it is only as they work in concert with other risk factors that different symptom complexes emerge.

Karmiloff-Smith (1992) has emphasized that development is complex and dynamic. Within this view developmental processes are clearly shared across children who are then growing up in diverse circumstances (biologically and culturally), thus there are likely to be shared and unique features across all children, and these may vary over development. It may be more important to focus on understanding these developmental processes as they generate differences and similarities across children throughout development. Such reconceptualization will hopefully lead to deeper insights into autism and SLI.

Challenges and Future Directions

- In order to directly test whether there is a subgroup of children with autism who also have SLI, research methods that have been developed to test for continuities or discontinuities in individual differences should be applied to this problem (see, for instance, Lenzenweger, 2004; Markon & Krueger, 2006; Ruscio et al., 2006).
- Parallel genetic studies of children with autism and children with SLI using high density SNP platforms for GWAS or nextgen sequencing for rare variants and carefully selected language phenotype and endophenotypes should provide a means to test for shared versus unique risk genetic variants.
- Parallel structural and functional imaging studies using children with autism and children with SLI.

Anxiety and Mood Disorders in Individuals with Autism Spectrum Disorder

⣿
Points of Interest

- To establish comorbidity, assessment measures must establish that anxiety/mood symptoms are independent of the core symptoms of ASD and are causing additional distress or impairment.
- Anxiety and mood disorders are more common in individuals with ASD than in the general population.
- Prevalence estimates for anxiety disorders range from 10 to 50%.
- Prevalence estimates for mood disorders range from 25 to 50%.
- When an individual with ASD presents with a significant change in behavior (e.g., increase in aggressive behavior; intensification of restricted interests), clinicians should be aware that anxiety and/or mood symptoms may be a contributing factor.
- Cognitive behavior therapy can be used successfully with individuals with ASD for the treatment of anxiety.

The social and communication deficits and restricted behavior that characterize autism spectrum disorders (ASD) make it challenging for affected individuals to navigate a complex social world. Too often individuals with ASD have the added stress of managing anxiety and mood problems. Considering how anxiety and depression can affect behavior in a typically developing person, it is easy to appreciate how the added burden of an internalizing disorder can impact the day to day functioning of individuals with ASD.

The study of anxiety and mood disorders is a relatively new area in the field of ASDs. For many years, it was thought that people with ASD could not express anxious or depressive symptoms, given that early estimates suggested more than 50% were nonverbal. More recently, DSM-IV has stipulated that comorbid anxiety and mood disorders could not be diagnosed in individuals with ASD. Such disorders were thought

to be part of the ASD phenotype or could not be assessed properly in individuals with ASD. This has had the unfortunate effect of not recognizing this type of comorbidity and the attendant impairment that it entails. Since treatment of anxiety and mood disorders has progressed remarkably in the last 10 years with now good evidence of effective treatments, it would be important to screen for and diagnose these conditions. Fortunately, many clinicians and researchers now recognize that comorbid psychiatric symptoms are a significant and often disabling issue for this population. The present chapter highlights a number of issues and questions that research is beginning to address:

1. How common are anxiety and affective disorders in the ASD population?
2. How do we assess and treat psychiatric comorbidity in this group?
3. What are the causes and correlates of anxiety and mood disorders for individuals with ASD?
4. What should clinicians and researchers do next to further our understanding of these issues?
5. What are the clinical implications of comorbidity for this population?

⣿
What Does Comorbidity Mean?

Before beginning a review of the literature, it is worth considering what comorbidity actually means. The term was originally coined by Feinstein (1970) to describe the co-occurrence of two diseases either by chance, by shared vulnerability, or by some common etiologic mechanism. There are two types of comorbidity: sequential and simultaneous. Simultaneous comorbidity refers to the co-occurrence of two disorders that arise at the same time. Sequential comorbidity refers to the situation when one disorder precedes another disorder. In this

circumstance, it is possible that one disorder is a true risk factor for the other disorder. However, it is also possible that the two disorders share a third, common, risk factor that gives rise to both. The distinction between simultaneous and sequential comorbidity is an important one, since the meaning of the comorbidity and its mechanism may be different in these two circumstances.

The determination of comorbidity can be confusing when this involves two psychiatric disorders. For example, individuals with autism often have symptoms of "sensory defensiveness"; that is, they put their hands over their ears, or get upset at the feel of certain clothes, or smells. These are not part of the diagnostic criteria for ASD or of any other disorder yet they may occur in other conditions as well. These might be considered associated symptoms or behaviors, but are not an example of comorbidity. Similarly, an individual with ASD may present with sadness, poor sleep, lack of motivation, and being a picky eater. The assessment of comorbidity must make a determination as to which of these symptoms is part of ASD, and which is part of a possible comorbid mood disorder. Poor sleep, lack of motivation, and being a picky eater are behaviors seen in both ASD and depression. How does one decide? The key is to determine whether there was a change over time in symptom presentation. If depression were a true diagnosis, then the symptoms of sadness, poor sleep, etc., would have to occur in a constellation, represent a change in behavior, and not be present from early in development.

In addition to observing a change in adaptive functioning, it is important to determine whether the symptoms are associated with added impairment over and above the primary diagnosis. An individual with ASD may develop new symptoms of depression and poor sleep, but unless those symptoms cause, or are associated with, extra impairment it is not possible to make another, comorbid diagnosis. ASD itself is associated with considerable impairment in terms of adaptive functioning and performance in certain roles. While a child with an ASD might have comorbid anxiety or mood symptoms, it can be difficult to establish whether or not the impairment associated with those symptoms is over and above the impairment due to autism itself. To meet criteria for a comorbid disorder, it is important that there be impairment specifically due to that comorbidity. Again, there must be a deterioration in adaptive functioning if a comorbid disorder occurs. This can often be hard to demonstrate if a person with ASD is already profoundly impaired due to his or her autism or intellectual disability.

Measurement

Quantitative research using questionnaire data has repeatedly shown that anxiety symptoms are more common in individuals with ASD than in the general population or controls with other developmental disabilities. When compared to the general population, anxiety symptoms are 3 to 4 times more common among high-functioning children with ASD than

their age- and sex-matched counterparts (Kim, Szatmari, Bryson, Streiner, & Wilson, 2000). Several studies have shown that anxiety symptoms are also more common among the ASD population than other clinical groups (e.g., non-ASD clinical controls, language impaired controls, IQ- and age-matched controls; Bradley et al., 2004; Gillott, Furniss, & Walter, 2001; Gillot & Standen, 2007; Weisbrot, Gadow, DeVincent, & Pomeroy, 2005).

The most reliable prevalence estimates of anxiety and affective *disorders* (as opposed to symptoms) are from studies using semistructured diagnostic interviews. Unlike self-report questionnaires, diagnostic interviews allow clinicians to probe for additional details to determine whether endorsed symptoms are sufficiently impairing and persistent to warrant a clinical diagnosis of a mood or anxiety disorder. The problem is that it is unclear whether the instruments that have been traditionally used to measure psychiatric disorder in typically developing children are appropriate for those with ASD. To date, two measures have been developed to assess psychiatric comorbidity specifically in the ASD population: The Schedule for the Assessment of Psychiatric Problems with Autism (and Other Developmental Disorders) (SAPPA; Bolton & Rutter, 1988) and the Autism Comorbidity Interview-Present and Lifetime Versions (ACI-PL; Leyfer, 2006).

The SAPPA is a semistructured interview used to assess psychiatric disturbances in individuals with an ASD. The SAPPA corresponds to the Research Diagnostic Criteria (RDC; Spitzer, Endicott, & Robins, 1978) with respect to major psychiatric disorders. The SAPPA is still under development but has been used in three follow-up studies (Bradley & Bolton, 2006; Hutton, 1998; McConnell et al., 2011). The primary purpose of the SAPPA is to identify an episode of *new* behaviors and/or symptoms that are independent of ASD-related symptoms exhibited since early development. The interviewer must first establish a baseline of behaviors to which any change in behavior or symptoms (an "episode" of change) is compared. In order for an "episode" of a psychiatric disorder to be deemed clinically significant, it must meet one of the following criteria: psychiatric symptoms (anxiety, mood, delusions, hallucinations, catatonia, etc.) that are present for at least 3 days, OR a change in behavior that is outside the range of normal variation for an individual, present for at least 1 week AND definite decline in level of social functioning as indicated by at least two of the following: loss of interest in "play," loss of self-care, loss of social participation, loss of initiative, need for change in supervision/placement.

The ACI-PL is a modified version of the Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS; Chambers et al., 1985), an instrument used to assess for the presence of psychiatric disorders in typically developing children and adolescents. The ACI-PL has been piloted in one study (Leyfer et al., 2006). The major modifications made to the KSADS to develop the ACI-PL include an introductory section to ascertain a baseline of emotional and behavioral functioning against which to evaluate psychiatric symptomatology. The administration of this instrument also includes descriptions of how

specific disorders typically present in children with ASD. The ACI-PL also attempts to assess whether certain symptoms are applicable to a particular child. For instance, if a child has not demonstrated an understanding of guilt in the past then asking questions about feelings of guilt in the context of depression is not appropriate (Leyfer et al., 2006).

Both the SAPPA and ACI-PL highlight the need to assess whether or not psychiatric symptoms are a departure from an individual's baseline level of functioning. There is also an emphasis on ensuring that the symptoms are causing significant and persistent impairment in functioning beyond the impairment caused by the ASD alone. Both can elicit information from the parent (or guardian) and the individual with ASD. A common problem is that many people with ASD are nonverbal and cannot be interviewed. In that situation, a reliance on behavioral manifestations of anxiety and depression as observed by a parent is warranted (Matson & Nebel-Schwalm, 2007; Matson et al., 1997). The approach used by the SAPPA and ACI-PL is theoretically appropriate and represents a movement toward establishing a gold standard for the assessment of comorbidity in the ASD population.

Prevalence

We carried out a systematic review to identify all the studies that reported on the comorbidity of anxiety and mood disorders in ASD (also see Wood et al., 2009, for a useful review). We specifically focused on papers that used diagnostic interviews to assess comorbidity. We also wished to provide a systematic review of studies discussing potential causes and correlates of comorbidity and treatment studies of the accompanying disorder. We were able to identify 8 studies that used a structured or semistructured approach to making a diagnosis. The prevalence estimates from these studies for specific disorders are summarized in Table 20-1 and described in more detail below.

Specific Phobias

In a sample of 44 children and adolescents with ASD, Muris et al. (1998) identified specific phobias in 63% of the sample, the highest estimate to date for any anxiety disorder. Other studies report prevalence estimates ranging from less than 10% to as high as 43% (Rumsey et al., 1985; Green et al., 2000; Klin et al., 2005).

It has been argued that fears and phobias are part of the ASD phenotype (Evans, Canavera, Kleinpeter, Maccubbin, & Taga, 2005). Using mental age–matched children, chronologically age-matched children, and children with Down syndrome as comparisons, Evans et al. (2005) explored what types of fears children with ASD exhibit and whether these fears are normative given their developmental level. They found that ASD children had more situational fears and more fears of medical situations. They also found that externalizing

problems (e.g., impulsivity, hyperactivity) were associated with these fears, whereas fears were "less symptomatic" in the other groups. Leyfer et al. (2006) also found discord between the types of fears endorsed by typically developing children and those with ASD. Such data suggest that certain fears may be part of the syndrome of ASD and not simply a developmental phase that the children will outgrow.

OCD

Estimates for OCD range from less than 10% to as high as 37% (Klin et al., 2005; Leyfer et al., 2006; McConnell et al., 2011). When assessing for the presence of obsessions and compulsions in individuals with ASD it can be difficult to ascertain if the symptoms have the required ego-dystonic quality. One must also be certain that obsessions do not merely reflect intense interests. Adherence to routines and rituals are also characteristic of ASD and needs to be distinguished from the anxiety-reducing compulsive behaviors seen in OCD. See Chapter 16 for a comprehensive discussion of OCD in the ASD population.

Social Phobia

Fear and avoidance of social situations and social awkwardness are extremely common in ASD. Prevalence estimates for social phobia range from 7 to 23% (Klin et al., 2005; Leyfer et al., 2006). Determining whether anxiety is attributable to the social (e.g., fear of negative evaluation or looking stupid) versus nonsocial (e.g., unfamiliar people, noise, change in routine) aspects of a situation is a critical distinction when making a diagnosis of social anxiety. On the other hand, it has been argued that poor social skills and increased awareness of social deficits in high-functioning individuals with ASD make them especially vulnerable to social anxiety (Meyer, Mundy, Van Hecke, & Durocher, 2006; Wing, 1981). Understanding the source of anxiety in social situations is, therefore, critical to making an appropriate diagnosis.

Generalized Anxiety Disorder (GAD)

In the first study of comorbidity in autism, Rumsey et al. (1985) reported symptoms of chronic generalized worry in half of an adult sample of men with autism. However, the worry symptoms were judged to be part of the autism symptomatology, and an additional diagnosis of GAD was not assigned. While subsequent studies report prevalence rates between 20 and 35% for GAD, a recent study reported GAD in only 2.4% of the study sample (Leyfer et al., 2006; see Table 20-1). Leyfer et al. described the anxiety exhibited by children in their sample as being more trait-like and less variable in content than one would expect from GAD. McConnell et al. reported much higher rates of GAD in a population of adolescents and young adults with high-functioning autism and Asperger's syndrome (AS). Further clinical research is needed to clarify the nature, chronicity, and variability of worry symptoms and how they manifest in the ASD population.

Table 20–1.

Summary of prevalence data on comorbid psychiatric disorders among individuals with autism spectrum disorders

Study	Sample Size	Age	Measure	Disorders	Percent

Panic Disorder

Reported rates for panic disorder are consistently below 10% (Leyfer et al., 2006; McConnell et al., 2011; Muris & Steerneman, 1998; Rumsey et al., 1985). Although some studies report discrete episodes of panic attacks among individuals with ASD, it appears that few evolve into full-blown panic disorder. A relatively high rate of agoraphobia (45%) was reported in the Muris and Steerneman sample, but no details regarding the nature of the anxiety were provided. Individuals with ASD may feel anxious in a variety of situations for a variety of reasons. Establishing whether anxiety is related to having panic symptoms is critical for establishing a diagnosis of agoraphobia. Clinically, a diagnosis of specific phobia may be more appropriate if the avoidance occurs in response to only a few specific situations.

Post Traumatic Stress Disorder (PTSD)

Few studies have looked at the rates of PTSD in the ASD population. Our study identified a single case triggered by severe bullying at school (McConnell et al., 2011).

Mood Disorders

The rates for mood disorders are also high in the ASD population. In a sample of adolescents with Asperger's syndrome, 25% were found to have chronically low mood or dysthymia (Green et al., 2000). Klin et al. (2005) diagnosed depression in 34% of a sample of adolescents and young adults with ASD. In a population-based study comparing the rate of psychiatric disturbances between individuals with mental retardation with and without autism, 50% of the autism group was diagnosed with depression (Bradley, Summers, Wood, & Bryson, 2004). The rate of mood disorders in the McConnell sample was 31% (n = 22/70). Depression was the most common mood disorder diagnosed in the sample (n = 20), but dysthymia was also reported (n = 6). No episodes of mania or hypomania were identified.

Summary

As seen in Table 20-1, there is significant variability in prevalence estimates for anxiety and affective disorders in the ASD population. Depending on the specific disorder, estimates range from approximately 10% to 63% (Bradley & Bolton, 2006; Green, Gilchrist, Burton, & Cox, 2000; Klin, Pauls, Schultz, & Volkmar, 2005; Leyfer, et al, 2006; Muris & Steerneman, 1998; Szatmari, Bartolucci, & Bremner, 1989). The range in prevalence estimates is due, in part, to variability in the criteria for judging whether or not a symptom is independent of the ASD diagnosis. In addition, the lack of a truly valid and reliable instrument to assess for psychiatric disorders in the ASD population makes the data difficult to summarize and interpret in a meaningful way, even when diagnostic interviews are used by experienced clinicians.

Among the ASD population with a diagnosed Axis-I disorder, rates of multiple disorders are not uncommon. For example, in the McConnell et al. study (2011), 41% had more than one such diagnosis. Anxiety and mood disorders had the highest rate of co-occurrence, with 21% of the sample meeting criteria for both. In addition, nearly half the cases with comorbid anxiety and mood disorders had an additional diagnosis of an externalizing disorder (i.e., ADHD, conduct disorder, or oppositional disorder). By comparison, only one third of the cases diagnosed with an externalizing disorder did not have a comorbid diagnosis of an anxiety and/or mood disorder. Thus, behavioral problems occurred predominantly in the presence of clinically significant persistent anxiety and/or affective symptoms.

Research with typically developing teens presenting with depression has also shown a high rate of comorbidity between depression and aggressive behavior (Knox, King, Hanna, Logan, & Ghaziuddin, 2000). Given the frequency with which children and adolescents with ASDs are treated for behavioral problems, it is important to consider that anxiety and/or mood symptoms may be important factors in the development of aggressive behavior in adolescence and young adulthood. Otherwise, interventions may be misguided by failing to also target the underlying internalizing disorders.

This pattern of comorbidity is commonly seen in psychiatric clinics among adolescents without ASDs. But it is interesting to speculate on how the clinical manifestations of anxiety and mood disorders are modified by the ASD. It is unfortunate that few studies have reported on the manifestations of anxiety and mood disorders in the ASD population and how the ASD phenotype is modified by the comorbid disorder. Anecdotally, McConnell et al. (2011) saw that children with anxiety and mood disorders tended to demonstrate an increase in their restricted interests and preoccupations. This led to more social withdrawal and apparent apathy. Anxiety was also associated with more repetitive questioning and ruminating over worries, concerns, and past events. Both the anxiety and mood disorders were frequently associated with pacing, inappropriate laughter and sleep disturbance. Aggressive behavior of a reactive nature, often in response to teasing and bullying at school or to limitations imposed at home, were frequent in those who had anxiety and depression.

Causes and Correlates

Finally, it is not known whether risk factors for anxiety and mood disorders are specific to ASD or similar to those reported in other adolescents with similar disorders. Very little is known about the correlates of mood disorders in ASD children, and only a few studies report on correlates for comorbid anxiety disorder. It has been reported that adolescents with ASDs who are depressed have a higher frequency of a family history of depression and more negative life events than ASD adolescents without mood disorder (Ghaziuddin, Alessi, &

Greden, 1995; Ghaziuddin & Greden, 1998). While it may be true that a family history of depression and negative life events might be associated with depression in this population, these correlates do not explain why such comorbid disorders are more common in this group than in the general population (unless the mood problems are indeed more common in their parents and are genetically transmitted). To understand specifically why such comorbid disorders might be particularly prevalent one needs to think of characteristics of ASD children that could be associated with increased risk.

IQ

Several studies have found that higher IQ is associated with greater levels of anxiety and depressive symptoms in children and adults with ASD (Gadow et al., 2008; Lecavalier et al., 2006; Sterling, Dawson, Estes, & Greenson, 2007; Sukhodolsky et al., 2008; Weisbrot et al., 2005). This does not imply that lower functioning individuals are unaffected but does suggest a degree of heterogeneity within the ASD population. Such heterogeneity may be mediated by a number of additional factors. For example, Sukhodolsky et al. (2008) found that anxiety was not only associated with higher IQ but with the presence of functional language and more stereotyped behavior. The same study also found that higher IQ *combined* with greater impairment in social reciprocity led to more severe anxiety. Interestingly, social phobia and specific phobia occurred with equal frequency in the lower and higher IQ groups. One implication of this finding, as suggested by Sukhodolsky et al., is that these two disorders are more a part of the core phenotype of ASD compared to other disorders.

Stressors

Gillot and Standen (2007) found high levels of anxiety to be associated with certain types of stressors, including sensory stimuli, anticipation, coping with change, and unpleasant events. Individuals with higher levels of anxiety were less capable of coping with these stressors. During the diagnostic interview, McConnell et al. (2011) made notes regarding precipitating events, if any, of depressive episodes. Participants reported a variety of events, including moving, death of a family member, loss of significant relationships, and bullying. Their findings are consistent with previous research indicating that life stressors contribute to the onset of depression in individuals with ASD (Ghaziuddin, Alessi, & Greden, 1995), just as they do in typically developing individuals (Kendler, Karkowski, & Prescott, 1999). Anecdotal evidence suggests that teasing and bullying experienced at school were particularly important background factors in the precipitation of the anxiety and mood disorders.

Social Information Processing

Although social impairments are characteristic of ASD, that does not mean that affected individuals lack awareness of social situations or their own limitations. On the contrary, research suggests that many children with ASD are capable of self-reporting social difficulties and are sensitive to the reactions of others (Meyer et al., 2006; Wing, 1981). Furthermore, it may be that increased social awareness in high functioning individuals with ASD makes such individuals especially vulnerable to anxiety and mood problems (Sterling, Dawson, Estes, & Greenson, 2007; Wing, 1981). An emerging area of research attempts to identify the types of social information processing deficits that may contribute to this vulnerability (Hedley & Young, 2006; Meyer, Mundy, Van Heckem, & Durocher, 2006). Hedley and Young (2006) found an association between depressive symptoms and a measure of social comparison. Specifically, adolescents with AS who rated themselves as "more different" than others also reported greater depressive symptomatology. Other research suggests an association between the social information processing patterns of adolescents with AS and anxiety and mood symptoms (Meyer et al., 2006). For example, a tendency toward social encoding errors and hostile intent attributions was associated with greater comorbidity.

Treatment

Psychological Intervention

Cognitive behavior therapy (CBT) is recognized as an effective treatment for anxiety and mood disorders in both adults and children without ASD. Adapting CBT for use with the ASD population has been attempted in several case studies with positive results (Cardaciotto & Herbert, 2004; Hare, 1997; Reaven & Hepburn, 2003).

Using a CBT protocol developed for use with adults with social phobia, Cardaciotto and Herbert (2004) describe only minor modifications to the treatment plan for a 23-year-old male with Asperger's syndrome. In addition to exposure exercises and cognitive therapy, the social skill deficits of the participant were identified and targeted in treatment. Appropriate verbal and nonverbal social skills were explained and rehearsed in session. Following treatment, the participant continued to report fear in social situations but experienced a reduction in anxiety symptoms. The participant also reported less impairment and avoidance in response to his fears.

Reaven and Hepburn (2003) reported successfully treating a 7-year-old female with AS for OCD. A comprehensive assessment distinguished obsessions and compulsions (e.g., contamination obsessions, "need to know") from the child's intense interests and preoccupations. The CBT protocol was adapted principally from March and Mulle (1998) and is outlined in the article. Reaven and Hepburn (2003) also discuss the types of modifications that may be necessary when undertaking CBT with children with ASD. These include the liberal use of visual supports to reinforce intervention strategies and the involvement of parents to maximize the generalization of strategies learned in treatment.

While case reports are useful preliminary steps toward identifying potentially effective treatment for anxiety and mood difficulties in individuals with ASD, more rigorous methods are required to assess efficacy. To date, the literature includes two randomized controlled trials of CBT in a group of children with Asperger's syndrome or ASD (Sofronoff, Attwood, & Hinton, 2005; Wood et al., 2009). Children in the first study were identified with anxiety through questionnaires and assigned to one of two treatment groups (Sofronoff et al., 2005); a child-only treatment group and a child and parent treatment group in which the parent was trained as a cotherapist. A waitlist control group was also included in the study. The treatment protocol included a variety of CBT techniques that have shown effectiveness with typically developing children with anxiety. Relative to a waitlist control group, both intervention groups showed significant reductions in anxiety levels. In the study by Wood et al. (2009), 47 children with ASD were randomized to receive a modified form of CBT or waitlist control condition. The experimental group received 16 sessions consisting of behavioral experimentation, parent training, and school consultation. At the end of treatment, 78.5% of the experimental group had made a clinically significant improvement compared to 8.7% in the control group (number needed to treat = 2). These results are consistent with research evaluating interventions with typically developing children, which has shown that including both the child and parent in the treatment process leads to greater improvements.

Pharmacological Intervention

The issue of medication efficacy is complex. There is now reasonably good evidence that antidepressants such as selective serotonin reuptake inhibitors are effective among typical children and youth with anxiety disorders and major depression (Hetrick, Merry, McKenzie, Sindahl, & Proctor, 2007). There is a concern about increased suicidal *thinking* (Olfson & Shaffer, 2007) but no evidence of more suicide *attempts* on SSRIs than placebos. Whether or not medications are more effective than CBT is somewhat unclear. There are no controlled clinical trials of SSRIs to treat depression or anxiety when it is comorbid with ASD. Kolevzon et al. (2006) recently published a comprehensive systematic review of SSRIs in ASD and concluded that although the quality of the evidence is poor and more rigorous studies are required, there is some evidence that SSRIs can reduce significant anxiety symptoms in ASD.

Conclusions

The prevalence data presented in this review highlight the importance of doing a systematic assessment for comorbid anxiety and mood disorders in children and adolescents with ASD who present with a change in behavior. Clinicians must be alert for episodes of depression, especially in those who present with significant anxiety symptoms, increased aggressive behavior, and/or intensifying restricted interests and preoccupations. Anecdotal evidence suggests the importance of ensuring that the social context for these adolescents and young adults remains supportive and encouraging. To prevent the development of a comorbid disorder, it may now be time to focus on *changing* the social context of the adolescent with ASD rather than attempting to "treat" the ASD as service providers did during childhood. If a comorbid anxiety or mood disorder does occur, there is now some evidence for the usefulness of medication as well as cognitive behavior therapy (Sofronoff et al.; Cardaciotto & Herbert, 2004; Wood et al., 2009). Health care professionals working in the field of developmental disabilities will need to develop skills in this form of treatment. In addition, mental health professionals can no longer justify excluding ASD youth and adults from the benefits of their services. Finally, perhaps it is ironic to point out that while those with good language and nonverbal problem-solving skills have a better outcome when it comes to autistic symptoms and overall adaptation they appear to be at higher risk for often debilitating anxiety and mood disorder. It's as if this particularly vulnerable population of high-functioning adolescents with ASD cannot win in their developmental struggles!

Challenges and Future Directions

- Ensuring that we have reliable ways to assess for psychiatric comorbidity in this vulnerable population should be a primary goal for future research. Both the SAPPA and ACI-PL are promising measures but the development of consensus guidelines detailing how anxiety and mood disorders present in the ASD population are essential and outstanding.
- We also need consensus guidelines to address two questions paramount to making a valid and reliable clinical diagnosis: (1) Is the anxiety/mood symptom independent of the core symptoms of ASD? (2) Is the anxiety/mood symptom causing significant distress or impairment above and beyond that caused by the ASD diagnosis? The majority of studies have relied on measures validated on the typically developing population. The problem with relying exclusively on such measures is the lack of consideration for how anxiety presents in individuals with ASD and how some core features of ASD can be mistakenly attributed to other disorders (e.g., distinguishing between preoccupations and obsessions). Only once guidelines are established and reliable measures become available can we compare studies in a meaningful manner.
- As seen in Table 20-1, there is great variability in prevalence estimates and only eight studies from which to draw conclusions. There is clearly a need for more clinical research using diagnostic interviews and comparison groups.

As much as possible, researchers need to provide clinical details to convey how critical distinctions are made in the diagnostic process (e.g., distinguishing obsessions from preoccupations; judging whether symptoms cause significant distress/impairment). As assessment methods and measures are refined, consistency between prevalence estimates will no doubt emerge.

- Another important area of research is studying the development of comorbid anxiety and mood symptoms over time. We were not able to identify any longitudinal studies that investigate the developmental trajectories of these symptoms from early childhood to adolescence. This is critical in understanding the earliest manifestations of the comorbidity and in developing early interventions to reduce further morbidity.

Stereotypy and Self-Injury

Points of Interest

- Stereotypy and self-injury are behaviors commonly associated with a number of developmental disorders, including autism spectrum disorders.
- A variety of neurological systems have been implicated in the expression of stereotypy and self-injury, particularly the dopaminergic, opioidergic, and glutamatergic systems.
- Animal models provide insight into putative neurological mechanisms and social/emotional factors that may contribute to the development and maintenance of stereotypy and self-injury.
- It has been demonstrated that impoverished environments and sensory deprivation can impact the development of stereotypy and self-injury in a variety of animal species, including humans.
- Pharmacological and behavioral treatments have been somewhat efficacious in ameliorating stereotypy and self-injury, though much work still needs to be done to successfully target these symptoms.

Stereotypy is a core feature of autistic disorder and refers to behavior(s) that are typically repetitive and nonfunctional or non–goal directed (Berkson, 1967). A child might cock her head and look out of the corner of her eyes at her hand while she waves it side to side in front of a ceiling light. Another may hold a string between his thumb and index finger and appear to become lost in its dance as he wiggles it rapidly up and down or from side to side. He may turn a toy car upside down and incessantly spin its wheels rather than play with it as intended.

"A low grade… child [with profound intellectual disability who] would rush about, leaping over or knocking against articles of furniture, or dashing her head against the walls or floor, so that, if left alone for a minute or two her face and hands would be hurt and bruised. Along with motor restlessness there was often a strange indifference to pain." From Ireland, 1898.

Some stereotyped behaviors are associated with tissue damage; for example, repetitive licking can cause dry, cracked skin. Other behaviors appear to be quite specifically designed to cause injury—like head banging and face slapping and have been described in case reports dating back over a century (e.g., Ireland, 1898). These behaviors pose a serious risk of bodily tissue damage and increase the risk of hospitalization. They can also lead to intensive and possibly restrictive special education programming, reduced opportunities for social interactions, and physical restraint. Significant medical problems can also arise as a result of self-injurious behaviors such as cataracts, retinal detachment, permanent scars, contusions, soft tissue lacerations, and even death. Among families affected by autism, higher repetitive behaviors increase perceived stress on families (Bishop et al., 2007). The effect of self-injurious behaviors on families and care providers can be absolutely overwhelming.

For all of these behaviors, the fact that they are repetitive and seem so compelling perhaps begs the question of how they can be truly "non–goal directed." Indeed, stereotyped behaviors are typically discriminated from involuntary movements like tics because they are more rhythmic and under some measure of voluntary control (e.g., Crosland et al., 2005).

Additional confusion about the nonfunctional nature of these behaviors might also derive from the fact that stereotypy exists on a continuum and within a context. The child who incessantly bounces a ball on the pavement despite the complaints of neighbors may be internally motivated to hone his basketball skills, or reinforced by the sight or sound or feel of the activity, or even by the psychological impact he is having on the neighborhood. It is thus perhaps more accurate to suggest for stereotypy that the goals of the behavior are not always

immediately apparent or that they are atypical or uniquely held. However, it is also the case that certain environmental and physiological factors are likely to increase the probability for expression of stereotypy that is regarded as pathological because of its intensity and interference. In this chapter we will review the biology and treatment of stereotypy with a focus on stereotyped self-injury as an extreme manifestation of this behavior.

Definitions of Stereotypy and SIB

As noted earlier, over the past several decades, definitions of stereotypy have incorporated both a description of the behavior—as repetitive, topographically invariant, and often rhythmical—as well as purposeless (Baumeister & Rollings, 1976; LaGrow & Repp, 1984).

> **Stereotypy**: behavior that is repetitive, topographically invariant, often rhythmical, and seemingly without purpose.

This latter qualifier allows one to discriminate stereotyped basketball bouncing from basketball practice; to discriminate stereotyped hair twirling from grooming; string wiggling from untangling; pacing from ambulating. The *Diagnostic and Statistical Manual of Mental Disorders-4th Edition-Text Revision* (DSM-IV-TR; APA, 2000) highlights hand or finger flapping

Table 21–1.
DSM-IV-TR Diagnostic criteria for stereotypic movement disorder

A. Repetitive, seemingly driven, and nonfunctional motor behavior (e.g., hand shaking or waving, body rocking, head banging, mouthing of objects, self-biting, picking at skin or bodily orifices, hitting own body).

B. The behavior markedly interferes with normal activities or results in self-inflicted bodily injury that requires medical treatment (or would result in an injury if preventive measures were not used).

C. If mental retardation is present, the stereotypic or self-injurious behavior is of sufficient severity to become a focus of treatment.

D. The behavior is not better accounted for by a compulsion (as in obsessive-compulsive disorder), a tic (as in tic disorder), a stereotypy that is part of a pervasive developmental disorder, or hair pulling (as in trichotillomania).

E. The behavior is not due to the direct physiological effects of a substance or a general medical condition.

F. The behavior persists for 4 weeks or longer.

Specify if:

With self-injurious behavior: if the behavior results in bodily damage that requires specific treatment (or that would result in bodily damage if protective measures were not used).

and complex whole-body movements in the diagnostic criteria for autism as well as a variety of other examples in the criteria for stereotypic movement disorder (Table 21-1). Although some behaviors, for instance, amphetamine-induced stereotypies in the rat (Fowler et al., 2003), and body rocking in humans (Ross, Yu, & Kropla, 1998) are highly rhythmic, not all stereotyped acts are consistently so. Repetitive hitting may occur at different rates and even involve different targets. Although a potentially helpful discrimination between perseveration and stereotypy has been suggested as a function of whether the behavior involves excessive activity (Ridley, 1994), this distinction is complicated. In practice, stereotypy invariably reduces other, typically more adaptive behaviors because of their mutual incompatibility. Thus, stereotypy is virtually always perseverative, but a perseveration may not be stereotyped.

DSM-IV-TR incorporates all of the above features in the diagnostic criteria for stereotypic movement disorder (Table 21-1). In this definition, the fact that stereotyped movements can occur in the context of intellectual disability, or in conditions other than an autism spectrum disorder, is highlighted by exclusions. For example, criterion C allows for concurrent diagnoses of mental retardation and stereotypic movement disorder only when the latter behavior becomes a focus of treatment. And criterion D essentially allows for the diagnosis of a pervasive developmental disorder to absorb the presence of stereotypic movement disorder. However, because self-injurious behavior, and even intense stereotypy that may be a focus of treatment, is not necessarily clear from the diagnosis of autism alone, it is best to utilize this diagnosis in autism when all other criteria are met (e.g., "stereotypic movement disorder with self-injurious behavior" should be included as a diagnosis in addition to an ASD if the stereotypic behavior is a focus of treatment).

Relationship Between Stereotypy and SIB

Self-injurious behavior (SIB) has long been viewed as occurring on a continuum of other stereotyped behaviors. Some early stereotypy scoring conventions in animal models place self-injurious behavior at the extreme end of the scale. In humans, stereotypy is regarded as a precursor of SIB (Schroeder et al., 1990; Richman & Lindauer, 2005), and SIB is viewed as an extreme manifestation of stereotypy (Gal, Dyck, & Passmore, 2009).

Prevalence of Stereotypy and SIB

Studies that have examined the prevalence of stereotypy are influenced by sampling strategies, but rates can be upward of 30% in institutional settings (Dura, Mulick, & Rasnake, 1987). The prevalence of self-injury in people with intellectual disabilities also varies, and estimates between 4%
Figure 21–1. Relationship between severity of intellectual disability and severity of self-injurious behavior (SIB) as assessed by total score on the SIB items of the Aberrant Behavior Scale in an institutional setting.

Figure 21–2. Lesion on the dorsum of the paw from self-biting in a rat treated with pemoline. (See Color Plate Section for a color version of this figure.)

(Oliver, Hall, Hales, Murphy, & Watts, 1998) and 16% (Schroeder, Rojahn, & Oldenquist, 1991) have been reported. Several years ago, King and colleagues surveyed a large institutional setting of adults with mostly severe to profound intellectual disability in the context of a study looking at the relationship between whole blood serotonin and behavior. Caretakers completed the Aberrant Behavior Checklist (ABC) on 358 residents. The total scores on the three items of the ABC provide a sense of the distribution of SIB as it relates to severity of intellectual disability.

Thelen's (1981) seminal work demonstrated that stereotyped behaviors are part of typical development, and may help infants to gain motor mastery. Students taking exams commonly exhibit stereotyped mannerisms presumed to reflect or to allay anxiety (Rafaeli-Mor, Foster, & Berkson, 1999).

In genetic syndromes such as Lesch-Nyhan, Prader-Willi, Cornelia de Lange, Cri du Chat, and Smith-Magenis, self-injury is common (and in some cases so frequent as to be considered part of the clinical manifestations of the disorder itself), while in people with other disabilities such as Down syndrome, SIB appears to be more associated with severity of intellectual disability than with trisomy 21 per se. Both visual and auditory sensory impairment increase the likelihood of stereotypy and self-injury (Troster, Brambring, & Beelman, 1991; Bachara & Phelan, 1980; Murdoch, 1996; McHugh & Pyfer, 1999; Gal, Dyck, & Passmore, 2009), as discussed in more detail below.

Predisposing Factors and Biology of SIB

As suggested above, many conditions have been associated with stereotyped SIB, including specific genetic disorders, intellectual disability more broadly, sensory impairment, and severe deprivation and neglect. There are also more purely psychological constructs for repetitive self-injury, but all invoke a failure of self-regulation with attendant neurophysiological

underpinnings. Experience from the use of pharmacological agents, animal models, and patients in clinical settings exhibiting stereotypy and self-injurious behavior (SIB) advances our understanding of potential underlying neurobiological processes involved in its expression.

Neuropharmacology of Stereotypy and SIB

In the 1960s, stereotypic behaviors were reported in people abusing amphetamine (e.g., Ellinwood, 1967), prompting researchers to explore the role of agents that stimulate the central nervous system (CNS) in the expression of repetitive motor behavior (Lewis, Gluck, Bodfish, Beauchamp, & Mailman, 1996). Because amphetamines increase the concentration of dopamine at the synapse, understanding dopamine function in the production of stereotypy became a logical focus of research. As reviewed by King (2002), a number of such dopaminergic manipulations have been explored. Experimenter-induced dopaminergic lesions, for example, through administration of neurotoxins such as 6-hydroxy-dopamine (6-OHDA), have been conducted in attempts to isolate brain regions or systems related to the etiology or expression of stereotypy and self-injury.

In one of the earliest such studies, 6-OHDA was injected bilaterally into the substantia nigra of young adult male rats (Ungerstedt, 1968). Subsequent injection of a single dose of the dopamine agonist apormorphine 3 days later resulted in stereotypy and SIB—including violent self-biting and compulsive gnawing. Similar behaviors, then characterized as *self-aggressiveness,* were observed in mice and rats administered high doses of the stimulant 5-phenyl-2-imino-4oxo-oxazoli-dine, or pemoline (Genovese, Napoli, & Bolego-Zonta, 1969). Pemoline has subsequently been used in a number of studies to investigate drug-induced repetitive behavior in animal models (King, 2002; Muehlmann, Brown, & Devine, 2008).

These behavioral effects were first described in detail in rats by Mueller and Hsiao (1980). Injection of high doses of pemoline resulted in persistent self-biting (primarily of the medial foreleg) and stereotypy, as well as other behaviors including hyperactivity, abnormal social and sensorimotor behavior, and unresponsiveness or avoidance of moderate levels of sensory stimuli. These behaviors appeared in as few as 3 hours or as many as 2 days, and persisted despite a variety of efforts to interrupt the behavior including prodding with a cotton swab, presentation of highly palatable food, the introduction of a nondrugged cagemate, banging on the cage with a metal can, or even dousing with water. Mueller and Hsiao (1980) noted that the pemoline-induced biting response was similar to certain aspects of the normal grooming sequence exhibited by rodents. Specifically, areas groomed initially in a typical sequence were the areas of most likely injury. Therefore, the authors posited that the pemoline-induced self-biting behavior was a fragmented grooming response. Because pemoline-induced behaviors, including hyperactivity, stereotypy, abnormal social behavior, avoidance of physical contact, and grooming-associated self-mutilation, are similar to those observed in the de Lange (Mueller & Hsiao, 1980) or Lesch-Nyhan syndromes (Mueller & Nyhan, 1982), pemoline was an early rodent model utilized to elucidate self-injury in individuals with mental retardation.

In a more recent study examining the relation between stereotypy and the dopaminergic system in humans, Bodfish and colleagues (1995) measured blink rates in individuals with intellectual disability and repetitive behavior disorders versus control subjects. Previous evidence has implicated the dopamine system in the regulation of spontaneous eye blinks in humans, as documented in individuals with dopamine-related pathologies. For example, persons with Parkinsonism have decreased dopamine levels, and have lower blink rates (Karson, 1983; Karson et al., 1984), while patients with schizophrenia, and presumably increased dopamine levels, demonstrate higher blink rates (Mackert et al., 1991). Using eye blink rate as a dependent variable of dopaminergic function, Bodfish and colleagues (1995) found that individuals with stereotypy exhibited lower blink rates than the control group, providing further evidence for the role of the dopaminergic system in stereotypic behavior in humans.

Taken together, the directionality of impaired dopaminergic function (e.g., enhanced or diminished), and its relationship to stereotypy, is perplexing. Stereotypy appears to be associated both with increased synaptic concentrations of dopamine (e.g., amphetamine abuse) and also decreased synaptic concentrations of dopamine and consequent increased sensitivity of dopamine receptors. Thus, dopamine-induced stereotypy can be attenuated using dopamine antagonists, such as haloperidol, in primates (Ridley, Baker, & Scraggs, 1979). Many clinical reports demonstrate successes with the use of dopamine antagonists for stereotyped behavior and/or self-injurious behaviors (King, 2000). Largely as a result of the Research Units on Pediatric Pharmacology (RUPP) trial (RUPP, 2002), the atypical antipsychotic and dopamine antagonist risperidone has an FDA approved indication for the treatment of behaviors including self-injury in autism.

At the same time, pharmacologically induced stereotyped behavior also responds to manipulations of other neurotransmitters, calling into question the specificity of the role of dopamine. In both the pemoline and 6-OHDA models of self-biting behavior, glutamatergic antagonists have been shown to exert important effects to prevent the emergence of self-injury (King et al., 1998; Muehlmann & Devine, 2008). Evidence suggests dopaminergic and glutamatergic interactions in the neostriatum play a role in the development and expression of self-biting in the pemoline model (King et al., 1998). The potential utility of glutamate antagonists in treating SIB and related behaviors remains a focus of research, but while clinical case reports of successes with drugs like dextromethorphan and lamotrigine (Welch & Sovner, 1992; Davanzo & King, 1996) have been described, no controlled trials with these or related agents have been undertaken.

The opiate system has long been implicated in the expression of stereotypy with early observations of morphine-induced behavior (Ayhan & Randrup, 1972; Charness, Amit, & Taylor, 1975). Subsequent studies linked opiate-induced stereotypy with both dopaminergic and glutamatergic effects (Feigenbaum & Yanai, 1984; Capone et al., 2008). However, given the role of the endogenous opioid system in pain responsivity and brain reward mechanisms (reviewed in Harris, 1992), it has been posited that repeated SIB could be associated with increased release of endogenous opioid peptides that inhibit pain, leading to opioid-mediated reward (e.g., Sandman, 1988). Self-injurious behavior might thus be a means of self-administering opioid peptides. In clinical observations made over a century ago (Ireland, 1898) and subsequently (Symons, 2002) it has also been suggested that individuals with developmental disabilities such as autism have altered pain sensitivity or responsivity that may be related to the opioid system (Gillberg, 1995). However, reports are inconsistent, with some findings indicating normal response to pain in individuals with autism (e.g., Nader, Oberlander, Chambers, & Craig, 2004). Further, the ability to discriminate atypical pain perception from an atypical pain response (including an atypical affective response) is a significant challenge in autism.

If endogenous opioid release reinforces or maintains SIB, then blocking the effects of opioids with antagonists could interrupt this cycle. Many clinical studies have examined naltrexone in this regard. A literature review of 27 research articles (Symons, Thompson, & Rodriguez, 2004) revealed that treatment with naltrexone improved symptoms relative to baseline in 80 percent of subjects. Fifty-three percent of subjects showing improvement in SIB had a diagnosis of autism. An additional review of 3 case reports, 8 case series, and 14 clinical studies suggests naltrexone treatment is generally efficacious in treating SIB in autism (Elchaar, Maisch, Augusto, & Wehring, 2006). Other reviews (e.g., King, 2000) have indicated mixed results for the efficacy of naltrexone in treating SIB, including the results of larger controlled trials;

heterogeneous findings may reflect inconsistencies in study design and symptoms measured.

Self-injurious behavior and stereotypy have also been associated with serotonin function in human and nonhuman primates. As reviewed by King and colleagues (1998), hypotheses regarding the role of serotonin in SIB developed in the 1970s were based on animal studies demonstrating that the administration of serotonin agonists attenuate aggressive behavior. More recently, it has been shown that in small rodents called bank voles, administration of citalopram, a selective serotonin reuptake inhibitor (SSRI), prevents the increase of stereotypy after stress (Schoenecker & Heller, 2001). However, reports have failed to show evidence of altered serotonin system function in rhesus monkeys with SIB (Tiefenbacher, Davenport, Novak, Pouliot, & Meyer, 2003; Weld et al., 1998). A number of studies have reported reduced serotonin function in human patients with psychiatric illness (e.g., personality disorder, depression, bulimia nervosa) and with history of self-injurious behavior (New et al., 1997; Herpertz, Steinmeyer, Marx, Oidtmann, & Sass, 1995; Rinne, Westenberg, den Boer, & van den Brink, 2000; Steiger et al., 2001). Case reports and open label trials of treatment with the SSRIs, including sertraline (Hellings, Kelley, Gabrielli, Kilgore, & Shah, 1996) and fluoxetine (Cook, Rowlett, Jaselskis, & Leventhal, 1992; King, 1991; Markowitz, 1992) have been moderately effective in improving self-injury in adults with autism and mental retardation. Notably, dysregulation of the serotonin system has long been reported in autism (see Chapter 32, this volume, for review). A review of the literature, including 2 controlled trials and 10 open-label trials or chart reviews revealed SSRIs have been somewhat efficacious in improving global functioning in individuals with autism (Kolevzon, Mathewson, & Hollander, 2006), but a recent large study was negative (King et al., 2009). Interestingly, it has been proposed that serotonin levels are more specifically related to SIB and aggression, which are common features of autism, rather than to the core features comprising the full syndrome of autism (Schroeder et al., 2001).

Impoverished Environments and Social/ Sensory Deprivation on the Development of Stereotypy and SIB

A variety of animal species demonstrate stereotypic or self-injurious behavior when housed in confined environments, including zoo enclosures and standard laboratory cages (e.g., Harris, 1992; Hosey & Skyner, 2007; Marriner & Drickamer, 1994; Wolfer et al., 2004; Würbel, 2001), perhaps because captivity hinders ability to appropriately adjust to the environment by engaging in species-specific behaviors. For example, a variety of rodents caged as research models engage in bar-mouthing (Cooper, Odberg, & Nicol, 1996; Garner & Mason, 2002; Nevison, Hurst, & Barnard, 1999; Powell, et al., 1999); parrots demonstrate oral and locomotor stereotypies when

housed in impoverished conditions (Meehan, Garner, & Mench, 2004); horses housed in a confined stable or barn exhibit stereotypic behavior, including crib-biting, weaving, and box walking (Bachmann, Audigé, & Stauffacher, 2003; Waters, Nicol, & French, 2002); nonhuman primates demonstrate stereotypic and self-injurious behavior when housed in captivity (Lutz, Well, & Novak, 2003; Tarou, Bloomsmith, & Maple, 2005). Self-injury in nonhuman primates usually consists of self-biting, where rips and slashes of the skin or muscle may occur (Novak et al., 1998).

Nonhuman primates also exhibit stereotyped and self-injurious behaviors as a consequence of social deprivation (e.g., Harlow, Dodsworth, & Harlow, 1965). In his classic early experiments, Harlow and his colleagues (1965) described the emergence of "autistic self-clutching and rocking" behavior when monkeys were housed in total social isolation. Others have observed similar phenomena. For example, increased amount of time spent in individual cages was associated with self-injury, self-biting, hair-pulling, body-flipping, and swinging in rhesus monkeys (Lutz et al., 2003); greater amount of time spent singly housed (separate from their mothers) during infant and juvenile periods was significantly related to development of abnormal behaviors, including locomotor stereotypies and self-injury (Bellanca & Crockett, 2002). Similarly, rhesus monkeys reared by artificial surrogates were significantly more likely to self-bite than monkeys reared by peers or mothers (Lutz, Davis, Ruggiero, & Suomi, 2007).

Evidence suggests that humans are also susceptible to the development of stereotypy as a result of social deprivation. Children reared in orphanages with a paucity of caregiver social-emotional interactions and limited opportunity to develop relationships with their caregiver exhibit a variety of developmental delays. Drawing on theories of infant-mother attachment (e.g., Ainsworth, 1979), it has been proposed that early experience devoid of warm, nurturing, and socially-emotionally responsive adults is related to problem behavior and delayed development of appropriate social-emotional behavior. As summarized by the St. Petersburg-USA Orphanage Research Team (2008), research compiled over six decades across a number of countries has demonstrated that children reared in severely deficient institutional environments demonstrate delays in physical growth and general behavior development, and engage in atypical behavior, including stereotyped self-stimulation. While conditions vary across orphanages, according to Rutter (1999), the institutionalized children typically "remained in cots all day, had few if any toys or playthings, and were fed gruel through bottles with large teats (often left propped up for self-feeding); there was no personalised caregiving and very little talk or interaction with caregivers" (p. 538). A number of reports have suggested that a subset of children reared in such conditions display behaviors consistent with an autism spectrum disorder, including difficulty establishing friendships, developing empathy, using eye contact and gestures appropriately, and lack of proper language development and ability to engage in reciprocal conversation (e.g., Hoksbergen, ter Laak, Rijk, van Dijkum, & Stoutjesdijk, 2005;

Rutter et al., 1999). Rutter (1999) termed this constellation of behaviors, observed in 6% of a sample of 111 children adopted from Romanian orphanages, "quasi-autistic patterns." Though children described in Rutter's sample demonstrated circumscribed interests, they did not engage in stereotypic behavior such as rocking. However, Hoksbergen and colleagues (2005) reported that 13 of 80 (16%) Romanian adoptees showed symptoms of autism; eleven of the children exhibiting symptoms of autism engaged in stereotypic behavior, including rocking, and four of the children engaged in other stereotypic behavior.

A number of reports have indicated that sensory deprivation produces similar "autistic-like" behaviors in children, specifically as a result of congenital blindness (Brown, Hobson, Lee, & Stevenson, 1997). Sensory deprivation may limit the capacity to explore one's surroundings, as well as impede the ability to communicate effectively and develop the skills necessary to engage reciprocally and socially with others. In 1969, Wing compared children aged 4 to 16 years with perceptual impairments (e.g., congenital receptive aphasia, congenital executive aphasia, congenital partial blindness combined with partial deafness) to groups of children with autism, Down syndrome, and typical development with respect to behaviors characteristic of autism. In addition to exhibiting social difficulties, the group with partial blindness/deafness showed similar patterns of abnormal body movements, defined as jumping, spinning, toe-walking, and flapping arms or legs, as the group with autism. Since that time, a number of studies have reported similar behaviors in children with sensory impairments. Brown and colleagues (1997) compared congenitally blind children to age- and IQ-matched children using measures of autism-related behaviors. The blind group demonstrated significantly more communication difficulties than the sighted children, as well as more postural oddities and motor stereotypies. In a sample of 25 congenitally blind children, 19 (73%) demonstrated stereotyped behaviors, including body rocking, repetitive handling of objects, hand and finger mannerisms, eye pressing and eye poking, and jumping (Fazzi et al., 1999). Fazzi and colleagues suggested that repetitive body movements (hand mannerisms, jumping) might be interpreted as self-comforting behaviors, performed as a means of controlling anxiety or reducing tension in stressful situations; conversely, eye pressing, typically observed when the child was alone or bored, may increase levels of stimulation. These observations are consistent with previous reports of young blind infants and preschoolers who demonstrate stereotypies such as rocking and hand and finger mannerisms when aroused, and eye poking during more monotonous situations (e.g., Tröster, Brambring, & Beelmann, 1991). Taken together, these findings suggest stereotypies may represent a process of achieving an optimal state of arousal (Fazzi et al., 1999).

Inasmuch as sensory impairments may also compromise important social interactions, it is noteworthy that a number of studies have shown that reduced social contact may be a significant contributor to the development of stereotypy. Lewis and colleagues (1996) followed a group of rhesus monkeys deprived of social contact with their mother or peers for the first 6–9 months of life. Socially isolated monkeys exhibiting stereotyped behavior failed to exhibit a component of associative conditioned learning that requires inattention to irrelevant or redundant information, which is mediated in part by central dopamine function. Further, deprived monkeys showed potentiated response (i.e., increased stereotyped behaviors) to apomorphine, compared to control monkeys, suggesting long-term or permanent alterations in dopamine receptor sensitivity (Lewis et al., 1996). Examination of brain tissue in the group of socially isolated monkeys confirmed alterations in dopamine function, characterized by reduced dopamine innervation of the corpus striatum. These findings suggest a disrupted dopaminergic system is a consequence of social deprivation and directly related to the expression of stereotypic behaviors.

Thus, stereotypy appears to emerge as a result of being reared in environments lacking certain features essential for proper development. Impoverished environments and perceptual/sensory impairments inhibit one's ability to explore his or her surroundings, observe social behavior, interact with others, and at times, develop the social-emotional relationships necessary to facilitate a safe and secure attachment. A subset of young animals and children who are reared in such conditions appear to develop social and communication deficits, as well as repetitive behavior and stereotypy, which are common features of autism spectrum disorders. Given observations of analogous behavioral patterns exhibited by children as a result of these distinct conditions (impoverished environments, perceptual/sensory deprivation, and autism), one might consider the common elements inherent in each. Children in each condition experience barriers to developing social communication, rendering it difficult to achieve connections and establish relationships with other people. The impedances to developing these skills may differ in each situation; for example, an impoverished environment would limit opportunities to interact with a caregiver during a crucial period in the formation of attachment relationships, perceptual/sensory deprivation might pose challenges to interpreting social cues and responses such as facial expression, and a child with ASD may have diminished attention to faces and limited perspective taking. In each case, social-communication deficits and stereotypy emerge. These commonalities may have implications for possible shared mechanisms of intervention. For example, the St. Petersburg-USA Orphanage Research Team (2008) employed interventions that successfully altered the social-emotional-relationship experience of children from impoverished environments by providing training to caregivers to increase social-emotional responsiveness and support, and changing structural organization of orphanages in St. Petersburg, Russian Federation. Results of the intervention indicated substantial improvements in typically developing children and children with disabilities, in terms of physical growth, general behavioral development, social-emotional-relationship behaviors, and various measures of attachment. These findings provide support for the potential utility of behavioral interventions and

environmental enrichment in treating children with atypical behavior, regardless of its etiology.

In sum, impoverished environments and social deprivation appear to impact the development and maintenance of stereotyped behaviors and SIB in primates and other species. Dopamine function is clearly altered as a result of stressful environments in some cases. While environmental enrichment may enhance brain development and attenuate atypical behavior in mice (Lewis, 2004) and rats (see Sackett, Novak, & Kroeker, 1999, for a review), little work has been done to examine effects of enrichment on primate brain morphology. The neurological and behavioral changes resulting from environmental enrichment reported using rodent models support the notion that the behavioral treatment (e.g., enhanced socialization) can impact brain plasticity in addition to modifying behavior. This is particularly relevant given recent advances in the use of behavioral interventions to treat humans exhibiting stereotypy and SIB.

Animal Models Pertinent to Autism

It has been hypothesized that early risk factors for the development of autism are those that may alter a child's responses to and perception of his or her environmental surroundings (Dawson, Sterling, & Faja, 2008). Distorted interactions between child and environment may disturb critical input supporting proper brain development. As such, the study of animals experiencing environmental challenges, including impoverished housing conditions or deprivation, provide models of experience-dependent changes in behavior and associated neuropathology.

Lewis, Tanimura, Lee, and Bodfish (2007) reviewed and expanded on studies of deer mice exhibiting repetitive behaviors associated with environmental restriction. Findings suggest that repetitive behaviors are the most common consequence of physical confinement, and enriching environmental conditions reduces the presence of these behaviors. Moreover, stereotypy was associated with alterations in cortical-basal ganglia circuitry, elucidating possible etiology and underlying neuropathology in individuals with autism exhibiting such behavior (see also Cromwell & King, 2004).

In a study of Orange-Wing Amazon parrots, Garner, Meehan, and Mench (2003) demonstrated that increased stereotypy was associated with poor performance (i.e., perseveration) on a gambling task measuring executive function. Deficits in executive function are consistently reported in autism (e.g., Hill & Frith, 2003; Pennington & Ozonoff, 1996). Based on previous evidence (Norman & Shallice, 1986), the authors suggested that repetition of responses made by parrots during the gambling task is indicative of disinhibition of the behavioral control mechanisms of the dorsal basal ganglia, which parallels neural circuitry of stereotypy in humans.

Animal models of stereotypy developing as a consequence of social deprivation (e.g., Lutz et al., 2003) are also of

particular relevance to understanding autism. It has been proposed that initial damage to anatomical structures and systems supporting social function in autism (e.g., the amygdala), results in failure to assign social stimuli as salient, reducing inherent reward value of social stimuli, thereby hindering experience with such stimuli and specialization of cortical brain regions involved in social perception (Dawson et al., 2005; Schultz, 2005). Recent experiments by Bauman and colleagues (2008) are particularly salient in this regard. Juvenile rhesus monkeys received bilateral amygdala or hippocampal lesions and were assessed for later development of repetitive and stereotyped behaviors. Interestingly, these neonatal lesions resulted in distinctly different stereotypies depending on the brain structure involved, and did not develop until fully a year after the initial brain lesions. While a direct connection between nonhuman and human primates is a conceptual leap, these studies are consistent with the suggestion that a child's lack of social experience may contribute to and exacerbate more complex social perceptual deficits later in life. As such, animal models of social deprivation (including lesions that interfere with social communication) and consequential behavioral abnormalities may shed light on developmental processes associated with the emergence of symptoms associated with autism.

Using animal models to understand physiological responses to *changes* in the environment can also inform our understanding of the physiological aspects of SIB in humans. Many individuals with autism are characterized by insistence on sameness and experience difficulty with changes in routine. In a study of adult rhesus monkeys with SIB, exposure to the stress of housing relocation was associated with increase in self-biting behavior, sleep disturbance, and elevated levels of cortisol (Davenport, Lutz, Tiefenbacher, Novak, & Meyer, 2008). These findings lend support to the notion that life stresses, particularly change in environment, may exacerbate SIB in individuals with autism.

Evaluation and Treatment of Stereotypy and Self-Injury

Perhaps the best way to treat stereotypy and self-injury is to prevent it. Specific attention should be paid to those with autism who are at particularly increased risk for the development of the behavior such as those with sensory impairments or severe intellectual disability. The effectiveness of functional communication training is well established as a means to impact maladaptive self-injurious and other behaviors (see Carr & Durand, 1985).

Based on consensus development (AAMR, 2000) the first line of assessment methods for psychiatric and behavior problems in the context of intellectual disability include an interview with family/caregiver, direct observation of behavior, medical history and physical examination, functional behavior assessment, medication and side-effects evaluation,

and unstructured psychiatric diagnostic interview. From a behavioral intervention standpoint, first line treatments for challenging behaviors, and SIB in particular, include client and family education, functional behavior assessment, and managing the environment. Educating the family and the client about behavior problems and how to manage them can decrease stress and address situations that predispose to the expression of the behavior. A comprehensive assessment of stereotypy and/or self-injury will include a variety of assessments and examine the whole person. For a review of positive behavior support strategies, see Chapter 65 (this volume).

Current best practices in the field of applied behavior analysis for the assessment of stereotypy and self-injury focus on a function based model (Rapp & Vollmer, 2005a). Applied behavior analysis determines the functional relationships between the environment and behavior (Skinner, 1953). Procedures using these principles have been used to assess and treat a variety of behaviors including stereotypy and self-injury. Indeed, some 400 papers have been written since 1964 that specifically described behavioral intervention for SIB (Kahng, Iwata, & Lewin, 2002).

The standard of care for the treatment of stereotypy and self-injury has developed significantly over the past three decades primarily due to advances in behavior analysis. Research has consistently focused on decreasing the stereotypy and/or self-injury while increasing adaptive behaviors. However, early attempts at reducing stereotypy and self-injury were based on punishment. Current approaches have developed with advances in an assessment methodology that incorporates reinforcers that are specifically linked to the putative function of the challenging behavior. While these strategies have brought about significant change to the methodology of assessment and treatment, the use of restraint, seclusion, and even punishment may still be necessary to prevent immediate harm to some individuals with self-injury (Brown, Genel, & Riggs, 2000). Clinicians who employ restraint in the management of self-injury, do so in the context of a comprehensive behavior plan with specific procedures to decrease the use of restraint (Fisher, Piazza, Bowman, Hanley, & Adelinis, 1997).

With the behavioral approach, it is believed that stereotypy is an operant behavior that is maintained or reinforced by its consequences (Rapp & Vollmer, 2005). When determining the function of the behavior, information is gathered to identify the challenging behavior and possible replacement behaviors. There are two basic approaches to determining the function of the behavior: a functional assessment and/or a functional analysis. A functional assessment usually is based on observations that are conducted in the natural environment and do not require environmental manipulation during the initial data collection. Indirect assessments include rating scales that can be filled out by teachers, parents, and occasionally even the affected individual. The indirect assessments require no direct observations but can help determine the function of the challenging behavior. A functional analysis involves more systematic manipulation of environments to isolate potential variables that impact the behavior (Iwata et al., 1982/1994).

During a functional analysis, potential antecedents and consequences are systematically manipulated so that their effects on the problem behavior can be observed and measured. Such functional analyses usually consist of three test conditions: (1) contingent attention, (2) contingent escape, (3) alone. A control condition (sometimes called the play condition) where there are no demands on the individual and reinforcement is continuously available is also assessed. Each of the conditions is repeated over multiple sessions in order to determine if the behavior occurs more often under particular circumstances.

When analyzing the data from a functional analysis, the problem behavior is expected to be elevated in the conditions that maintain the behavior. For example, if the frequency of the problem behavior is high in the contingent attention condition, it suggests that the behavior is maintained by social positive reinforcement. If the problem behavior is high during the contingent escape condition, the behavior is maintained by negative reinforcement. If the problem behavior is high in the alone condition, the behavior is maintained by automatic or sensory reinforcement. It is of course possible for the problem behavior to serve multiple functions.

Due to the potential harm that could be caused, particular precautions during a functional analysis need to be addressed. In order to assess self-injury, the behavior needs to occur and thus there is the potential to cause harm. However, allowing the behavior to occur during specific functional analysis conditions with the appropriate professional supervision could lead to an intervention that could potentially lower the behavior in the future. Another risk of conducting a functional analysis is the potential that the challenging behavior could come under control of contingencies that previously did not control the behavior. Because of the risks, it is extremely important that whoever conducts the functional analysis has specific training in the methodology.

A number of tools are routinely used in the service of assessing or monitoring treatment response in persons with SIB and stereotypy. The Aberrant Behavior Checklist (ABC; Aman, Singh, Stewart, & Field, 1985) and the Repetitive Behavior Scale-Revised (RBS-R; Bodfish et al., 2000; Lam & Aman, 2007) are each used widely as general assessment tools for problem behavior and for self-injury in particular. These scales may be sensitive to pharmacological or other interventions and are being utilized as outcome measures in clinical trials (RUPP, 2002; Aman, 2003; King et al., 2009). The Challenging Behavior Interview (Oliver, McClintock, Hall, Smith, Dagnan, & Stenfert-Kroese, 2003) can be used to capture problem behaviors including self-injury as well as its severity. The Motivation Assessment Scale (MAS; Durand & Crimmins, 1988) can be helpful in suggesting the possible function of the behavior. Joosten and colleagues recently modified this scale and administered it to a population of children with intellectual disability and stereotyped and repetitive behaviors. They observed that both intrinsic and extrinsic

motivators are commonly associated with these behaviors. The Self-Injurious Behavior Trauma Scale (SIT; Iwata, Pace, Kissel, Nau, & Farber, 1990) has also been used in some studies to classify the type of injury, number of wounds, severity of wounds, and injuries based on location.

Interventions for stereotypy and self-injury need to be matched with the function of the behavior so that the problem behavior becomes ineffective and irrelevant. Interventions can be based on positive reinforcement (extinction, differential reinforcement of other behavior, differential reinforcement of alternative behavior, differential reinforcement of incompatible behavior, and noncontingent reinforcement), negative reinforcement (extinction, noncontingent negative reinforcement, differential negative reinforcement, and response chain interruption), and/or automatic reinforcement (noncontingent competing reinforcers, sensory extinction, and differential reinforcement).

Treatment of non–socially mediated (automatically reinforced) stereotypy or self-injurious behavior is difficult, since the exact mechanism that maintains the behavior is difficult to identify. King (1995) has suggested that some forms of stereotypy associated with self-restraining behavior may be compulsive or driven, and might be more likely to yield to treatments that are commonly utilized for obsessive-compulsive disorder.

While the use of punishment is controversial, it is important to discuss the behavioral aspects and ethical considerations for its use. "Punishment" is a behavioral term that describes a response that immediately follows a stimulus that decreases the future frequency of a similar response (Azrin & Holz, 1966). For example, the use of a disapproving look to decrease whining, a stern "no" to stop a child from hitting, a manual restraint to stop a person from self-injury are all classified as punishment simply because they decrease the likelihood that the similar behavior will occur again. Ethical considerations include that the least restrictive alternative interventions have been tried and found unsuccessful, the type of punishment is consistent with local laws, the appropriate training has been conducted for all involved prior to the use of punishment, and a risk-benefit analysis confirms a greater risk without the use of punishment. For a comprehensive review of ethical guidelines of punishment see Bailey and Burch (2005).

It is common that challenging behavior serves more than one function. When this happens it is important to develop multicomponent treatments. As noted above, medications are commonly utilized in the treatment of stereotypy and SIB, and optimal approaches will address medical issues and behavioral issues concurrently.

Beyond behavior change, the measurement of quality of life and social validity are receiving increasing attention. Quality of life captures the broad range of social issues relating to the person's sense of self and patterns of daily living with respect to family, community, and society (Schalock, 1990). Social validity assessments are designed to gather the perspective of a given treatment's social acceptability in a particular

setting (Schwartz & Baer, 1991). Symons, Koppekin, & Wehby (1999) have reviewed studies that assessed social validity and quality of life following the treatment of people with self-injurious behaviors. They observed that reducing self-injury is a necessary component to an intervention, but it may not be enough to result in important life changes. Of the 138 studies they reviewed, only about a third included a quality of life measurement, and most of these were anecdotal with poorly defined terms. Objective and reliable quality of life measurements should be considered among the outcomes for interventions with this population.

Indeed, whether the interventions focus on behavioral or medical strategies, it is critical that a variety of outcomes be monitored. Typically data collected as a plan unfolds will inform appropriate fine-tuning, or the exploration of new directions in search of the best outcomes.

Conclusions

Between 4% and 16% of individuals with intellectual disabilities engage in stereotypy and self-injurious behavior. Stereotypy and self-injury are commonly observed in individuals with autism spectrum disorders, and/or significant intellectual disability, and can have a substantial impact on level of functioning. Research examining underlying biological factors and neurological processes has facilitated the development of improved pharmacological and behavioral treatments for individuals struggling with these behaviors. Animal models have also provided insight into putative mechanisms contributing to stereotypy and self-injury in humans. Studies examining the detrimental impact of impoverished environments and social/emotional deprivation underscore the role of one's surroundings and the importance of social interaction in development. Understanding the interaction between neurological processes and social/emotional functioning may facilitate development of more effective treatment strategies.

Much progress has been made in recent years concerning the conceptualization and measurement of stereotypy and SIB. However, much work remains to better understand the factors that lead to the development and maintenance of these behaviors. That these behaviors form part of the core autism phenotype highlights the potential for greater exploration of the links between stereotypy and developmental and social function.

The field has yet to produce a definition that fully encompasses the essence of stereotypy. In particular, the assertion that such behaviors are produced with a lack of goal or purpose contradicts much of our understanding regarding the nature of stereotypy. Given that stereotypic behavior arises as a result of impoverished environments, sensory deprivation, increased stress or discomfort, and other circumstances, it has been suggested that such behaviors are expressed to self-calm, self-regulate, experience sensations, or even explore oneself and one's surroundings. Stereotypy occurs as part of the

normal developmental process, suggesting there is a purpose to the behaviors in infancy; the fact that they persist in individuals with a variety of developmental disabilities might indicate the continued need or reliance on the behaviors in persons with altered developmental trajectories.

In moving toward a better understanding of stereotypy, more work needs to be done in a number of areas. Various neurotransmitter and brain systems have been implicated in the development and maintenance of stereotypy, particularly dopamine. However, the directionality of disrupted neuro-transmitter function remains unclear. Further, given that pharmacologically induced stereotyped behavior responds to manipulations of a number of neurotransmitters, the specificity for the role of any particular neurotransmitter system is still under debate. Elucidating the pathways of these systems will in turn lead to more targeted pharmacological treatment options.

Research has indicated that children who have been reared in impoverished environments, children with perceptual impairments, and children with autism engage in stereotypy, suggesting commonalities across these conditions. Perhaps consistent among them are barriers to developing appropriate communication skills, and lack of opportunity to form social-emotional connections and relationships with others. Animal models exist in which similar behaviors emerge spontaneously after early developmental or environmental manipulations and may significantly advance our understanding of effective interventions. Thus, environmental enrichment can impact brain development in rats and mice, and enhancement of social-emotional relationships has been shown to improve development generally and stereotypy more specifically in children reared in orphanages. Future research will no doubt examine pre- and posttreatment brain morphology in humans who benefit from such intervention, to better elucidate underlying neurological mechanisms involved in the expression of stereotypy. In the meantime, continued elaboration of animal models of stereotypy, perhaps in the context of other social-communication deficits, will facilitate our understanding of these behaviors in individuals with ASD.

Challenges and Future Directions

- Examine the factors that lead to the development and maintenance of stereotypy and self-injury.
- Continued development and refinement of the definition of stereotypy to include and better understand the role of possible underlying motivating factors.
- Examine pre- and post-treatment brain morphology in humans to better elucidate underlying neurological mechanisms involved in the expression of stereotypy.
- Continued elaboration of animal models of stereotypy to facilitate our understanding of these behaviors in individuals with ASD and/or intellectual disability.

Motor Functioning and Dyspraxia in Autism Spectrum Disorders

⠿

Points of Interest

- Motor impairments are present in the majority of individuals with ASD and may include deficits in vestibular functions, fine and gross motor abilities, eye movements, motor learning, and complex motor sequencing.
- Motor systems lend themselves to translational studies in ASD because their neurophysiological substrates are well defined via animal and human lesion studies, they have quantifiable spatial and temporal characteristics, and they can be administered to individuals across the autism spectrum with a range of cognitive disability.
- Neurophysiological, neuroimaging, and histological studies have identified alterations in ASD in multiple brain regions involved in motor functions, including sensorimotor cortices, basal ganglia, cerebellum, and brainstem nuclei.
- Motor disturbances appear to be among the first manifestations of developmental abnormalities in ASD and thus could serve as biomarkers of disease detectable in the first years of life.
- New family data on eye movement impairments suggests similar profiles in unaffected first-degree relatives and probands, indicating that these deficits may be familial and could serve as viable intermediate phenotypes for family-genetic research.

Investigation of neurobehavioral aspects of autism spectrum disorders (ASD; including autism, Asperger's syndrome, and Pervasive Developmental Disorder-NOS) primarily has focused on an analysis of abnormalities in complex cognitive operations including social cognition, communication, and executive functioning, which represent the defining clinical characteristics of the disorder. However, recent behavioral, neurophysiological, neuroimaging, and histological evidence suggests that motor system development is also abnormal

in ASD. These observations highlight the need for systematic investigation of the developmental trajectory and causes of atypical motor function and dyspraxia (i.e., difficulty in planning and executing sequences of movements) in these disorders.

> **Histology:** The study of microscopic anatomy of brain cells performed by examining slices of tissue under a light microscope or electron microscope.

> **Dyspraxia:** The partial loss of the ability to coordinate and perform purposeful movements and gestures that is not accounted for by other primary motor or sensory impairments.

Neurobehavioral studies of ASD have more recently devoted increased attention to dyspraxia, postulating that impairments in learning complex motor sequences may relate to social communication deficits such as impaired imitation (Dapretto et al., 2006; Martineau, Cochin, Magne, & Barthelemy, 2008; Williams et al., 2006b). While there is evidence for impairment in learning complex motor behaviors in the context of social interaction, these impairments also include more basic motor functions that are not specific to social learning. Converging evidence from behavioral and neurophysiological research (see below) indicate that individuals with ASD demonstrate deficits in vestibular control, gross and fine motor movements, and eye movements, and they are dyspraxic when performing both social and nonsocial behaviors.

Kanner (1943) and Asperger (1944, as translated by Frith, 1991) each noted a diverse set of motor atypicalities in their original case studies, including hand and finger stereotypies, lack of appropriate posturing in response to being held among young children, awkward motility, slow reflexes, delays in walking and an absence of crawling, and overall clumsiness. Motor abnormalities consistent with these observations have since been documented in more systematic analyses. These studies have identified impairments in vestibular functions (Baranek, 1999; Bryson et al., 2007; Gepner, Mestre, Masson, &

de Schonen, 1995; Kohen-Raz, Volkmar, & Cohen, 1992; Minshew, Sung, Jones, & Furman, 2004; Molloy, Dietrich, & Bhattacharya, 2003; Teitelbaum, Teitelbaum, Nye, Fryman, & Maurer, 1998), gross (e.g., Jansiewicz et al., 2006; Rinehart, Tonge, Bradshaw, Iansek, Enticott, & McGinley, 2006b; Vernazza-Martin et al., 2005) and fine motor skills (e.g., Freitag, Kleser, Schneider, & von Gontard, 2007; Green et al., 2002; Williams, Goldstein, & Minshew, 2006a), eye movements (e.g., Takarae, Minshew, Luna, Krisky, & Sweeney, 2004a; Takarae, Minshew, Luna, & Sweeney, 2004b; Thakkar et al., 2008), complex motor sequences (e.g., Dziuk et al., 2007; Rogers, Bennetto, McEvoy, & Pennington, 1996), and motor learning (e.g., Haswell, Izawa, Dowell, Mostofsky, & Shadmehr, 2009; D'Cruz et al., 2009). Still, current classification systems devote minimal attention to this area of impairment. The *Diagnostic and Statistical Manual–Fourth Edition* includes motor stereotypies within the restricted, repetitive behavior domain. It also notes that nonspecific neurological symptoms may be present, including primitive reflexes and delayed development of hand dominance (American Psychiatric Association [APA], 2000). Further, abnormalities of posture are noted to be characteristic of autism, and "motor clumsiness" is described as a feature of Asperger's disorder. The potential utility of disturbances of motor systems and dyspraxia to diagnostic practice remains largely unexplored, however, as does the potential of investigations of disturbances in these domains to clarify ASD pathophysiology.

Stereotypies: Nonpurposeful repetitive, ritualistic movements, postures, or utterances.

Motor system dysfunction affects a myriad of behaviors and thus may have critical implications for the development of core social and cognitive deficits in ASD. For example, early emerging dyspraxia and motor imitation deficits reported in children with ASD (see Williams, Whiten, & Singh, 2004, for a review) are known to affect oromotor skill development and concomitant maturation of language ability (Mandelbaum et al., 2006; Rogers, Hepburn, Stackhouse, & Wehner, 2003). Similarly, impaired visual pursuit ability, as demonstrated previously in ASD (Takarae et al., 2004a), may limit children's ability to visually follow shifts in eye gaze and attention that are inherent in social referencing and joint attention. Delays in basic motor operations and vestibular control also have been noted in individuals with ASD, including abnormal postural stability (Minshew et al., 2004). Similarly, gross and fine motor deficits are observed clinically and consistently have been identified in comprehensive neuropsychological investigations of children (Williams et al., 2006a) and adolescents and adults with ASD (Freitag et al., 2007; Ming, Brimacombe, & Wagner, 2007; Minshew, Goldstein, & Siegel, 1997). Hypotonia and dyspraxia are common in ASD, with estimated prevalence rates of 25% to 51% and 34% to 75% respectively (Ming et al., 2007; Rapin, 1996). Motor deficits also are observed in approximately 80% of genetic syndromes currently known to be associated with ASD, suggesting clear advantages in

studying motor disturbances in ASD for understanding etiological pathways (Abrahams & Geschwind, 2010). Taken together, these observations indicate that motor impairments are related to alterations in widely distributed neural networks, including those involved in vestibular control, gross motor movements such as walking, fine motor skill movements, oculomotor processes, and motor praxis.

Hypotonia: Disorder that causes low muscle tone (the amount of tension or resistance to movement in a muscle), often involving reduced muscle strength.

Multiple factors unique to motor impairments make them ideally suited for studies of atypical brain maturation in ASD (see Table 22-1). First, neural system correlates of motor

Table 22–1.

Factors supporting increased research focus on motor development in ASD

- Current neurobehavioral studies suggest that motor impairments are present in the majority of individuals with ASD. These deficits affect multiple motor systems, including those involved in vestibular functions, fine and gross motor abilities, eye movements, motor learning, and motor sequencing.

- Neural systems underlying motor behavior are well mapped via animal and human studies, making studies of motor development directly translational.

- Neurophysiological, neuroimaging, and histological studies implicate brain regions involved in motor functions, including sensorimotor cortices, basal ganglia, cerebellum, and brain stem nuclei.

- Motor disturbances appear to be among the first manifestations of developmental abnormalities in ASD and thus could serve as biomarkers of this disorder detectable in the first years of life. These deficits also may contribute to a cascade of social-communication and cognitive deficits.

- Approximately 80% of genetic syndromes currently known to be associated with ASD are characterized by motor impairments, suggesting several candidate genetic mechanisms.

- Family studies of motor deficits suggest similar profiles in unaffected first-degree relatives and probands. These findings indicate that motor impairments may be familial and could serve as viable intermediate phenotypes for genetic studies.

- Minimal task demands relative to higher-order cognitive/behavioral paradigms make motor tasks more suitable for young children and individuals with cognitive impairment.

- Practice effects for motor tasks are relatively modest compared to cognitive paradigms, making motor tasks more suitable for longitudinal studies.

- Precise quantitative measurements of temporal and spatial components of motor behaviors are available, enabling detailed models of neural system dysfunction.

behavior are well understood via studies of neurological conditions involving focal brain lesions, unit recording studies with behaving nonhuman primates, and functional neuroimaging studies. These studies have laid a foundation for translational research to develop better models of the links between brain and behavioral abnormalities in ASD. As an example, studies of patients with cerebellar damage including the vermis reveal failures to modulate the amplitude of eye movements when fatigued or during adaptation paradigms (Golla et al., 2008; Xu-Wilson, Chen-Harris, Zee, & Shadmehr, 2009). In contrast, patients with cerebellar lesions that do not extend to the vermis do not show deficits on these paradigms. These findings are compelling in the context of studies documenting Purkinje cellular abnormalities within the vermis in ASD (Bailey et al., 1998; Kemper & Bauman, 2002) and hypoplasia of oculomotor vermal lobules VI–VII (see Stanfield et al., 2008, for a meta-analysis). Second, in contrast to studies of higher-order cognition that rely on tasks that cannot be readily applied to animal models, motor system studies are directly translational, since identical behaviors can be studied in human and animal models under identical task conditions. Third, the understanding of complex task instructions that is required for many higher cognitive tasks is not relevant for motor system studies, so motor system studies using identical task conditions can be conducted across a wide range of age and general cognitive abilities. Fourth, practice effects are relatively modest with motor system studies compared to higher-order cognitive tasks (Kida, Oda, & Matsumura, 2005), so that they are particularly suitable for longitudinal studies of developmental processes. Fifth, precise quantitative measurements of motor behaviors are available, making it possible to study temporal and spatial dynamics of relevant neural operations in detail. Sixth, motor impairments are among the first manifestations of developmental abnormalities in ASD. They are present in infants later diagnosed with ASD (Teitelbaum et al., 1998) and predict the severity of clinical symptoms that emerge later in life (Dziuk et al., 2007; Gernsbacher, Sauer, Geye, Schweigert, & Hill, 2008). Additionally, although motor impairments alone are not sufficient for early identification of ASD (Provost, Lopez, & Heimerl, 2007), distinct patterns of motor impairments might be associated with unique patterns of development in ASD, such as early emergent or regressive courses (Ozonoff et al., 2008). Hence, assessment of motor skills might be useful for predicting developmental pathways for particular individuals and thus applying more individualized treatments and interventions. Finally, motor impairments might provide viable quantitative familial phenotypes associated with particular subtypes within ASD. For instance, unaffected parents of children with ASD have oculomotor impairments that are similar to those in affected individuals (Koczat, Rogers, Pennington, & Ross, 2002; Mosconi, Kay, D'Cruz, Guter, Kapur, et al., 2010) suggesting that certain eye movement impairments and associated neurophysiological alterations might be useful phenotypes for genetic research.

Cerebellar vermis: Narrow central structure within the cerebellum between the two hemispheres.

Purkinje cells: GABAergic neurons located in the cerebellar cortex and vermis that are the sole output of the cerebellar cortex to deep cerebellar nuclei.

Phenotype: Observable characteristics or traits of an organism, including morphology, development, or physiological properties, that result from the expression of an organism's genes as well as the influence of environmental factors.

Despite the multiple advantages of motor system research for resolving important questions about the pathophysiology of ASD, progress in understanding these disturbances has been modest. The generalizability of many studies of motor impairments in ASD has been limited by small sample sizes that cannot adequately account for biological and behavioral heterogeneity, reliance on clinical ratings rather than objective measurements of motor system function, a lack of longitudinal data that is necessary for understanding changes in motor deficits over the course of development, and failures to compare patients to suitable control samples (e.g., IQ-matched controls).

Motor System Neurophysiology and Its Dysfunction in ASD

Several distinct but highly interacting sensorimotor systems exist within the human central nervous system, reflecting the diversity of our motor capabilities. Cortico-cortical, cortico-striatal, and cortico-thalamo-cerebellar loops each innervate lower motor neurons indirectly through the brain stem (Dum & Strick, 1992; He, Dum, & Strick, 1993, 1995). Histological and single-cell recording studies of nonhuman primates indicate that efferent cortical pathways related to motor control predominantly derive from frontal cortex (Dum & Strick, 1991), including the primary motor cortex (Brodmann's area 4) and the lateral and medial zones of premotor cortex (Brodmann's area 6), as well as from the intraparietal sulcus and inferior parietal lobule (Brodmann's areas 5 and 7; Leichnetz, 2001; Cavada & Goldman-Rakic, 1989). While the primary motor and premotor areas of the frontal lobe are essential for the execution of basic and complex motor acts, supplementary motor areas, prefrontal cortex (PFC) and parietal cortex have been shown to be involved in the planning of complex motor sequences (Catalan, Honda, Weeks, Cohen, & Hallett, 1998; Grafton, Hazeltine, & Ivry, 2002; Honda et al., 1998). Frontoparietal integrity is therefore critical for efficiently executing everyday motor sequences and gestures, likely because integrating motor planning with spatial perceptual processes is necessary in order to optimize motor plans and actions. Disturbances in frontoparietal

function are associated with dyspraxia, and thus are implicated by demonstrations of dyspraxia and imitation impairments in individuals with ASD (Dowell, Mahone, & Mostofsky, 2009; Dziuk et al., 2007; Jansiewicz et al., 2006; Rogers et al., 1996).

In addition to frontoparietal systems, frontostriatal loops contribute to the execution and inhibition of motor output (DeLong & Strick, 1974). The basal ganglia is a network of subcortical gray matter structures, including the caudate nucleus, putamen, globus pallidus, and substantia nigra, that are involved in the planning, initiation, and inhibition of motor commands (DeLong, 1990; Kaji, 2001). Frontal cortical inputs into the basal ganglia are excitatory and involve glutamatergic innervations that synapse with neurons in the caudate nucleus and putamen (Pollack, 2001), two structures collectively referred to as the "corpus striatum." Dopaminergic neurons in the substantia nigra also provide input to the striatum (Khan et al., 2000; Yung et al., 1995). Direct and indirect pathways project to the globus pallidus and modulate ventral thalamic nuclei output to primary motor and premotor cortices, thus completing frontostriatal loops that are crucial for initiating and inhibiting goal-directed movements (Alexander, Crutcher, & DeLong, 1990; Rolls, 1994). Dysfunction within the basal ganglia can cause failures in motor inhibition, manifesting as repetitive motor movements or stereotypies similar to those observed in people with ASD (Ames, Cummings, Wirshing, Quinn, & Mahler, 1994; Canales & Graybiel, 2000). Additionally, some individuals with ASD show slowed walking patterns similar to patients with Parkinson's disease (Damasio & Maurer, 1978; Mari, Castiello, Marks, Marraffa, & Prior, 2003; Vernazza-Martin et al., 2005; Vilensky, Damasio, & Maurer, 1981), a disorder involving reduced dopaminergic input to the striatum (Dauer & Przedborski, 2003).

Motor commands generated through frontoparietal and frontostriatal loops are subsequently adjusted by the cerebellum (Houk & Wise, 1995; Ito, 1984; Stein & Glickstein, 1992). The cerebellum detects deviations between an intended movement and actual movement to correct motor output in real time. Through its projections to primary and premotor cortices, the cerebellum reduces these deviations in future planned action (Ohyama, Nores, Murphy, & Mauk, 2003). The cerebellum thus acts to continuously modulate motor behavior on line and enable more precise performance. These functions primarily are performed via the coordination of signals from motor cortices relayed to the cerebellum via pontine nuclei, where motor intentions and consequences of motor acts are compared (Brodal, 1978). Efferent pathways exiting deep cerebellar nuclei, including the dentate nuclei, interpositus nuclei, and fastigial nuclei, through the superior cerebellar peduncle, continuously modulate motor output via thalamic and brain stem projections (Middleton & Strick, 1997; 2001). Disturbances to cortico-cerebellar systems thus lead to ataxia or failures to accurately coordinate planned motor behavior (Timmann et al., 2008). In addition, the cerebellar vermis is involved in motor learning and adaptation. The vermis mediates implicit

motor learning and oculomotor control in nonhuman and human primates (Catz & Thier, 2007; Soetedjo, Kojima, & Fuchs, 2008; Takagi, Tamargo, & Zee, 2003; Takagi, Zee, & Tamargo, 1998; 2000; Thier, Dicke, Haas, Thielert, & Catz, 2002). Gait abnormalities (Damasio et al., 1978; Esposito & Venuti, 2008; Hallett et al., 1993; Rinehart et al., 2006b; Rinehart, Tonge, Iansek, et al., 2006c; Teitelbaum et al., 1998; Vernazza-Martin et al., 2005) and alterations in oculomotor control (Takarae et al., 2004a; Takarae et al., 2004b) in individuals with ASD have parallels with movement abnormalities of patients with cerebellar lesions implicating cerebellar dysfunction in ASD.

Ataxia: Gross lack of coordination of muscle movements often implicating cerebellar dysfunction.

Vestibular Modulation of Motor Control in ASD

Both the vestibular nuclei and the reticular formation help control posture in response to perturbations of the body in space (Keshner & Cohen, 1989). The vestibular nuclei make adjustments according to information from the inner ear, while the reticular formation controls postural stability based on an integration of inputs from motor centers in the cortex, basal ganglia, and brain stem (Drew, Prentice, & Schepens, 2004; Fitzpatrick & Day, 2004). These movements often are anticipatory, such as the excitation of lower limb muscles prior to lifting a heavy object. The reticular formation, therefore, is part of a feedforward motor planning process that initially stabilizes the body by altering posture and then, via its connections with the cerebellum, readjusts body position to maintain stability during the performance of motor actions (Kennedy, Ross, & Brooks, 1982).

Abnormalities in postural control have been reported in individuals with ASD, but these abnormalities have not been observed consistently when individuals were compared with IQ-matched control subjects, or beyond the first years of life. Baranek (1999) observed abnormal postural behaviors in 9- to 12-month-old children later diagnosed with ASD relative to typically developing children, but the children later diagnosed with ASD did not differ in their rate of abnormal posturing relative to age- and IQ-matched infants. Bryson and colleagues (2007) reported poor motor stability at age 6 months in three out of nine infants later diagnosed with ASD. Teitelbaum and colleagues (1998) reported that a small (3/3) subset of infants later diagnosed with ASD demonstrated abnormalities in early postural control, including sitting upright and righting from supine to prone position. These results are difficult to interpret because quantitative data regarding either behavior are not provided, and because only three children were observed. In contrast, more consistent deficits were observed for behaviors involving the coordination of complex motor movements of the arms, such as crawling. Kanner (1943) observed

inconsistent postural control disturbances among his patients with ASD. He noted that multiple children did not demonstrate changes in their posture in response to being held. Failures to alter posture in response to being held could reflect disturbances in vestibular control or could be attributable to poor social awareness in developing infants with ASD. Follow-up examination of the constituent components underlying abnormal postural responses in young infants identified with ASD now may be more clearly teased apart with the advent of infant sibling studies and retrospective videotape analyses that allow children later diagnosed with ASD to have their behavior within the first year of life retrospectively reviewed.

Studies of postural control in children beyond the first years of life and adults with ASD have been inconsistent, possibly due to differences in patient and control sample characteristics. The first quantitative study of postural control in ASD examined a large sample (N = 91) of cognitively impaired children and adults with ASD who were not age-matched with their non-ASD cognitively impaired subjects (Kohen-Raz et al., 1992). The ASD and non-ASD cognitively impaired subjects had underdeveloped postural stability relative to the typically developing controls, but only the subjects with ASD showed paradoxically superior stability when vision was occluded or somatosensory input was obstructed. These observations have not been replicated by subsequent studies that have noted decreased postural stability in children with ASD, but increased postural stability with visually perceptible external motion and more profound deficits when vision was occluded (Gepner & Mestre, 2002; Molloy et al., 2003). It is not clear why the original Kohen-Raz et al. paradoxical vision occlusion findings for postural stability have not been replicated, but these results may point to significant heterogeneity along the autism spectrum in motor dysfunction that may be unique to individuals with cognitive impairment. A more recent dynamic posturography study of a large sample of children and adults with ASD (N = 79) indicated that non–mentally retarded individuals with ASD have underdeveloped postural stability that is disproportionate under conditions in which somatosensory input is disrupted (Minshew et al., 2004). Examining cross-sectional data, the authors also suggested that the development of postural stability was delayed in children with ASD and that it does not achieve healthy adult levels in adulthood. The deficits observed across these studies suggest that postural instability is evident in at least a subset of individuals with ASD and not unique to those individuals with cognitive impairment.

Currently, several questions remain unanswered regarding postural stability mechanisms in ASD: (1) Do observed deficits in postural control affect only a minor subset of individuals with ASD (e.g., those with cognitive impairment) and under specific conditions (e.g., when sensory input is eliminated), or do a greater proportion of affected individuals show subtle alterations when laboratory-based analyses of behavior are performed? (2) Are these abnormalities more prominent within the first year of life? (3) Are abnormalities in the

development of postural stability evident exclusively in social contexts as suggested by observations that infants with ASD do not conform to physical gestures of caregivers? and (4) Is postural dyscontrol, if present, stable over time or does it reflect delayed maturation of brain stem circuitries that eventually "catch up" to normative trajectories? Further research is needed to address these questions.

Gross Motor Impairments in Individuals with ASD
